Introduction

PAST TO PRESENT

The previous edition of this manual, the 14th, described in detail the changes that took place in the coating industry from the early 1970s to the early- to mid-1990s. Published in 1995, the 14th edition classified powder coating, radiation-cured coatings, and higher-solids coatings as new, with a potentially reasonable growth curve. It noted that at the time, all liquid coatings were at higher solids content (lower volatile organic solvent content) than in the 1960s when Rule 66 came into being. Powder coating and radiation curing were sufficiently new enough that chapters related to testing them were not included in the manual. High-solids development still struggled with the difficulties of decreasing molecular weight for low viscosity purposes and achieving the low molecular weight with functionality on all molecules that quality coatings require. However, the solids level has increased in solvent-based coatings and achievements have been realized in decreasing volatile organic content (VOC).

Since that time, powder coating has exploded. Today the technology is well established, has a significant share of the coatings market, is internationally accepted, and has a strong technical society that aids in future growth. To illustrate the widespread acceptance of powder coatings, one merely needs to look at advertisements. Outdoor metal furniture advertisements, for example, proudly include words that imply quality and durability—that is to say, "powder-coated finishes."

Of course, such furniture certainly is not the only commercial outlet for powder coatings. Applications include lighting fixtures, tubing and aerosol cans, automobile and bicycle wheels, rebars, store fixtures, agriculture and construction materials, and on and on. Initially, colors and color changeovers were considered to be a major obstacle to powder coating development, but today a broad variety of colors is available, including many metallic and special effect finishes with abrasion resistance, brilliance, and overall high quality. Powder coating provides quality, economy in manufacturing space, increased production, energy usage reduction, and other facets important to product development and sales in today's marketplace.

As with powder coating, radiation curing of coatings with either ultraviolet or electron beam radiation is no longer a new process. This technology also has been experiencing strong growth since the last edition of this manual. It is the technology in which, through an *in situ* means, a low viscosity liquid system is converted into a polymeric film or coating directly on a substrate that can be varied in nature—i.e., metal, wood, plastic, composite structures, etc. In effect, the originally liquid system is instantaneously converted into the final high molecular weight, cross-linked coating. Radiation curing of liquid systems is not limited to coatings, and it is growing in the printing ink and adhesive areas. It is considered to be "green" technology, is well established in the marketplace, has garnered a significant portion of the total coatings market, has a strong technical society dedicated to it, and is internationally accepted.

Radiation-curing technology has many facets that will ensure future growth. Harbourne[1] has pointed out that over and above the usual advantages behind ultraviolet radiation curing technology—energy conservation, usage efficiency, and environmental conservation—its driving force is the fact that the UV process has enabled production and development of products that could not have been achieved with earlier existing technologies. Such products include flexible electronics for energy storage and circuit development, polymeric solar cells, printable electronics, medical devices, touch screens, optical films, and on and on. In the area of solar energy, highly efficient organic photovoltaic cells are being developed that are thinner and lighter in weight with significantly decreased production costs. Such cells are used in emergency power generation, lighting, and outdoor power generation. New smart materials with self-healing properties will provide overall cost savings through high value-added finishes on a variety of substrates. Solvent-based, high-solids coating systems continue to be developed. Such coatings have markedly decreased volatile organic content and provide high quality coatings and reduced environmental damage.

FUTURE

As described above, powder and radiation-cured coatings have been experiencing excellent growth over the past decade or so, with each technology growing on its own merits. More recently, a combination of the two technologies—UV–Curable Powder Coatings—has very good growth potential. New opportunities for the combination are due to the same benefits mentioned above—economic, environmental, process, energy savings, and increased productivity.[2] The combination is meeting the less expensive, more rapid, and high quality challenges required by the demanding customers of today. The coatings are being used on medium-density fiberboard, plastics and other heat sensitive substrates, composites, and preassembled parts including completed items. Preassembled items often contain a number of different materials such as electronic components, gaskets, rubber seals, and the like--all of which are heat sensitive in nature. The ability to coat and cure such combinations with systems based on the combined technologies results in less thermal damage to the sensitive materials and thus greater efficiency and productivity along with cost savings.

Nanotechnology is a field of emerging technology that may hold great promise in the future for the coatings, inks, and adhesives industry and certainly for a broad variety of other industries. Nanotechnology has broad implications

[2] Schwarb, Ryan and Knoblauch, Michael, "New Opportunities for UV-Curable Powder Coatings, " *Coatings World*, Volume 16, Number 5, pp 43-48 (May 2011).

for new products and there are multi- and interdisciplinary efforts in progress. The technology deals with science on the nano, or one billionth-size, scale. Nanometer "particles" are 0.000000001 meter or 0.001 of a micrometer in size. Within the technology, an assembler or molecular manufacturing technique is used to position molecules through chemical reaction or interaction into new products or existing products with enhanced properties. Although the term "nanotechnology" was initially used to define efforts conducted on a molecular scale, currently the term has taken on a loose connotation for anything that is very small where small means something that is most usually smaller than a micrometer. Many examples of nanometer-designed products exist and a few of these are given below.

Recently a plant was built of produce carbon nanotubes[3]. Such tubes in combination with aluminum result in new lightweight, high strength composite materials that have promise in the energy, electrical, and computer industries. In another area, a multilayered, polymeric nanocomposite has been devised and it is thought to have the potential to make a self-healing paint.[4] In this technology, emulsion polymerization processes are used to develop a polymeric product that is covered with a silica-based layer of nanoparticles. Nanocomposite coatings for fabrics have also been described[5]. These coatings improve gas barrier properties as well as enhance mechanical characteristics.

Another area that is receiving attention is additives for coating formulation. An additive that improves properties of water-based metal coatings has been described[6]. Although the additive is not chemically described, it is said to increase crosslink density and thereby various mechanical properties of cured films. An additive to accelerate the radiation-curing process is a small particle-sized version of nepheline syenite that is prepared by a micronizing process[7]. The micronized, ultra-fine form of this combination mineral—soda feldspar, potash feldspar, and nepheline--is said to enhance optical and physical performance in clear industrial and wood coatings. Properties such as gloss, hardness, and scratch resistance are altered in a desirable manner. Cure rate via double bond conversion was enhanced in the presence of these very small mineral particles.

TESTING

As listed in Table 1, ASTM International has developed several documents that are useful in the area of nanotechnology. Although the documents are not necessarily directly related to coatings and paints, they provide useful background for investigators in this field and, as is apparent, useful guides for laboratory efforts in the areas of terminology, particle handling, effect of nanoparticles on red blood cells, particle mobility through a graduated index, and other areas. In the future, it is expected that this area will further develop within ASTM International.

Preface

For historical purposes, it is important to point out that at a January 1967 meeting of ASTM Committee D01 held in Washington, D.C., the American Society for Testing and Materials (ASTM International) accepted ownership of the *Gardner-Sward Handbook* from the Gardner Laboratory. It was through this laboratory that Dr. Henry A. Gardner published the previous twelve editions of the manual. Acceptance of this ownership gave ASTM an assumed responsibility for revising, editing, and publishing future editions of this well-known, respected manual. The undertaking was assigned to "Committee D01 on Paint and Related Coatings, Materials, and Applications." This committee established a permanent subcommittee, "D01.19 on Gardner-Sward Handbook," whose stated scope is delineated below. The 13th edition was published in 1972 as the *Paint Testing Manual* (STP 500) with Mr. G. G. Sward as editor and contributor. It was updated, expanded, and published in 1995 as the 14th edition, *Paint and Coating Testing Manual* (MNL 17) with Dr. Joseph V. Koleske as editor and contributor. The manual has served the industry well in the past by providing useful information that cannot be readily found elsewhere.

It has been about fifteen years since the 14th edition was published. Interest in the manual has been strong through the years. This new edition of the *Paint and Coating Testing Manual*, the *Fifteenth Edition of the Gardner-Sward Handbook* (MNL 17), has been updated and expanded.

The scope of the new edition is in keeping with the stated scope of Subcommittee D01.19:

> To provide technical, editorial, and general guidance for the preparation of the Fourteenth and subsequent editions of the *Gardner-Sward Handbook*. The handbook is intended for review of both new and experienced paint technologists and the past, present, and foreseeable trends in all kinds of testing within the scope of Committee D01. It supplements, but does not replace, the pertinent parts of the Society's Book of Standards. It describes, briefly and critically all Test Methods believed to have significance in the world of paint technology, whether or not these tests have been adopted officially by the Society.

Once again, in this new edition, ASTM standard test methods, procedures, and other documents are described in minimal detail, with the various volumes of the *ASTM Book of Standards* remaining the primary source of such information. An effort was made to include references in the absence of ASTM documents concerning industrial, national, international, and other society test methods. The new edition contains either new chapters, or the previous topics/chapters in rewritten/revised form. In a few cases, the previous edition was merely updated, attesting to either the quality of the earlier writing, the lack of development in the area, or the apparent waning of interest in the topic. A variety of modern topics have been included. New chapters have been added as, for example, "Measurement of Gonioapparent Colors," "Surfactants," "Powder Coating," and "Coalescing Aids." As in the previous edition, individual authors, experts in their particular fields, were given a great deal of freedom in expressing information about their topics, but all chapters were subjected to peer review by two colleagues. Thus, style and content presentation may widely vary, but efforts were made to have understandable syntax and thus readers should find the information useful and "easy" to read and put to use.

Manuals such at this one are prepared though a great deal of effort by the various authors and through the able assistance and behind-the-scenes concerted efforts of people such as Ms. Kathy Dernoga and Ms. Monica Siperko of ASTM International and Ms. Christine Urso, Ms. Barbara Carbonaro, Ms. Theresa Fucito, Ms. Patricia Mayhew, and Ms. Benita Hammer, of the American Institute of Physics, all of whom ensured that the manual was uniform in style and grammar and that manuscripts were submitted and processed in a timely fashion. The real unsung and unnamed contributors are the reviewers who gave encouragement to the various authors through constructive criticism, editorial information, and recommendations without deleteriously attempting to alter manuscripts from the author's intent. To all of these people, a heart-felt "thank you." Your talents have been utilized, you sacrificed much personal time, and you were patient with the numerous delays encountered on the road to making the manual a success.

Part 1: Regulations

1

Regulation of Volatile Organic Compound Emissions from Paints and Coatings

J. John Brezinski[1] and Ronald K. Litton[2]

INTRODUCTION

PRIOR TO THE 1960s, THE COATINGS INDUSTRY enjoyed a somewhat predictable regulatory and economic environment. The paint formulator selected solvents based on evaporation rate, solubility parameter, density, flammability, and, of course, cost. There was no apparent need to consider the relative photochemical reactivity of these materials, nor was there any appreciable incentive to reduce the solvent content of commercially acceptable coatings.

It was recognized that objectionable odors were released from some paints and coatings. Further, air emissions resulting from the evaporation of solvents during high-temperature processing of oils and resins caused occasional complaints from persons living near the coatings plant. The prevailing view of this period was summarized by Francis Scofield in his article in the 13th edition of the *Paint Testing Manual* entitled "Atmospheric Pollutants" [1].

> These "nuisance" types of pollution are a continuing problem but, in general, can be dealt with by dilution and dispersion of the objectionable materials to bring the concentration below a level that can be detected by the neighboring citizenry. Fortunately, most of the materials used by the paint industry are not toxic at concentrations significantly below the range at which they can be detected by the human nose, and sophisticated analytical procedures are rarely needed to deal with these "nuisance" problems.

Since the 1960s, societal concern about health and the environment has increased appreciably. Actions taken by federal and state legislative bodies have resulted in a steady avalanche of new laws and associated regulations that affect virtually all of the chemical industry. Some of the federal laws administered by the U.S. Environmental Protection Agency (EPA) that impact the coatings industry are shown in Table 1. They are designed to control the emission of pollutants to air, to water, and to soil.

In addition, among the new federal standards administered by the Occupational Safety and Health Administration are those that require manufacturers—including those making paints and coatings—to evaluate the hazards of products they make and to provide appropriate safety information to employees and users through the Material Safety Data Sheet (MSDS) and product labels:

- Hazard Communication Standard (HCS), 1983
- Occupational Exposure to Hazardous Chemicals in Laboratories, 1990

The discussion in this section will focus on the Clean Air Act and its amendments that, in the authors' opinions, have had (and will continue to have) the greatest impact on coatings. However, it should be noted that regulatory activities in specific regions of the United States (for example, the state of California and the Ozone Transportation Commission—that includes 12 states in the U.S. Northeast plus the District of Columbia) have resulted in the development of VOC emissions rulings (see section on "Other Important U.S. Regulatory Activities"), which are more stringent than those enacted through EPA. In addition, other regions of the world are developing or have already enacted regulations addressing the emissions of volatile organic compounds.

THE CLEAN AIR ACT AND AMENDMENTS

Photochemical Smog

A precipitating factor influencing the basis for selection of solvents for coatings in the 1960s and early 1970s was the recognition that solvents emitted to the atmosphere contributed to the growing "smog" problem, particularly in Southern California. The frequency of smog conditions in this area had increased steadily during the 1950s and 1960s as the number of automobiles, trucks, buses, and airplanes increased and as industrial development expanded with the accompanying growth of petroleum and chemical processing and power plant utilization.

Examples of Processes that Produce Hydrocarbons

- Petroleum production, refining, transport
- Internal combustion engines
- Natural processes—forests and plants (isoprene and terpenes)
- Surface coatings

The smog problem was (and still is) very acute in the Los Angeles air basin, an area uniquely situated in a series of plains that originate in the high mountains to the east. The basin enjoys predominantly sunny days with cool, moist air flowing with a light westerly wind most of the year. These factors cause a nearly permanent temperature inversion layer, trapping air emissions that combine to produce persistent and eye-irritating smog in the basin. A summer

TABLE 1—Federal Environmental Laws Administered by the U.S. Environmental Protection Agency.

Law	Abbreviation
Clean Air Act, 1970	CAA
Amendments of 1977	CAAA-77
Amendments of 1990	CAAA-90
Clean Water Act of 1972	CWA
Amendments of 1977	
Safe Drinking Water Act, 1974	SDWA
Toxic Substances Control Act, 1975	TSCA
Resource Conservation and Recovery Act, 1980	RCRA
Comprehensive Environmental Response Compensation and Liability Act, 1980	CERCLA (Superfund)
Superfund Amendments and Reauthorization Act, 1986	SARA
Title III, Emergency Planning and Community SARA, Title III Right-to-Know, 1986	

period in Los Angeles revealed that the use of organic solvents (for all purposes) accounted for about 18 % of the organic gases. About one half of the organic solvent emitted was attributed to the coatings industry, chiefly to the use in paint and coatings [1].

Based on the results of laboratory studies in "smog chambers," in which a mixture of a solvent and nitrogen oxide was exposed for 6 h to light approximately the intensity of noon sunlight, the solvents could be classified as "low" or "high" in photochemical reactivity related to the amount of peroxides and ozone produced. These studies formed the basis for the well-known Rule 66, an air pollution control regulation passed by the Los Angeles Air Pollution Control District. Rule 66 identifies an "approved" solvent as one that contains less than 20 % by volume of specific chemicals and is further limited to certain combinations of these chemicals. Thus, approved solvents can contain no more than designated amounts of the combinations shown in Table 2.

In effect, Rule 66 promoted the use of specific solvents such as aliphatic and naphthenic hydrocarbons, alcohols, esters, normal ketones, chlorinated hydrocarbons (except trichloroethylene), and nitroparaffins. Rule 66, superseded in 1976 by Rule 442, Usage of Solvents, by the California South Coast Air Quality Management District, was subsequently adopted by various other state jurisdictions.

VOC Definition

The U.S. EPA was created in 1970 by Congress as part of a plan to consolidate several federal environmental activities. Studies directed by EPA laboratories in Research Triangle Park, NC, of the photochemical reactivity of materials in a laboratory smog chamber revealed that when organic materials and nitrogen oxide were irradiated for periods of up to 36 h, even those solvents considered acceptable under Rule 66 reacted to form peroxides and ozone. Only a few materials showed negligible photochemical reactivity,

TABLE 2—Rule 66: Limits of Solvent Categories in Approved Mixtures.[a]

5 %	8 %	20 %
Hydrocarbons,	Aromatic	Ethylbenzene, branched
alcohols,	hydrocarbons	ketones, toluene, or
Aldehydes,	(W/8 C atoms)	trichloroethane
esters, ethers or		
ketones *having*		
an olefinic or		
Cycloolefinic		
Unsaturation		

[a] Calculated as the percent by volume of the total solvent.

among which were: methane, ethane, methylene chloride, 1,1,1-trichloroethane, and fluorinated compounds.

Since 1977, EPA has used the reactivity of ethane (based on a series of smog chamber experiments) as the benchmark for determining negligible reactivity. Compounds deemed less reactive than, or equally reactive to, ethane under the assumed conditions were classified as negligible. In contrast, compounds more reactive than ethane continued to be classified as reactive VOCs and were subject to appropriate control regulations.

These studies, which were prompted in part by the passage of the Clean Air Act of 1970, led to the conclusion that most organic compounds emitted to the atmosphere contribute to the formation of ozone. On this basis, EPA adopted as a regulatory objective the limit of essentially all volatile organic compounds emitted to the atmosphere from all sources, including paint and coatings applications [2].

EPA Regulatory Definition of VOC

The regulatory definition of volatile organic compounds (VOC) was revised by EPA as of November, 2004. A part of this definition is as follows:

40 CFR Part 51 Section 51.100 Definitions[3]

Volatile organic compounds (VOC) means any compound of carbon, excluding carbon monoxide, carbon dioxide, carbonic acid, metallic carbides or carbonates, and ammonium carbonate, which participates in atmospheric photochemical reactions

1. This includes any such organic compound other than those which have been determined to have negligible photochemical reactivity. The original list is: methane; ethane; methylene chloride (dichloromethane); 1,1,1-trichloroethane (methyl chloroform); 1,1,2-trichloro-1,2,2-trifluoroethane (CFC-113); trichlorofluoromethane (CFC-11); dichlorodifluoromethane (CFC-12); chlorodifluoromethane (CFC-22); trifluoromethane (HFC-23); 1,2-dichloro-1,1,2,2-tetrafluoroethane (CFC-114); chloropentafluoroethane (CFC-115); 1,1,1-trifluoro 2,2-dichloroethane (HCFC-123); 1,1,1,2-tetrafluoroethane (HF-134a); 1,1-dichloro 1-fluoroethane

[3] Code of Federal Regulations (CFR) Part 51; Requirements for Preparation, Adoption and Submittal of Implementation Plans, *Federal Register,* Volume 2, 1 July 2002, pp. 131–136.

(HCFC-141b); 1-chloro 1,1-difluoroethane (HCFC-142b); 2-chloro-1,1,1,2-tetrafluoroethane (HCFC-124); pentafluoroethane (HFC-125); 1,1,2,2-tetrafluoroethane (HFC-134); 1,1,1-trifluoroethane (HFC-143a); 1,1-difluoroethane (HFC-152a); parachlorobenzotrifluoride (PCBTF); cyclic, branched, or linear completely methylated siloxanes; acetone; perchloroethylene (tetrachloroethylene); 3,3-dichloro-1,1,1,2,2-pentafluoropropane (HCFC-225ca); 1,3-dichloro-1,1,2,2,3-pentafluoropropane (HCFC-225cb); 1,1,1,2,3,4,4,5,5,5-decafluoropentane (HFC 43-10mee); difluoromethane (HFC-32); ethylfluoride (HFC-161); 1,1,1,3,3,3-hexafluoropropane (HFC-236fa); 1,1,2,2,3-pentafluoropropane (HFC-245ca); 1,1,2,3,3-pentafluoropropane (HFC-245ea); 1,1,1,2,3-pentafluoropropane (HFC-245eb); 1,1,1,3,3-pentafluoropropane (HFC-245fa); 1,1,1,2, 3,3-hexafluoropropane (HFC-236ea) 1,1,1,3,3-pentafluorobutane (HFC-365mfc); chlorofluoromethane (HCFC-31);1 chloro-1-fluoroethane (HCFC-151a); 1,2-dichloro-1,1,2-trifluoroethane (HCFC-123a); 1,1,1,2,2,3,3,4,4-nonafluoro-4-methoxy-butane (C4F9OCH3);2-(difluoromethoxymethyl)-1,1,1,2,3,3,3-heptafluoropropane ((CF3)2CFCF2O CH3); 1-ethoxy-1,1,2,2,3,3,4,4,4-nonafluorobutane (C4F9OC2H5);2-(ethoxydifluoromethyl)-1,1,1,2,3,3,3-heptafluoropropane ((CF3)2CFCF2OC2H5); methyl acetate and perfluorocarbon compounds which fall into these classes:

i. Cyclic, branched, or linear, completely fluorinated alkanes;
ii. Cyclic, branched, or linear, completely fluorinated ethers with no unsaturations;
iii. Cyclic, branched, or linear, completely fluorinated tertiary amines with no unsaturations; and
iv. Sulfur-containing perfluorocarbons with no unsaturations and with sulfur bonds only to carbon and fluorine.

2. For purposes of determining compliance with emissions limits—VOC will be measured by the test methods in the approved State implementation plan (SIP) or 40 CFR part 60, Appendix A, as applicable. Where such a method also measures compounds with negligible photochemical reactivity, these negligibility-reactive compounds may be excluded as VOC if the amount of such compounds is accurately quantified and such exclusion is approved by the enforcement authority.
3. As a precondition to excluding these compounds as VOC or at any time thereafter, the enforcement authority may require an owner or operator to provide monitoring or testing methods and results demonstrating, to the satisfaction of the enforcement authority, the amount of negligibly-reactive compounds in the source's emissions.
4. For purposes of Federal enforcement for a specific source, EPA shall use the test methods specified in the applicable EPA-approved SIP in a permit issued pursuant to a program approved or promulgated under title V of the Act, or under 40 CFR part 51, subpart I or Appendix S, or under 40 CFR parts 52 or 60. EPA will not be bound by any State determination as to appropriate methods for testing or monitoring negligibly-reactive compounds if such determination is not reflected in any of the above provisions.
5. The following compound(s) are VOC for purposes of all recordkeeping, emissions reporting, photochemical dispersion modeling and inventory requirements which apply to VOC and shall be uniquely identified in emission reports, but are not VOC for the purpose of VOC emissions limitations or VOC content requirement:

t-butyl acetate

Note—The category of "VOC-exempt compounds" can be modified (i.e., add compounds to or delete them from the list) by EPA. Since the development of the initial list, numerous petitions requesting "VOC exemption" on specific compounds were submitted to EPA by various companies and trade associations. The petitions submitted requested that compound A be exempted from VOC control based on its low reactivity relative to ethane. As a result of those initiatives, several solvents were exempted by EPA. This list includes:

Methyl Formate (2004)
t-Butyl Acetate (2004)
Propylene Carbonate (2009)
Dimethyl Carbonate (2009)

The majority of VOC exempt solvents in the initial list were not useful in formulating coatings with good solubility and application characteristics. The delisting of acetone, parachlorobenzotrifluoride, volatile methyl siloxanes (VMS), and methyl acetate in the mid-late '90s (coupled with the recent delisting of the 4 aforementioned solvents) has provided coatings formulators with greater latitude in developing lower VOC coatings.

States may also have their own list of VOC-exempt compounds. Although state lists are often modeled after EPA definition, users of coating products should confirm that a solvent deemed VOC exempt by the agency is classified similarly by the respective state.

Metrics for Defining "Negligible Photochemical Reactivity"

In an effort to define chemicals as having "negligible photochemical reactivity" (and, therefore, exempt from VOC regulations) EPA designated ethane as the benchmark for separating reactive from negligibly reactive compounds under the assumed conditions. Prior to 1994, EPA had only granted VOC exemptions based on the metric known as the k_{OH} value. This value represents the molar rate constant for reactions between the given compound and the OH radical in the air. If the k_{OH} value of a compound is less than ethane, the compound may be less reactive than ethane and may be declared to be "negligibly reactive."

In the mid-1990s, in response to a petition for VOC exemption, EPA used another type of comparison to ethane based on the ozone forming potential of other reactions of the compound in addition to the initial reaction with the OH radical. This method was based on the concept of maximum incremental reactivity (MIR). The MIR values are usually expressed either as grams of ozone formed per mole of VOC (molar basis) or as grams of ozone formed per gram of VOC (mass basis). Both metrics were used to exempt two compounds in the 1990s.

Thus, since 1997, EPA has considered three different metrics to compare the reactivity of a specific compound to that of ethane:

1. the reaction rate constant with the hydroxyl radical (known as k_{OH})
2. MIR expressed as reactivity per gram basis
3. MIR expressed as reactivity per mole basis

Even though much debate and critique has ensued on the merits of a mass versus mole comparison, in "Interim Guidance on Control of Volatile Organic Compounds in Ozone State Implementation Plans" published on September 13, 2005 (70FR 54046), EPA stated:

> "A comparison to ethane on a mass basis strikes the right balance between a threshold that is low enough to capture compounds that significantly affect ozone concentrations and a threshold that is high enough to exempt compounds that may usefully substitute for more highly reactive compounds.... When reviewing compounds that have been suggested for VOC exempt status, EPA will continue to compare them to ethane using k_{OH} expressed on a molar basis and MIR values expressed on a mass basis."

The MIR values (both by mole and mass) are developed measures of photochemical reactivity derived from a computer-based photochemical model. This concept, which demonstrates that VOCs have different reactivity, i.e., different ozone-forming potential, is now shaping revised ozone control strategies at both the federal and state levels (view section on "Alternative Concept for Controlling Ozone Formation").

VOC and Ozone Formation

The understanding of "photochemical smog" and its contribution to the formation of ground level ozone has increased dramatically since the days of Rule 66. Basically, VOCs react with oxides of nitrogen (NO_X) in the presence of heat and sunlight to form ground level. However, the interrelationship of VOCs and NO_X in ozone formation is a complex series of reactions. One suggested pathway is depicted below [3].

$$NO_2 + \text{Sunlight} \rightarrow NO + O$$
$$O + O_2 \rightarrow O_3$$
$$O_3 + NO \rightarrow NO_2 + O_2$$
$$\text{VOCs} + \text{Sunlight} \rightarrow \text{Radicals}$$
$$NO + \text{Radicals} \rightarrow NO_2$$

Primary Sources of NO_x: On-road mobile sources, electricity generating units, and nonroad mobile sources.

Other articles have been published on factors affecting photochemical ozone formation and the potential of a given compound to contribute to ozone formation in the troposphere (lower atmosphere) [4,5].

In addition to the concentration of NO_2 and available sunlight in the atmosphere, ozone formation is also affected by temperature, humidity, as well as the concentration and composition of other VOCs present in the atmosphere. Also, substantial biogenic (natural) VOCs released from trees and other green plants can impact ozone formation at ground level.

Considerable interest has developed recently in the consideration of individual solvent photochemical reactivity in state, federal, and international programs related to air quality control (see section on "New Concept for Controlling Ozone Formation").

Other VOC Definitions

The U.S. EPA defines a category of VOC-exempt compounds (as described in the section on "EPA Regulatory Definition of VOC"). However, for many consumer products (i.e., floor polishes, glass cleaners, automotive rubbing or polishing compounds, etc.), EPA has determined that low volatility compounds may also be exempted from regulations as VOCs. These include solvents:

> Having a vapor pressure (VP) < 0.1 mm Hg at 20°C; or
> Consisting of > 12 carbon atoms, if the VP is unknown; or
> Having a MP > 20°C, and which does not sublime (i.e., does not change directly from solid into a gas without melting), if the VP is unknown.

Currently, there is no explicit LVP (low vapor pressure) exemption for products used in paints and coatings. Thus, some LVP products are regulated as VOCs in coatings but not when used in consumer products.

Lastly, a wide disparity in the definition of a VOC exists across countries. A product classified as a non-VOC in the Unites States does not automatically receive the same classification in Europe. For example, the criteria for the EU eco-labeling scheme is that a VOC is "any organic compound with, at normal conditions for pressure, a boiling point (or initial boiling point) lower than or equal to 250°C" [ref—Official Journal 39 (L4), 6 January (1996)]. Thus, coalescing aids for latex paints with a boiling point (BP) >250°C would not be a VOC under the EU eco-labeling definition. Other countries are becoming more proactive in developing rules and definitions addressing VOC issues.

The Ozone Standard

The Clean Air Act of 1970 targeted six criteria pollutants for control: carbon monoxide, lead, nitrogen dioxide, ozone, particulates, and sulfur dioxide. Criteria pollutants are those for which criteria were issued by EPA. These documents include national ambient air quality standards (NAAQS) for each criteria pollutant—levels that protect against adverse effects to health and to plants and materials [6]. These criteria documents and standards were to be reviewed every 5 years and if necessary, revised to assure that the standards provided adequate health protection. Criteria pollutants are measured using a network of monitors nationwide. Standards for ozone and nitrogen oxides are:

Ozone: In July 1997, the U.S. EPA revised its NAAQS for ground-level ozone and particulate matter. The complete standards appeared in the July 18, 1997, edition of the *Federal Register* (pp. 38652–38896). The EPA began phasing out and replacing the previous 1-hour standard (last revised in 1979) with a new 8-hour standard. The new standard would be 0.08 ppm measured over 8 hours, replacing the old standard of 0.12 ppm measured over 1 h. In establishing the 8-hour standard, the EPA defined the new standard as a "concentration based" form, and it called for measuring the 3-year average of the annual 4th-highest daily maximum 8-hour ozone concentration.

On June 20, 2007, the EPA administrator signed proposed revisions to the NAAQS for ozone. The end result of the proposal was the 8-hour "primary" standard for O_3 set at 0.075 ppm in the March, 2008 final rule.

On January 6, 2010, the EPA proposed to strengthen the NAAQS for ozone. This provision proposed that the 8-h "primary" standard for ozone be set at a lower level within the range of 0.060–0.070 ppm. This action would provide increased protection for children and other "at risk" populations against the adverse health effects related to ozone exposure. According to the publication "Ozone Air Quality

Standards: EPA's Proposed January 2010 Revisions" (following public hearings and comments)—a final rule was scheduled to be issued by August 31, 2010.

The Clean Air Act requires that the EPA set a standard based on the need to protect public health "with an adequate margin of safety." For policy guidance, timelines, recent actions, etc., on the new ozone standard, see the following: www.epa.gov/air/ozonepollution/.

Note—Primary standards set limits to protect public health, including the "health" of sensitive populations such as asthmatics, children, and the elderly.

The implementation of a new ozone standard is of vital interest to the paint industry since the CAAA-90 specifically identifies paint and coatings for various controls for VOC emission reductions, one precursor for ozone formation. Under the new standard, there could be additional ozone nonattainment areas that will increase the need for compliant coating technology.

Nitrogen Dioxide: The nitrogen dioxide concentration in the atmosphere cannot exceed 0.053 ppm as the annual arithmetic mean concentration. In 2010, the EPA supplemented the existing annual standard for NO_2 by establishing new short-time standard based on the 3-year average of the 98th percentile of the yearly distribution of 1-hour daily maximum. EPA set the level of this new standard at 100 ppb. Final rule is listed at: http://www.regulations.gov.

As of February, 2010, there are no areas in the United States that are designated as nonattainment of the NO_x, NAAQS. Although no change has occurred in NAAQS for nitrogen dioxide, decreasing NO_x emissions [various nitrogen compounds like nitrogen dioxide (NO_2) and nitric oxide (NO)] are receiving more attention from the EPA in an effort to minimize ground level ozone, which is formed when NO_x and VOCs react in the presence of heat and sunlight. This is an important shift in strategy for controlling ozone formation since it recognizes that in geographical regions in which the ratio of VOCs to NO_x is high ("NO_x -limited conditions"), additional reductions in VOC emissions will have a minimal impact on air quality.

CONTROL OF VOC EMISSIONS FROM COATINGS

The Clean Air Act addresses air pollution emanating from both existing sources and that from future new plant construction or significant modification of existing sources. States with areas that did not comply with the ozone standard were given primary responsibility to develop appropriate regulations for existing sources to meet the time schedule for compliance specified by Congress. The plan outlines the measures that the state will take in order to improve air quality.

The Federal EPA was assigned oversight responsibility for the state programs that were described in "State Implementation Plans" (SIPs). The plan outlines the measures that the state will take in order to improve air quality. No SIP can mandate weaker pollution controls than those established by the EPA. The SIP is reviewed by the EPA and if deemed unacceptable, the EPA must prepare one for it. For example, failure by a state to submit an adequate SIP can result in restrictions on federal highway funds.

Control Technique Guidelines

In 1977, the Agency issued the first of a series of guidance documents for the states related to various industrial coating operations or end-use categories. These documents, called "Control Technique Guidelines (CTG) Series, Control of Volatile Organic Emissions from Stationary Sources," include recommended VOC emission limits, based on the EPA's assessment of Reasonably Available Control Technology (RACT): the limits are expressed as pounds of VOC per gallon of coating (minus water), as applied. The EPA has defined RACT as the lowest emission limit that a source can meet by the application of control technology that is reasonably available considering technological and economic feasibility.

The Clean Air Act Amendments of 1977 directed that states had to revise their implementation plans for areas out of compliance with the national ozone standard. The revised SIPs were to include sufficient control of VOC emissions from stationary sources (buildings, structures, facilities, and installations), such controls to incorporate the RACT limits for coatings operations for which a CTG was published.

Note—CTGs are not federal regulations. However, they do provide federally prescribed control measures to be incorporated as a part of approved SIPs.

Under the CAAA-90, the EPA scheduled issuance of CTG documents for 29 categories of VOC sources, which covered a variety of surface coating operations. Section 183 of the amended act also requires that the EPA issue CTGs for an additional number of surface coatings processes by 1993. In addition, the EPA planned to integrate HAP (Hazardous Air Pollutant) rulemaking with VOC requirements under 183 (e).

For the industry source categories, the approach to reduce VOC emissions has been for applicators to either adopt an alternate coating technology (high-solids, waterborne, powder, UV cure), or install engineering controls (carbon adsorption, incineration, etc.).

NEW SOURCE PERFORMANCE STANDARDS

The control of VOC emissions from new coatings plants and from significant modifications of existing plants was addressed by the EPA in a series of New Source Performance Standards (NSPS), the first of which issued in 1980. These mandatory standards, which apply uniformly to all parts of the country, define the emission sources more narrowly and impose a tighter level of emission control than that for related existing sources. Facilities that are constructed, modified, or reconstructed after the NPSP was proposed by the EPA are subject to NSPS.

The VOC limits defined in the NSPS, expressed as kilograms of VOC per liter of applied solids, are based on the best demonstrated technology (BDT) for the specific coating operation. The NSPS requirements can be found in the Code of Federal Regulations at Title 40 (Protection of Environment), Part 60 (Standards of Performance for New Stationary Sources): http://ecfr.gpoaccess.gov/cgi/tZtext/text-idx?sid=474f779beade290997e4611971d078f4&c=ecfr&tpl=/ecfrbrowse/Title40/40tab_02.tpl.

The emission limits in both the CTG and NSPS documents, in the majority of cases, focus on restricting the VOC content per unit of coating or of coating solids applied in the operation, rather than placing a ceiling on individual plant emissions. The responsibility for establishing emission limits for particular plants, if appropriate, was left to the states [7].

TABLE 3—Clean Air Act Amendments—1990 major source identification based on VOC I emissions; limits for area classifications

Ozone Nonattainment Area Classification	VOC Emission Limit, tons/year
Marginal or moderate	100
Serious	50
Severe	25
Extreme	10

DETERMINATION OF VOC CONTENT

EPA Federal Reference Method 24

The procedures specified by the federal EPA for testing paint products for compliance with VOC limits are described in Federal Reference Method 24: Determination of Volatile Matter Content, Density, Volume Solids, and Weight Solids of Surface Coatings [8]. This standard employs several ASTM test standards, including those shown in Table 3. In addition, Reference Method 24A: Determination of Volatile Matter Content and Density of Publication Rotogravure Inks and Related Publication Rotogravure Coatings incorporates these ASTM standards. These two documents provide the framework for referencing these ASTM standards in determining VOC levels under regulation.

Method D2369 is a key procedure of Federal Method 24. Since 1980, several important revisions have been made in this standard to make it compatible with revisions in Method 24, including the addition in 1990 of instructions for testing multicomponent coatings and the deletion of sections dealing with testing at shorter times. The revised version of Federal Reference Method 24 is also included in the *ASTM Manual on Determination of Volatile Organic Compound* (*VOC*) *Content in Paints, Inks, and Related Coating Products,* 2nd ed., 1993 [9].

Substantial revisions were also made in ASTM D3960, Practice for Determining Volatile Organic Compound (VOC) Content of Paints and Related Coatings, a standard developed in ASTM Subcommittee D01.21 to provide a guide for the calculation of VOC and to establish a base for the investigation in ASTM of the precision of VOC content determination. The definitions and symbols used in D3960 are those adopted by the EPA and included in the Agency document "Procedures for Certifying Quantity of Volatile Organic Compounds Emitted by Paint, Ink and Other Coatings" that was published in 1984 [10].

Studies and discussions in ASTM Subcommittee D01.21 that led to the modification and improvements of ASTM standards referenced in Federal Method 24 and in ASTM Practice D3960 were conducted with the cooperation of EPA personnel of the Office of Air Quality Standards Development at Research Triangle Park, NC.

EPA Method 24 was designed to be used for measuring the VOC content of all coatings that are intended for either ambient or baking film conditions. However, that method was not applicable to ultraviolet (UV) radiation-cured coatings. Therefore, the method was subsequently amended to incorporate ASTM Method D5403-93, which does contain those procedures. The test methods in D5403 determine the weight percent volatile content of paint, coatings, and inks that are designed to be cured by exposure to ultraviolet light or to a beam of accelerated electrons. After radiation cure, the specimens are baked at 110±5°C for 60 min.

The general expression for calculating VOC content [ASTM D5201-05a (2010) Standard Practice for Calculating Formulation Physical Constants of Paint (Physical Constants of Paint and Coatings)] is available from ASTM International at the following link: http://www.astm.org/Standards/D5201.htm.

The expression "VOC" includes all organic emissions from a coating, not just the solvent in a coating. These emissions can include volatile additives, by-products of the cure reaction, etc. "Formulation" VOC content may or may not be an acceptable means for compliance, depending on the specific wording of the applicable regulation. It would be acceptable if the same VOC content is obtained when tested using EPA Method 24.

The EPA would have preferred to limit VOC emissions in the CTG on the basis of the unit volume of coating solids applied. However, the general expression for calculating VOC content in which VOC content is defined as mass per unit volume of coating less water and less exempt solvent was necessary as no acceptable consensus procedure was available for determining the volume percent nonvolatile content. In a presentation in Copenhagen in 1990, James C. Berry of the U.S. EPA stated: "Though certainly less than ideal, the major attraction is that the expression permits the determination of compliance from the analysis of a coating sample obtained during a plant inspection. In the simplest case, these units require only one volumetric and one gravimetric measurement" [7].

The measurement of low VOC content waterborne coatings (e.g., architectural) using EPA Reference Method 24 was found to be unreliable (confirmed by industry round-robin lab trials). Studies demonstrated that the error in VOC measurements in waterborne coatings was inversely proportional to the VOC content of the coating (i.e., the lower the VOC content, the poorer the precision to be expected). As industry moved toward lower VOC coatings for compliance purposes, it was prudent that a more reliable test method be found that more accurately quantified VOC content in waterborne coatings. After much stakeholder corroboration, the following test was developed: ASTM D6886-03 "Speciation of the Volatile Organic Compounds (VOCs) in Low VOC content Waterborne Air-Dry Coatings by Gas Chromatography," ASTM International. The method was designed primarily for the analysis of waterborne coatings in which the material VOC content is <5 wt %. Presently, ASTM D6686-03 is being revised (ASTM WK24436) to include VOC analysis of a wider range of materials.

OTHER VOC-RELATED METHODS AND STUDIES

ASTM development activity on other VOC-related standards continues to expand. Some standards have not been approved as yet by the Federal EPA for use in demonstration of compliance with VOC emission control regulations. Use of any of these standards to demonstrate compliance should be coordinated with appropriate regulatory agencies. Document summaries on all ASTM standard test methods are located at: http://www.astm.org.

Additional information on ASTM test methods and the EPA's surface coating rules are available at: http://www.epa.gov/ttn/atw/coat/common/coatingscalc.html.

Supplementary Information

Further information about the development, significance, and limitations of these VOC-related ASTM standards as well as about the use of ASTM standards for the demonstration of compliance with VOC emission control regulations is available in the ASTM *Manual on Determination of Volatile Organic Compounds in Paints, Inks, and Related Coating Products* [9]. Attachments in the second edition of this manual include the 1992 revision of Federal Reference Number 24 and a publication from EPA's Emission Standards Division titled "Procedure for Certifying Quantity of Volatile Organic Compounds Emitted by Paint, Ink and Other Coatings" [10]. Included in the latter publication are "VOC Data Sheets," applicable to coatings "as supplied" by the manufacturer and for coatings "as applied" by the user. The form used for "as supplied" coatings is patterned after a recommendation of the American Coatings Association (ACA). Other resources include other chapters from the *Paint and Coating Testing Manual.*

CLEAN AIR ACT AMENDMENTS OF 1990

The Clean Air Act Amendments of 1990 defined a comprehensive long-term approach "to achieve and maintain a healthy environment while supporting a strong and sustainable economic growth and sound energy policy."[4] A major impetus for these amendments was the continued inability of a number of heavily populated urban areas to meet the requirements of the national ambient air quality standards for ozone and carbon monoxide.

Among the specific issues addressed in the Act were: control of ozone in the atmosphere; control of hazardous air pollutants (HAPs); reduction of acid rain; and the protection of ozone in the stratosphere.

Features of the Act that have had a major impact on the coatings industry include:

Title I—Ozone Control in the Atmosphere

Title I specifically directed the EPA to develop control technique guidelines and maximum achievable control technology (MACT) standards for aerospace coatings and for shipbuilding coatings and repair. The EPA was also directed to prepare new control technique guidelines for additional coatings uses that included:

- Auto body refinishing
- Plastic parts (business machines)
- Plastic parts (others)
- Offset lithography
- Wood furniture

In 1997, the Coatings and Consumers Product Group of the U.S. EPA began the development of additional CTGs for a series of new surface coatings and for some of the categories, national rules. This coordinated rule development was an effort by the agency to ensure consistency in the rule developments within the surface coatings industries and composite operations (collectively known as the "Coatings and Composites Coordinated Rule (CCCR)." Coupled with this effort was the development of National Emission Standards for Hazardous Air Pollutants (NESHAPs) under section 112 of the CAA (see following section "Title III—Air Toxics Program"). The EPA involved a wide variety of industry stakeholders in the rule-making process in order to expedite the promulgation of rules and to make the process more cost effective for both the agency and industry. Extensive information on the current status of the Coatings and Composite Coordinated Rule Development is available at: http://www.epa.gov/ttn/uatw/coat/coat.html.

While coating formulators worked under established CTG and SIP guidelines, the CAAA-1990 (Section 183e) also required the EPA to conduct a study of the role of VOC emissions from consumer and commercial products (including that from aerosols) in ozone formation. This led to the development of national rules addressing VOC emissions from AIM (architectural and industrial maintenance) coatings and consumer products. The national AIM rule was finalized on Sept. 9, 1998. Details of the rule are available at: http://www.epa.gov/ttnatw01/183e/aim/aimpg.html.

This rule was directed at area sources, a collection of similar emission units within a geographical area. Therefore, engineering controls were generally not an option for coatings applied to structures in the fields. Thus, it was necessary that the applied coating meet the specified VOC content in the rule. Several states, including California and other northeastern states (OTC), have introduced rules regulating VOC emissions from AIM coatings. Typically, these are more stringent than the existing EPA national AIM rule (see subsequent section "Other Important U.S. Regulatory Activities").

National Rules for Consumer Products were promulgated in 1998. The regulation was designed to control VOC emissions from household consumer products, such as floor polishes, personal care, etc. Details of the rule are available at: http://www.epa.gov/ttn/atw/183e/cp/cppg.html.

In the CAAA-90, ozone nonattainment areas were placed in five classifications (marginal, moderate, serious, severe, and extreme) based on the mid-1991 ozone level and compliance with the national ozone standard by specific years is mandated in the law. In addition, a Northeast Ozone Transport Region was created, consisting of all states north of Virginia and east of Ohio.

Increasingly strict provisions, including further reduction of VOC emissions, were imposed on areas, the magnitude to be related to the severity of the ozone problem (i.e., the more severe the problem, the longer that Congress has provided for an area to reach attainment). Depending on the area classification, several or all of the following were required:

- Increased monitoring and more accurate VOC and NO_2 emission inventory
- Revision of state implementation plans to incorporate RACT limits from previous and future CTGs for all major stationary sources
- New source review and permits for new or modified stationary sources
- Reduced emission threshold levels for the definition of major stationary sources, ranging between 10 tons/year for severe classification areas to 100 for marginal or moderate areas
- Higher VOC emission offset requirements for new or modified sources

[4] U.S. EPA Office of Air and Radiation, "Implementation Principles for the Clean Air Amendments of 1990."

However, with the ongoing transition in the ozone standard, the agency had to designate and reclassify all nonattainment areas in the United States with respect to the latest standard. In the interim, the nonattainment area must demonstrate to EPA that they are making reasonable further progress toward improving their air quality.

Additional information as related to ozone compliance can be accessed at: http://www.epa.gov/air/ozonepollution/index.html.

Title III—Air Toxics Program

Before 1990, the EPA listed and regulated only eight HAPs as National Emission Standards for Hazardous Air Pollutants (NESHAP) under 40 CFR Part 61. The listed HAPs were based on risk findings and "Risk-Based" NESHAP were then developed to reduce the emissions of the designated pollutants. By the late 1980s, total HAP emissions remained largely uncontrolled.

Under Title III, the EPA is directed to evaluate and control the emission of air toxics (also known as hazardous air pollutants-HAPs) from major sources of air pollution. HAPs are materials known or suspected to cause cancer or other serious health problems, or to cause environmental and ecological effects. Originally 189 products and product categories (now 187) were identified in the Act, and the EPA has the authority to delete or add additional products to this list. Industry groups have petitioned the EPA to delist products (see following note). A list of the materials included on the HAP list can be found on the following website: http://www.epa.gov/ttn/atw/allabout.html.

Note—Three petitions were submitted by the American Chemistry Council (ACC) requesting that the EPA delist MEK, EB glycol ether, and MIBK from the HAP list.

The EPA issued a final rule on November 29, 2004, removing ethylene glycol monobutyl ether (EGBE) from the Clean Air Act list of Hazardous Air Pollutants (HAPs).

Later, on December 15, 2005, EPA issued a final rule removing Methyl Ethyl Ketone (MEK) from the list of Hazardous Air Pollutants (HAPs) under section 112(b) of the Clean Air Act.

In the Spring 2010 Semiannual Regulatory Agenda (SAN 4849, Sequence 688—Petition to Delist a Hazardous Air Pollutant from Section 112 of the Clean Air Act: Methyl Isobutyl Ketone (MIBK)), the EPA reported the following:

> "However, since the last submittal by the petitioner, a 2-year MIBK bio-assay by the National Toxicology Program (NTP) has been completed. A draft report of this study was reviewed by the NTP Board of Scientific Counselors Technical Reports Review Subcommittee, which accepted unanimously the conclusions in the report that there is some evidence of carcinogenic activity of MIBK. EPA has notified the petitioner that further review of the petition will require that the petitioner submit information regarding the relevance of the NTP study and a risk characterization for the human risk of cancer from MIBK exposures, which would include the derivation of a cancer unit risk estimate."

In a previous ruling (40 CFR Parts 63 and 302), low molecular weight EO glycol ethers such as 2-ethylhexyl ether have been excluded from the glycol ether category in the list of HAPs established by Section 112(b)(1) of the CAAA-1990.

The control of emissions of hazardous air pollutants was to be achieved through the promulgation of emission standards for facilities within an industry group (or source category) that emit these products. The initial list of categories of sources published by the EPA (57FR31576, July 16, 1992) included under *Surface Coatings Processes* those processes for which CTG or national rules have been issued or planned.

Under the "technology-based approach," the EPA was directed to develop MACT standards based on the best-performing existing sources and the current status of control technology. The MACT standards are based on emission levels already achieved by the best performing facilities. These emission levels define a baseline (often referred to as the "MACT floor"—typically the control achieved by the best 12 % controlled of existing facilities in the source category). Normally, the emission limit in a MACT standard is expressed as a per cent reduction in emissions or a concentration limit that regulated sources must achieve.

The legislation addresses the amount of HAPs emitted into the air—not the amount that may be used at a specific site. Thus, facility owners have flexibility in determining the most effective method to comply with the regulations. It should be noted that the standards do not apply to coatings that contain < 1 wt. % HAP content (cumulative total) or < 0.1 wt. % (if the HAP is a carcinogen). Thus, coatings that contain less than these de-minimis levels are considered to be HAP-free.

MACT standards apply to sources that are major emitters of HAPs. "Major" sources are defined as sources that emit or have the potential to emit 10 tons per year of any listed HAP, or 25 tons per year of a mixture of HAPs. New sources must comply immediately upon startup and existing sources within three years.

The Act directs that the health impact and economic factors be considered in defining appropriate MACT limits. The EPA must insure that MACT compliance is protecting public health and must establish residual risk standards within 9 years after promulgation of each MACT standard. If studies show excessive risk, EPA must enforce stricter standards.

Further, by the end of 1995 sufficient categories and sub-categories must be listed to ensure that 90 % of the area sources that emit the 30 most hazardous air pollutants are subjected to regulation. An "area source" is defined as any area that is not a major source, including structure, building or installation that emits or may emit HAPs.

A draft timetable for regulating the categories of sources of hazardous air pollutants was published by EPA in 1992 (57FR44147, 24 Sept. 1992). The Act established a schedule for promulgating MACT standards as follows:

1. By 11/15/92, not less than 40 categories.
2. By 11/15/94, 25 % of listed categories
3. By 11/15/97, another 25 % of listed categories
4. By 11/15/2000, all categories

EPA's published list of "source categories" contains numerous surface coating operations. By the end of 1994 HAP emission standards were due for the following surface coating processes: magnetic tapes, printing/publishing, shipbuilding and ship repair, and wood furniture. Once promulgated, each NESHAP is published as an individual Subpart to Title 40 Code of Federal Regulations (CFR) Part 63.

The EPA was required under Section 112 to complete promulgation of all MACT Standards by November 15, 2000. If that date was not met, then individual facilities within those categories must apply for case-by-case MACT determinations by May 15, 2002. This provision became known as the "MACT Hammer," and was intended to assure that the EPA would issue the designated NESHAPs on schedule.

Even though some NESHAPs were completed for surface coating categories prior to 2000, the promulgation of many of those standards was delayed. Additionally, the EPA was unable to meet the required deadline (May 15, 2002) for promulgating a NESHAP for any category of major sources. As a result, the agency promulgated a regulation on April 5, 2002, that would allow affected sources a pathway (two-part application procedure) to satisfy the requirements of Section 112(J). Environmental groups challenged the regulation in court and a settlement was issued giving states and industry guidance and new timelines on the permitting necessary for the remaining MACT rules that were not promulgated in the required time period. The status of the NESHAPs affecting coating processes can be found at several EPA websites: http://www.epa.gov/ttn/uatw/coat/coat.html and http://www.epa.gov/ttn/atw/mactfnlalph.html.

In addition to the federal HAP program, many states have their own air toxics program. These programs may include compounds not on the federal HAP list. One example is the California Air Toxics "Hot Spot" Information and Assessment Act. Thus, coatings users need to aware of state guidelines regulating air toxics as well.

Determination of HAP Content

The EPA's National Emission Standards for Hazardous Air Pollutants (NESHAP) for surface coatings specify that EPA Method 311 shall be used for determining the type/amount of volatile HAPs used in a coating (40 CFR Part 63 Appendix A). This method (gas chromatographic separation and quantification) applies only to HAPs that are included in the original coating as manufactured, not to those HAPs (methanol and formaldehyde) that may form as the coating cures.

This method is suitable for the determination of most compounds designated as HAPs by the EPA. Styrene, ethyl acrylate, and methyl methacrylate can be measured by ASTM D4827-93 or ASTM 4747-87. Formaldehyde can be measured by ASTM PS 9-94 or ASTM D1979-91. Toluene Diisocyanate (TDI) can be measured by ASTM D3432-89.

Issues remain over the precision of Method 311, particularly at very low HAP levels. Since no specific conditions (carrier gas, oven temperature, etc.) are given for the analysis in the test method, one single methodology may not be applicable for all HAPs in the formulation. Therefore, prior information on the volatile composition of the coating will aid in choosing the proper conditions for that analysis and ensure greater accuracy in the measurements. Certified Product Data Sheets (CPDS) from suppliers is one source of such information.

Title V—State Operating Permit Program

The state operating permit program is considered by the EPA as a cornerstone of the CAAA-1990 amendments designed to ensure that the ozone nonattainment areas meet compliance deadlines. This program will impact many previously unregulated coatings manufacturers and users. The final rule for the operating permit program was issued in 1992 (57FR32250, 21 July 1992—codified at 40 CFR Part 70).

The operating permit program has been called the "air pollution equivalent" of the NPDES permit program of the Clean Water Act, under which operating permits are required of sources that discharge pollutants to water. In the program under Title V, all federal and state air pollution rules and regulations will be consolidated under a single document wherein the states are given authority to monitor and enforce the regulations. Sufficient funds will be available to the states from a minimum annual fee of $25 per ton (with the Consumer Price Index Adjustment) for each regulated pollutant emitted the fee to be assessed against all major sources.

Major sources required to have state operating permits include those that have the potential to emit [i.e., the maximum capacity of a stationary source to emit any air pollutant under its physical or operational design (taking into account federally-enforceable emission restrictions)] 10 tons or more per year of a single regulated hazardous air pollutant or 25 tons per year of a combination of hazardous air pollutants. These pollutants include those materials for which a national emission standard (NESHAP) has been established. Under Title V of CAAA-90, and the final rule on operating permit programs, the EPA is to approve (or disapprove) state permit programs within one year of receipt; the major sources must apply for the five-year permit within one year of the EPA's approval of the state program, and all permits must be issued and be legally binding by the end of 1997. In addition, federal requirements specify that renewal applications must be filed 18 months before current permit expires; state programs may stipulate a shorter time. Under the rule, states have the option of exempting all non major sources, with some exceptions, from requiring a permit for five years after the state permit program is approved by the EPA.

The characterization of a major source in ozone nonattainment areas is also based on the amount of volatile organic compounds emitted annually. The threshold amount is related to the area classification and sources in ozone nonattainment areas that emit above the designated amount of VOC shown in Table 3 are identified as major sources. These limits vary between 10 tons/year for the "extreme" classification to 100 tons/year for the "marginal or moderate" classification. For ozone transport regions (e.g., one is established in the Northeast), a threshold limit of 50 tons/year of VOC emissions applies.

The earlier amendments of the CAA had also established specific permitting requirements. Permits were required for a variety of sources, including new major sources of criteria pollutants, which must undergo a preconstruction review and permitting process in accordance to federal law and regulations. In nonattainment areas, the process is called "New Source Review" (NSR). Several rule requirements must currently be met before a new or expanded facility can obtain a permit to operate in a nonattainment area. The permit applicant must adopt the most stringent pollution controls as well as certify that other facilities under its control in the state are in compliance with the air pollution control requirements. Thirdly, the permit applicant must obtain sufficient surplus emission reductions to "offset" their net emission increases. The "offset" ratios for nonattainment areas are not a one-to-one

offset. The ratio is greater for areas with more severe ozone problems. EPA guidance on the use of emission offsets is available in 40 CFR Appendix S to Part 51.

In addition to the permitting requirements for major sources in nonattainment areas, EPA wanted to assure that areas (attainment) currently meeting the NAAQS maintain a healthy level of air quality. An attainment area is governed by the "Prevention of Significant Deterioration" (PSD) program, which requires the new source to obtain a preconstruction permit. Now under the CAAA-90, such sources must also obtain and maintain an operating permit. Since attainment is pollutant specific, an area may be nonattainment for one pollutant and attainment for others.

The permitting process is quite detailed and often requires the assistance of an environmental consultant and/or attorney. The "Minimum Operating Permit Application Requirements" are defined at 40 CFR 70.5. Likewise, the "Minimum Requirements for the Permit Content" are defined at 40 CFR70.6.

Title VI—Stratospheric Ozone Protection

The CAAA-1990 directs the EPA to protect the stratospheric ozone layer. Scientists found that certain chemicals, particularly chlorofluorocarbons (CFCs), were causing destruction of the ozone layer in the stratosphere. The EPA was directed to publish and periodically update a list of Class I and Class II substances. Class I must include at least 15 CFCs, three halons, carbon tetrachloride, and 1,1,1 trichloroethane. Class II must include at least 33 HCFCs. Other substances found to have harmful effects on the stratospheric ozone layer could be added to either list, depending on their ozone depleting potential. Class I ODS has a high potential for ozone depletion, whereas the propensity for ozone depletion for Class II ODS is lower. Once the substances are properly categorized, the production and use of the substances in each class is reduced according to a specific schedule in the Act.

The most significant feature of the program to protect ozone in the stratosphere was the staged phaseout of 1,1,1-trichloroethane (also known as methyl chloroform, or MCF), a material widely used in coatings and classified as a "VOC-exempt" solvent by the EPA. The rule specified a time schedule for manufacturers to gradually reduce their production of methyl chloroform and to completely phase out the chemical by 2002. However, in March 1993, following additional scientific findings, the EPA proposed rules to accelerate the phaseout CFCs, methyl chloroform and carbon tetrachloride to January 1, 1996. Additional rule information on the accelerated phase out schedule for Class I substances can be found at: http://www.epa.gov/ozone/title6/phaseout/accfact.html.

In conjunction with Title VI of the CAAA-1990, an international effort to protect the stratospheric ozone layer was already in effect. A multinational agreement known as the Montreal Protocol was originally signed in 1997 and substantially amended in 1990 and 1992. In November of 1992, the parties of the Montreal protocol agreed to accelerate the phaseout of CFCs, methyl chloroform and carbon tetrachloride to January 1, 1996, in developed countries. Developing countries could continue to produce and purchase CFCs and carbon tetrachloride for use until 2010 and methyl chloroform until 2015. More information on this protocol and phase out schedules can be located at: http://www.unep.org/ozone/index.asp.

Section 612 of the CAA requires the EPA to establish a program to determine acceptable substitutes for the ODS listed in both Class I and II. On March 18, 1994, the EPA published the Final Rulemaking (59FR 13044), which provides the process for administering the SNAP (Significant New Alternatives Policy). Substitutes are reviewed on the basis of ozone depletion potential, global warming potential, toxicity, flammability and exposure potential. Lists of acceptable and unacceptable substitutes will be updated periodically in the *Federal Register*. The present list of substitutes for ozone-depleting substances is available at: http://www.epa.gov/ozone/snap/lists

Title VII—Enforcement

In addition to the requirements for enhanced monitoring, the EPA is granted broad new authority to impose penalties and substantial fines for various actions, including: violations of the SIP; violation of some of the operating permit provisions; and false statements in records, monitoring data, and reports. Also included are provisions for field citations by inspectors, which can lead to a substantial per-day-per-violation fine against a facility.

Criminal penalties are also built into the CAAA-1990 as well. "Any person" who knowingly violates the act can receive fines as well as imprisonment. This is true also if an individual fails to file or maintain records as required or negligently releases any air toxics that causes harm danger.

OTHER IMPORTANT U.S. REGULATORY ACTIVITIES

In the United States, other organizations besides the EPA are developing more stringent VOC levels for paints and coatings. The two primary ones are the South Coast Air Quality Management District (SCAQMD) with a myriad of regulations in effect; and the Ozone Transport Commission (OTC), with regulations that affect 13 Northeastern and Mid-Atlantic states.

In 1998, the SCAQMD passed AIM Coating Rule 1113, imposing severe VOC limits on AIM coatings sold in its district. In most categories, the VOC limits for AIM products were more stringent than the federal standards. Subsequent revisions (enforcing even more stringent VOC limits for AIM paints) were challenged by industry representatives and trade associations. Current information on Rule 1113 is available from the district's website: http://www.aqmd.gov.

Outside of California, the OTC developed model rules of control measures for a number of source categories, including AIM. The AIM Model Rule was developed for the OTC northeastern states based on California's Suggested Control Measure (SCM) for VOC limits for AIM coating applications. More information on OTC AIM Coatings Rule Development can be located at: http://www.otcair.org/.

In addition to the organizations listed above, another regional cooperation for working together on regional air problems was established in 1989 by the states of Illinois, Indiana, Michigan, and Wisconsin. This was known as the Lake Michigan Air Directors Consortium (LADCO). The state of Ohio joined LADCO in 2004. See the following website for further details: http://www.ladco.org/.

ALTERNATIVE CONCEPT FOR CONTROLLING OZONE FORMATION

Background

When the EPA developed its original VOC control policy for ozone formation, its general approach was based upon the control of total VOC emissions by mass, without distinguishing individual species of VOC (except those that were deemed "negligibly reactive"). And, collected emission data from earlier years appeared to confirm that this approach was relatively successfully. Specifically, the EPA estimated that emissions from man-made sources nationwide declined by 54 % from 1970 to 2003 even though population, vehicle miles traveled and gross domestic product rose 39 %, 155 % and 176 %, respectively [11].

Ongoing science led to a better understanding of how ozone forms and the rate of ozone formation in the atmosphere. Thus, questions were raised by various stakeholders about the current VOC policy for ozone control. For example, are other regulatory methods, such as a VOC reactivity scale, more effective for controlling ozone formation? And, if so, will and how does the EPA include a "reactivity" option in its current VOC policy?

Historical Perspective on Reactivity Concept

The continued research on photochemical reactivity led many to believe that a reactivity-based approach for reducing VOC emissions would be more effective (especially in areas requiring more aggressive VOC control) than the current mass-based approach. Reactivity is a measure of how much a volatile organic compound contributes to the photochemical formation of ozone. It is a property of the compound as well as the environment in which the compound is formed. Therefore, the reactivity of a specific VOC varies with ambient conditions, VOC:NOx ratios, the identity of other VOCs in the atmosphere, and the time interval of interest. Thus, assigning a value to the reactivity of a specific VOC and developing a ranking scale or method for regulatory purposes would require an extensive research effort.

Research over the last several decades led to the ultimate development of a concept known as "incremental reactivity" which enables one to assess relative atmospheric reactivity differences in VOCs. As early as 1952, it was noted that different organic compounds vary in their potential to form ozone [12]. Subsequent work in the late 1970s and early 1980s [13,14] led to the development of reactivity scales. Correspondingly in the 1970s, the EPA recognized the variability of the ozone-forming potential of different VOCs and created an extensive two-class reactivity bin ("negligibly reactive" and "reactive").

In the late 1980s, Dr. William P.L. Carter at the University of California Riverside [15], funded by the California Air Resources Board (CARB), investigated 18 methods of ranking the reactivity of individual VOCs. Subsequently, Dr. Carter and coworkers at Statewide Air Pollution Research Center (SAPRC) and later continuing at the College of Engineering Center for Environmental Research and Technology (CE-CERT) at the University of California at Riverside (UCR) studied further incremental reactivities using smog chambers and computer modeling. Three scales were suggested for further consideration:

1. Maximum Incremental Reactivity (MIR)
2. Maximum Ozone Incremental Reactivity (MOIR)
3. Equal Benefit Incremental Reactivity (EBIR)

Following further investigations, Dr. Carter concluded that the MIR scale was the most appropriate for regulatory purposes [16] and is now the most common measure of incremental reactivity in the United States. MIR is defined as a measure of the average ozone yield of VOCs derived by adjusting the NO_x emissions in 39 base case urban scenarios to yield the highest incremental reactivity of the base ROG mixture, where ROG is reactive organic gas. Using this methodology, each VOC is assigned an individual reactivity value. MIR values for hundreds of organic compounds have been determined and continue to be revised. IR values, including MIR values for coating solvents, can be downloaded from Dr. Carter's website: http:/www.engr.ucr.edu/~carter/SAPRC/saprc07.pdf.

Note—File is large—refer to Appendix B—Mechanism and Reactivity Listings for Individual VOCs. This report is a completely updated version of the SAPRC-99 chemical mechanism, designated SAPRC-07 that provides updates to MIR values and other ozone reactivity scales for over 1,100 types of VOCs.

Many other scientists [17–20] and stakeholders have been active in the past two decades in advancing the science of the reactivity concept. One such effort has been the work of R. G. Derwent [21,22] and coworkers in Europe who created a reactivity scale known as POCP (Photochemical Ozone Creation Potential). This scale incorporated the meteorological conditions prevalent in Europe. In December 2008, Derwent reported in a presentation at the Atmospheric Chemical Mechanisms Conference that the two chemical mechanisms [SAPRC-07 and MCMv3.1 (Master Chemical Mechanism)] appear to have generated consistent reactivity scales (MRI and POCP), respectively, under California conditions.

Note—The stated references [3–5,12–22] are only samples of the comprehensive literature available on "atmospheric chemistry." Refer to section "Regulatory Information" for more guidance on locating information on VOC reactivity.

A major contributor to the development of an improved scientific basis for reactivity-related regulatory policies has been RRWG (Reactivity Research Work Group) that was sponsored by NARSTO (formerly known as the North American Research on Tropospheric Ozone) http://www.narsto.org.

The RRWG was organized in 1998 to bring together multiple stakeholders (government, industry and academia) actively interested in assessing future policies germane to the reactivity of organic compounds emitted to ambient air. Prior to its formation, the most advanced VOC reactivity potential regulations had been implemented by California for the purpose of controlling emissions from automobiles.

The RRWG organized and continues to commission research efforts on VOC reactivity under various environmental scenarios. The ongoing research has not only led to a significantly better understanding of VOC reactivity under a variety of environmental conditions but has helped address policy-relevant science issues. The recent progress in atmospheric science as it relates to ozone formation has encouraged all stakeholders and their belief that future regulatory approaches using VOC reactivity metrics will be realized.

AEROSOL COATINGS REGULATIONS (ARB)

On Sept. 13, 2005, the EPA approved California Air Resource Board's (CARB) SIP for ozone control,[5] including a reactivity-based approach to reduce ozone formation from aerosol coatings. This regulation mandates that formulators of aerosol products must meet reactivity-based limits and encourages reductions of higher reactivity VOCs. In this regulation (using the MIR concept) the product-weighted reactivity of the volatiles are controlled rather than the total mass of VOC that is emitted. Thus far, it appears that the implementation and "workability" of this rule has not been problematic [23]. The details of the process by which CARB estimates "ozone equivalent" VOC reductions are located at: http://www.arb.ca.gov/regact/conspro/aerocoat/aerocoat.htm.

In late 2008, the EPA also approved a National (reactivity-based) Volatile Organic Compound Emission Standards for Aerosol Coatings: http://www.epa.gov/EPA-AIR/2008/March/Day-24/a5589.htm.

EPA and CARB believe that the new aerosol rules will create additional incentives for formulators to use solvents with relatively low contribution to ozone formation. By doing so, it will be possible to achieve more ozone reductions than through traditional VOC mass-based regulations.

SHAPING FUTURE REACTIVITY POLICY

As the science of reactivity continues to evolve, policymakers will be even better equipped for assessing the feasibility of using reactivity-based standards. As stated in the "Aerosol Coating" section, the EPA has already been proactive in employing reactivity-based regulations at both the state and federal levels.

The EPA continues to review its Photochemical Reactivity Policy. There are many pathways to update and/or revise EPA's existing rule [24]. According to the NARSTO Review Panel Final Report on February 25, 2009:

> On September 13, 2005, U.S. EPA published in the Federal Register a Notice of Interim Guidance on SIP Development, in lieu of a more formal Advance Notice of Public Policy (ANPR). The interim guidance "encourages States to consider recent scientific information on the photochemical reactivity of volatile organic compounds" and "summarizes recent scientific findings" but "does not change any existing rules." The guidance is available on EPA website at: http://www.epa.gov/ttn/oarpg/t1/memoranda/27601interimguidvoc.pdf and http://www.epa.gov/ttncaaa1/t1/meta/m27601.html. It encourages the states to incorporate reactivity features into their individual State Implementation Plans.

The EPA believes that traditional mass-based VOC control measures continue to be effective tools for minimizing VOC contributions to ozone nonattainment problems in many situations. However, as demonstrated by the recent aerosol rulings, the EPA also believes that it is possible to use reactivity-based limits to exceed what is achievable with mass-based limits in a specific source category. Is the aerosol coatings scenario viable for other source categories?

[5] 70FR 53930, September 13, 2005: Final Rule: Revisions to the California State Implementation Plans and Revision to the Definition of Volatile Organic Compounds (VOC)—Removal of VOC Exemptions For California's Aerosol Coatings Products Reactivity-Based Regulation.

Given the current unified effort of all stakeholders involved with reactivity science, it is believed that a pathway forward on VOC reactivity and how it may be incorporated into the development of ozone control will be expanded. And, when evidence supports that a reactivity-based regulation for a category is more effective than mass-based in ozone reduction benefits, then the current regulation should be reviewed for revision.

SCENARIO FOR THE NEXT DECADE

CAAA-1990 and the myriad of new federal and state regulations associated with implementation of this comprehensive law have had a major impact on the coatings industry. And, challenges still remain for essentially all coating operations: the level of new or stricter VOC emission limits for coating operations (both federal and state); and the time, manpower, and cost associated with complying with the many new regulations associated with the amendments.

Other issues such as NO_x reduction strategy, global harmonization of VOC definition, and the expanded use of the incremental reactivity concept can potentially impact coating formulators. Regardless of the regulatory issue, coating formulators must remain informed about changing environmental regulations.

The paint market will continue to globalize, which will require increased monitoring of developments in VOC reduction programs in other countries. Important to the coating formulators will not only be regulations germane to a specific region but other labeling initiatives (i.e., EU Eco Label, Green-label certification, LEED, etc.), specifying coatings with lower VOC content.

As in the decades of 1970 through 1990, the new millennium will continue to offer opportunities for raw material suppliers to develop and provide environmentally acceptable materials to paint formulators. This, in turn, will facilitate the development of new or modified coatings with reduced VOC/HAP content. Continued attention to the improvement of coating processes and to the use of abatement equipment for emission control during the application of coatings (when feasible) will be ongoing. Ultimately, the challenge for the paint chemist is to develop cost-effective products that are tailored to meet or exceed the performance and environmental requirements of the customer.

FINDING REGULATORY INFORMATION

EPA Sources

Federal environmental regulations, including those promulgated under the CAA, are published in the *Code of Federal Regulations* (CFR), a series of books that are generally available on the internet as well as in major libraries and law libraries. These regulations as well as those of related state and local codes are also obtainable from the associated regulatory offices. Regulations of particular interest to the coatings industry can be found in subchapters of the *Code of Federal Regulations* (Table 4): http://www.epa.gov/ttn/.

Proposed regulations are published by the EPA in the *Federal Register*. Typically, a public (written) comment period of 30 to 90 days on the proposals is allowed, and often a public hearing is scheduled at which oral comments can be presented. The comments received are considered by the Agency in the development of a final regulation that is published in the *Federal Register* together with the regulation compliance date.

TABLE 4—Code of Federal Regulations Sub-chapter Topics

Sub-chapter	Subject	Parts
C	Air programs	50–87
	New source performance standards	60
D	Water programs	104–149
I	Solid waste	240–281
J	Superfund/right-to-know	300–372
N	Effluent guidelines and standards	401–471
R	Toxic substances control act	700–799

Questions relating to the interpretation, applicability, and compliance to air quality regulations may be addressed to the U.S. EPA regional offices or to the specific state regulating body responsible for air quality control. The EPA regional offices as well as satellite locations and laboratories can be accessed at: http://www.epa.gov/epahome/postal.htm.

The EPA maintains a comprehensive website with links to current regulatory and technical information germane to the CAA. The primary site for information on air quality issues, ozone depletion, air toxics, etc., is EPA's Office of Air and Radiation site, located at: http://www.epa.gov/oar/.

Other Sources

Among the industry trade organizations (list is not exhaustive) that provide information to their membership about pending regulations and guidance on compliance with finalized regulations are: America Chemistry Council (ACC), American Coatings Association (ACA), RadTech International North America, Chemical Coaters Association International (CCAI), Electrocoat Association (ECA), Paint Research Association (PRA), Steel Structures Painting Council (SSPC), Powder Coating Institute (PCI), Reactivity Research Work Group (RRWG), Chemical Specialty Products Association (CSPA), and European Solvents Industry Group (ESIG).

Several coatings journals publish excerpts from regulations and summary reviews. In addition, numerous universities have programs devoted to scientific advancements in coatings technology related to changes in air quality regulations.

Information regarding paint raw materials, coating technology, equipment, and environmental issues impacting the industry are also available through various trade shows and websites devoted to paints and coatings. Another valuable resource for environmental issues associated with the coatings industry is raw material manufacturers, especially solvent producers.

Note—the websites in this chapter were accessed on August 30, 2010.

Part 2: Naturally Occurring Materials

2

Bituminous Coatings

Ben J. Carlozzo[1]

INTRODUCTION

General Overview

IN THE UNITED STATES, THE TERMS "BITUMINOUS" and "asphaltic" are often used interchangeably. In Europe, bitumen usually refers to the mixture of heavy hydrocarbons, free of inorganic impurities. Asphalt is often considered the impure form of the generic material [1]. For our purposes, the ASTM definitions will be used.

ASTM Standard Terminology Relating to Roofing, Waterproofing, and Bituminous Materials (D1079-09) [2] defines bitumen as either "(1) a class of amorphous, black or dark colored, (solid, semi-solid, or viscous) cementitious substances, natural or manufactured, composed principally of high molecular weight hydrocarbons, soluble in carbon disulfide, and found in asphalts, tars, pitches and asphaltites; or, (2) a generic term used to denote any material composed principally of bitumen."

Asphalt is similarly defined as "a dark brown to black cementitious material in which the predominating constituents are bitumens which occur in nature or are obtained in petroleum processing." While the term has historically implied the natural deposits (the Trinidad Lake asphalts on the Island of Trinidad or the Bermudez Lake, Venezuela, asphalts), most asphalt used in the United States today for coatings applications is from petroleum processing [3].

History and Background of Bitumens

As one of man's oldest engineering materials, the adhesive and waterproofing properties of bitumen have been known since the earliest days of civilization. The area between the Tigris and Euphrates rivers in Iraq, long believed to be "the cradle of civilization," contains the earliest deposits of asphalt and liquid petroleum. Early historical and biblical accounts tell of the use of asphalt in shipbuilding and foundation mortars. The Egyptians were known to have used asphalt in the mummification process; in fact, the part-Persian word for asphalt, "mumiya," is believed to be the origin of our word "mummy" [4].

The first asphalts produced in the United States were derived from California crude oils in the late 19th century. A straight run distillation, often without steam, was able to produce a good-quality material suitable for paving work. Most of this material was competing with foreign imports from the Lake Trinidad region on the Isle of Trinidad off the north coast of South America. In the early 20th century, Mexican asphalt obtained from Mexican crude oil was used extensively in the eastern United States and gained a reputation as a high-grade standard paving bitumen.

Today, asphalts are found throughout the world in several natural deposits of soft bituminous material or as hard glassy, black bitumen associated with certain rock formations or impregnating various limestone or sandstone-type formations. Additionally, asphalts are derived from colloidally dispersed asphalt hydrocarbons in crude petroleum. This leads to the classification of bitumens into the two following classes: (1) natural asphalts (bitumens) and (2) artificial or oil asphalts (petroleum asphalts)

The purity of bituminous materials is generally related to the degree that they are soluble in certain organic solvents. For years, the degree of solubility in carbon disulfide (CS_2) has been a typical method for determining the purity of natural asphalts. ASTM Standard Test Method for Bitumen Content [D4-86(2004)] formalizes this procedure with CS_2 solubility as the primary screening test. Most oil asphalts are generally greater than 99 % soluble in CS_2.

The natural asphalts can be further classified by the geographical region of their origin, as well as the extent to which impurities are present. For example, Trinidad, refined, of approximately 50 %–57 % bitumen; Cuban, refined, of 80 %–90 % purity; Bermudez, refined, of 85 %–92 % purity; and various rock asphalts, i.e., limestone, sandstone, tar sands, etc., with varying degrees of bitumen content.

A separate class of natural bitumens is the asphaltites. These are also called the solid bitumens and are asphalts without impurities (silts, clays, salts, etc.), although their degree of CS_2 solubility varies. Examples of these materials are Gilsonite, grahamite, glance pitch, or manjak, as well as harder materials that show no softening point, such as the pyrobitumens. The most important of these for coatings applications is Gilsonite.

Artificial bitumens have been classified into the three following major groups [5].

1. Oil or petroleum asphalts are soft to hard asphalts of high solubility in carbon disulfide (more than 99 %) and are classed as pure bitumens. They are obtained from the vacuum or steam distillation of crude oils containing high asphalt content. The distillation concentrates the colloidally dispersed asphalt into the "still bottoms" or "residuum" and is often a solid material. Precipitation methods are also used to recover asphalt from raw lubricating oils. This de-asphalting operation uses propane or other low-boiling hydrocarbons. The

[1] *DCA Coatings, Cleveland, OH*

Copyright © 2012 by ASTM International

materials produced are the so-called asphaltic resins, with the hard, high asphaltene asphalts as the precipitate. Variations are made by controlling the propane stream. Oxidized or "blown" asphalts are obtained by blowing air at high temperatures through soft or liquid petroleum residues. This procedure can take semi-asphaltic materials of low purity and produce considerable amounts of bitumen. The resulting material is harder, with a higher softening point.

2. "Cracked" asphalts are also petroleum derivatives, but are obtained from by-products in oil-cracking processes. Residues are distilled to produce asphalt. They are variable in composition and may contain a certain amount of uncracked paraffinic material. These materials represent asphaltic hydrocarbons approximately intermediate in aromaticity between oil asphalts and the completely aromatic, highly condensed bitumens found in coal tars, water-gas tars, coal carbonization tars, and their pitches.
3. Coal tar, water-gas tars, and their pitches are derived from tars. ASTM D1079 defines tar as "a brown or black bituminous material, liquid or semi-solid in consistency, in which the predominating constituents are bitumens obtained … from the processing of coal, petroleum, oil-shale, wood, or other organic materials." The "free carbon" content, or other carbon disulfide insoluble matter, distinguishes coal tar from the asphaltites and oil asphalts. The latter are devoid of free carbon. Coal tars and their products are not included in the category of asphalt.

In the early 1960s, approximately 70 % of all oil asphalts were consumed by the road-paving industries with 20 % used in roofing. The solid bitumens and asphaltites of natural origin found their greatest consumption in lacquer, paint, and electrical insulation. Today, the paving industry is still the largest user of these materials, but the scope and area of specialty coatings has broadened considerably. In recent years, asphalts and other bitumens have become increasingly important as the cost of other natural and synthetic binders has continued to escalate. Their ability to act as adhesives with excellent moisture vapor transmission properties continues to result in new and varied uses.

Coating Types

The types of asphaltic or bituminous coatings available can be classified, in a large part, by the industry of use. Industries considered are as follows:

1. The paints and coatings industry, where bituminous coatings have been used to protect metal from the effects of water and oxygen degradation.
2. The roofing industry, where asphaltic coatings are used extensively to weatherproof buildings.
3. The construction industries, where concrete and mortar are waterproofed.
4. The paving industry, where the adhesive properties of asphalt as binder are put to good use in roads.

Specialty Paints and Coatings

Asphalt, coal tar, and other bitumens have been used in several specialty areas in the paint and coatings industry. The predominating use has been in the area of pipe coatings and automotive under-body coatings, although containment coatings are fast becoming a sizable market.

In pipe coatings, the base bitumen forms an interpenetrating network with a thermosetting resin to form an impervious barrier to groundwater and the effects of catastrophic rusting. On deep buried pipes or those set in concrete, the cost associated the use of an expensive binder is offset by the replacement costs involved. The thermoset resins most frequently used have been the epoxides. The bitumens used in these coatings have generally been the coal tars and pitches. This was primarily due to the compatibility of these highly aromatic materials with epoxy resins as well as the ease of working with a liquid material. The final film hardness is derived from the cross-linked epoxy network.

There has been a growing concern over the years with the toxicity of highly aromatic systems. The result has been that trade sales and light industrial coatings have moved away from coal tar or its pitches. Recently, the asphaltites and oil asphalts have been used in these types of coatings. The trend has been to use softer asphalts. Some form of compatibilizer has also been necessary to make these lower aromatic-content systems stable.

In automotive under-body rust proofing, bituminous coatings have found extensive use. These materials are modified with rubbery materials to give flexible coatings with excellent adhesion to metal parts. Many years ago, the predominant bitumen in use had been coal tar. Today, with the move away from highly aromatic products, petroleum asphalts are generally used. To use the harder bitumens such as asphaltites and petroleum asphalts, plasticizers are incorporated to soften and liquefy the bitumen. Originally these plasticizers were materials such as di-octyl phthalate (DOP) or butyl benzyl phthalate commonly found in other coatings applications. However, the toxicity of DOP has limited its use and items such as di-isodecyl and di-isononyl phthalates are being used instead. Aromatic processing oils were also used for this purpose but their toxicity has also limited their use. Natural and synthetic waxes are added to prevent chipping from road debris.

Given the severe penalties associated with contamination of groundwater, chemical and moisture-resistant coatings for containment dikes are being used more and more in the chemical process industry. Most state and local regulations require the use of a containment wall around every storage tank that may potentially rupture and contaminate the water table.

Coatings for this application have included coal tar epoxies and other coal tar/organic resin blends. Gilsonite-based resinous coatings have been widely used and, depending on the chemical nature of the contained material, petroleum asphalt urethanes and epoxides are available.

Additional areas where bitumens have shown applicability as specialty coatings have included the areas of sealing soil to minimize water penetration (pond liners, seepage control for levees and dams, and hazardous waste containment) as well as sound deadening on sheet metal and their use in binding other bituminous materials such as coal or lignite for pelletization.

Roof Coatings

In roof coatings, bitumens have been important raw materials since the turn of the century. Today, many commercial roofing systems use some form of asphalt or chemically modified asphalt in their construction. The application of

an asphalt or polymer-modified hot melt asphaltic material, followed by the application of a reinforcing membrane, is the basic construction of a modern built-up roof.

In some markets, the current industry trend has been away from the use of hot melt coatings, where a roofing kettle that heats the materials up to 450°F (232°C) to reach their application viscosity is required, and toward cold-applied systems. Here, the asphalt is usually modified with solvents, fillers, and thixotropes as well as various additives to result in a formulation that can be applied at ambient temperatures with good flow properties and that which will subsequently dry or cure into a weatherproofing membrane.

In these coatings, volatile solvents are varied to control cure times. In general, the solvents are either mineral spirits or naphthas. While asbestos was long a preferred additive for thixotropy and reinforcement, the hazards of working with and removing old installations with asbestos-containing materials have driven the products toward asbestos-free roofing materials. This has led to the use of cellulose, synthetic, and glass fibers as a partial replacement for asbestos. Bentonite and attapulgite clays are then used to obtain the required thixotropy. Today, the use of asbestos has been almost entirely eliminated in roofing.

The asphalt portion of these coatings usually consists of materials referred to as cutbacks. Various solvents are used to cut (solubilize) the asphalt, depending on the cure times required. The solvent predominantly used today is mineral spirits with a flash point of 104°F (40°C). Faster evaporating versions of these cutbacks have been used as primers for better substrate adhesion. These materials generally use faster aromatic solvents, including toluene, xylene, and the aromatic naphthas. The asphalt content varies from 30 % to 70 % by weight.

The preceding materials, while they can, in the strictest sense, be considered coatings, are actually closer to adhesives in performance; that is, these coatings are applied to hold the reinforcing membranes together. Although the last coat applied may be a flood coat of the adhesive coating, the roof is usually not left this way. Weathering characteristics are significantly improved when these roofs are gravel surfaced. This graveled surface blocks harmful ultraviolet (UV) radiation and serves to improve the fire resistance. The most common roof gravels are river-washed crushed stone, granite, and blast-furnace slag recovered from the iron ore reduction process and composed of silicates and aluminosilicates of lime [6]. Other materials, also available for this purpose, include a variety of small, synthetic, colored roofing granules, similar to those used on shingles.

From 400 to 600 lb (181–272 kg) of river-washed gravel per 100 ft^2 (9.29 m^2) of roof is used, or, if weight considerations are important, 50–60 lb (22.68–27.2 kg) of the smaller roofing granules can be used. The bituminous coating is then an adhesive for these gravels.

Due to weight limitations on existing roofs and costs associated with roof tear-offs and subsequent reroofing, current philosophy is to maintain the existing roof. When physically possible, restoration instead of replacement is very cost effective. This requires the use of coatings whose purpose is to repair damage to the roof and re-establish or maintain the weather-tight seal. After the repairs are complete, a reflective coating may be applied to act as a UV barrier and thermal reflector, or additional gravel added. Several different types of coatings have been available for each of these purposes.

Asphalt cutbacks and emulsions are the primary coating used for restoration. They are applied in heavy applications of 40–80 mm thick. This allows the coating to cover minor surface defects that are present on the old roof. Splits and cracks can be repaired by using these materials with either fiberglass or polyester reinforcements. A final application gives a reasonably watertight monolithic appearance.

Asphalt emulsions consist of two types. In one, the water is dispersed in the asphalt external phase. In the other, the asphalt is dispersed in a water external phase. The first are called water-in-oil (W/O) emulsions. The latter are oil-in-water (O/W) emulsions. Roofing emulsions are predominately water-in-oil emulsions. The oil-in-water emulsions are more widely used in the paving industry and will be discussed in more detail in that section.

The water-in-oil emulsions are produced from finely powdered clays, which act as dispersants for the water. Dispersing agents of this type show some affinity for water or are sufficiently hygroscopic to hold water and bring it into dispersion in the asphalt. The bentonite clays form extremely colloidal gelatinous mixtures and pastes with water and result in asphalt dispersions of very small particle size. These smooth buttery emulsions are very stable and can be fibered for reinforcement and modified with latex resins to obtain a degree of elasticity. Most commercial products are unmodified and yield a final coating possessing all the properties of a gelled asphalt after evaporation of the water. Several books are available that offer more detail in the area of emulsion technology [7–9].

Asphalt emulsions can be left untopcoated, but are frequently coated with reflective topcoats to help control rooftop temperatures. For several years, the major types of coatings for this application have been solvent-borne aluminum pigmented bituminous coatings. A wide variety of bitumens have been used, including asphalt, asphaltite, tar, and pitch. Their viscosity has generally been low with moderate levels of volatile solvents present. Most of the solvent-based aluminum bitumen paints in use today are asphalt vehicles made from petroleum asphalt cutbacks. Mineral spirits have been the predominately used solvent. The pigment used has been a leafing grade of aluminum paste. It is reported that some early formulations used cumerone indene resin to improve the leafing characteristics and act as an anti-bronzing agent. Bronzing occurs when low molecular weight residue migrates to the surface, staining the aluminum surface weeks to months after the film has cured, making it look brown and limiting its reflectivity. A level of 2.0 lb (0.91 kg) of aluminum paste is typically used per gallon in these coatings [10].

With the recent increase in environmental legislation and an increased awareness of health issues, alternatives to these solvent-borne coatings are beginning to find their place in the market. Specifically, asphalt emulsions of various solids are being used in conjunction with new aluminum pigment technology, which allows the manufacture of relatively stable waterborne versions [11,12]. These materials generally consist of petroleum asphalt emulsions that use organophosphate-treated leafing-aluminum pastes. The phosphate passivates the aluminum, giving it more stability on storage. The solids of such coatings vary from 25 %

to 50 % by weight. Additional modification similar to other emulsion systems is also used in these coatings.

Newer technologies to stabilize aluminum pigments in water have recently been introduced. Chemically bound chrome is used to passivate the aluminum [13]. While quite expensive, these products are finding use in the automotive industry. As their cost decreases, perhaps they will be available for the waterborne bituminous aluminum market.

Other technologies exist that are non-bituminous in composition. These coatings include elastomeric latexes, solvent and waterborne urethanes, epoxides, and alkyds. These are usually pigmented with titanium dioxide (TiO_2), aluminum or the newer infrared reflective pigments, to give thermally reflective coatings. These types will be discussed elsewhere in this manual.

Waterproofing Membranes

Bitumen-modified waterproofing membranes are used extensively in the construction industry. The most common substrate is poured or precast concrete or mortared "cinder block." Pre-stressed concrete in the foundations, walls, and roof decks of high-rise buildings is also a suitable candidate for these membranes. In the home construction and repair industries, cinder block foundations and concrete footers are commonly waterproofed with bitumen-modified polymeric coatings.

The bitumen of interest in these markets has predominately been coal tar pitch and petroleum asphalts. Waterproofing membranes are generally composed of bitumen in an elastomeric polymer matrix. The aromatic polyurethanes are frequently used for this purpose.

In coating structural steel and steel reinforcement bars, coal tar epoxies have been extensively used. Their composition and purpose is similar to that of pipe coatings used for the prevention of underground corrosion. Their composition can be modified to conform to a particular steel coatings application.

As in other markets, the use of aromatic coal tars is slowly being replaced by safer soft petroleum asphalts. Environmental issues aside, higher technology systems are beginning to be seen. Other types of coatings for rebar in the past five years have included fused epoxy powder coatings systems and polyethylene dip-coated systems. While much more expensive than bitumen-modified systems, their improved performance have made them of interest.

Coatings for Paving

The paving industry is probably the oldest using bitumen and its coatings. Asphalt cutbacks have also been known as "road oils." For years, these solvent cut materials were used to seal roads as well as coat aggregates for application to the road surface. Today, hot asphalt or cutback is used to prime new paving as well as to repair damaged or worn areas.

Today, most road coating uses asphalt emulsions. These are generally chemically stabilized emulsions. The emulsion is prepared beforehand and mixed with aggregate on site and is referred to as *chip* and *seal*. Hot asphalt is not required in this application, making it much easier than the use of hot mix paving, where the asphalt is heated to melting before application. In paving, oil-in-water emulsions predominate.

The oil-in-water emulsions are formed from the action of a chemical emulsifier, which can be anionic, cationic, or nonionic in nature. The anionic and cationic emulsifiers form an emulsion in which the dispersed phase shows a definite charge. These emulsions are said to "break" upon contact with a charged aggregate, yielding the exclusion of one phase from the other. The speed of break can be modified, yielding rapid, medium, or slow-setting emulsions. The cat-ionic versions are preferred because the coating formed does not re-emulsify. With anionic emulsifiers, break occurs when emulsions destabilize due to water loss on drying. One disadvantage of this is the possibility of re-emulsification in the early stages of cure. Once the coating has dried, water is no longer a problem.

Paving sealers are used to protect new or old asphalt driveways or parking lots. The sealers are generally coal tar in nature due to good resistance to gas and oil. Asphalt sealers can also be used, but must be latex or polymer modified to improve solvent resistance.

Other types of bituminous coatings used in the paving industry include slurry seals and microsurfacing, which uses latex or polymer-modified asphalts with fine aggregate filler as a surface treatment for repair of minor damage to roads. Coal tar is not used in this application because the resulting coating is too slippery. Tack coats consisting of asphalt cutbacks are also used when one layer of asphalt needs to be adhered to another.

IDENTIFICATION OF BITUMINOUS MATERIALS

This section will catalogue several test methods currently available through ASTM for characterization of bituminous paints and coatings. Many of these methods are familiar to the coatings chemist as standard paint-related tests found in Volumes 6.01 through 6.04 of the *Annual Book of ASTM Standards*. Several others are under the jurisdiction of Committee D8 on Roofing, Waterproofing, and Bituminous Materials. These methods appear in Volume 4.04 of the *Annual Book of ASTM Standards*.

Tests on Bituminous Materials

The following test methods are used to differentiate one type of bitumen from another. They also can distinguish mixtures of bitumens and their purity. As bitumens are considered pseudo-plastic materials, with no true melt point, softening point and penetration are the two major tests routinely performed to identify differences within grades of the different bitumen classes. Viscosities at elevated temperatures are also very important with several instruments and their methods listed.

In earlier editions of this manual, several tests were described that were in common use in 1972. Among the tests described were the solubility of bitumens in carbon disulfide (CS_2) to identify the purity of a bitumen sample, since by definition only CS_2 soluble matter is bitumen. Also listed were tests to determine the presence of asphalt and tar in suspected mixtures (the Oliensis Spot Test) and the characteristics of bituminous samples dispersed in solvent. These methods have since been incorporated into the *Annual Book of ASTM Standards* and will not be described in detail.

It is important to point out that each industry that uses bitumens has tended to develop its own series of common pertinent tests. Today most of those pertinent tests have been incorporated as ASTM standards. In addition to ASTM, other organizations have tried to compile these tests for their members' use. The Asphalt Institute, an international nonprofit organization sponsored by members of the

petroleum asphalt industry, also publishes a handbook that has evolved over the past 50 years as the standard reference work in the field of asphalt technology and construction, especially in the paving industry [14]. This reference book cites both ASTM test methods and, where applicable, American Association of State and Transportation Officials (AASHTO) counterparts to these methods. A large part of the manual is devoted to practical how-to information about how to use asphalt, as well as comprehensive data on asphalt technology, and is highly recommended.

Standard Specifications and Standard Test Methods for Bituminous Materials

D4-86(2004)	Standard Test Method for Bitumen Content
D5-06e1	Standard Test Method for Penetration of Bituminous Materials
D36-06	Standard Test Method for Softening Point of Bitumen (Ring-and-Ball apparatus)
D70-09e1	Standard Test Method for Specific Gravity and Density of Semi-Solid Bituminous Materials
D88-07	Standard Test Method For Saybolt Viscosity
D92-05a	Standard Test Method For Flash and Fire Points by Cleveland Open Cup
D95-05e1	Standard Test Method for Water Petroleum Products and Bituminous Materials by Distillation
D140/D140M-09	Standard Practice for Sampling Bituminous Materials
D529-04	Standard Practice for Enclosed Carbon Arc Exposures of Bituminous Materials
D1079-09	Standard Terminology Relating to Roofing, Waterproofing and Bituminous Materials
D1669-07	Standard Practice for Preparation of Test Panels for Accelerated and Outdoor Weathering of Bituminous Coatings
D1670-04	Standard Test Method for Failure End Point in Accelerated and Outdoor Weathering of Bituminous Materials
D4798/ D4798M-09	Standard Practice for Accelerated Weathering Test Conditions and Procedures for Bituminous Materials (Xenon-Arc Method)
D4799-08	Standard Practice for Accelerated Weathering Test Conditions and Procedures for Bituminous Materials (Fluorescent UV, Water Spray, and Condensation Method)
D4989-90a(2008)	Standard Test Method for Apparent Viscosity (Flow) of Roofing Bitumens Using the Parallel Plate Plastometer
E96/E96M-05	Standard Test Methods for Water Vapor Transmission of Materials
E102/E102M-93(2009)	Standard Test Method for Saybolt Furol Viscosity of Bituminous Materials at High Temperatures
E108-07a	Standard Test Methods for Fire Tests of Roof Coverings

Specifications and Test Methods for Asphalt

D71-94(2004)	Standard Test Method for Relative Density of Solid Pitch and Asphalt (Displacement Method)
D312-00(2006)	Standard Specification for Asphalt Used in Roofing
D449-03(2008)	Standard Specification for Asphalt Used in Dampproofing and Waterproofing
D1370-00(2007)	Standard Test Method for Contact Compatibility Between Asphaltic Materials (Oliensis Test)
D1856-09	Standard Test Method for Recovery of Asphalt from Solution Abson Method
D2042-09	Standard Test Method for Solubility of Asphalt Materials in Trichloroethylene
D2521-76(2008)	Standard Specification for Asphalt Used in Canal, Ditch, and Pond Lining
D2746-07	Standard Test Method for Staining Tendency of Asphalt (Stain Index)
D3461-97(2007)	Standard Test Method for Softening Point of Asphalts and Pitches (Mettler Cup-and-Ball Method)
D4402-06	Standard Test Method for Viscosity Determination of Asphalt at Elevated Temperatures Using a Rotational Viscometer

Specifications and Test Methods for Coal Tar, Pitches, and Highly Cracked Petroleum Products

D61-75(2004)	Standard Test Method for Softening Point of Pitches (Cube-in-Water Method)
D450-07	Standard Specification for Coal Tar Pitch Used in Roofing, Dampproofing, and Waterproofing
D2318-98(2008)	Standard Test Method for Quinoline-Insoluble (QI) Content of Tar and Pitch
D2319/D2319M-98(2008)e1	Standard Test Method for Softening Point of Pitch (Cube-in-Air Method)
D2320-98(2008)	Standard Test Method for Density (Relative Density) of Solid Pitch (Pycnometer Method)
D2415-98(2008)	Standard Test Method for Ash in Coal Tar and Pitch
D2416-84(2004)	Standard Test Method for Coking Value of Tar and Pitch (Modified Conradson)
D2764-99(2004)e1	Standard Test Method for Dimethylformamide-Insoluble (DMF-I) Content of Tar and Pitch
D2962-97(2007)	Standard Test Method for Calculating Volume-Temperature Correction for Coal-Tar Pitches

D3104-99(2005)	Standard Test Method for Softening Point of Pitches (Mettler Softening Point Method)
D4072-98(2008)	Standard Test Method for Toluene-Insoluble (TI) Content of Tar and Pitch
D4312-95a(2005)	Standard Test Method for Toluene-Insoluble (TI) Content of Tar and Pitch (Short Method)
D4616-95(2008)	Standard Test Method for Microscopical Analysis by Reflected Light and Determination of Mesophase in a Pitch
D4715-98(2008)e1	Standard Test Method for Coking Value of Tar and Pitch (Alcan)
D4746-98(2008)	Standard Test Method for Determination of Quinoline Insoluble (QI) Content in Tar and Pitch by Pressure Filtration
D4892-89(2009)	Standard Test Method for Density of Solid Pitch (Helium Pycnometer Method)
D4893-94(2004)	Standard Test Method for Determination of Pitch Volatility
D5018-89(2009)	Standard Test Method for Shear Viscosity of Coal Tar and Petroleum Pitches

TESTS AND SPECIFICATIONS FOR COATINGS

General Tests for Coatings

Several of the test methods familiar to the industrial paints and coatings chemist can also be used to characterize the performance and physical properties of bituminous coatings. The following methods can be found in Volume 3.02 and Volumes 6.01 through 6.04 of the *Annual Book of ASTM Standards*.

Tests and Specifications

B117-07a	Standard Test Method of Salt Spray (Fog) Testing

Solvent-Thinned or Cut-Back Coatings

The following test methods relate specifically to solvent thinned or cut-back bituminous coatings such as those used for weatherproofing roofs or protecting metal structures and appurtenances. Although volatile organic content of coatings has become increasingly more important, leading to the greater use of emulsified bitumen, the sealing and waterproofing properties of straight asphalt have continued to make these types of coatings viable. This in turn has made their test methods pertinent.

WITHDRAWN SPECIFICATIONS AND TEST METHODS

The following specifications and test methods have been withdrawn by ASTM since the last printing of this book. The dedicated researcher may wish to investigate archived copies of these methods for the potential insight they bring to testing bituminous based coatings in general and asphalt in particular. D1328 is the only method for which an alternate method was established. The others were withdrawn the year specified.

D255-70	Method for Steam Distillation of Bituminous Protective Coatings—Withdrawn 2000—No Replacement
D466-42	Method of Testing Films Deposited from Bituminous Emulsions—Withdrawn 1991—No Replacement

D555-94(1999)	Standard Guide for Testing Drying Oils—Withdrawn 2007—No Replacement
D1328-86	Standard Test Method for Staining Properties of Asphalt—Withdrawn 1992—Replaced by D2746-97
D1540-82	Standard Test Method for Effect of Chemical Agents on Organic Finishes Used in the Transportation Industry—Withdrawn 1991—No Replacement
D1542-60	Standard Test Method for Qualitative Detection of Rosin in Varnishes—Withdrawn 1997—No Replacement
D2569-97(2002)	Standard Test Method for Distillation of Pitch—Withdrawn 2006—No Replacement
D2963-78	Standard Test Method for Testing Flow Table Consistency of Clay-Stabilized Asphalt Emulsions—Withdrawn 1997—No Replacement
D3805-85	Standard Practice for Application of Aluminum-Pigmented Asphalt Roof Coatings— Withdrawn 1996—No Replacement

CONCLUSION

Bituminous coatings are still used extensively today. The waterproofing and adhesive properties, coupled with the relatively inexpensive costs for most bituminous materials, continue to drive their many diverse industrial applications. The preceding information will give the reader an understanding of the chemistry and uses of bituminous coatings in industry and a realization that even several thousand years after their discovery and first use the usage of these bituminous raw materials as an engineering raw material is still growing.

Cellulose Esters of Organic Acids

Jos S. de Wit[1] and Deep Bhattacharya[2]

INTRODUCTION

CELLULOSE ESTERS ARE BASED ON ONE OF THE most abundant naturally occurring biopolymers, namely cellulose. This polysaccharide represents a readily available, sustainable feedstock alternative to petroleum-based materials. Although a broad variety of cellulose esters can be made, this chapter only provides a general discussion on the commercially available organic acid esters of cellulose: cellulose acetate (CA), cellulose acetate propionate (CAP), and cellulose acetate butyrate (CAB).

Cellulose esters are the reaction product of combining organic acids and/or acid anhydrides with the hydroxyl groups found on the anhydroglucose repeating units of a cellulose molecule [1, 2]. In addition to esterification, several subsequent processing steps are required in the manufacture of cellulose esters including hydrolysis to obtain the desired residual hydroxyl level, filtration, precipitation, washing, dewatering, drying, and screening. Details about these and other manufacturing steps can be found at various places in the three volumes of Ott, Spurlin, and Grafflin [3]. The final product is a dry, free-flowing powder in most instances, although other physical forms can be produced when required.

Basic information about physical properties, solubility properties in various solvents and monomers, and compatibility properties of various cellulose esters is provided. Typical uses as well as selected new uses for cellulose esters are briefly discussed as a general guide to selecting these polymeric materials for a variety of applications.

TYPES OF CELLULOSE ESTERS

Three types of cellulose esters are commercially available, including CA, CAP, and CAB (Fig. 1). Table 1 shows the types of commercially available cellulose esters. Cellulose acetate butyrate is the most commonly used organic cellulose ester for coating applications.[3] Many types have been manufactured by varying acetyl/butyryl ratios, hydroxyl content and molecular weight to meet the requirements of the applications for which they were developed.

Cellulose acetates are the least soluble and least compatible of the cellulose esters, and they require strong solvents for dissolution. They have high glass transition temperatures and produce tough and hard films with excellent chemical resistance. CAPs have improved compatibility and solubility and are used in applications where low odor is required. CAB esters are used as binders in protective and decorative coatings for metal, wood, textiles, cloth, paper, plastic, human nail care, printing inks, trucks and buses, polarographic oxygen electrodes, solid rocket propellants, and leather. They provide excellent color and color retention, toughness, flexibility, flow control, as well as good weather resistance. All three products are available with a range of substituents and molecular weights that determine their solubility, compatibility, viscosity, and hardness. Recently, Yuan et al. [4] have investigated the permeability characteristics of cellulose acetate butyrate coating films and their importance as semipermeable membranes in osmotic drug delivery systems. Similar studies related to this end use include the use of CAB as a matrix tableting and/or taste masking material when combined with CA and hydroxypropyl cellulose [5–7]. A novel technique for forming very thick but wrinkle-free membranes that involves solvent-nonsolvent mixtures has been described [8]. Table 1 contains a listing of properties for commercial cellulose esters.

CAB esters are also useful as coatings additives where they can provide a significant performance edge. Frequently, these polymers are described as versatile problem solvers because cellulose esters provide qualities such as good flow and leveling, faster drying, sag resistance, viscosity control, intercoat adhesion, and metal flake orientation.

Cellulose esters are typically supplied as dry, free-flowing fine powders and they should be handled accordingly since any free-falling powder can generate static electricity. Proper precautions should be taken when handling the dry-powder cellulose esters.

FACTORS AFFECTING PERFORMANCE OF CELLULOSE ESTERS IN COATINGS

Performance attributes of cellulose esters are affected by the chemical composition and the molecular weight of the ester. The larger size and lower polarity of the propionyl or butyryl group on the molecule alters the packing density of the cellulose chains, causing them to spread farther apart and lowering the attraction between the neighboring units. In solution, these groups affect the configuration and conformation of the molecular chains and thus alter properties. The extent to which these factors occur depends on the degree of substitution (DS) and the particular substituents. DS is commonly used to quantify the number of hydroxyls per anhydroglucose unit groups being replaced by acyl

[2] *Technical Associate, Eastman Chemical Company, Kingsport, TN.*

[3] Although not discussed in this chapter, other cellulose derivatives are in commercial use. For example, cellulose nitrate is used as a lacquer in the furniture coating business and alkylene oxide derivatives of cellulose are used in thickening and other liquid flow altering areas (see Chapter 33 of this Manual).

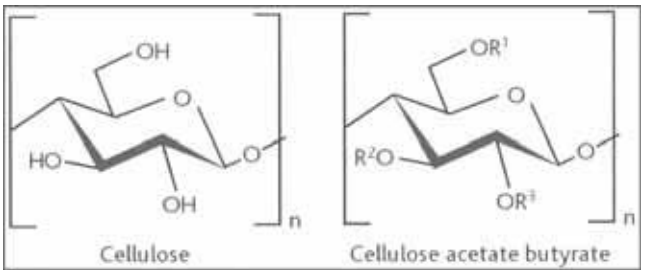

Fig. 1—Repeating unit in cellulose esters; R^1, R^2, R^3 = acetyl, butyryl, or H.

groups. The DS ranges from 0 (cellulose) to 3 (tri-esters). CABs are the most commonly used cellulose esters in coatings and are discussed in more detail below.

As the butyryl content increases, solubility, compatibility, flexibility, diluent tolerance, and moisture resistance are increased. Lower butyryl levels are associated with increased chemical and grease resistance, hardness, and melting range.

Most of the butyrates are manufactured with a hydroxyl content best suited for general applications (about 1.5 %), permitting good solubility, compatibility, and performance in coatings applications. Most CABs are soluble in esters, ke-tones, glycol ethers, glycol ether esters, blends of alcohols, and aromatic hydrocarbons, and they are quite tolerant of diluents such as aromatic hydrocarbons and alcohols. At levels around 5 %, solubility in lower molecular weight alcohols occurs. At higher hydroxyl levels, reactivity increases, providing cross-linking capability with amino and isocyanate resins. However, in non-cross-linking systems, higher levels decrease moisture resistance due to increased hydrophilicity.

When considering the hydroxyl functionality in the stoichiometry of a cross-linkable coating system, the following calculations may be useful:

TABLE 1—Typical properties[a]

Eastman™ Cellulose Ester	Viscosity[b] S	Viscosity[b] Poise	OH (%)	Melting range (°C)	T_g (°C)	Wt/Vol (lb/gal)	Wt/Vol (kg/L)	MW_n[c]	Comments

Hydroxyl equivalent wt = 1700 × wt % hydroxyl

In general, CABs are compatible with most acrylics, polyesters, phenolics, ureas, and isocyanates. They are also compatible with some epoxides and poly(vinyl acetates). CABs are often incompatible with melamines, urea formaldehydes, and most alkyds.

The molecular weight (often related to as viscosity) of cellulose esters also influences physical properties of the esters as well as coatings formulated with them. Increasing the molecular weight slightly lowers its solubility and compatibility with other polymers, but it does not affect hardness and density. Generally, toughness and flexibility are improved as molecular weight is increased.

CELLULOSE ESTERS AS FILM FORMERS, MODIFIERS, OR ADDITIVES

In some protective and decorative coatings, cellulose esters serve as the primary film-forming polymer or as a modifying copolymer to impart a specific property to the liquid or solid coating. There are four characteristics that explain the benefits cellulose esters bring to coatings when they are used as additives.

1. Due to their rapid viscosity build, cellulose esters prevent film distortion and craters, sags and runs, picture framing, poor metal flake orientation, color separation in multipigment systems, pigment flooding and floating, inconsistent gloss control with matting agents, and poor holdout.
2. Due to their Newtonian rheology, cellulose esters improve flow and leveling, rheology control, reduction of surface defects such as pinholes and craters in atomization, roll coat, and curtain coat applications.
3. Due to their high glass transition temperatures, cellulose esters provide rapid dry-to-touch times and excellent hardness development.
4. Due to their cellulose backbone, cellulose esters have good UV stability and dimensional stability.

APPLICATIONS FOR CELLULOSE ESTERS IN COATINGS

In the automotive industry, cellulose esters have been used for decades in both original equipment manufacturer and refinish basecoats, refinish primers, clear coats, and monocoats. They are often an integral component in enabling the formulator to achieve desired color effects, particularly through consistent metallic flake orientation. CAB used in the basecoat of a basecoat/clear-coat system provides improved flake alignment and resistance to redissolve from the topcoat solvents. CAB is also used in pigment dispersions for automotive applications to provide consistent tints and to achieve the maximum color development from a given pigment.

In addition to automotive metal coatings, CAB lacquers are especially useful on structural aluminum, aluminum foil, stainless steel, chromium, brass, silver, and tin, where protection of the metal surface and maintenance of the metallic luster are desired. By appropriate selection of modifying resins, butyrate lacquers may be formulated into clear or pigmented coatings that have good adhesion to metallic surfaces and that are resistant to salt-fog, oxygen, and other tarnishing and corroding elements. CABs used in metallic coil coatings reduce surface defects, improve metallic and pearlescent flake alignment, as well as providing improved flow and leveling, better gloss consistency, and purer white color value.

CAB has been used for many years in coatings for various plastic materials. Portions of the surface of molded plastic articles are frequently coated with a lacquer that primarily serves a decorative purpose; for example, metallic coatings on cell phones or casings for DVDs. CAB polymers are effective as release coatings for silicone rubber molds used in forming rigid polyurethane articles. The base release coating not only protects the mold from attack by the poly-urethane components, it also becomes an integral part of the plastic article and serves as a tie coat for other coatings on the molded article.

A major use of CAB is in wood coatings for furniture, plywood paneling, particleboard, and hardboard, both in thermoplastic and thermoset systems. It can be formulated into coatings (often a butyrate/acrylic composition) that are nonyellowing, possess good durability, stain resistance, plasticizer migration resistance, depth of finish, color, and color stability.

Crosslinking systems such as a CAB/urea-formaldehyde composition is frequently used in coating kitchen cabinets, and high quality furniture finishes exhibiting outstanding toughness and chemical resistance can be prepared by blending CAB with an isocyanate prepolymer.

TABLE 3—Selector guide for graphic arts applications		
Technology	**Cellulose Ester**	**Comments**
Digital	CAB551, CAP482	Solvent based and UV
Flexography	CAP504, CAP482, CAB553, CAB551	Solvent selection will be limited by the chemical resistance of the image roll
Gravure	CAP482, CAP504, CAB381, CAB531, CAB553, CAB551, CAB500, CA398	The inert image roll allows wide selection of resin and solvents
Screen	CAP482, CAB381, CAB531, CAB500, CA398	Viscosity is a benefit in these applications
OPV	CAB551, CAB381	Flow and leveling and improved adhesion

Flexible cloth lacquers made from CAB 381 are used in coating nonyellowing window shades and flame-resistant artificial leathers. CAB is used with urethane elastomers to coat fabrics used in the production of sportswear, rainwear, footwear, hats, coats, handbags, luggage, and upholstery for furniture and automobiles. Blending CAB with these polymers increases hardness, reduces tack, raises blocking point, improves slip, and reduces dirt pickup of the coating.

Other applications include paper and lacquer emulsions for leather topcoats. CAB is used worldwide in topcoats for leather items such as automotive upholstery, footwear, and furniture. These topcoats containing CAB are tough and have good resistance to abrasion and plasticizer migration.

Cellulose esters are used as additives in radiation curing (RC) systems as well. Here, they provide similar benefits as in solvent-borne coatings, such as flow and leveling, improved gloss control, adhesion, and reduction of surface defects. CAB 551 types are used in overprint varnishes at levels of 1–5 %. In applying RC coatings, CABs can reduce or eliminate holes in curtain coatings and reduce spattering in high-speed roll coat applications. Most commonly, the CAB is dissolved in a monomer and then added to the formulation. The viscosities of certain CABs in a variety of monomers are given in Table 2.

Cellulose esters are also used in graphic arts as thermoplastic and thermoset inks, including over print varnishes. Guidance for selecting the appropriate cellulose ester is provided in Table 3.

COMPLIANT COATINGS

Environmental legislation across the globe has resulted in the paint industry attempting to move toward greener and more “eco-friendly” lower volatile organic component (VOC) products with similar performance attributes as conventional coating formulations. Some approaches for achieving low VOC include: (a) increasing the solids loading in a solvent-based system [9]; (b) using UV curable formulations [10]; (c) replacing solvent with water [9]; and (d) using powder coatings. Applicability of conventional cellulose esters has been limited in modern reduced VOC, high solids coating systems because of their high solvent demand.

To meet the increasing demand of sustainable solutions for compliant coatings, a new class of cellulose-based additives has been introduced [11]. Solus Performance Additives are very similar to conventional cellulose esters, but these compounds have very low viscosity and allow high solids systems to be formulated.

TESTING OF CELLULOSE ESTERS

Cellulose acetate is tested by the manufacturer in accordance with ASTM Test Methods for Cellulose Acetates (D871), and mixed esters Cellulose Acetate Propionate and Cellulose Acetate Butyrate (D817), which cover color and haze, combined acetyl, free acidity, heat stability, hydroxyl content, intrinsic viscosity, moisture content, sulfur or sulfate content, and solution viscosity. Coatings manufacturers usually restrict their testing to viscosity of the ester, solubility and appearance, and color and haze. Viscosities

are determined using the falling-ball method, according to ASTM D1343 in the solution described as Formula A, ASTM D817. Viscosities in poises are converted to ASTM seconds equivalent to values obtained under ASTM D817. In Eastman nomenclature for cellulose esters, the viscosity of each individual ester is indicated in its product code. For example, CAB 381-2 has a viscosity of 2 s, CAB 381-20 has a viscosity of 20 seconds, and CAB 531-1 has a viscosity of 1 s. The above ASTM standard documents as well as others related to the testing and terminology used for cellulose esters are listed in Table 4. In addition to the listing in Table 4, there are numerous other ASTM test methods and documents that relate to the testing of cellulose esters for fibers, for molding compounds, and for other solid-state uses.

Drying Oils

Joseph V. Koleske[1]

NOTE: IT MUST BE POINTED OUT THAT FROM AN ASTM standpoint, this chapter is mainly included for historical purposes. In general, ASTM no longer deals with the standard test methods and specifications for drying oils in paints and coatings. This activity is dealt with by the American Oil Chemists' Society (AOCS) with research and technology in the area reported in the Journal of the American Oil Chemists' Society. Since the ASTM documents listed in the previous edition of this manual are found in the technical literature, this chapter provides a route to the past, some information about recent activities in the area, and information about AOCS's current role. As indicated, many of the ASTM documents listed in the previous edition of this chapter are no longer available from ASTM. Those applicable ASTM standards that can be downloaded from ASTM are so indicated. A listing of some AOCS documents that refer to drying oils can be found in Table 5.

Drying oils represent a small portion of the huge fats and oils industry.[2] Soybeans are the largest oilseed crop with a U.S. farm value of about $12.5 billion in 2000/2001. This oil accounts for about 90 % of U.S. oilseed production with the remainder comprised of oils such as cottonseed, sunflower seed, flaxseed, canola, linseed, and other oils. Argentina and Brazil are also important soybean growers and processors. Drying oils are included in the oilseed category. In regard to coatings, the industry is very mature with relatively little growth expected. The paint and coating industry's need for drying oils is in an overall decline along with other end use markets, such as binders for hardboard, sealants, plasticizers, linoleum, and core oils. Drying oils used in paints and coatings are being replaced with oil-free, synthetic, petroleum-derived oligomeric and polymeric binders carried in a variety of media or in a neat manner. The printing ink market is the only one expected to have small growth in the area of drying oils.

However, because drying oils have certain desirable attributes and represent a readily available renewable resource, interest is being renewed in certain oils through sponsorship by interested organizations and through new opportunities for modified vegetable oils. In the United States, the United Soybean Board is funding research dealing with catalysts for radiation curing of epoxidized soybean oil at Bowling Green State University's Center for Photochemical Sciences [1,2]. Other investigators are studying the use of soybean oil modifications in waterborne paints, high solids coatings, and inks [3]. In Malaysia, where palm oil is readily available, research is being conducted at the School of Industrial Technology at Universiti Sains Malaysis on epoxidized and acrylated derivatives of palm oil [4,5]. Again, the studies deal with using the products in the rapidly growing radiation curing market [6]. Oilseed Growers LLC has members who have commercially produced carambe oil in the United States since 1996 [7]. This oil is rich in mono unsaturated erucic acid, and it is used as a food emulsifier, as an ingredient in industrial slip agents, pour point depressants, lubricants, hair care, textile softening, and other end uses.

The processing techniques as well as the chemistry of drying oils have been well known for some time. However, within the past few decades, computer control and robotics, EPA and OSHA regulations in the United States and similar concerns elsewhere, rising energy costs, and similar developments have led to important improvements in the processing field whereby fish or plant components are converted into the final use-products. Lusas [8] has recently detailed a great deal of the old and new chemistry, nomenclature, and processing technology regarding drying oils in a detailed book chapter. The chapter also includes information about other animal and vegetable fats, oils, and waxes as well as edible uses for the oils and fats, industrial uses of the oils, numerous historical references, sources, and several analytical methods that have been adopted by the American Oil Chemists' Society (AOCS). This chapter and the previous edition of the chapter [9] are very useful references for those working in this field. Hutchinson [10] has reviewed new and traditional uses, technology advances, environmental factors, and development strategies for vegetable oils in surface coatings.

Most naturally occurring fatty oils have their double bonds occurring in a cis configuration, and heating such oils as in industrial processing causes a portion of the cis configured double bonds to be converted into a trans configuration. Infrared absorption spectroscopy or gas chromatography are the usual methods of determining trans content, but Milosevic and Kocak [11] used attenuated total reflection (ATR) Fourier transform infrared spectroscopy [12] to analyze oils, such as soybean oil and sunflower oil, that had been untreated and heated for various times at elevated temperatures. A FatIR heated single-reflection ATR accessory was used for the analysis. The studies demonstrated that the technique could be used for routine analysis of trans double bond content and thus permit investigation

TABLE 1—Classification of drying oils by iodine value

Oil Class	Iodine Value
Drying oil	>140
Semidrying oil	125–140
Nondrying oil	<125

of reaction kinetics and the optimization of reaction parameters. Larock et al. [13] have found that small amounts of homogeneous transition metal catalysts will affect the isomerization transformation of soybean oil to conjugated oil under mild conditions. Their preliminary tests indicate that the conjugated oils have exceptional drying properties with good solvent resistance.

Although new studies are currently being conducted, modified drying oil products have been known for sometime. A variety of oils have been epoxidized [14, 15] and many of these have been further reacted to form acrylates for use in radiation curable coatings and inks [16–19]. Recent investigations of seed oils include castor oil that has been used in the preparation of a variety of oil-based binders [20], blown soybean oil that has been used in combination with acrylates such as 1,6-hexanediol diacrylate to make novel coatings [21], epoxidized soybean oil that has been used in cationic-initiated, thermally cured coatings [22], soybean oil that has been used to make phosphate ester polyols for use in novel coatings [23], the synergistic effect between metallic driers and soybean oil-based coatings [24], and a method for modifying cashew nut shell liquid by ozonolysis to form products useful in adhesives and other products [25]. A variety of drying oils have been reacted with multifunctional isocyanates to form products that have been termed "urethane oils" and are akin to alkyds [26]. Neat or raw drying oils have been mixed with polymerized drying oils to form homogenous admixtures used by artists as a painting medium [27]. Coatings that have controlled release of organic solvents, particularly formaldehyde, and improved properties have been prepared from drying oils, such as linseed oil, and waxes as the main compositional components [28]. Adhesives with substantially no or low volatile-organic-compound emissions and based on drying oils have been prepared [29]. Novel thermal processes that do not involve solvent extraction or caustic refining, which produce soybean oil that is low in phospholipids have been recently developed [30]. A method for determination of the primary hydroxyl content of soybean oil polyols by reaction with monoisocyanates, such as phenyl isocyanate, has been recently reported [31].

Usually in the fats and oils industry, products that are solid or semisolid at room temperature are referred to as fats, and products liquid at room temperature are termed oils. Often times the terms "fats" and "oils" are used interchangeably within the industry. In a general sense, fats are usually of animal origin or are vegetable oils that have been hardened by hydrogenation or some other process. Drying oils, except for fish oil, are of vegetable origin and are extracted from seeds or plant tissue.

Chemically, drying oils are water-insoluble, unsaturated glycerides of long chain fatty acids with the generalized structure:

$$\begin{array}{l} CH_2\text{–}O\text{–}OC\text{–}R_a \\ | \\ CH\text{–}O\text{–}OC\text{–}R_b \\ | \\ CH_2\text{–}O\text{–}OC\text{–}R_c \end{array}$$

Generalized Triglyceride

where R_a, R_b, and R_c are the same or different and represent the hydrocarbon chain residues of fatty acids. In simple terms, this means that most oils are mixed triglycerides. The triglycerides are produced by the condensation reaction that occurs between a glycerol molecule and three fatty acid molecules:

$$\underset{\text{Glycerol}}{HOCH_2 - CH(OH) - CH_2OH} + \underset{\text{Fatty Acid}}{3R_xCOOH} \rightarrow$$

$$R_xCOOCH_2 - CH(OOCR_x) - CH_2OOCR_x + 3H_2O$$

Triglyceride or Drying Oil

where R_x is any one of R_a, R_b, or R_c. This reaction is reversible and when the oils are heated they can transesterify with R_a, R_b, and R_c and thus are capable of changing their positions in an intermolecular and an intramolecular sense. Drying oils also contain saturated glycerides of fatty acids, but these are usually present at relatively low levels and they do not participate in drying or polymerization phenomenon. Hydrolysis of drying oils results in separation into glycerol and the fatty acid.

Drying oils can be classified in many ways, but one principal way is to divide them into drying, semidrying, and non-drying (an oxymoronic term) oils in accordance with their iodine values, which is a measure of unsaturation content. Although such classification has been rather arbitrary, Rheineck and Austin [32] defined the classes as given in Table 1.

The main fatty acids found in drying oils and their chemical compositions are given in Table 2. The unsaturated-component content of selected drying oils is given in Table 3. Stearic (18-carbon) and palmitic (16-carbon) acids are the most widely distributed saturated fatty acids found in drying oils. Except for cottonseed oil, which contains 29 % palmitic acid, the drying oils listed in Table 3 contain less than about 10 % of any particular saturated fatty acid residue. The degree of double bond unsaturation controls the drying rate. The higher the degree of unsaturation or iodine number (see below), the faster the drying or polymerization of the oil. The double bond position is also important because conjugated bonds, which is the term used to describe two carbon-carbon double bonds separated by one carbon-carbon single bond, are more susceptible to autoxidation [34].

Physical characteristics of some typical commercial drying oils are given in Table 4. The oils are particularly characterized by their iodine value, which is a measure of the amount of unsaturation present, and saponification number, which is an indication of fatty acid chain molecule weight. Selected property requirement ranges or minimum values for various drying oils. The following drying oils are the most important members of this class of coating raw materials.

Castor oil is obtained from beans of the plant *Ricinus communis*. The oil differs from the other oils in that it is

TABLE 2—Main unsaturated fatty acids found in drying oils

Fatty Acid	Number Carbon Atoms	Number Double Bonds	Structural Formula
Linolenic	18	3	$HOOC(CH_2)_7CH=CHCH_2CH=CHCH_2CH=CHCH_2CH_3$
Linoleic	18	2	$HOOC(CH_2)_7CH=CHCH_2CH=CH(CH_2)_4CH_3$
Oleic	18	1	$HOOC(CH_2)_7CH=CH(CH_2)_7CH_3$
Eleostearic	18	3	$HOOC(CH_2)_7CH=CHCH=CHCH=CH(CH_2)_3CH_3$
Licanic	18	3	$HOOC(CH_2)_2CH(O)(CH_2)_4CH=CHCH=CHCH=CH(CH_2)_3CH_3$
Ricinoleic	18	1	$HOOC(CH_2)_7CH=CHCH_2CH(OH)(CH_2)_5CH_3$

TABLE 3—Weight percentage of major unsaturated fatty acid residues in selected drying oils [32,33] (remainder of oils is essentially all saturated fatty acid residues)

	Unsaturated Fatty Acid

[a] There is wide variation in reported values for sunflower oil.

made up of a very high percentage of the hydroxyl-containing ricinoleic acid residue. Although the fatty acid residues in this oil contain on the average only a single double bond and for this reason castor oil is essentially a nondrying oil, it can be converted into a drying oil by a dehydration process in which its hydroxyl group and an adjacent hydrogen atom are removed as water to form a double bond conjugate to the previously existing double bond. The resultant product is known as dehydrated castor oil, which has good drying characteristics.

Cottonseed oil is obtained from the plant *Gossypium malvaceae.* Although it is a drying oil, cottonseed oil is seldom used as an oil in the paint and coating industry. Its main use is as a source of fatty acids that are used in the manufacture of alkyds.

Linseed oil, which is obtained from seed of the flax plant *Linum usitatissimum,* is the most common and widely used drying oil. In the Western Hemisphere, it is the oldest known drying oil. Linseed oil has a high degree of unsaturation, which imparts a short drying time, due to its large percentages of linolenic and linoleic triglycerides. It is marketed in a number of modifications, including alkali-refined, acid-refined, boiled, blown, and polymerized linseed oil [1]. Polymerized linseed oils of various acid values and viscosities are available. The effect of water and air on the thermal oligomerization of linoleic acid has been investigated, and it was found that water inhibited the reaction and continuous air flow enhanced dimerization and trimerization [36].

Oiticica oil is obtained from the nuts of the tree *Licana rigida,* which grows wild and is only grown in Brazil. It has a very high licanic acid content, and the three conjugated double bonds of this acid result in rapid drying characteristics. When the price of linseed oil is too high, oiticica oil is used as a substitute for linseed oil and is often used as an alternative or supplement to tung oil.

Safflower oil is obtained from seed of the plant *Carthamus tinctorius.* This semidrying oil has drying characteristics between those of linseed and soybean oils. Because of its low linolenic acid content, it has low residual unsaturation after cure and very good antiyellowing characteristics.

Soybean oil is obtained from the seeds of the widely grown plant *Soja hispida.* Its main use is in the preparation of alkyds. It has a wide variety of uses other than as a drying oil. In an epoxidized form, this oil is widely used as a reactive plasticizer and as an acid scavenger. Both epoxidized soybean and linseed oil have been reacted with acrylic acid to form products with residual acrylate functionality and markedly higher viscosity. These acrylated oils have been used as components in radiation-cure coating systems that are initiated with free radicals.

Although tall oil is classified as a drying oil, it is not a triglyceride. The product is obtained as the major byproduct of sulfate or Kraft pulping of pine and certain other

TABLE 4—Physical characteristics of some typical drying oils [35]

Oil	Specific Gravity 25.5/25.5°C	Iodine Value, Wijs	Saponification Value	Acid Value	Refractive Index 25°C
Cottonseed	0.919	105	192	1.0	1.465
Dehydrated Caster	0.931	135	190	5.0	1.481
Fish	0.925	158	187	4.0	1.485
Linseed	0.926	180	190	3.0	1.478
Oiticica	0.967	150	190	4.0	1.510
Safflower	0.922	145	192	2.0	1.474
Soybean	0.920	135	190	2.5	1.473
Sunflower	0.917	135	192	2.0	1.473
Tall oil	. . .	133	196	194.0	. . .
Tung	0.915	170	192	0.2	1.517

softwoods such as spruce and hemlock that are pulped in Scandinavian countries. Crude tall oil is an approximately 50/40/10 by weight mixture of fatty acids, rosin acids, and unsaponifiable compounds, such as higher alcohols, waxes and other hydrocarbons, and sterols.

Tung oil is obtained from seeds (fruit or nuts) of the trees *Aleurites fordii* and *Aleurites Montana,* and it is mainly produced in China and South America, though in 1966 production began in the United States (Mississippi). Tung oil contains mainly eleostearic acid with smaller amounts of linoleic, oleic, and palmitic fatty acids. This relatively high viscosity and refractive index oil is rapid drying and is used in varnishes and alkyds where water resistance is of principal importance. Tung oil is also known as wood oil, Chinese wood oil, chinawood oil, and mu oil. Martyak et al. [37] have investigated the controlled oxidative curing of tung oil with cobalt driers and anti-skinning agents as the control agents. When the process is properly controlled, improved through cure and other properties are obtained.

Vernonia oil is a unique oil that contains an epoxy group and an unsaturated group in each of three vernolic acid resides that are attached to a triglyceride residue [38]. It is obtained from the weed termed *Vernonia galamensis* and is being investigated as a potential industrial crop in certain frost-free African countries. The oil has a relatively low viscosity, 100 cPat85°F, dual functionality, and a potential for derivitization into acrylates or other compounds. In addition, it has utility without alteration and may function as a reactive diluent or other additive.

Agave fiber has been treated with acid to form hydroxylates that contain furfural [39]. These plant extracts have been condensed with tannins from tamarind to form oligomers that were added to various drying oils to form varnishes with improved mechanical characteristics.

Fish oils are the only nonvegetable oils in the drying oil class. They are principally obtained from menhaden *(Alosa menhaden).* These oils are semidrying in nature and contain a significant amount of saturated fatty acid residues. In addition to 16- and 18-carbon fatty acid residues, fish oils contain 30 %–40 % of arachidonic (20-carbon with four double bonds), clupanodonic (22-carbon with five double bonds), and nisinic (24-carbon with five double bonds) acid residues. Because of the presence of acid residues with high degrees of unsaturation, fish oils have a strong tendency to yellow after cure due to residual unsaturation. Fish oils do represent a source of the very long chain fatty acids that are not present in vegetable oils. Currently, they are not widely used in the coatings industry, and their use is often dictated by relative price of linseed and soybean oils.

Although raw drying oils are used in coating formulations, the oils are often further processed before use. Such processing includes alkali-refining, dehydration, drier addition, heat polymerization that involves heating an oil to selectively advance molecular weight and viscosity, and oxidation or blowing wherein air is bubbled into heated oil and oxygen is taken up with a resultant molecular weight increase. Drying oils are also modified by reaction with maleic anhydride, by copolymerizing with vinyl monomers such as styrene, and by epoxidation.

Reaction with oxygen is the most important reaction that drying oils undergo in the drying or polymerization process [40, 41]. Oxidation can result in trans isomer formation, cleavage of the carbon-carbon chain along with formation of volatile byproducts, and polymerization. These reactions can be catalyzed with metallic salts, such as cobalt naphthenate (see next chapter), that promote free radical formation by reaction with hydroperoxides and other peroxides that are formed in the oxidation process [42]. Farmer and Sutton [43] were the first to describe the mechanism of auto-oxidation wherein they found that four different monohydroperoxides were formed when oxygen was reacted with the methyl ester of oleic acid. A different reaction path was involved when linoleic esters were auto-oxidized since two monohydroperoxides and one cyclic diperoxide were formed. Polymerization is initiated by reaction of oxygen with an unsaturated fatty acid residue and free radical formation followed by chain propagation in which free radicals react with oxygen to form peroxy radicals, which in turn react with other unsaturation sites [44]. The polymerization is terminated by combination of various free radicals that exist in the reaction mass. Availability

TABLE 5—AOCS test methods for industrial oils and derivatives. See specific methods for detailed scopes and methods

AOCS Official Method	Title	Scope—Applicable to
Tt 1a-64 (Reapproved 1997)	Acetone Tolerance	heat-bodied oils
Te 2a-64 (Reapproved 1997)	Acid Value	drying oils, epoxidized oils, fatty alcohols and esters
Tm 1a-64 (Revised 2003)	Ash	drying oils, fatty acids—not applicable to boiled oils
Td 1a-64 (Revised 2000)	Color Gardner 1963 (Glass standards)	drying oils, fatty acids and oil derivatives similar to standards
Th 1a-64 (Revised 2005)	Diene Value	all normal drying oils
Tn 1a-64	Flash and Fire Points, Cleveland Open Cup Method	drying oils and fatty acids except those with flash points below 149°C (300°F)
Tg 1-64 (Reapproved 1997)	Iodine Value, Wijs Method	normal industrial oils and derivatives
S 2-64 (Revised 2003)	Methods for the Testing of Commercial Fatty Acids	selection and use of procedures for testing drying oils used in paint and related products
Ca 2c-25 (Reapproved 1997)	Moisture and Volatile Matter Air Oven Method	animal and vegetable fats but not to drying or semidrying oils of the coconut group
Tc 1a-64 (Reapproved 1997)	Nonvolatiles (Solids) Solutions of Drying Oils, Hot Plate Method	solutions of natural and synthetic drying oils in organic solvents
Cd 7-58 (Reapproved 1997)	Polyunsaturated Acids, Ultraviolet Spectrophotometric Method	various detailed isomers
Tp 1a-64 (Revised 2003)	Refractive Index	drying oils and all fatty acids
To 1b-64 (Revised 2003)	Specific Gravity	drying oils and derivatives
Ce 5b-89 (Reapproved 1997)	Triglycerides in Vegetable Oils by HPCL	vegetable oils containing triglycerides of long-chain fatty acids
Tk1a-64 (Reapproved 1997)	Unsaponifiable Material	fatty acids, drying oils, and polymerized fatty acids

of multiple double bonds in some of the molecules results in a cross-linked polymeric network.

Solidification or polymerization of a drying oil, such as linseed oil, can be thought of in the following manner. When the drying oil is exposed to air, there is an induction period during which oxygen is absorbed and it consumes antioxidants present in the system. In this step, there is very little apparent change in physical or chemical properties. This is followed by a period in which there is a marked oxygen uptake and an appearance of peroxides that decompose to form free radicals. The free radicals then initiate an addition polymerization of the unsaturation and a cross-linked network results. During the reaction, low molecular weight cleavage products including carbon dioxide and water are formed.

ASTM D1640 Standard Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature has procedures recommended for determination of the stages and rates of film formation in the drying or curing of organic coatings that are to be used at room temperature.

Included are methods for determining tack-free, dry-to-touch, dry-hard, dry-through, print-free, and dry-to recoat times. In one instance (Section 7.5.1) a particular procedure is specified for drying oils. ASTM Standard Test Method for Gel Time of Drying Oils (D1955) deals with determination of the gel time of oiticica and tung oil. This simple test method, which involves heating the oil in a test tube and observing the time required for the oil to congeal around glass rod relative to a standard of known behavior, can be used for other oils that have conjugated double bond or other gelling characteristics. ASTM Standard Guide for Testing Drying Oils (D555) is an overall guide to selection and use of procedures for testing drying oils that are commonly used in coatings. ASTM D1640 is an active standard; however, ASTM D1955 and D555 have been withdrawn by ASTM but may still (at time of writing) be downloaded from the ASTM website. A number of other ASTM standards that were dedicated to drying oils have been withdrawn and are no longer available. However, as mentioned at the beginning of this chapter, AOCS deals with this topic. Some of their standards are listed in Table 5.

Driers and Metallic Soaps

Marvin J. Schnall[1]

INTRODUCTION

METALLIC SOAPS ARE COMPOUNDS OF ALKALINE metals or heavy metals and monobasic carboxylic acids containing from 7 to 22 carbon atoms. The water-insoluble metallic soaps are of particular interest to the coatings industry, although potassium and lithium soaps have limited water solubility.

Basically, the known techniques for preparation of metallic soaps are divided in two processes—a fusion process and a double decomposition process. The fusion process involves reacting a metal oxide or hydroxide with a fused fatty acid such as a triglyceride in the presence of water [1]. The process yields the desired metallic soap and glycerin. The double decomposition process involves reacting an alkali soap that is comprised of an alkaline metal salt or an ammonium salt of a fatty acid with an inorganic metal salt. Both processes are usually carried out in a batch mode; and, as a result, a product contaminated with unreacted starting materials and by-products that must be further purified is formed. To obtain a product essentially free of contamination, a continuous process [2] involving the double decomposition scheme has been devised. An aqueous solution of the alkali soap and an inorganic metal salt are separately fed onto a rotating impeller surface whereon they are instantaneously mixed. The resulting aqueous slurry is rapidly discharged and a contamination-free metallic soap results. Recently, a process for making basic zirconium carboxylates of branched-chain, five- to ten-carbon, aliphatic monocarboxylic acids has been described [3]. The compounds are useful as driers for paints and inks.

The applications of metallic soaps in coatings include their use as driers, catalysts, stabilizers, biocides, bodying agents, and flatting agents. An overview of metallic soap applications is presented in Table 1. An interesting particular end-use for metallic soaps is in the formation of a thin metallic oxide coating on a substrate [4]. A solution of the metallic soap is applied by reverse roll coating and then baked in a manner such that a thin, about 1–10 μm, film of the metallic oxide is formed. Although this chapter concentrates primarily on metallic soaps used as driers, a brief review of bodying and flatting applications for these materials is included.

METALLIC SOAPS AS BODYING AND FLATTING AGENTS

Aluminum stearates, aluminum octoates, and calcium linoleate pulp were at one time widely used as bodying and pigment-suspending agents in solvent-based coatings. Their advantages include fairly high efficiency and ease of incorporation. However, they have a number of deficiencies, including sensitivity to variations in the formulation and in the processing of paints, as well as adverse effects on film hardness and resistance properties. As a result, they have been replaced to a considerable extent by the bentonite clay and organic wax derivatives [5].

Zinc and calcium stearates are used on occasion as flatting additives in clear solvent-based coatings. However, precipitated and fumed silicas are now more commonly used for this purpose. Zinc stearate is also used to facilitate sanding of primers and sealers for wood furniture finishing [5].

THEORY OF OXIDATIVE DRYING AND FUNCTION OF DRIERS [5,6]

It is generally accepted that vehicles based on unsaturated oils, including alkyds and oleoresinous varnishes, dry by oxidation according to the following steps:

1. Induction period.
2. Oxygen absorption.
3. Peroxide formation.
4. Peroxide decomposition to free radicals.
5. Free radicals promote reactions that cause cross-linking.

The induction period occurs because most drying oils contain natural antioxidants, the effects of which must be overcome before the drying process can begin. Oxygen is then absorbed from the air at the unsaturated sites on the oil molecule, and, as the absorption continues, forms peroxides. These peroxides then decompose to form free radicals that act as catalysts to promote cross-linking of the oil or alkyd molecules at the unsaturated sites, resulting in dried films.

These same steps will occur in the absence of driers, but driers are used to accelerate the drying or curing process by means of the following mechanisms [5,6]:

1. Removal of natural antioxidants.
2. Acceleration of oxygen absorption.
3. Acceleration of peroxide decomposition.

Naturally occurring antioxidants may be considered as negative catalysts for oxidation, whereas driers are positive catalysts, counteracting the effects of the antioxidants.

The multivalent nature of the drier metal is considered to be a key factor accelerating oxygen absorption in the film. The drier metal is initially in a divalent state and is

TABLE 1—Coatings applications of metallic soaps

Applications	Metals	Acids
Driers	Cobalt, manganese, lead, iron, rare earth, cerium, zirconium, zinc, calcium, barium, bismuth, potassium, vanadium, aluminum	Tallates, octoates, naphthenares, neodecanoates, synthetic acids, linoleates, rosinates
Catalysts	Potassium, lithium, cobalt, copper, tin, zinc, manganese	Octoates, naphthenates, laurates, neodecanoates
Stabilizers	Barium, cadmium, tin, zinc, calcium, lead	Proprietary, sulfates, carbonates, stearates
Biocides	Copper, tin, zinc, mercury	Naphthenates, octoates, phenyl acetates, phenyl oleates, laurates, butyl oxides
Bodying agents	Aluminum, calcium	Stearates, octoates, linoleates
Flatting agents	Zinc, calcium	Stearates

converted to a trivalent state by the presence of oxygen in the film. The metal then releases the oxygen to the film and is converted back to the divalent form. This action accelerates the process of oxygen absorption, peroxide formation, and peroxide decomposition, which is responsible for oxidative film drying.

DESCRIPTION OF DRIER METALS

The metals that act as catalysts to promote oxidation and which may be used in driers are indicated below:

Cobalt
Manganese } Active or Primary
Vanadium

Lead
Calcium
Zirconium
Zinc
Iron } Auxiliary or Secondary
Rare Earth
Cerium
Aluminum

Cobalt and manganese, particularly cobalt, are the most active drier metals. Cobalt promotes surface drying of films, while manganese affects both surface and through drying. Vanadium has been mentioned in the literature as an active drier but is seldom used in coating formulations. Driers based on these active metals are often termed primary driers since they have inherent catalytic action.

The auxiliary or secondary driers are seldom used alone, but rather in combination with cobalt and/or manganese or other metals. Their functions are to increase the efficiency of the active drier metals and to increase film hardness. In the past, lead was the most frequently employed auxiliary drier, but it is presently out of favor due to toxicity and other health considerations. Calcium and zirconium driers are most frequently used as lead replacements. Zinc is used primarily for improved film hardness and to prevent wrinkling of thick films. Iron driers are used mainly to improve drying of baking systems when their dark color can be tolerated. Rare earth and cerium driers are recommended occasionally for improved through drying and as oxidation catalysts for baking. Interest in aluminum compounds as auxiliary driers has recently increased with the advent of high-solids alkyds. Aluminum compounds are being recommended to improve film hardness with these compounds, but at times they may adversely affect viscosity stability and promote gelation.

DESCRIPTION OF DRIER ACIDS

To perform their function, driers should be soluble in the vehicles to which they are added. Solubility is achieved by reacting the drier metals with organic acids to form metallic soaps. The most commonly employed acids are as follows:

- Linoleates,
- Rosinates,
- Tallates,
- Naphthenates,
- Octoates (2-ethyl hexanoates),
- Synthetic acids, and
- Neodecanoates.

Chronologically, the linoleates, rosinates, and tallates were the first types developed, followed by the naphthenates and the octoates. A more recent development is the synthetic acid type, which is proprietary but closely related to the octoates. The synthetic acid and neodecanoate driers can be prepared at higher metal concentrations than the other types and are gradually replacing the older acids.

Water-dispersible driers may be prepared by adding non-ionic surfactants to naphthenate or synthetic acid driers. However, proprietary cobalt and manganese drier compounds are available that are purported to be more suitable for water-based coatings.

Trade names of the various commercial drier types available are listed in Table 2.

MISCELLANEOUS DRIERS

Restrictions on solvent emissions have stimulated the development of both higher-solids and water-reducible coatings. In the process of formulating these coatings, chemists are experiencing difficulty obtaining satisfactory drying properties with the conventional metallic soap driers. Alternative drier compounds, including both organics and proprietary metallic complexes, are currently being offered [7]. Some typical examples are shown in Table 3. They are usually recommended in combination with conventional metallic soap driers for improved drying efficiency.

Another class of metallic compounds closely related to driers is loss of dry inhibitors or "feeder" driers. These are compounds designed to prevent loss of drying efficiency of paints on aging resulting from the adsorption of driers by

TABLE 2—Commercial drier types [3]

Type of Drier	Trade Name	Supplier
Synthetic acid	Cem-All	Mooney Chemical, division of OMG
	NuXtra	Huls America
	Troymax	Troy Corp.
Octoate	Hex-Cem	Mooney Chemical, division of OMG
	Octoate	Huls America

Nutra ADR 10 %	Huls America	proprietary metal complex
Nutra LTD 18 %	Huls America	proprietary metal complex

pigments, particularly carbon black and organic red pigments. They function by dissolving gradually into the coating vehicle so that the metals are available over a period of time rather than immediately. In this manner, they replace the drier metals that have been absorbed by the pigments, thereby maintaining satisfactory drying on prolonged storage. Lead compounds, including litharge, were used formerly but have been replaced by lead-free compounds based primarily on less soluble forms of cobalt and other drier metals.

Commercially available feeder driers are listed in Table 4. All are lead-free metal complexes except for the last item [8].

TABLE 4—Commercial feeder driers

Company	Trade Name
Mooney Chemical, division of OMG	Hex-Cem LFD
Mooney Chemical, division of OMG	Hydroxy Ten-Cem Cobalt
Troy Corporation	Troykyd Perma Dry
Huls America	Nuact Cobalt 254
Huls America	Nuact NOPB
Huls America	Nuact Paste (lead-based)

DRIER LEVELS IN COATINGS

Drier requirements for coatings are usually expressed in terms of percent drier metal based on oxidizable vehicle nonvolatile content. A typical calculation is as follows [9]:

Assume:

1. In a 1,000 g paint formulation, there are 300 g of vehicle nonvolatiles.
2. Cobalt drier used is 12 % metal by weight.
3. Calcium drier used is 10 % metal by weight.
4. Required for optimum drying: 0.05 % cobalt plus 0.2 % calcium (percent metal based on vehicle nonvolatiles). per 1,000 g of paint:

cobalt metal required = 0.0005×300 g = 0.15 g

calcium metal required = 0.002×300 g = 0.6 g

The optimum levels of drier metal required will vary depending on the type of polymeric system employed and the conditions of drying. Typical metal concentrations for a number of common vehicles are indicated in Table 5. A guide to the selection of the proper ASTM test methods for determining volatile and nonvolatile content of driers and related products is ASTM D4140, Standard Guide for Determining Volatile and Nonvolatile Content of Driers, Drying Oils, Naval Stores, and Solvents.

TESTING OF DRYING EFFICIENCY

The procedures used to determine the stages of film formation during the drying of coatings are described in ASTM D1640, Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature. With coatings containing metallic driers, it is recommended that the paint samples age overnight following the drier additions before drying tests. The drying conditions, shown in Table 6, are usually specified but are subject to agreement between the purchaser and the seller.

The methods used to determine the various stages of drying may be summarized as follows:

1. *Set-To-Touch-Time*—no transfer of the coating upon lightly touching the film with the finger.
2. *Dust-Free-Time*—(a) cotton fibers dropped on the film can be removed by blowing lightly; (b) fine calcium carbonate extender dropped on the film can be completely removed by blowing gently and wiping with a cloth or brush.
3. *Tack-Free-Times*—a specified type of paper or aluminum foil will no longer adhere to the film when applied under specific conditions.

[b]If off the scale, as observed by the unaided eye.
[c]Only one drier was listed in this category.
[d]The metal content represents total rare earth metals calculated as cerium but the drier contains cerium and lanthanum, as well as minor amounts of other rare earth metals.

determined by photographic standards shown in ASTM D2091, Test Method for Print Resistance of Lacquers.

In addition to the above subjective tests, a number of mechanical drying time recorders are available. The instrument referred to most frequently in recent literature is the Byk-Gardner improved circular drying time recorder [10]. This functions by moving a Teflon stylus over the applied film in a circular path. The pattern left in the film by the stylus after a complete revolution is observed. Recorders are available, which make complete revolutions in 1, 6, 12, or 24 h. With the use of a plastic template, set-to-touch, surface dry, and through-dry times may be noted.

Development of film hardness is also an important criterion of drier efficiency. Tests used to measure hardness include:

1. *ASTM D3363, Test Method for Film Hardness by Pencil Test*—a series of pencils varying in lead hardness from 6B (softest) through 6H (hardest) are pushed into the film, and the hardest pencil that will not penetrate the film is noted.

TABLE 8—Metal analysis by EDTA titration

Metal	ASTM Method	Solvent	Indicator	Titrating Solution
Cobalt	D2373	Glacial acetic acid	PAN[a]	Cupric sulfate
Lead	D2374	Glacial acetic acid	PAN[a]	Cupric sulfate
Manganese	D2375	Toluene-ethanol	Eriochrome black-T	Zinc chloride
Calcium or zinc	D2613	Toluene-ethanol	Eriochrome black-T	
Iron	D3869	Isopropanol	Eriochrome black-T	Zinc chloride
Zinc	D3969	HSO-HO	Xylenol orange	Bismuth nitrate
Vanadium	D3988	Isopropanol-HCL	Xylenol orange	Zinc chloride
Total rare earth	D3989	Isopropanol-HCL	Xylenol orange	Zinc chloride

[a] 1(2-Pyridylazo)-2-Naphthenol.

2. *ISO 1522 Paints and Varnishes—Pendulum Damping Test*—either a König or a Persoz pendulum hardness tester is employed with the time, in seconds, noted for the swing amplitude of the pendulum to decrease by a specified degree when set into oscillation on the dried film.
3. *ASTM D1474, Test Methods for Indentation Hardness of Organic Coatings*—either a Knoop or a Pfund indenter is applied to a film under a specified loading, and the depth of indentation is measured with the aid of a microscope. The depth is converted to either a Knoop or a Pfund hardness number using the equations in the standard.

SPECIFICATIONS FOR LIQUID PAINT DRIER

Drier specifications as described in ASTM D600, Specification for Liquid Paint Driers involve the following classes:

- *Class A*—2-Ethyl hexanoic acids in petroleum spirits.
- *Class B*—Naphthenic acids in petroleum spirits.
- *Class C*—Neodecanoic acids in petroleum spirits.
- *Class D*—Tall oil fatty acids in petroleum spirits.
- *Class E*—Any of the above, plus additives to make the driers water dispersible.
- *Class F*—Other unidentified acids and acid blends.

A comprehensive table of liquid paint driers of the above classes is given in ASTM D600. The typical properties of the driers listed and reproduced in Table 7 include percent metal concentration, percent nonvolatile content, specific gravity, Gardner color, and Gardner-Holdt viscosity.

TESTING OF LIQUID PAINT DRIERS

ASTM D564, Test Method for Liquid Paint Driers outlines the test procedures employed, including both physical and chemical tests. The physical tests include:

1. *Appearance*—visual observations may be made for clarity and cleanness.
2. *Color*—according to ASTM D1544, Standard Test Method for Color of Transparent Liquids (Gardner color scale, which employs the Gardner numerical color scale). However, a number of driers, including cobalt, manganese, nickel, and rare earth, do not fit into this scale and are reported descriptively.
3. *Nonvolatile Content*—ASTM D1644, Test Methods for Nonvolatile Content of Varnishes, according to method A or B. Method A involves heating samples at 105°C for 10 min, while method B specifies 150°C for 10 min.
4. *Miscibility with Oil*—One volume of the drier sample is mixed with 19 volumes of raw linseed oil. The mixture is observed for any signs of separation or clouding over a 24 h period.
5. *Stability*—The drier sample is stored for 7 days at 25, –20, and 50°C and examined for indications of clotting, gelation, or precipitation.
6. *Drying power*—As described in the section entitled "Testing of Drying Efficiency."
7. *Viscosity*—According to ASTM D1545, Test Method for Viscosity of Transparent Liquids by Bubble Time Method. This involves comparing the time of travel of bubbles in tubes of the sample versus Gardner-Holdt standard tubes. The standards were formerly designated by letter but are now indicated directly in stokes. A table in this test method indicates the conversion from letters to stokes.

Chemical analysis is used to determine the metal content of liquid paint driers. The EDTA method is used for most drier metals (Table 8). The liquid drier is dissolved or digested in solvents and then treated with an excess of standard EDTA solution (disodium salt of ethylenediamine tetraacetic acid dihydrate). The excess of EDTA is then titrated to an end point determined by a specified indicator. This method is applicable to single metal driers only, not to drier blends. An EDTA method is not yet available for cerium, and an oxidimetric determination is specified (ASTM D3970, Test Method for Cerium in Paint Driers by Oxidimetric Determination). Table 8 outlines the ASTM designations, indicators, and titrating solutions for analysis of drier metals by EDTAtitration.

Alkyds and Polyesters

Dan Nelson[1]

ALKYDS ARE SYNTHETIC POLYMERIC MATERIALS that have been used in the coating industry since the 1930s. Today, they continue to be workhorse polymers for the paint, coating, and printing ink industries. Alkyds and chemically modified alkyd resins are the condensation products of poly-basic acids and polyhydric alcohols. They are used in liquid organic coatings for the architectural, industrial, automotive, and industrial maintenance markets. Alkyds are also known as oil-modified polyesters because of the presence of vegetable or marine oils or other fatty acids. These oils are coreacted into the polyester backbone. The type of oil or fatty acid present in the alkyd contributes to its oxidative cure characteristics. In a chemical sense, alkyds are polyesters that are formulated with drying or nondrying oils. In contrast, polyesters are oil free. Alkyds are often modified with other polymeric materials for particular property attainment.

Three major classifications of alkyds are those designed for conventional solids, higher solids, and waterborne coatings. Because there are a large variety of commercially available intermediates and chemical modifiers, i.e., monomers, for the preparation of alkyds, they continue to be a very versatile type of polymers for coatings and printing inks.

Most alkyds are film-forming polymers with a relatively low glass transition temperature (T_g), i.e., below 0°C. They have inherently excellent pigment wetting characteristics and readily accept additives to form coatings with a wide range of appearance, performance, and application characteristics. Alkyds and modified alkyds have a good combination of hardness and flexibility, very acceptable corrosion resistance, good gloss retention, good adhesion to ferrous and nonferrous metals, and other properties that make them acceptable for use on wood, metal, plastic, composite, and other substrates. They are used in areas such as architectural coatings, automotive under-body and under-hood coatings, coil coatings, drum and metal container coatings, electrical insulating enamels, exterior trim paints, maintenance paints, and similar end uses.

Alkyd technology has generally evolved slowly over the past few decades. The past few years have shown that technology advances have been made to (a) increase the performance of higher solids alkyds, (b) develop new methods for delivering alkyds in water, and (c) around blend and hybridization science involving other chemistries.

Polyesters used in coatings are reaction products of polyhydric alcohols and polybasic acids. Synthetic formulators have the luxury of selecting a variety of multifunctional reactants depending on end use applications, required economics, and coating performance needs.

HISTORY

Although condensation polymers of dihydric alcohols and dicarboxylic acids were known at the start of the 20th century, polyesters modified with drying oils were developed in the late 1920s by Kienle and co-workers [1–5]. The early condensation polyesters were not soluble in common solvents and did not air dry until triglyceride oils or their fatty acids were incorporated into the polymeric material. Kienle coined the term "alkyd" from the alcohols ("al") and acids ("cid") used in their preparation. Air-dry films are the result of oxicative polymerization and cross-linking that took place through free radical reaction with atomospheric oxygen at the carbon-carbon double bond of the fatty acids. The use of vegetable or marine oils and/or their fatty acids as coreactants with the early developed polyesters was the developments contributed to the general interest in the product such as new techniques for the production of phthalic anhydride, synthetic glycerin, and other new and novel multifunctional alcohols.

Typically, an alkyd could be based on glycerin as the polyol, phthalic anhydride as the polybasic acid, and soybean or linseed oil as the vegetable oil. These compounds are coreacted and then reduced with aliphatic or aromatic petroleum-based hydrocarbon solvents. Monofunctional fatty acids such as tall oil fatty acids or special blended fatty acids are commonly found in alkyds as alternatives to vegetable oils.

ALKYD SYNTHESIS, PROCESSING, AND MANUFACTURE

Three major categories of chemical intermediates are utilized in the manufacture of alkyd resins:

- Polybasic organic acid/anhydride—example, iso-phthalic acid, phthalic anhydride
- Polyhydric alcohol—example, glycerin
- Monobasic fatty acid or triglyceride oil—example, tall oil fatty acid, soya fatty acids or soybean oil

The stoichiometric proportions and the equivalent weight of these monomers led to the desired physical properties and molecular weight distribution of the resulting alkyd. The solvent selection and quantities used influence the viscosity, nonvolatile content, and the solvent evaporation rate from coating films.

Alkyd processing is mainly a condensation reaction between the hydroxyl and carboxyl groups of the chemi-

[1] *Eastman Chemical Co., 99 Cottage Pl., Carpentersville, IL 60110.*

Copyright © 2012 by ASTM International

cal intermediates. The main by-product of the reaction is water, and it must be removed during the polymerization process or it will transesterify back into the alkyd and reverse or undo the polymerization thus changing the polymer characteristics. Other chemical reactions are possible during preparation such as transesterification and dimerization of fatty acids or vegetable oils depending on their unsaturation and the alkyd processing temperature. Vegetable oils are used for manufacturing economical alkyds. Fatty acids are used in high-performance alkyds—particularly in higher solids, water reducible, and water dispersed types.

An alkyd resin can be modified with a number of intermediates. Some of the more common types are:

- Acrylates and methacrylate monomers
- Benzoic acid
- Epoxides
- Isocyanates
- Hydrocarbon resins
- Phenolics
- Polyamides
- Rosin and rosin esters
- Silicone
- Styrene
- Vinyl toluene

Alkyds can be modified with the above intermediates to significantly alter the performance attributes of coatings made with them.

MANUFACTURE

There are two major chemical processes used for developing and manufacturing alkyds. These are the fusion process and solvent reflux process.

Fusion Process

In this method, the alkyd intermediates are charged into the reaction vessel. Then an inert gas, such as dry nitrogen or carbon dioxide, is introduced to "blanket" the vapor space above at the top of the reaction vessel. The reaction mixture is heated from 350 to 500°F (175 to 260°C). The main polymerization is due to condensation reactions forming ester groups. Water, the reaction by-product, escapes at the top opening of the reactor. Vigorous mixing and inert gas must be bubbled through the reactor throughout the process to minimize reaction by-products (Fig. 1). The alkyds made by this process tend to be darker in color and higher in molecular weight than alkyds made by the solvent reflux process.

Solvent Reflux Process

In the solvent reflux process, an azeotropic solvent such as xylene or a higher boiling ketone is commonly used in the reaction mixture. The purpose of the azeotropic solvent is to aid in the removal of water formed during the condensation reaction. The reflux solvent and water volatilize together and liquefy in the condenser placed above the reaction vessel. A separator or Dean-Stark trap below the condenser collects this liquid mixture, and the azeotrope solvent is returned to the reaction vessel (Fig. 2).

In both fusion and solvent reflux processes, acid number and viscosity are measured until the final desired values are reached. During the course of the reaction, viscosity will increase and the acid number will decrease. Once the pre-established end points are reached, the alkyd is thinned with the desired type and amount of organic solvent. The amount of reflux solvent used is usually less than 3 % of the theoretical reaction yield and is retained throughout the reaction. The key advantages of the reflux process include limiting the emission of by-products into the atmosphere, faster processing time, and consistent finished product. This process is now the preferred way for manufacturing alkyds. The final alkyd physical characteristics include color, acid number, hydroxyl number, specific gravity, viscosity, and percent nonvolatiles.

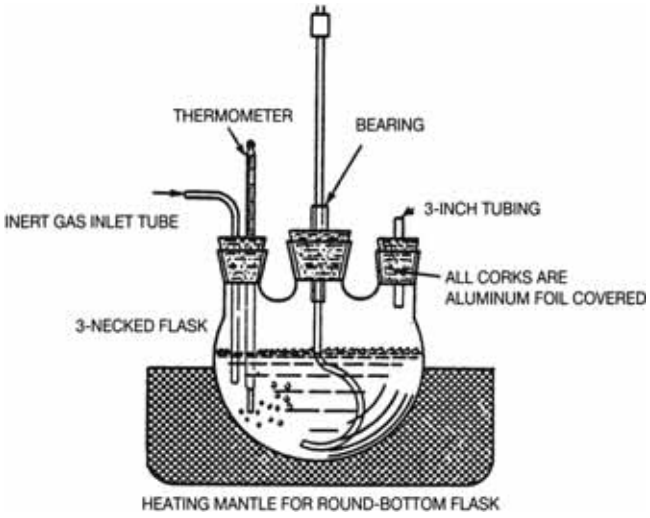

Fig. 1—Apparatus that could be used for fusion cooking of alkyds.

RAW MATERIALS USED TO MANUFACTURE ALKYD RESINS

Typical polybasic acids, polyhydric alcohols, and monobasic fatty acids or oils are given in Tables 1–3. The numerous possible raw materials available and economic considerations of these lead to versatility of alkyds and to a wide range of commercially available products.

PHYSICAL PROPERTIES

The most common physical properties used to identify characteristics of alkyd resins are determined by the following ASTM methods.

Viscosity

Alkyds cover a wide viscosity range and must be compared to the nonvolatile content and type organic solvent used, ASTM D1545, Standard Test Method for Viscosity of Transparent Liquids by Bubble Time Method. The bubble tubes and measured times in seconds are easy to run with proper testing equipment and a constant temperature set at 25°C. Viscosity is used as a relative measure of alkyd molecular weight and of the final coating application and performance properties. It also is used as a primary means of minimizing batch-to-batch variations of a specific product. Relatively high-molecular-weight alkyds need to be reduced to application viscosity with a greater amount of solvent

or solvent mixture or with solvents that have a particular solvency for the specific alkyd.

Nonvolatile Content

The nonvolatile content of alkyd solutions is determined with ASTM D1259, Standard Test Methods for Nonvolatile Content of Resin Solutions. Alkyd specifications are designed to show a 1 or 2 % variation from an agreed upon nonvolatile by weight requirement. This method is sometimes adjusted to a higher oven temperature of 150°C and a shorter dwell time.

Alkyd resin solutions vary from 30 % nonvolatile (flat wall, medium-oil alkyds) to 100 % nonvolatile content by weight (very long oil alkyds for exterior paints, stains, latex modifiers, and similar products).

Color

The color of alkyd solutions is typically still determined by comparison with a range of color standards referred to as the Gardner-Holdt color standards, ASTM D1544, Standard Test Method for Color of Transparent Liquids (Gardner-Holdt scale). The color or degree of yellowness of the alkyd solution may or may not have an effect on the color of the final coating films.

Density

The density or specific gravity of alkyds is also referred to as the weight per gallon or density and can be determined by ASTM D1475, Standard Test Method for Density of Liquid Coatings, Inks, and Related Products.

Flash Point

The flash point of alkyds is mainly of importance as it pertains to shipping the polymers and formulated paints, i.e., bill of lading and other regulations. ASTM D3278, Standard Test Methods for Flash Point of Liquids by Small Scale Closed-Cup Apparatus, is the most common test that will provide conformance with Department of Transportation regulations. However, other ASTM methods are utilized. The method utilized depends on flash cup availability and other specified requirements.

Neat alkyds have relatively low vapor pressure. Therefore, the flash point of an alkyd solution is related to the flash point of the solvent used for dissolution. It is recommended that flash points on alkyd solutions actually be measured by laboratory methods to ensure reporting accuracy, as the flash point of an alkyd solution may be slightly different from that of the actual solvent or solvents incorporated into the solution.

Drying Properties

The drying properties of alkyds are of importance when describing the product. Metallic driers are based on cobalt, manganese, aluminum, iron, zinc, calcium, or rare earth metals reacted with synthetic organic acids, such as vegetable fatty acids, to form soaps. Mixtures of these driers are added to the alkyd-based coating and act as catalysts by accelerating the rate of air drying and cross-linking. Drier blend compositions and ratios are chosen to maximize in-can stability and provide the desired film surface dry and through dry characteristics. In recent years, synthetic acid-based metallic driers have gained popularity for two main reasons: (1) higher metal concentration in the drier and (2) greater uniformity of drier performance. Methods associated with determining drying are given in ASTM D1640, Standard Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature.

Acid Value

The free organic acid groups present in the nonvolatile portion of an alkyd resin are an important property for pigment wetting and performance properties of organic coatings. It is also part of a primary mechanism for providing water compatibility in water reducible or dispersed compositions. The acid value of alkyds is typically determined with ASTM D154, Standard Guide for Testing Varnishes. Reasonably accurate and consistent results can be obtained with this test procedure.

Hydroxyl Value

The hydroxyl value or number is a measurement of the free hydroxyl groups remaining in the alkyd that have not been reacted with carboxyl groups during the condensation stage of the alkyd resin preparation process. Hydroxyl value determinations are more difficult to perform than acid number determinations. There are several reasons for this. First, the hydroxyl group can be sterically hindered or less available within the polymer and thus difficult to reach with the reactants. Second, hydroxyl groups on primary carbon atoms are more reactive than those on secondary carbon atoms, and these are more reactive than those located on a tertiary carbon atom. Tertiary-positioned hydroxyl groups are the most difficult to esterify in this determination. Manufacturers can often specify methods that can be used for secondary hydroxyl groups.

Hydroxyl numbers are important in determining equivalent weight, which in turn is important to determining the amount of urea formaldehyde, melamine formaldehyde, or urethane prepolymer to react with baking type alkyds. In the case of oil-modified urethanes, also called uralkyds, the hydroxyl groups coreact with free isocyanate functionality. Although theoretical equivalency based on hydroxyl numbers is a good guideline to establishing performance characteristics, a ladder of coreactant ratios is important to optimizing particular performance characteristics.

Hydroxyl numbers can be determined by means of ASTM D4274, Standard Test Methods for Testing Polyurethane Raw Materials: Determination of Hydroxyl Number of Polyols, and ASTM D6342, Standard Practice for Polyurethane Raw Materials: Determining Hydroxyl Number of Polyols by Near (NIR) Spectroscopy.

ALKYD RESIN CLASSIFICATION

Unmodified alkyds are classified into four types that depend on oil content—very long-oil, long-oil, medium, and short-oil alkyds. Properties such as speed of drying, ease of brushing, film flexibility, chemical resistance, and exterior gloss retention are all dependent on the oil content. These properties are summarized in Table 4.

A summary of alkyd resins comparing types of oil/fatty acids, nonvolatile, solvent, and typical application is given in Table 5.

HIGHER SOLIDS ALKYD RESINS

Higher solids alkyds have been developed to reduce organic solvent emissions in those applications under regulatory

TABLE 4—Alkyd resin properties related to oil length

	Very Long Oil	Long Oil Medium	Short
Oil content	Highest	↔	Lowest
Speed of drying	Slowest	↔	Fastest
Ease of brushing	Best	↔	Worst
Film Flexibility	Highest	↔	Lowest
Chemical resistance	Worst	↔	Best
Exterior gloss retention	Worst	↔	Best

restrictive requirements. This is accomplished by the development of polymers with lower molecular weights than conventional alkyds. A narrower molecular weight range of the resin species is necessary to meet air-dry, non-volatility, and performance properties of the coatings. Another important factor is solvent selection. Organic solvents with greater viscosity reduction of the base or neat alkyd are needed to lower coating hydrocarbon atmospheric emissions. The release of these solvents during coating film formation is an important consideration. The higher-solids alkyd resins are available in all classes of "conventional alkyds" such as those shown in Table 6.

Higher-solids alkyds can replace their conventional solids counterparts in many coating applications, thus affording decreased atmospheric emissions. Such products are used in air-dry architectural enamels and both air-dry and baking industrial primers and topcoats.

Typical compromises of moving toward higher-solids alkyds are consequences of the polymer's lower molecular weight and include reduction in dry rates, and decreases in film performance. Recent advances in alkyd technology are now available to partially offset these deficiencies.

WATER-REDUCIBLE ALKYD RESINS

Usually, these water-reducible alkyds are medium- to short-oil compounds that have high acidity. Water reducibility is attained by amine neutralization of the carboxyl groups on the polymers and the use of coupling solvents, such as glycol ethers and four-carbon alcohols [6]. Typical coupling

TABLE 5—Description of unmodified alkyd resins

Type Alkyd	Oil or Fatty Acid	Nonvolatiles	Solvent	Typical Applications
Very long	Linseed	85–100 %	Aliphatic hydrocarbon	Exterior latex modifier
	Soya			House paint modifier
	Tall oil			Oil-based stain and ink vehicles and modifiers
Long	Linseed	60–70 %	Aliphatic hydrocarbon	Architectural coatings
	Safflower			Maintenance coatings
	Soya			One-coat enamels
	Sunflower			Exterior enamels
	Tall oil acids			Primers Topcoats
Medium	Linseed	45–50 %	Aliphatic hydrocarbon	Farm implements
	Safflower		Aromatic hydrocarbon	Railway equipment
	Soya			Maintenance
	Sunflower			
	Tall oil acids			
	Blends			
Short	Castor	50 %	Aromatic hydrocarbon or Rule 66-type solvent blend[a]	Industrial coatings
	Dehydrated castor			
	Coconut			
	Linseed			
	Soya			
	Tall oil acids			
	Blends			

[a]A typical Rule 66-type solvent is isobutanol, VM&P naphtha, and xylene at 8 % maximum volume solids. Rule 66 is a 1966 regulation from California's South Coast District that restricted the amount of aromatic hydrocarbon solvent in a coating formulation. In the 1960s, research indicated that these types of solvents contributed greatly to atmospheric ozone formation. Rule 66 legislation was adopted by many other local and state regulators.

TABLE 6—Higher-solids alkyd resin types and end uses

Type	Typical End Use
Long oil	Architectural enamels
Medium oil	Transportation enamels
Short oil	General industrial air-dry and bake enamels
Benzoic acid terminated	Implement enamels
Phenolic modified	Primers
Silicone modified	Maintenance topcoats
Copolymer	Aerosol enamels

solvents are ethylene glycol monobutyl ether (Ektasolve EB), propylene glycol monoethyl ether, propylene glycol monopropyl ether, and four-carbon alcohols such as sec-butyl alcohol. Water-borne alkyds are available in most classes of "conventional alkyds" such as those shown in Table 7. Ikhuoria et al. [7] recently described preparation of water-reducible alkyds from fumarized rubber seed oil.

Probably the next step in water-borne alkyd technology will center on alkyd dispersions, which are acrylic-alkyd co-polymers in particulate form that are dispersed in water. Typical cosolvents used in water-reducible systems may or may not be required with their use dependent on the particular binders and the application techniques involved. In such dispersion systems, the submicron particles are usually surfactant free and are felt to be shell-and-core in nature. It is thought that an alkyd core is protected from the aqueous environment by the acrylic shell.

SATURATED POLYESTERS

Saturated polyesters are also called oil-free alkyds. Due to their lack of unsaturated oil, they do not self cross-link or auto-oxidize. Polyesters are made into coatings by formulating with curing agents or cross-linkers. Depending on the type of cross-linkers used, the polyester paint film could be cured at ambient or elevated temperatures. The curing agent can be a urea-formaldehyde or melamine formaldehyde resin, both of which require baking. Polyisocyanates are formulated with polyester resins for air-dry or low-bake coatings. Due to the reactive nature of the polyisocyanates, these coatings are supplied in two separate components. The two components are mixed prior to application of the coating. A typical application time window or "pot-life" ranges from 2 to 12 h. In both types of cross-linked systems, the saturated polyester provides the hydroxyl groups for reaction with the cross-linking agent [8].

TABLE 7—Waterborne alkyd resin types and end uses

Type	Typical End Use
Long oil	Stains and enamels (limited package stability)
Medium oil	General industrial air-dry enamels
Short oil	General industrial baking enamels, automotive under-the-hood parts
Benzoic acid terminated	Implement enamels
Phenolic modified	Primers
Silicone modified	Maintenance topcoats

The physical properties of these coatings are outstanding due to the absence of the oils or fatty acids, and they afford coatings with excellent chemical resistance, color retention, flexibility, exterior durability, and hardness.

These types of materials can be adapted to provide higher-solids saturated polyesters by redesigning the polymer structure and molecular weight while using organic solvents with higher solvency (ketones or esters) rather than the customary blends of aromatic hydrocarbons with ketones, alcohols and glycolethers [9].

Water-reducible and water dispersed polyesters are available through design of polymers having acid numbers in the range of 25–60. When these products are neutralized with an amine, they become soluble in blends of water and cosolvents and yield systems with fairly low volatile organic compound content. Formulation of a coating from these products involves the use of water-soluble or water dispersible ureas, melamines, or isocyanates. The cured films offer excellent chemical resistance, hardness, gloss, and flexibility.

Recent advances in polyester technology include (a) new water delivery systems, (b) cyclo-aliphatic backbones with high UV transparency, and (c) compositions leading to highly cross-linked coatings with resistance to highly aggressive chemicals often found in aerospace applications.

SILICONE-MODIFIED POLYESTERS

Conventional Types

Silicone modification of polyesters is accomplished by use of a silicone intermediate incorporated through reaction at levels typically ranging from 30 to 50 % of the total polymer. The silicone intermediates are of hydroxy or alkoxy functionality, and when they are reacted with the polyester, water or alcohol is eliminated. This modification improves the weather-ability and/or heat resistance of the resulting organic coating. Silicone-modified polyesters are available in both self-curing and externally cross-linked types. They are used as coil coatings for prefabricated building panels, prefabricated architectural products, metal advertising sign stock, and other applications requiring excellent exterior durability and/or good heat resistance.

Higher-Solids Types of Polyesters

Higher-solids silicone-modified polyesters are made by lowering the polyester base molecular weight and/or using oxygenated solvents such as ketone and ester types as replacements for aromatic hydrocarbons. This substitution yields increased solvency, lower viscosities, lower solvent amounts, and higher nonvolatile content for the polyester solution. The end uses are similar to conventional solvent-borne silicone polyesters. However, the higher-solids, silicone-modified polyester resins do not have the self-cross-linking option available for conventional types and are always combined with an external cross-linking agent. Porreau [10] has described high-solids alkyds based on styrene-allyl alcohol oligomers.

Amino Resins (Reaction Products of Melamine, Urea, etc., with Formaldehyde and Alcohols)

William Jacobs[1]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CONTENTS of the 14th edition of this manual were drawn upon. The author acknowledges the author of the chapter in the 14th edition, J. Owen Santer. The current edition will review and update the topics as addressed by the previous author, introduce new technology, and include up-to-date references.

INTRODUCTION

Definition and Description

Amino or aminoplast resins for coatings are mainly the products of the reaction of either urea (Fig. 1) or melamine (Fig. 2) with formaldehyde and an alcohol. Besides urea and melamine, other compounds with similar functionality—such as benzoguanamine, glycoluril, etc.—are also used in specific applications where certain property advantages are required. However, the sales of amino resins are dominated by those based on urea and melamine, with U.S. consumption increasing from about 100 million lb in 1990 to over 400 million lb by 2004 [1].

As prepared, amino resins are usually water-white viscous materials that may contain added solvent to reduce viscosity for ease of handling. Where a solvent is used, it is most often an alcohol such as *n*-butanol, iso-butanol, or isopro-panol, all of which are excellent solvents for amino resins. Mixed solvents, such as *n*- or iso-butanol with xylene, are also used, especially for the higher-molecular-weight resins made with butanol as a co-reactant. Some amino resins are water soluble or water reducible with co-solvent.

Amino resins for coatings are grouped somewhat arbitrarily into two classes: (1) high-solids resins, i.e., resin solutions at 80 % or higher solids (weight/weight), including resins that contain no solvent, and (2) conventional resins, i.e., resin solutions at <80 % solids (weight/weight).

History

Historically, the first amino resins used in coatings were the reaction products of urea or melamine with formaldehyde and butanol (either *n*-or iso-). They were substantially polymeric and were formulated at about 50 %–60 % solids in butanol/xylene mixtures. They have been commercially available at least since the 1940s. Parenthetically, it should be noted that resins made by reacting urea or melamine with formaldehyde without subsequent reaction with an alcohol had been available even earlier. These resins are used as molding powders and adhesives and are generally unsuitable for coatings applications.

High-solids coating resins, usually made with higher ratios of reacted formaldehyde than the older, conventional resins, have been widely available since the 1970s. They are almost always made with methanol or combinations of methanol and butanol, although a small number of high-solids resins are available, which are made exclusively with butanol.

Applications

Amino resins are used in coatings to cross-link the primary film-former, usually an acrylic, polyester, or alkyd resin typically carrying primary or secondary hydroxyl groups, although other nucleophilic functionality, such as carboxyl, amide, or carbamate, are sometimes employed. The cross-linking reaction ("cure") is principally one of trans-etherification between hydroxyl groups on the primary film-former and alkoxymethyl or alkoxybutyl groups on the amino resin. In addition to the trans-etherification reaction, the amino resin almost always undergoes self-condensation reactions to some extent, more or less dependent upon the amino resin type.

The major by-products of the cure reaction include methanol and/or butanol, formaldehyde, and water. Cure temperatures are typically in the range of 180–465°F (82–232°C) for times that vary from 15 to 30 min at the lower end of the temperature range to perhaps only a few seconds at the upper end. An acid catalyst may be used to accelerate cure, depending on the cure temperature and the particular amino resin used. There are highly catalyzed amino resin formulations that cure at room temperature, such as those found in the wood and plastics coatings industry, but the majority of commercially available formulations for metal substrates are typically cured at elevated temperatures.

Urea resins are less expensive than melamine resins, which is understandable given that melamine is made from urea. Urea resins are also faster curing than melamine resins, but are moisture sensitive and therefore not suitable for use outdoors. They are used widely for wood finishing, e.g., furniture, kitchen cabinets, and in paper, film, and foil

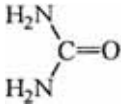

Fig. 1—Urea.

applications. Wood and paper applications capitalize on the relatively rapid cure of the urea resin since lower temperatures must be used to avoid damage to the substrate. As mentioned previously, in some wood applications, the cure temperature is often at ambient or only slightly higher.

Melamine resins, on the other hand, find much broader application since they are not nearly as water sensitive as the ureas. Perhaps the largest single use for melamine resins is in automotive OEM (original equipment manufacture), where the finished paint must stand up to extremes of temperature, humidity, the degradative effects of sunlight, etc. Melamine resins are used also in coil coatings, metal containers, etc. (see End Uses of Amino Resins).

SYNTHESIS OF AMINO RESINS

Reactions of Synthesis

The synthesis of amino resins for coatings is a two-step process. In the first step, the parent compound is reacted with formaldehyde (methylolation reaction). In the second, the methylolated intermediate is reacted with an alcohol (etherification reaction). Equations (1)–(4) exemplify the process, with urea as the parent compound. Reactions with melamine are analogous.

$$H_2NCONH_2 + CH_2O \rightarrow \underset{\text{monomethylolurea}}{H_2NCONHCH_2OH} \quad (1)$$

$$H_2NCONHCH_2OH + CH_2O \rightarrow \underset{\text{dimethylolurea}}{HOCH_2NHCONHCH_2OH} \quad (2)$$

$$HOCH_2NHCONHCH_2OH + ROH \rightarrow HOCH_2NHCONHCH_2OR + H_2O \quad (3)$$

$$HOCH_2NHCONHCH_2OR + ROH \rightarrow \underset{\text{bis(alkoxymethyl)urea}}{ROCH_2NHCONHCH_2OR} + H_2O \quad (4)$$

Reactions shown in Eqs (1) and (2) proceed quite rapidly when catalyzed by either acid or base. Reactions shown in Eqs (3) and (4) take place only under acid conditions, with the rate of reaction strongly *p*H dependent; the lower the *p*H, the faster the reaction. All four reactions are equilibrium reactions. Hence, the extent of the reaction is dependent on the charge ratios of the various reactants and on whether or not the reactions are driven by removal of by-products in order to shift the equilibrium.

The reactions of melamine are similar to those of urea with one exception. With urea, two of the four available hydrogens are readily reacted with formaldehyde [Eqs (1) and (2)], while the remaining two hydrogens react more slowly and require an excess of formaldehyde to force the reaction toward completion. With melamine, on the other hand, all six hydrogen atoms may be reacted with relative ease to give hexa(methylol)melamine.

The kinetics of the methylolation reactions of urea and melamine has been studied extensively [2–8], but there is little in the literature on the kinetics of the etherification reaction. Although both of these reactions are superficially straightforward, a number of other reactions may take place that complicate the kinetics. These reactions are all self-condensation reactions in which two or more molecules of the parent species are joined together through either a $>NCH_2N<$ (methylene) or $>NCH_2OCH_2N<$ (methylene ether) bridge. The reactions leading to self-condensation may be written as follows:

$$>NCH_2OR + HN< \rightarrow >\underset{R=H,alkyl}{NCH_2N<} + ROH \quad (5)$$

$$>NCH_2OH + HOCH_2N< \rightarrow >NCH_2OCH_2N< + H_2O \quad (6)$$

The bridging groups in amino resins manufactured for coatings applications can be either methylene or methylene ether bridges, but methylene bridges tend to dominate. It should be noted that methylene ether bridges could still readily participate in curing reactions whereas methylene bridges are virtually inert. When formulated and cured, additional bridges of both types may be formed. How many of each will depend on factors such as the composition of the amino resin, cure temperature, and catalyst level.

It can be seen, then, that a variety of amino resins may be prepared, with properties that depend on such factors as the choice of starting material, i.e., urea, melamine, etc., the combining ratios of the various reactants, the choice of alcohol (or alcohols, if more than one is used), and the degree of polymerization of the resin. The principal manufacturers of amino resins for coatings typically offer a product line of 25 or more resins. A generalized composition of a typical melamine resin is shown in Fig. 3.

Structure/Property Variations

The difference between conventional solids and high-solids amino resins represents not so much a difference in solids content as it does a distinction between resin structures. The conventional solids (<80 %) resins are made from melamine or urea reacted with relatively low levels of formaldehyde, typically 1.5–2.0 mol for urea resins and 2.5–3.5 mol for melamine resins and those etherified with either *n*-or iso-butanol. Because of these low reaction ratios, considerable self-condensation takes place during the synthesis, leading in the case of melamine resins to products with degrees of polymerization (DP) of 3 and perhaps somewhat higher for the ureas. Because of the rela-

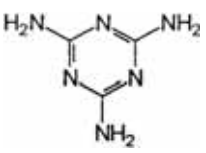

Fig. 2—Melamine.

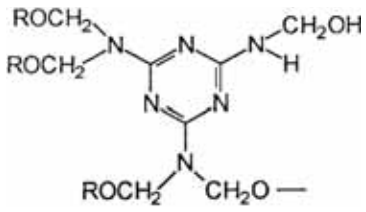

Fig. 3—Representative structure of a melamine resin.

tively high polymer content, these resins are viscous and must be reduced with solvent to less than 80 % to obtain a manageable viscosity.

Another, possibly the major, contributor to high viscosity is the residual imino (>NH) and methylol (>NCH_2OH) groups on the amino resin, which can form strong hydrogen bonds with unshared electrons on nitrogen and oxygen.

The high-solids amino resins have much higher levels of combined formaldehyde than the conventional solids resins. Typical values for combined formaldehyde are in the range 2.0–2.7 for urea resins and 3.5–6.0 for melamine resins. The etherifying alcohol is most often methanol, although resins made with both methanol and butanol or even butanol alone are also widely used. These resins are less polymeric, with DP <3, and usually more fully etherified and so less polar than the conventional resins. In some cases, these resins are sufficiently low in viscosity that no solvent is needed. Where solvent is required, it is usually either isopropanol or butanol (<*n*-or iso-). Resins are also made which can be reduced with water.

Analysis/Analytical Methods

Structural analysis of amino resins has been reviewed by Christensen [9]. Methods discussed include ^{1}H NMR and ^{13}C NMR for determining levels of combined formaldehyde and alcohol, analysis of alkoxy groups by Zeisel cleavage, and by trans-etherification followed by gas chromatography. A more detailed analysis for melamine resins by ^{13}C NMR is due to Tomita and Ono [10]. An overview of the IR spectra of various triazines has been published by Larkin, Makowski, and Colthup [11]. The study involves the observed IR and Raman vibrations for several ring modes where decreased vibrational coupling with the substituents explains why certain bands make good group frequencies in related melamine resins. Christensen [9] and Kambanis and Rybicki [12] also describe non-destructive methods for removing solvent from amino resin solutions in order to determine nonvolatile content.

Classically, amino resins for coatings have been characterized by three test procedures. These procedures, which tell the coating formulator most of what he needs to know with regard to formulation and cure conditions, are measurement of (1) solids content, (2) viscosity, and (3) solvent tolerance. These are discussed below.

Solids Content

The most common methods used to determine solids content are gravimetric. Solvent is allowed to evaporate from a weighed sample under carefully controlled conditions of time and temperature. The sample is then reweighed. The loss in weight gives a measure of solvent content, and the solids content is obtained by difference. One difficulty with this test is the tendency of amino resins to deformylate and/or self-condense when heated, with evolution of formaldehyde, alcohol, and water. To the extent that this occurs, the measured solids content will be lower than the "true" value. Frequently, however, the paint formulator is interested in the "contributed solids," i.e., what fraction of the amino resin solution remains in the cured film. In that case, a solids test method that approximates the time and temperature of cure might be more appropriate.

For these reasons, solids test methods fall into two groups: (1) Methods that reflect the solids content in the absence of self-condensation, etc., and (2) other methods, which reflect varying degrees of self-condensation in addition to loss of formaldehyde and solvent(s).

The more common of the first methods is the so-called "foil solids test," which is used almost universally for high-solids amino resins. Essentially, a 1 g sample of resin solution is weighed onto a piece of pre-weighed aluminum foil. The foil is folded over on itself and the sample compressed between the two foil surfaces to provide a thin film about 3–4 in. (7–10 cm) in diameter. The foil is then opened up to give a thin film on each foil surface. The foil is placed in a 45°C oven for 45 min, at the end of which time it is removed, reweighed, and the solids content calculated. These conditions are known to be sufficiently mild that no resin condensation occurs, nor does the resin lose formaldehyde via demethylolation. Surprisingly, the foil solids test may on occasion overestimate the solids content, particularly when (1) the resin is relatively polar, i.e., carries appreciable >NH and >NCH_2OH groups, and (2) the solvent is not low boiling. Apparently, the increase in viscosity as solvent evaporates slows the diffusion rate and effectively prevents complete removal of solvent within the time frame of the test. There may also be a hydrogen-bonding effect between solvent and resin that contributes to the retention of solvent.

Other test methods involve much higher temperatures, where resin condensation/degradation does occur. One standard method is the ASTM Test Methods for Volatile Content of Coatings (ASTM D2369), where a small resin sample (0.3–0.5 g) is diluted with xylene and placed in a 110°C oven for 1 h. There are a number of other, similar tests.

Viscosity Measurement

Amino resin viscosities are most commonly measured by the Gardner bubble viscometer method. This method is similar to the Test Method for Viscosity of Transparent Liquids by Bubble Time Method (ASTM D1545). A tube containing the resin under test is placed in a rack containing reference tubes of known viscosity. The tubes are equilibrated to 25°C in a constant temperature bath. The rack is quickly inverted, and the rate of rise of an air bubble in the sample tube is compared against similar bubbles in the reference tubes. The reference tubes are letter graded A–Z and Z1–Z6.

Solvent Tolerance

There are a number of different solvent tolerance tests. All involve titrating a weighed sample of the amino resin with a standard reagent (solvent). The object of the test is to measure how much of the reagent the amino resin can accept before the solution turns cloudy/milky. Results are typically reported in milliliters of reagent per gram of sample. Typical reagents used include xylene, iso-octane, and the iso-octane/decahydronaphthalene/toluene mixture described in ASTM Test Method for Solvent Tolerance of Amine Resins (D1198), which was withdrawn (with no replacement) in March 2007 in accordance with section 10.5.3.1 of the Regulations Governing ASTM Technical Committees.

While the immediate objective of the solvent tolerance test is to determine the amount of reagent that the amino

resin can accept before solution clouding occurs, the real purpose of the test is to gain insight into the structure and composition of the resin and hence have a better understanding of how it will perform in a given coating application. In general, amino resins of high molecular weight, or having high levels of polar functional groups, i.e., >NH and >NCH_2OH, will have limited compatibility with the typical hydrocarbons used and hence will give low tolerance test results. Experience shows that a low tolerance value means a faster curing resin and vice versa, especially in the absence of acid catalyst. However, although the tolerance test represents a quick and easy way to measure potential cure response, it does not uniquely define the resin structure. Thus, a low tolerance reading can be caused by either high polarity or high molecular weight or both.

Size Exclusion, High-Performance Liquid Chromatography, and Mass Spectrometry

To obtain more detailed knowledge of resin structure, amino chemists now rely very heavily on gel permeation or size exclusion chromatography (SEC) and on high-performance liquid chromatography (HPLC) sometimes coupled with mass spectrometry (Mass Spec). The size exclusion chromatograph provides an excellent measure of number and weight-average molecular weight and molecular weight distribution (polydispersity), while HPLC, which fractionates the resin components primarily by functional groups, provides information on resin composition, especially if coupled with Mass Spec. Typically the more polar species are eluted first, followed by the less polar fractions. Thus, taken together, SEC and HPLC provide detailed information on molecular weight and functionality, which cannot be directly obtained or inferred from any of the various solvent tolerance tests. Size exclusion and liquid chromatograms for a representative commercial high-solids methylated melamine resin are shown in Figs. 4 and 5.

More recently the combined technique of liquid chromatography and mass spectrometry has been used to obtain very detailed knowledge of amino resin structure. Advances in ionization techniques have resulted in mass spectra capable of discerning individual components in even the higher molecular weight oligomeric portions in amino resin compositions. This unique ability to discern numerous individual components and their concentration

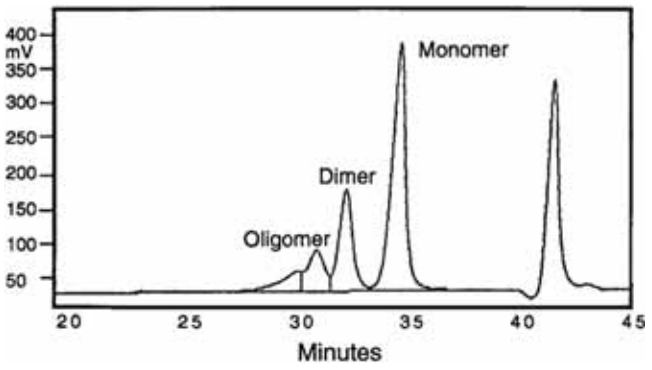

Fig. 4—Size exclusion chromatogram of a typical high-solids methylated melamine resin.

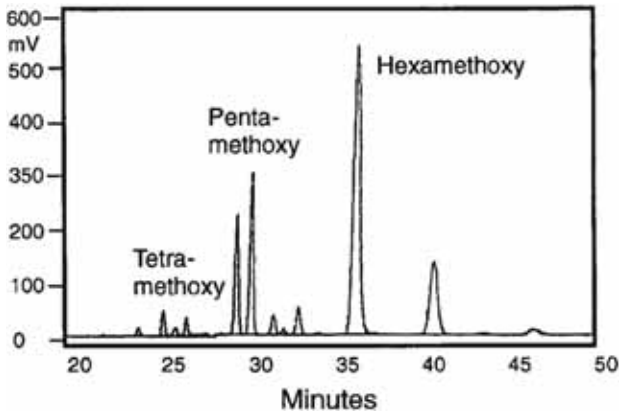

Fig. 5—High-performance liquid chromatogram of a typical high-solids methylated melamine resin.

by LC-Mass Spec techniques is described in various publications by Chang [13].

Combining Ratios

Amino resins may also be characterized by measurement of the amounts of formaldehyde and alcohol that have reacted. For example, see hexa(methoxymethyl) melamine (HMMM) (Fig. 6), which has exactly 6 mol each of combined formaldehyde and methanol per mole of melamine. Unlike HMMM, most resins are, of course, mixtures of products, which are best described by an average composition. One of the most widely sold commercial high-solids methylated melamine resins has an average combining ratio melamine/formaldehyde/methanol of about 1/5.6/5.1. Because methanol reacts with an already-reacted formaldehyde molecule, a resin can never have combined methanol greater than the combined formaldehyde. The excess formaldehyde, 0.5 mol in the commercial example, represents formaldehyde that has not reacted with methanol and which must therefore be present as methylol (>NCH_2OH), bridging groups (>NCH_2N<) or (>NCH_2OCH_2N<), and acetals (>$NCH_2OCH_2OCH_3$>). Acetals are formed when an excess of formaldehyde is used in the synthesis. They are therefore present in many high-solids amino resins.

Determination of combining ratios may be done most easily by either ^1H or ^{13}C NMR techniques [9,10]. Older methods involve complete hydrolysis of the resin to the starting materials, followed by wet-chemical analysis for nitrogen and formaldehyde and gas chromatographic determination of alcohol(methanol or butanol).

Free Formaldehyde

Amino resins always contain some unreacted formaldehyde, usually referred to in product specifications as "free" formaldehyde. Free formaldehyde may be analyzed quantita-

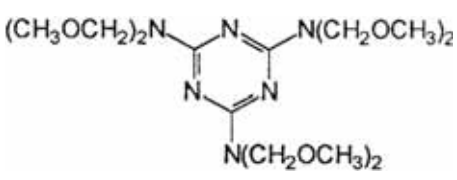

Fig. 6—Hexa(methoxymethyl)melamine.

tively by a number of methods. One of the most commonly used is the sodium sulfite method [14]. Formaldehyde reacts rapidly and completely with aqueous sodium sulfite to form a bisulfite addition complex. Sodium hydroxide is liberated quantitatively on a mole-for-mole basis.

$$CH_2O + Na_2SO_3 + H_2O \rightarrow NaOH + HOCH_2SO_2Na \quad (7)$$

The NaOH is either titrated directly with a standard HCl solution, or neutralized with a known excess of standard HCl, which is then back-titrated with NaOH. Care must be taken to ensure that reacted formaldehyde, particularly methylol groups, is not analyzed as free formaldehyde. This can occur because of the following reaction, which can be minimized by performing the titration as rapidly as possible at cool temperatures, e.g., room temperature or lower.

$$> NCH_2OH \rightarrow\!\!> NH + CH_2O \quad (8)$$

PHYSICAL PROPERTIES

General

Amino resins are typically viscous liquids with an amine-like odor. Depending on composition, they may also smell of formaldehyde and/or solvent. They are readily soluble in alcohols, ketones, hydroxyl-functional glycol ethers, esters, etc., but have limited solubility in hydrocarbons. Some resins, especially methylol-rich resins with low levels of both combined formaldehyde and combined methanol, are water soluble. Many more are water reducible in the presence of other solvents, e.g., alcohols and glycol ethers.

Because of their resinous nature, aminos have neither a well-defined freezing point nor boiling point. Uncured resins typically have glass transition temperatures around –40°C. When heated at temperatures above about 140°C, some aminos, especially urea resins, may undergo decomposition with release of formaldehyde and alcohol. This tendency to decompose causes difficulties in determining the solids content of resin solutions, as described in Analysis/Analytical Methods. The problem is particularly acute with resins having high methylol functionality.

Viscosity

The viscosity of an amino resin is a function of (1) polymer content (degree of polymerization) and (2) the nature of its functional groups. The latter may be a more important contributor to viscosity than the former. Amino resins are not generally very polymeric, especially in comparison with other coating resins, e.g., polyesters, alkyds, and acrylics. Typically, average degrees of polymerization are in the range of 1–5. High-molecular-weight "tails" increase viscosity significantly.

Because of strong hydrogen bonding, resins carrying significant amounts of >NH and $>NCH_2OH$ functionality are quite viscous, even though they may not be highly polymerized. There is a marked drop in viscosity when amino resins are diluted with solvent, largely due to breaking of hydrogen bonds. Good solvents (e.g., alcohols) are more effective at reducing viscosity than poor ones [15]. Methanol is probably the best, although it is not widely used because of its low boiling point. Isopropanol is almost as effective, and because it is somewhat higher boiling, represents a good compromise.

Surface Tension

The surface tension of amino resins is quite strongly related to the nature of the etherifying alcohol and is much less affected by the level of combined formaldehyde and alcohol. Surface tension measurements on high-solids, solvent-free resins using a DeNouy tensiometer have given values ranging from about 45 dynes/cm for methylated resins to about 28 dynes/cm for butylated resins [16]. Mixed methyl/butyl resins give intermediate values, depending on the methyl and butyl content. The reduction in surface tension when butanol is the etherifying alcohol may be one reason that high-solids butyl and methyl/butyl resins provide improved flow and leveling in high-solids formulations compared to their fully methylated counterparts.

REACTIONS OF AMINOS IN COATINGS

Cure Reactions

Amino resins in coating formulations cure by reactions that are chemically and mechanistically similar to those that take place during synthesis of the resin. The principal reaction of cure is one of trans-etherification, wherein a hydroxyl group on the primary film-former (acrylic, polyester, or alkyd) reacts with an alkoxymethyl group on the amino resin

$$> NCH_2OR + HO - A \rightarrow\!\!> NCH_2O - A + ROH \quad (9)$$

where:

R = alkyl and
A = primary film-former.

Additionally, direct etherification may take place, the end result being the same

$$> NCH_2OH + HO - A \rightarrow\!\!> NCH_2O - A + H_2O \quad (10)$$

where:

A = primary film-former

These two reactions both result in chemical bond formation between the amino and the primary film-former (co-condensation). Two other reactions may also take place, both of which involve reaction of the amino resin with itself (self-condensation). These are

$$> NCH_2OR + HN <\!\!\rightarrow\!\!> NCH_2N < + ROH \quad (11)$$

where:

R = H, alkyl

$$> NCH_2OH + HOCH_2N <\!\!\rightarrow\!\!> NCH_2OCH_2N < + H_2O \quad (12)$$

Besides the co-condensation and self-condensation reactions, hydrolysis and deformylation reactions may also occur:

$$> NCH_2OR + H_2O \rightarrow\!\!> NCH_2OH + ROH \quad (13)$$

$$> NCH_2OCH_2OR + H_2O \rightarrow\!\!> NCH_2OH + CH_2O + ROH \quad (14)$$

$$> NCH_2OH + H_2O \rightarrow\!\!> NH + CH_2O \quad (15)$$

The relative contributions to cure of the co-condensation and self-condensation reactions will depend on a variety of factors. These include:

1. The functionality of the amino resin, i.e., the relative proportions of $>NCH_2OR$, $>NCH_2OH$, and >NH groups present initially, as well as those generated during formulation and/or cure.

2. The functionality (hydroxyl, carboxyl, amido, carbamyl, etc.) and the equivalent weight (i.e. hydroxyl number, carboxyl number, etc.) of the primary film-former (co-reactant).
3. The amino/co-reactant ratio.
4. The level and type of catalyst (weak acid/strong acid).
5. Cure time and temperature.

A co-reactant resin with a low hydroxyl number is best if formulated with a "polar" amino (i.e., one rich in >NH and/or NCH_2OH) since these groups help build molecular weight during cure via self-condensation, particularly if little or no catalyst is present. Conversely, a high hydroxyl resin is best if matched with an alkoxymethyl-rich amino and cured with a strong acid catalyst. Where high cure temperatures are employed (e.g., can or coil coating operations), the choice of amino resin is less obvious, and, in practice, both polar and nonpolar aminos are used.

Acid catalysts are usually used as an aid in curing amino-based formulations. These catalysts include very strong acids, such as *p*-toluenesulfonic acid (PTSA), dodecyl-benzenesulfonic acid (DDBSA), dinonylnaphthalenedisulfonic acid (DNNDSA), etc., and weaker acids, such as phenyl acid phosphate (PAP), butyl acid phosphate (BAP), etc. Amine blocking agents are sometimes used to help minimize resin advancement prior to cure. Some coatings, particularly those designed for high-bake temperatures, need no catalyst, relying instead on the combination of high temperature and perhaps carboxylic acid functionality on the primary film-former to bring about cure [17]. While all of the various reactions that take place during cure are accelerated by either acid or heat, it is fair to say that reactions of trans-etherification are most influenced by catalyst level and type, while reactions of self-condensation are most influenced by heat. The trans-etherification reaction takes place very rapidly under strong acid catalysis, even at low temperatures. This is especially true for aminos with a high level of alkoxymethyl substitution, i.e., a very low NH content, which tends to inhibit catalysis. Thus, most formulations involving resins with high alkoxymethyl ether content and designed for low-temperature cure (250°F or lower) will call for a sulfonic acid catalyst, either blocked or free.

Although the individual reactions of cure are reasonably well understood and have been described in numerous papers [18–23], there is still much to be learned about the overall behavior of amino resins during cure, in particular the relative contributions of each of the various reactions. One of the difficulties is, of course, that the coating becomes intractable as cure progresses. Hence, a majority of studies involve analysis of the by-products of cure [18,22,24]. Other methods, such as dynamic mechanical analysis [25], nuclear magnetic resonance [26,27], FTIR [22], ESCA, etc., investigate the structure of the cured film.

These techniques are useful not only for analyzing the freshly cured coating, but also as a means of following the coating through its lifetime, either natural or accelerated.

Degradation and Weathering

Amino-based crosslinked coatings exposed to the atmosphere are subject to both hydrolysis and UV-degradation at different rates dependant upon their structures. The mechanisms by which melamine resins hydrolyze have been described in detail by Berge and co-workers [28–30], who was the first to distinguish between mono- and di-substituted nitrogen with respect to their behavior towards acid or base hydrolysis. Thus, in an alkaline medium, hydrolysis of an alkoxymethyl group on a singly substituted nitrogen is initiated by removal by the base of the proton attached to nitrogen:

$$-NHCH_2OR + B \rightarrow -^{-}NCH_2OR + BH^{+} \quad (16)$$

$$-^{-}NCH_2OR \rightarrow -N=CH_2 + {}^{-}OR \quad (17)$$

$$-N=CH_2 + H_2O \rightarrow -NHCH_2OH \quad (18)$$

$$^{-}OR + BH^{+} \rightarrow ROH + B \quad (19)$$

This mechanism is clearly not applicable to di-substituted nitrogen ($N(CH_2OR)_2$), and these groups are in fact extremely resistant to alkaline hydrolysis.

On the other hand, acid hydrolysis takes place readily for both mono- and di-substituted nitrogen. Berge proposed two mechanisms: (a) specific acid catalysis

$$>NCH_2 - OR + H^{+} \rightarrow\!\!> NCH_2OHR^{+} \quad (20)$$

$$>NCH_2OHR^{+} \rightarrow\!\!> NCH_2^{+} + HOR \quad (21)$$

$$>NCH_2^{+} + H_2O \rightarrow\!\!> NCH_2OH + H^{+} \quad (22)$$

and (b) general acid catalysis

$$-NHCH_2OR + HA \rightarrow -NHCH_2OHR^{+} + A^{-} \quad (23)$$

$$-NHCH_2OHR^{+} + A^{-} \rightarrow -N=CH_2 + ROH + HA \quad (24)$$

$$-N=CH_2 + H_2O \rightarrow -NHCH_2OH \quad (25)$$

The work of Berge and co-workers with melamine resins is undoubtedly relevant to acid hydrolysis of paint films based upon hydroxyl functional primary film formers, which has been studied by a number of workers.

English and co-workers [31,32] found that coatings prepared from highly alkylated melamines underwent extensive hydrolysis of residual methoxy groups during two years' exposure in Florida, but there was no evidence of hydrolysis of bonds between melamine and the primary film-former. Bauer and Briggs [33,34] used IR to analyze acrylic-melamine coatings exposed to both UV and moisture and found evidence of hydrolysis of both residual methoxy groups and acrylic-melamine bonds, with the rate of hydrolysis being faster in the presence of UV light. The rate of hydrolysis was slowed considerably when a hindered amine light stabilizer was used.

During the early 1990s, degradation of melamine-containing automotive coatings had become particularly severe because of etching and spotting due to acid rain. The problem was compounded because the high-solids automotive coatings used very high levels of melamine resins (35 %–45 % of total binder weight) to help meet the lower amount of volatile organic (VOCs) requirements, giving rise to correspondingly high levels of acrylic-melamine bonds and residual alkoxymethyl groups in the cured film, all of which are susceptible to hydrolysis under acid conditions. The suppliers of high-solids coatings for automobiles were faced with a dilemma—either switch to more expensive alternative crosslinkers, such as isocyanates and aliphatic epoxies, which are more stable under

acid rain conditions, or modify the hydroxyl functional backbone to achieve increased resistance to spotting due to acid rain. An interesting aspect of the acid etch problem was that the damage was always more severe on relatively new coatings. If a newly painted automobile was protected from the acid environment for the first 6 to 12 weeks, damage thereafter was much less severe. One theory at the time was that the paint is undergoing some type of additional cure. Another possibility is that some type of protective surface oxidation occurs as it ages. In fact, Lamers et al. [35] eventually presented evidence that the melamine methylene ether carbon, involved in crosslinking, can be oxidized to a more acid etch-resistant urethane linkage in the presence of UV light and oxygen, lending support to the latter, protective surface oxidation theory. This protection mechanism (by oxidation to urethane) has since been all but proved by Wu et al. [36] with the introduction of acid etch-resistant automotive top coats based on tris-(alkoxycarbonylamino) triazine (TACT). The chemical structure of crosslinked hydroxyl functional acrylics and TACT is the same as those first prepared by Jacobs and DiLeone [37] using melamine tri-isocyanate as the crosslinker for hydroxyl functional automotive acrylic top coats. TACT forms crosslinks with hydroxyl functional acrylics by a trans-carbamylation reaction, affording acid etch-resistant melamine-urethane bonds.

Since these early observations, suppliers of high-solids coatings have essentially solved the acid etch problem for automobiles in a very clever way by modifying their acrylic backbones (primary film-former) from hydroxyl functionality to primary and/or secondary carbamate functionality. This is usually done by a trans-carbamylation reaction on the poly-hydroxyl functional acrylic similar to TACT chemistry, but with mono-functional alkyl carbamates, such as methyl carbamate, to avoid premature cross-linking [38,39]. High levels of melamine resins can once again be used with the new carbamate functional acrylics, but this time resulting in melamine-primary carbamate cross-links, or melamine-secondary carbamate cross-links, both of which are very resistant to acid etch damage [40–42].

Automotive paint manufacturers are also actively pursuing water-borne systems, which use higher molecular weight, less hydroxyl functional co-reactant resins, and lower levels of melamine cross-linker. Mostly, these water-borne systems are used in the base coat, where in any case, the protective clear top coat minimizes acid attack. It is the clear top coat, with its high melamine content, that provides the excellent gloss and "distinctness of image" (DOI), characteristic of basecoat/clear coat technology. The melamine resin also minimizes the amount of solvent required because of its low viscosity at high-formulated solids, behaving in some ways as a reactive diluent and plasticizer.

End Uses of Amino Resins

Amino-based surface coatings protect and decorate the substrate to which they are applied. Their technology and use has developed over many years. As already mentioned, resins based on urea and melamine dominate the field. Urea resins are traditionally used in clear coatings for wood, e.g., furniture, kitchen cabinets, in paper, film, and foil applications, and in some appliance and general industrial coatings. They are also used to some extent in automotive primers. Urea resins cannot be used in automotive topcoats because of their sensitivity to hydrolysis.

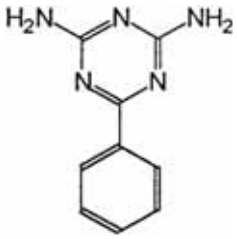

Fig. 7—Benzoguanamine.

Melamine resins are much more widely used than urea resins. They give better chemical resistance, as well as resistance to weathering in exterior applications, despite some of the earlier difficulties described in connection with acid etch of automobiles before the use of carbamate functional acrylics. Besides automobiles, they are used in appliance formulations (both coil appliance and conventional post-sprayed), general metal applications, container coatings (beer and beverage cans), etc.

In choosing an amino resin for a particular application, consideration must be given not only to interior versus exterior use, but also to possible restrictions on cure conditions and compatibility of the amino resin with its co-reactant resin, both when formulated and as the paint film is formed during solvent flash-off and cure, etc. Compatibility of the amino is especially important in water-borne coatings, which are becoming more widely used. Another factor is the stability of the amino toward advancement (molecular weight buildup) during storage of the formulated paint.

Benzoguanamine-based (Fig. 7) amino resins are used where film flexibility and hardness are required, as in some appliance applications (e.g., refrigerator doors made from coil stock, etc.). They also have good corrosion, humidity, and detergent resistance. Their use is limited by cost and poor exterior durability due to the pendant phenyl group on the benzoguanamine molecule.

Glycoluril (Fig. 8) resins have been available since the late 1970s.

In some pigmented formulations, they may require a higher cure temperature or a higher catalyst level than melamine-based resins, but show excellent corrosion and humidity resistance and release lower amounts of formaldehyde during cure [43]. Because of their increased resistance to hydrolysis, the glycolurils often find uses in container coatings where retort resistance is important and in some very interesting specialty applications, such as rheological thickeners for waterborne paints [44] and as curatives for optical electronics and photoresist fine line applications [45,46]. The tetra functional, fully methylated methylol glycolurils are high melting solid resins that find use in durable powder coatings [47], especially the wrinkle or "textured" finish applications [48].

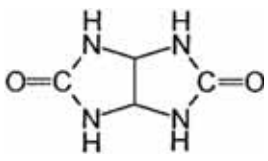

Fig. 8—Glycoluril.

ENVIRONMENTAL/TOXICITY

At least since the end of the 1970s, and perhaps starting even earlier, there has been an increased emphasis on the quality of the environment both in the workplace and beyond. In the coatings industry, this has meant strict controls on exposure of workers to hazardous ingredients in the coating formulation when applied, as well as on the nature and amounts of VOCs released to the environment when the formulation is cured.

Amino resin suppliers have responded to these environmental challenges in a number of ways. Chief among these has been a progressive shift towards higher-solids, lower-molecular-weight aminos, which are now the resins of choice of coatings formulators. Many amino resins are supplied at 100 % non-volatiles, especially for the automotive industry. Where solvents are needed, those presenting the least hazard to worker and environment are selected. For their part, paint producers have increased the functionality of the co-reactant resin while lowering its molecular weight to minimize solvent use with the object of building molecular weight to the maximum possible extent during cure. This has meant using higher levels of amino resin, as much as 40 %–50 % of total binder weight in some cases.

Perhaps the most intractable environmental problem with amino resins is the use of formaldehyde in their manufacture. Formaldehyde is recognized by the International Agency for Research on Cancer as a carcinogen. The American Conference of Governmental Industrial Hygienists lists formaldehyde as an "A2" substance, i.e., one suspected of carcinogenic potential for man, and the Occupational Safety and Health Administration (OSHA) has set workplace exposure limits of 0.75 ppm (8 h time weighted average) and 2 ppm (15 min short-term exposure limit).

The formaldehyde content of amino resins is predominantly "combined," i.e., chemically reacted, and represents about 30 %–50 % by weight of the resin. A small amount, ranging from about 0.1 % to about 3 % is present free, or un-reacted (see the section entitled Analysis/Analytical Methods). Amino resin suppliers have made considerable progress over the past several years in lowering the level of free formaldehyde in their products, which is important because of OSHA labeling requirements.

In an ideal situation, all of the combined formaldehyde would remain in the coating after cure as part of the polymer network. In practice, however, some of the combined formaldehyde and all of the free formaldehyde is released during cure and may reach the environment, depending on the mechanics of the coating and curing operation. Since typically the free formaldehyde from reputable amino resin suppliers is very low, it is the partial release of combined formaldehyde during cure that is of concern. Efforts should be taken to optimize formulations for minimal release, not just for performance properties. Of course, scrubbing or incineration of any off gases, where possible, is one of the surest solutions.

Ceramic Coatings

Richard A. Eppler[1]

CERAMIC COATINGS ARE AN ALTERNATIVE TO organic or polymer based coatings for selected surface coating applications. When protecting a surface, it is usually less expensive to use organic coatings rather than other materials such as ceramic coatings. However, organic paints have limitations and will not meet all service requirements. Though more expensive, for some applications ceramic coatings may be a more suitable form of protection.

Vitreous (glassy) ceramic coatings are chosen for application over a substrate for one or more of several reasons [1]. These reasons for selecting a ceramic coating in preference to an organic paint include rendering the surface more chemically inert, impervious to liquids and gases, more readily cleanable, and more resistant to service temperature, abrasion, and scratching.

The chemical durability of ceramic coatings in service substantially exceeds that of organic paints [2]. Vitreous coatings are formulated to be resistant to a variety of reagents, from acids to hot water to alkalies, as well as to essentially all organic media. The only important exception is hydrofluoric acid, which readily attacks all silicate glasses. This outstanding durability, combined with a very smooth surface, renders many ceramic coatings suitable for applications requiring the highest standards of cleanability, such as ware that comes in contact with food and drink. These coatings are also suitable for applications requiring true hermeticity, usually to protect sensitive electronic equipment. No organic resins are truly hermetic.

Even the most thermally stable organic resins depolymerize at temperatures on the order of 300°C. Hence, organic paints are not suitable for applications requiring thermal stability above 300°C. For example, stove side panels are painted, but stove tops are porcelain enameled. A similar argument can be made for abrasion resistance. Organic resins are soft (Moh 2–3). By contrast, vitreous coatings are harder (Moh 5–6), and some plasma coatings are much harder. For example, alumina coatings, plasma sprayed, have Moh = 9.

Vitreous coatings are thin layers of glass fused onto the surface of the substrate. When the substrate is a ceramic, the coating is called a glaze. When the substrate is a metal, the coating is called a porcelain enamel. When the substrate is a glass, the coating is called a glass enamel.

GLAZES

A ceramic glaze is a vitreous coating applied to a ceramic substrate, usually a whiteware. Glazes are applied to their substrates by one of several powder-processing techniques: dipping, spraying, and waterfall or bell application. The raw materials are both crystalline oxides and frits. In these wet processes the raw materials are dispersed in an aqueous slip for application. After application, the coatings must be dried and fired at high temperatures (up to 1300°C, typically 1000–1100°C) to fuse them onto the substrate.

Applications for Glazes

Ceramic glazes find their way into a wide range of applications ranging from coffee mugs to automotive spark plugs. The major markets for ceramic coatings have different requirements, but one common theme is chemical durability and cleanability.

The major products that normally use glazes are distributed as follows:

44.5 %	sanitary-ware,
31.1 %	wall and floor tile,
12.4 %	tableware,
11.9 %	artware,
10 %	electrical porcelain and electronics.

The total market for these products in the United States is estimated to be $12.4 billion for 2005 [3], of which the glaze component typically consumed 10 %–15 % of the total manufacturing cost. Hence, the value of the protective, functional, and decorative properties provided by the coating usually far outweighs the cost.

Leadless Glazes

Glazes are essentially mixtures of silica with other oxides added to permit the glaze to form at a readily achievable temperature. In a leadless glaze, the alkali and alkaline earth oxides, together with magnesia (MgO), zinc oxide (ZnO), and boron oxide (B_2O_3), are used to provide the fluxing action. Table 1 gives the formulas of a few typical ceramic glazes. Glaze 1 is a feldspathic glaze suitable for use on soft paste porcelains or hard stoneware [4]. This glaze is typical of that used on medieval Chinese porcelains.

Glaze 2 is a sanitary-ware glaze [5]. It is derived from the soft paste porcelain glaze by the addition of ZnO. In the tile industry, the trend to ever faster firing rates (as low as 35 min cold-to-cold) has led to the formulation of glazes such as glazes 3 or 4 [6]. Here the melting rate is increased by both increasing the percent of fluxes, and increasing the alkaline earths and zinc oxide at the expense of the alkalis. Glaze 3 is opacified, while glaze 4 is a clear base for dark colors. To produce a glaze for tableware, the coefficient of

thermal expansion must be reduced to match that of the ware. Glaze 5 is an example of a glaze for vitreous hotel china [7]. When the durability requirements of a food contact surface are not needed, processing can be improved by the use of a more fluid glaze, such as the spark plug glaze 6 [6].

Lead-Containing Glazes

Although historically important, the use of lead oxide in glazes is no longer acceptable, except in special applications [6]. The cost of meeting the regulalatory requirements for handling lead oxide are prohibitively expensive for most applications [6]. An exception is the coatings used on integrated circuit packages to seal them [8].

Satin and Matte Glazes

Satin and matte effects are due to dispersed oxide crystals of appropriate refractive index in the glaze [5]. Calcium aluminosilicate and zinc silicate crystals are commonly used. The crystals must be very small and evenly dispersed if the glaze is to have a smooth, velvet appearance. Glaze 8 in Table 1 is an example of a matte glaze.

Testing of Glazes

ASTM Committee C21 on Ceramic Whitewares and Related Products has developed several test methods to evaluate the physical properties of ceramic glazes. These are listed in Table 2 [9]. These tests form the basis for most quality control testing programs.

There are several methods concerned with the fit of the glaze to the substrate. These include: C554—Test Method for Crazing Resistance of Fired Glazed Ceramic Whitewares by a Thermal Shock Method; C424—Test Method for Crazing Resistance of Fired Glazed Whitewares by Autoclave Treatment; C1300—Test Method for Linear Thermal Expansion of Glaze Frits and Ceramic Whiteware Materials by the Interferometric Method; and C372—Test Method for Linear Thermal Expansion of Porcelain Enamel and Glaze Frits and Fired Ceramic Whiteware products by the Dilatometer Method.

Several other ASTM methods are concerned with chemical durability. These include: C650—Test Method for Resistance of Ceramic Tile to Chemical Substances; C1378—Test Method for Determination of Resistance to Staining; and C556—Test Method for Resistance of Overglaze Decorations to Attack by Detergents. Of particular concern are ASTM methods used to control release of lead and cadmium from glazed surfaces. These include: C738—Test Method for Lead and Cadmium Extracted from Glazed Ceramic Surfaces; and C895—Test Method for Lead and Cadmium Extracted from Glazed Ceramic Tile.

PORCELAIN ENAMELS

Porcelain enamel coatings are ceramic coatings designed for application to metals. Conventional porcelain enamel coatings are prepared in an aqueous system and applied to the substrate by spray, dip, or flow coating. The coating is dried before firing. Newer technology involves dry application of powdered porcelain enamel by electrostatic spray.

The total market for porcelain-enameled products was reported to be $6.0 billion in 1999 [10]. About 86 % of the products are appliances, such as ranges, water heaters, home laundry, and dishwashers. About 6 % are cast-iron sanitary ware, and 8 % are architectural, cookware, and miscellaneous items.

A porcelain enamel must be formulated such that it will bond to the metal substrate. For proper adherence of the enamel to the metal, it is necessary to develop a continuous electronic structure across the interface [11]. This structure is developed by saturating the enamel coating and the substrate metal with an oxide of the metal [12], which for iron and steel substrates is ferrous oxide.

Certain transition metal oxides, such as cobalt oxide, nickel oxide, and cupric oxide, can be added to an enamel formulation to improve the adherence between the metal and the substrate. Ground coat enamels contain adherence oxides, while cover coat enamels do not.

Ground Coat Enamels

A general-purpose ground coat enamel such as Enamel 1 in Table 3 is an alkali borosilicate containing small amounts of adherance oxides to promote the bonding process. Enamel 2 is a home laundry enamel that has been formulated for outstanding alkali resistance through the addition of large quantities of zirconia [13]. Hot water tank coatings such as Enamel 3 have very stringent thermal- and corrosion-resistance requirements.

Enamel 4 is a continuous clean coating. This is a porous coating that provides a means of volatilizing and removing food soils from the internal surfaces of ovens during normal operation [14].

Cover Coat Enamels

Cover coat porcelain enamels are formulated to provide specific color and appearance characteristics, abrasion resistance, surface hardness, and resistance to corrosion, heat, and thermal shock. They can be clear, semi-opaque, or opaque. Opaque enamels such as Enamel 5 are used for white and pastel coatings [15]. They contain high concentrations of titania to provide the opacification. Semi-opaque enamels such as Enamel 6 are used for most medium-strength colors. Clear enamels such as Enamel 7 are used to produce strong bright colors. They are similar to ground coat formulations without the adherance oxides.

Testing of Porcelain Enamels

Test methods for porcelain enamel coatings are under the jurisdiction of ASTM Committee B-8 on Metallic and Inorganic Coatings. The methods are listed in Table 4. Again, they form the basis for most quality control test programs.

Several of these test methods are concerned with the chemical durability of porcelain enamels. They include: C282—Test Method for Acid Resistance of Porcelain Enamels (Citric Acid Spot Test); C614—Test Method for Alkali Resistance of Porcelain Enamels; C756—Test Method for Cleanability of Surface Finishes; C538—Test Method for Color Retention of Red, Orange, and Yellow Porcelain Enamels; C872—Test Method for Lead and Cadmium Release from Porcelain Enamel Surfaces; and C283—Test Method for Resistance of Porcelain Enameled Utensils to Boiling Acid. A related issue is the possibility of defects providing a pathway from the surface to the substrate, usually called continuity of coating. Methods in this area include: C536—Test Method for Continuity of Coatings in Glassed Steel Equipment by Electrical Testing; C743—Test Method for Continuity of Porcelain Enamel Coatings; and C537—Test Method for Reliability of Glass Coatings on Glassed Steel Reaction Equipment by High Voltage.

GLASS ENAMELS

Glass enamels are vitreous coatings applied on glass. They provide a means of decoration, not an improvement in chemical durability or in cleanability. These coatings must be matured at temperatures below the deformation point of glass (1000–1200°F, or 538–649°C). Hence, they require large quantities of fluxing elements so that chemical durability is difficult to achieve.

Glass enamels are produced in ready-to-use form (paste, thermoplastics, spray mediums, ultraviolet curable mediums) by a few select manufacturers. They represent a specialty product that is more akin to organic paints than to other ceramic coatings. The markets for this specialty product are categorized as tableware, glass containers, architectural, lighting, and automotive. As supplied to the user, glass enamels are mechanical mixtures of pigments, fluxes, and organic suspending media. The requirement for low maturing temperatures necessitates the use of very high lead oxide containing borosilicates for the flux. Leadless fluxes are now available, but have not yet achieved properties equal to the lead-containing fluxes. The organic suspending media are similar to materials used to make organic paints.

Testing of Glass Enamels

Test methods for glass enamels are under the jurisdiction of Subcommittee 14.10 on Glass Decoration of ASTM Committee C-14 on Glass and Glass Products. These methods [9] are listed in Table 5.

Most of these methods are concerned with the chemical durability of glass decorations. They include: C724—Test Methods for Acid Resistance of Ceramic Decorations on Architectural-Type Glass; C735—Test Method for Acid Resistance of Ceramic Decorations on Returnable Beer and Beverage Glass Containers; C675—Test Methods for Alkali Resistance of Ceramic Decorations on Returnable Beverage Glass Containers; C676—Test Method for Detergent Resistance of Ceramic Decorations on Glass Tableware; and C927—Test Method for Lead and Cadmium Extracted from the Lip and Rim Area of Glass Tumblers Externally Decorated with Ceramic Glass Enamels.

REFRACTORY COATINGS

Flame spray techniques can be used to apply ceramic coatings in the molten state to heat-sensitive or massive substrates that cannot themselves be heated to high temperatures. Most ceramic coating materials used currently can be applied by flame spraying [17]. Silicates, silicides, carbides, oxides, and nitrides have all been deposited by this process.

In these processes, the coating material is melted and projected as heated particles onto the substrate, where it instantaneously solidifies as a coating. Three methods of heating and propelling the particles in a plastic condition to the substrate surface include: (1) combustion flame spraying, (2) plasma arc flame spraying, and (3) detonation gun spraying. Combustion flame spraying is used for coating materials that melt readily. Plasma arc flame spraying is used for very refractory materials such as metal carbides. Detonation gun spraying is used for hard, wear-resistant materials such as tungsten carbide.

Flame spray coatings generally lack smoothness and are usually porous. They are, therefore, limited to applications such as thermal barrier coatings, where porosity is a virtue, and wear-resistant coatings, where the materials cannot be applied readily by any other technique.

Testing of Refractory Coatings

There is only one test method for flame spray coatings in the ASTM standards: C633—Test Method for Adhesion or Cohesive Strength of Thermal Spray Coatings [16].

COATING APPLICATION

Ceramic coatings are applied to their substrates by one of several powder-processing techniques. In wet processes, the raw materials are dispersed in a slip. Slip preparation involves mixing the ingredients, particle-size reduction, dispersion in water, and the addition of minor amounts of additives to modify the rheological properties of the slip [18,19]. These processes are carried out together in a ball mill comprising a rotating cylinder partly filled with freely moving impact-resistant shapes.

The application process for a ceramic coating must be straightforward and foolproof, reproducible, economical, and flexible [6]. Selection of the application technique is one of the most important decisions the coatings engineer makes. Criteria for this selection are type of ware, shape and size of ware, throughput required, energy and labor costs, and space available. All of these factors affect the quality and the cost of a coating process so that the best solution must be determined on an individual basis.

Dipping is a simple, efficient, rapid technique requiring no capital equipment. The ware is immersed in the coating slip, moved around in a controlled way, removed from the slip, shaken to remove excess slip, and set down to drain and dry. Any bare spots are touched up with a finger wet with coating material. Its limitations are extreme sensitivity to operator skill and difficulty in automating volume production.

Spraying is a process whereby a coating slip is broken down into a cloud of fine particles that are transferred to the substrate by either pneumatic, mechanical, or electrical forces. The method requires a gun, a container or feed mechanism, an impelling agency, and a properly designed hood or booth maintained under negative pressure [20], Spraying lends itself to high-volume automated systems [21]. The articles are continuously fed under a battery of angled spray guns. Coating reclaim is an essential part of automated systems.

Slip can also be applied mechanically with a rotating atomizer. Slip is passed onto a set of closely spaced rotating

disks, which throw the coating into a fan of droplets. Costs are similar to spraying. The primary use of this technique is in producing textured coatings on tile.

If the substrate is conductive (that is, a metal), the surface quality and uniformity of a ceramic coating can be improved by using the electrostatic spray coating technique [22,23]. In this system, the slip is broken into droplets either by air atomization or by centrifugal force from a sharp-edged rotating surface. The drops acquire a high negative charge and are dispersed as a fine mist. They are driven forward to the grounded substrate following the lines of force. Hence, coating material can reach the underside of the ware, and full-edge coverage is achieved.

There are other techniques for specific applications. Tile require only one face to be glazed, but with a very smooth coating. This suggests the Bell or waterfall technique [6], where a continuous feed of tiles is carried under a curtain of fluid slip made by pouring a stream of slip over a bell shaped device. Painting and brushing are seldom used except for special effects and for applying glaze to inaccessible areas.

For substrates that require precisely positioned areas of coating, the silk screen process can be used [20]. Finely powdered dry coating material is dispersed as a smooth paste. Using a squeegee, this paste is pressed through the open areas of a fine mesh screen stretched on a frame. For coating a total piece, costs are excessive.

There are a few techniques of application that do not require the preparation of a slip. They include flame spraying, dry powder cast iron enameling, and electrostatic dry powder enameling.

Flame spraying can be used to apply ceramic coatings in the molten state to heat-sensitive or massive substrates. Flame spray coatings generally lack smoothness and are usually porous. Equipment and material costs are generally high.

In dry powder cast-iron enameling, a casting is heated in a furnace to red heat. It is then withdrawn from the furnace and, while still hot, dusted with dry powdered frit by means of a vibrating sieve placed over the surfaces to be coated. The powdered frit melts and adheres as it falls on the hot surface. This process is also extremely operator sensitive. Recently, it has been adapted for robot application, which serves to reduce variations over time.

The most important dry application method, and the one most recently introduced, is dry powder electrostatic application of all-fritted coatings to conductive substrates. This technique involves charging individual coating particles at a high voltage and then spraying them towards the substrate surface. Charging of particles is accomplished by encapsulating the coating material with an organic silane. It is then suspended in clean compressed air in a fluidized bed container [24]. The fluidized powder is siphoned and propelled through powder feed tubes to special electrostatic powder guns for low-pressure application. The powder carries a potential of up to 100 kV, which causes it to seek out and attach itself to the grounded workpiece. Capital costs of this process are substantial, but operating costs are reduced through elimination of slurry preparation and drying of the ware.

Epoxy Resins in Coatings

Michael J. Watkins[1]

PREFACE

THE AUTHOR COLLABORATED WITH RONALD Bauer and Edward Marx in preparing this chapter for the previous or 14th edition of this manual. This revised edition includes expanded descriptions of epoxy materials and curing agents currently used in coating formulations. Epoxy resins are versatile materials that are used in a wide variety of coatings. In the interests of brevity, this chapter focuses on the epoxy resins, curing agents, and coating types that are commercially most important and account for the largest usage of epoxy resins. As an example, epoxy coating technologies, which reduce volatile organic compound (VOC) emissions, have grown rapidly. Waterborne, high solids, and powder epoxy coatings account for about 80 % of all epoxy resin used in coatings. On the other hand, low solids epoxy coatings have declined significantly in importance and account for less than 15 % of epoxy resin usage. So this chapter naturally focuses on the low VOC technologies. Similarly, epoxy ester coatings were described in the previous edition, but have declined in importance, so they are not discussed here. Also, epoxy coatings are formulated with other materials described in this manual, and attempts have been made to reference those chapters where appropriate.

INTRODUCTION

Generically, epoxy resins can be characterized as a group of oligomeric materials that contain one or more epoxy (oxirane) groups per molecule. Almost all commercially significant epoxy functional materials are derived by reacting epichlorohydrin with various materials containing groups with active hydrogen (such as phenolic hydroxyl, aliphatic hydroxyl, carboxylic acid, or amine). The initial reaction yields a chlorohydrin, which is subsequently dehydrochlorinated to yield the glycidyl (epoxy) group. One exception to this generalization is the class of cycloaliphatic epoxy resins discussed in Chapter 16, Miscellaneous Materials and Coatings, in this manual. Another exception is represented by epoxy functional acrylic resins that are made by copolymerizing various acrylic monomers with glycidyl methacrylate or similar epoxy functional acrylic monomers.

Epoxy resins based on bisphenol A (BPA) and epichlorohydrin are commercially the most important epoxy resins by a very wide margin. These resins have become technologically important materials that find extensive application in high-performance coatings, adhesives, and reinforced composites. Almost since their commercial introduction in about 1947 [1], epoxy resin systems have been used in protective coatings. Historically, protective coatings were the largest single end use for epoxy resins. Although in recent years the non-coating applications of epoxy resin have been growing, coatings still represent about half of the annual epoxy resin usage.

The principal components of any epoxy coating system are the epoxy resin and the curing agent or hardener. Epoxy resins are reactive intermediates that can be liquid or solid, and they are converted into the final coating by reaction with curing agents (hardeners). Curing agents function by reacting with specific groups in the epoxy resin molecule to give a three-dimensional, infusible polymer network. Although the resin and curing agent are common to all epoxy coatings, other materials are incorporated to achieve the desired rheological characteristics, cure speed, appearance, and film performance.

BPA EPOXY RESINS

BPA-based epoxy resins were developed independently by Pierre Castan in Switzerland and by Sylvan Greenlee in the United States during the 1930s and 1940s [1–3]. The generalized structure for these resins is given in Fig. 1. In commercial products, the n value ranges from 0 to about 60. Table 1 displays a range of typical epoxy resins that are commercially available, along with their properties and applications. As n increases, the epoxy equivalent weight increases, as does the number of hydroxyl groups. Thus epoxy resins with low n values are normally cured by reaction of the epoxy group, whereas those resins with higher n values are cured by reaction of the hydroxyl functionality. The highest molecular weight BPA epoxy resins, or phenoxy resins, are described in Chapter 16, Miscellaneous Materials and Coatings, in this manual.

Resins having n values less than 1 are viscous liquids; they are used mainly in two-pack, ambient-temperature cure coatings, as well as in electrical castings, flooring, electrical laminates, and fiber-reinforced composites. Resins having n values in the range of about 1–2 are low melting solids that are used in solution in two-pack, ambient-temperature cure coatings. Resins having n values in the range of about 2–6 are solids, which do not sinter at room temperature. They are predominately used in powder coatings. All of these applications are cured through the epoxy groups. The higher n value resins, particularly those with $n > 10$, are normally used in solution and find their greatest application in heat-cured coatings. In these resins, the concentration of epoxy groups is low, and so they are cured with materials that react with the hydroxyl groups along the backbone.

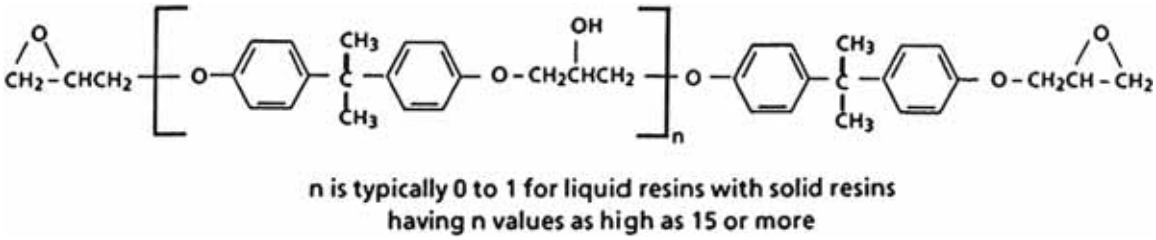

Fig. 1—Idealized structure of a bisphenol epoxy resin.

Coatings based on BPA epoxy resin offer a unique combination of performance characteristics and are used in a wide variety of technologically important end uses. These characteristics include exceptional adhesion and corrosion resistance, excellent chemical resistance, low shrinkage, high strength, good heat resistance, toughness, and excellent electrical properties. Because of the adhesion and corrosion resistance, epoxy resins have been used in corrosion-resistant primers and coatings since epoxy resins were first commercialized. In addition, the excellent chemical resistance has resulted in the formulation of epoxy coatings that provide outstanding protection against severe corrosive environments. They are used extensively in coatings for refineries, chemical plants, and marine equipment, such as ships and offshore platforms. Other important applications where epoxy resin coatings are used almost exclusively because of the corrosion protection they afford include automotive, aircraft, and appliance primers as well as coatings for both the inside and outside of pipelines.

The chemical and corrosion resistance resulted in the development of BPA epoxy coatings used for the interior linings of beer and beverage cans, the interior linings of food cans, and for chemical-resistant linings of pails and drums. Guidelines for the safe use of coatings based on BPA epoxy resins for direct food contact have been established by the U.S. Food and Drug Administration [4]. These coatings are used not only to protect the metal of the container from corrosion, but also to protect the flavor of the contents, which can be affected by direct contact with metal.

The one significant weakness of coatings based on BPA epoxy resins is that they are not resistant to ultraviolet (UV) exposure. When exposed to direct sunlight, they tend to yellow and chalk. The aromatic structure of the BPA backbone absorbs the UV energy and the backbone degrades. Thus, BPA epoxy resins are typically used as primers, which are subsequently top coated with coatings that are resistant to UV degradation. This strategy takes advantage of the excellent corrosion resistance of the epoxy primer, while protecting it from its one weakness.

OTHER EPOXY MATERIALS USED IN COATINGS

Although BPA-based epoxy resins are far and away the largest volume commercial epoxy resins, other epoxy functional materials are also important. The diglycidyl ether of bisphenol F is a low viscosity liquid epoxy resin that it useful in high solids or 100 % solids coatings or floorings. For comparison, the viscosity of the standard commercial grade of BPA liquid resin is about 120–140 Poises at 25°C, while that for a typical BPF liquid resin is about 25–45 Poises. This advantage over BPA resins diminishes at higher molecular weights so BPF solids resins are not generally used.

Epoxy phenol novolacs, epoxy alkylphenol novolacs (i.e., epoxy cresol novolacs), or epoxy BPA novolacs are multifunctional epoxy resins that are used to increase cross-link density and subsequently increase the chemical resistance, hardness, heat deflection temperature, etc. for epoxy coatings and other applications. These

TABLE 1—Typical properties of BPA-based epoxy resins

Average Molecular Weight	Average EEW[a]	Approximate Average Value of *n*	Viscosity (P @ 25°C)	Softening Point (°C)[b]	Applications
350	182	0	80	. . .	Solventless and solvent-borne ambient cure coatings, electrical encapsulation, flooring, and filament winding
380	188	0.2	140	. . .	Solvent-borne, ambient cure coatings
600	310	1	Semi-solid	40	Solvent-borne, ambient cure coatings
900	475	2	Solid	70	Solvent-borne, ambient cure coatings
1400	900	4	Solid	100	Powder coatings
2900	1850	10	Solid	130	Heat cured, solvent-borne coatings for cans, drums, primers, etc.
3750	3050	13	Solid	150	Heat cured, solvent-borne coatings for cans, drums, primers, etc.

[a] EEW—epoxide equivalent weight, grams of resin providing 1 mole of epoxide. Also referred to as WPE (weight per epoxide) and EMM (epoxy molar mass). All three terms are interchangeable.
[b] Softening point by Duran's mercury method (ASTM D1763).

resins have epoxy functionality in the range of 2–8. (By comparison, BPA resins and BPF resins have typical functionality of about 2.) As an example, epoxy novolac resins are used in combination with BPA resins in powder coating formulations to enhance chemical and corrosion resistance.

Another multifunctional resin that may be used is the glycidated tetraphenol of ethane. This has a nominal epoxy functionality of 4. As with the epoxy novolacs, it can be used along with BPA epoxy resins to improve chemical and corrosion resistance.

Brominated epoxy resins can be prepared from epichlorohydrin and tetrabromobisphenol A, or from liquid BPA epoxy resin and tetrabromobisphenol A. These have a broad use in electrical laminating (i.e., circuit board) applications. The bromine content makes them suitable for flame retardant coatings.

Epoxy resins such as the polyglycidyl ether of castor oil are multifunctional resins that are used with BPA epoxy resins to improve the flexibility and water resistance.

A whole series of epoxy functional materials are used as reactive diluents and modifiers in epoxy coatings. Monofunctional epoxies are typically used as reactive diluents in high solids or 100 % solids, two-pack ambient cure coatings. One group of monofunctional epoxies are made by reacting epichlorohydrin with alcohols. One widely used example is the glycidyl ether of mixed alkyl C_{12}–C_{14} alcohols. Another commercially important example is the glycidyl ether of mixed alkyl C_8–C_{10} alcohols. The glycidyl ether of *n*-butanol gives the best viscosity reduction of any reactive diluent in BPA epoxy systems and is also important commercially. Another group of monofunctional epoxies are made by reacting epichlorohydrin with phenol or alkylphenols. The most widely used example is *o*-cresyl glycidyl ether. Other examples include phenyl glycidyl ether, *p*-tert-butylphenyl glycidyl ether, and nonylphenyl glycidyl ether. A third type of monofunctional epoxy is the glycidyl ester of neodecanoic acid.

Monofunctional epoxies of this type are useful as reactive diluents to reduce viscosity and VOC. However, because they are monofunctional, they also decrease cross-link density of the cured coating, generally resulting in some loss of chemical resistance, corrosion resistance, hardness, etc. So the coatings formulator must carefully balance the need for low viscosity with other coating performance requirements.

A group of multifunctional epoxies are available to serve as reactive diluents, but still maintain functionality and cured film properties. These are generally prepared by reacting epichlorohydrin with polyols. Examples include neopentyl glycol diglycidyl ether, butanediol diglycidly ether, cyclohexanedimethanol diglycidyl ether, trimethylolpropane triglycidyl ether, and trimethylolethane triglycidyl ether.

Resorcinol diglycidyl ether is an effective difunctional reactive diluent. Unfortunately, it is a strong skin irritant and sensitizer and can cause severe allergic reactions. Therefore, relative to other reactive diluents, it is difficult to handle safely.

Another specialty epoxy resin is made by reacting epichlorohydrin with hydrogenated BPA. Since this material is saturated, rather than aromatic, it has UV resistance superior to that for BPA epoxy resins.

CURING AGENTS

Epoxy resins are reactive intermediates composed of mixtures of oligomeric materials containing one or more epoxy groups per molecule. To convert epoxy resins into useful products, they must be cross-linked or "cured" into a three-dimensional polymer network. Cross-linking agents, or curing agents as they are generally called, function by reaction with or cause the reaction of epoxide or hydroxyl groups in the epoxy resin. The number of curing agents that have been developed over the years for epoxy resins is overwhelming. Selection of the curing agent is as important as that of the base resin; it is dependent on the performance requirements of the film and the constraints dictated by the specific method of application.

The most widely used types of curing agents employed in epoxy resin coatings are the amine-functional materials for ambient-cure coatings, dicyandiamide or acid-functional polyesters for powder coatings, and amino resins (see Chapter 8, Amino Resins, in this manual) or phenolic resole resins (see Chapter 11, Phenolics, in this manual) for heat-cured liquid coatings.

The principal amine-functional curing agents used in two-pack, ambient-cure epoxy coatings are polyamides (see Chapter 12, Polyamides, in this manual). Amidoamines, aliphatic amines, and epoxy-amine adducts are also used. Specialty amine curing agents include phenalkamines, cycloaliphatic amines, and ketimines. These materials cure epoxy resins by reaction of the amine with the epoxy groups. Typical aliphatic amines used include diethylenetriamine (DETA), triethylenetetramine (TETA), and tetraethylenepentamine. Aliphatic amines such as DETA and TETA can be pre-reacted with low molecular weight epoxy resins to make epoxy-amine adducts that are very useful as epoxy curing agents. Amidoamines are made by reacting fatty acids with aliphatic amines (i.e., DETAor TETA).

Polyamides are made by reacting dimerized fatty acids with aliphatic amines (i.e., DETA or TETA). More pounds of polyamide curing agents are consumed annually in the United States than any other type of epoxy resin curing agent. Polyamide cured epoxy coatings develop superior adhesion to moist and poorly prepared surfaces, and they provide a high degree of corrosion resistance. Like epoxy resins, polyamides are also mixtures of oligomers. Thus, a range of polyamides that vary in viscosity, amine equivalent weight, and reactivity is available. Polyamide cured coatings exhibit somewhat better retention of flexibility and impact resistance on aging than polyamine adducts. Although resistance to solvents and acids is not quite as good as with other types of amine curing agents, polyamides are adequate and cost-effective for most applications where amine cure epoxy coatings are used.

Typical cycloaliphatic amines include isophorone diamine, bis(*p*-aminocyclohexyl)methane, and 1,2-diaminocyclohexane.

Ketones add reversibly to primary amines with the loss of water to give ketimines. The ketimines obtained from the typical polyamine curing agents have rather low volatility compared to the precursor polyamine. Ketimine curing agents can be considered blocked polyamines, which in the presence of water hydrolyze to produce a ketone and a polyamine. These ketimines react at a practical rate of cure under ambient conditions. Atmospheric moisture, which is absorbed during and following application of the coating,

serves as the source of water required to activate the curing agent. Ketimine curing agents are similar in behavior to the aliphatic amine polyamines and amine adducts in rate of cure and performance of cured films, but they provide much longer pot lives.

Epoxy resins are formulated with acid-functional polyesters to make hybrid powder coatings. Catalysts are often used to facilitate this reaction. The ratio of epoxy to polyester is typically in the range from 50:50 to 30:70. When the powder coating is baked, the acid groups on the polyester react with the epoxy groups to make a cured polymer matrix. The principal curing agent for epoxy powder coatings is dicyandiamide. At elevated temperature, this reacts with the epoxy groups to cure the coating. Catalysts such as imidazoles or epoxy-imidazole adducts are commonly used to speed up this reaction. Strong bases such as imidazole-type catalysts can also be used alone as curatives. They cause homopoly-merization of epoxy groups as a means of cure. Specialty curing agents for powder coatings include phenolic-functional polyethers, phenolic resoles (see Chapter 11, Phenolics), and anhydrides.

Baked liquid coatings employ high molecular weight epoxy resins. These resins contain relatively low epoxide functionality and relatively high hydroxyl functionality. These are cured through the hydroxyl groups with melamine-formaldehyde resins and urea-formaldehyde resins (see Chapter 8, Amino Resins), as well as phenol-formaldehyde resins (see Chapter 11, Phenolics). Strong acids, such as phosphoric acid or p-toluene sulfonic acid, are used as catalysts. Strong organic acids blocked with volatile amines can also be used to achieve enhanced package stability. The acid-amine salt is non-catalytic. However, at elevated temperature, the amine volatilizes, leaving the acid to catalyze the curing reaction.

EPOXY COATINGS

The four coating types that account for the highest usage of epoxy resins are powder coatings, high solids solvent-borne coatings, electrodeposition coatings, and waterborne coatings. These coating types account for over three quarters of epoxy resin usage in coatings. Low solids, solvent-borne epoxy coatings are clearly declining in volume. This is not surprising, as a major driver for change in the coatings industry is the reduction of VOCs in coatings. These four coating types are used to reduce VOC emissions.

EPOXY POWDER COATINGS

Powder coatings are produced by melt blending homogenous dispersions of solid resins, curing agents, pigments, fillers, and various additives. The dispersion is solidified by cooling, ground into a finely divided powder form, and classified by particle size for subsequent use. The resultant powder is normally electrostatically deposited onto grounded substrates and, through the application of heat, converted into very high performance thermoset films. The process of applying coating powders allows nearly 100 % powder utilization and evolves almost no VOCs.

The 1970s volatiles regulations and energy concerns raised interest in powder coating technology. The real sustaining driving forces for growth, however, have been improvements in powder coating raw materials, formulations, manufacturing technology, and application equipment. The advantages for the use of powder coatings can best be summed up in the "Four E's," used by the Powder Coating Institute: (1) Excellence of finish, (2) Economy in use, (3) Energy efficiency, and (4) Environmental acceptability. The Clean Air Act, as amended in 1990, has contributed to even greater interest in the use of powder coatings to meet more stringent volatile organic requirements. Powder coatings comprise one of the fastest growing areas of coatings technology. Current growth rate for epoxy powder coatings is approximately 6 % versus about 2 %–4 % for other coating types.

The unique characteristics of solid epoxy resins account for their choice by formulators for use in powder coatings applications. BPA-based epoxides with equivalent weights greater than about 650 are non-sintering and friable. They have relatively low melt viscosity and high reactivity via the terminal oxirane functionality. The addition reaction with amines, phenolics, or carboxylic acid functional curatives allows a wide range of formulations. The primary limitations for BPA-based epoxy resins in powder coatings are yellowing and loss of gloss that occur when these coatings are exposed to exterior weathering conditions.

Powder coatings are broadly divided into either "functional" or "decorative" uses. Functional coatings are normally applied at film thicknesses greater than about 3 mils and are expected to withstand some rather severe service. Examples of functional uses are coatings for exterior and interior pipe, rebar, and various electrical devices. Although decorative powder coatings are functional, these are normally used at a film thickness of 3 mils or less and are not expected to perform significantly better than baked films derived from "wet" coatings. Some examples of decorative uses are coatings for appliances, furniture, and under hood automotive parts.

HIGH SOLIDS, SOLVENT-BORNE COATINGS

Industrial maintenance and marine paints account for nearly all of these coatings. These are two-package, ambient cure coatings. A two-package coating is comprised of the epoxy component and the curing agent, which are packaged separately and often in volume ratios of 2 to 1 or 4 to 1 of epoxy component to curing agent. Two-package epoxy coatings are mixed just prior to application and are characterized by a limited working life or pot life after the resin and curing agent components are mixed. Commercial systems will have pot lives of a few hours to a couple of days, with typical working times of about 4–8 h.

Historically, maintenance and marine coatings were formulated with solid epoxy resins (average n approximately 2) in solution, cured with high molecular weight polyamides. These gave excellent corrosion protection, but were high in VOC (about 4 lb/gal, or more). In order to achieve lower VOC and higher solids, formulations have shifted to using lower molecular weight BPA epoxy resins (n = 0.2) or BPF liquid epoxy resin with lower viscosity curing agents, such as amidoamines, aliphatic amines, phenalkamines, cycloaliphatic amines, and ketimines. By using lower viscosity resins and curing agents, higher solids systems can be achieved. Another strategy to reduce VOC has been to formulate coatings with some exempt solvents, such as acetone, methyl acetate, *t*-butyl acetate, and *p*-chlorobenzotrifluoride.

ELECTRODEPOSITION COATINGS

Epoxy resin electrodeposition coatings are waterborne coatings formulated from either anionic or cationic epoxy

resin polymers. The part to be coated is dipped into the electrodeposition bath, and an appropriate electrical charge is applied, causing the coating to deposit onto the part. The part is then removed from the bath, rinsed, and baked to cure the coating. In the United States, epoxy-based electrodeposition coatings account for over 90 % of all electrodeposition coatings. Epoxy-based cathodic electrodeposition (CED) automotive primers dominate this application, accounting for over 70 % of all electrodeposition coatings. Over 40 million pounds of epoxy resin are used in the United States in CED automotive primers, making this one of the largest single end uses for epoxy resins in coatings. Virtually every automobile made in the United States, Europe, and Japan is primed with an epoxy CED primer. CED primers are used because they afford exceptional corrosion protection and because they are deposited uniformly to all areas of the automobile, even in areas that would be inaccessible to other coating application methods such as spray. Because of their major importance, the remainder of this discussion will deal with CED automotive primers.

The preparation of CED [5] coatings generally begins by reacting a BPA-based liquid epoxy with BPA to give an epoxy resin with an epoxy equivalent weight in the range of 500–1000. This epoxy resin may then be reacted with a flexibilizing diol. This diol can be an aliphatic diol or a polyether diol. The principal requirement is that the diol contain primary hydroxyl functionality. These primary hydroxyls are reacted with the epoxy groups in the presence of a suitable catalyst (e.g., a tertiary amine) to form ether linkages between the epoxy and the flexibilizing diol. At this point, the resin may have an epoxy equivalent weight in the range of 1000–1500. The remaining epoxy functionality is then reacted with amines. Generally, secondary amines are chosen to minimize further chain extension. One favored method to accomplish this is to use a diketimine of diethylenetriamine. During coating preparation, the ketimine groups decompose to give primary amines. These primary amines are fairly basic, resulting in stable dispersions at a relatively high bath *p*H (*p*H > 6). At this point, the CED resin preparation is complete. In practice, specialized CED resins are used to make the pigment grind pastes. These are developed to efficiently make stable pigment dispersions, which retain good stability in the CED coating bath.

Curing agents used are generally blocked isocyanates. These are chosen to be stable and unreactive in the coatings bath, but to unblock and cure the coating at baking temperature. An example of such a curing agent would be the reaction product of 3 mol of toluene diisocyanate with 1 mol of trimethylolpropane. This is then reacted with 3 mol of a suitable blocking agent. Historically, 2-ethyl-1-hexanol has been used. However, much research has been done in recent years to find blocking agents that unblock at lower temperatures, permitting lower bake temperatures and energy savings. One example of many is provided in Ref. [6], where oximes are used as blocking agents. Catalysts such as tin or lead salts are generally used to facilitate unblocking and coating cure. Recent formulation efforts have eliminated lead catalysts. One example of many is provided in Ref. [7]. The coating is prepared by blending the resin with pigment paste, curing agent, catalysts, additives, and solvents. A low-molecular-weight organic acid, such as lactic or acetic acid, is then added to the mixture to make ammonium salts with the amine groups in the resin. This mixture is then dispersed in water to make the CED coating. Solvents may be required in the preparation of the CED resin or other components. In order to reduce the VOC content of the finished coating, it is usually subjected to a vacuum stripping step, which can reduce VOC to less than 0.7 lb/gal. When the automobile is dipped into the CED bath, a negative charge is applied to it (making it the cathode) relative to counter electrodes in the bath. Electrolysis of water occurs, forming hydroxide ions in the immediate vicinity of the automobile surface. These hydroxide ions react with the ammonium ion groups in the resin near the surface, regenerating the neutral amine groups and causing the coating to be deposited onto the surface. In this way, a uniform film is applied to the entire conductive surface of the automobile. The automobile is then removed from the bath, rinsed, and baked.

WATERBORNE COATINGS

It was determined early on that epoxy coatings are safe and highly effective linings for food and beverage cans. Historically, these coatings were solvent borne. Recently, there has been concern about low molecular weight materials that may be extractable from can linings, such as BPA, BPA diglycidyl ether (BADGE), or derivatives of BADGE. Although research is ongoing, the current consensus is that epoxy-based can linings are safe and effective [8–10].

The need to reduce VOC has driven the development of waterborne food and beverage can linings [11]. Waterborne linings for beer and beverage cans are used exclusively and are an important use for epoxy resins. This is not surprising when one considers that over 100 billion beer and beverage cans are manufactured in the United States every year. These coatings are based on high-molecular-weight epoxy resins (average n of about 10–13), onto which are grafted acrylic terpolymers (i.e., styrene/methacrylic acid/ethyl acrylate). These epoxy/acrylic graft polymers are neutralized with base, such as dimethylethanolamine, to give a resin easily dispersible in water. The dispersed resin may be cured with an amino resin (see Chapter 8, Amino Resins) to give coatings with properties that make them suitable for beer and beverage containers.

Food can linings are typically solvent-borne high-molecular-weight epoxy resins (average n of about 10–13), which are cured with amino resins (see Chapter 8, Amino Resins) or phenolic resins (see Chapter 11, Phenolics). Generally, food can linings require more chemical resistance than beer and beverage cans. Waterborne epoxy food can linings have been developed, which are based on similar technology to the beer and beverage can linings. These coatings are being used, and are growing in share of the food can lining market.

Waterborne two-pack ambient-cure coatings comprise a small but growing end use for epoxy resin. BPA-based epoxy resins are rather hydrophobic and are not easily dispersed in water. Initial waterborne epoxy resins were modified with large amounts of surfactants to form stable dispersions. But the surfactant made subsequent coatings relatively hydrophilic, resulting in loss of corrosion resistance when applied to metallic substrates. These early waterborne epoxy coatings performed well when applied to non-metallic (e.g., cementitious) substrates. One solution to this problem was to make aqueous epoxy dispersions by using nitroparaffin cosolvents in place of surfactants [12–14]. The nitroparaffin

evaporates from the coating after application and does not affect the hydrophobicity or performance of the coating. This approach has been used to formulate waterborne aerospace coatings. Advances in surfactant technology and in dispersion technology have resulted in waterborne epoxy resins and curing agents, which give excellent performance on metallic substrates [15–17]. The need to lower VOC is encouraging the use of these systems in industrial maintenance, aerospace, and railroad coatings.

Phenolics*

John D. Fisher[1]

HISTORY

PHENOLIC RESINS, INITIALLY COMMERCIALIZED in 1909, were the first completely synthetic materials of the burgeoning plastics business. The expansion of several new technologies of the time, namely the electrical, communications, and automotive industries, all required and depended on new materials that had better electrical insulating properties, higher heat resistance, and improved resistance to chemicals, acids, oils, and moisture. The heat-reactive or "resole" resins, developed by Dr. Leo H. Baekeland [1], were formulated into blends that were convenient for mass production of compression molded parts that satisfied these requirements. Improved and new items, such as coil supports, commutators, distributor heads, telephone sets, vacuum tube bases, radio parts, and electrical switches, all blossomed onto the market within a few years.

FIRST PHENOLIC RESIN-BASED COATINGS

Concurrent with the above developments, the non-heat-reactive phenolic resins or "novolak" resins were prepared as a hoped-for substitute for shellac. These resins were not as resilient as shellac and, when used alone, were not successful in coatings. However, combined with a formaldehyde donor such as hexamethylene tetramine, the novolaks could be compounded into another family of thermosetting molding materials, which found early use in phonograph records.

While novolaks had to wait for success in coatings, the resole resins in alcohol solutions by 1911 were found to form excellent films when cross-linked by baking [2]. These coatings, still in wide use today, are hard and glass-like and have excellent resistance to chemicals, acids, water, and solvents. Early applications included protective coatings for brass beds as well as other hardware items. These solution resins also initiated the manufacture of laminates, which were used to make early radio circuit boards and, later, printed circuit boards.

PHENOLIC RESINS IN COATINGS

Coatings Based on Phenolic Resins

The early coatings based on phenolic resoles developed over time into a family of products used as protective coatings. Coatings based on similar technology are still found in a variety of applications. Chemically resistant protective coatings for stationary and mobile tanks, drums, and pipes are produced based on phenolic resole solutions that are applied and then cured in place with the application of heat. Regulations limiting the release of volatile organic compounds led to the development of higher solids versions and waterborne versions in the 1970s and 1980s, but other than these changes the products are essentially the same as the products developed many years ago. Coatings of this nature possess excellent chemical resistance, good high temperature performance, high hardness, and hence good abrasion resistance and good specific adhesion to metal substrates. They suffer from low flexibility and deterioration upon prolonged exposure to UV light. Their use is limited to applications with rigid substrates and applications where UV light exposure will not be a concern.

One innovation by scientists at the General Electric Company in the early 1950s led to the development of phenolic resins modified by reaction with allyl chloride [3–8]. Coatings produced from phenolic resins that use this technology have even greater chemical resistance than typical phenolic resins due to the replacement of the mildly acidic proton of the aromatic hydroxyl group with the allyl group. This yields a coating that is less susceptible to reaction with strong bases than a typical phenolic resin-based coating and hence has higher chemical resistance. However, this modification does not significantly help the flexibility of the coating (Fig. 1).

Coatings Based on Polymer Alloys with Phenolic Resins

As noted, coatings based wholly or primarily on phenolic resins possess some properties that make them desirable coatings, but they suffer from being extremely brittle. While they are suitable for applications where little or no flexibility is required, the lack of flexibility precludes them from use in many applications where this property is required or desired. Use of phenolic resin technology in a wider variety of applications had to wait for further developments. This came in two ways. The first was modification of the phenolic resins to achieve compatibility with traditional resins used in coating applications. The second was the development of other synthetic resin technology for use in the coatings market.

One of the traditional coating technologies is the use of drying oils of various types as the principal vehicle to

*DEFINITION: a polymeric, resinous reaction product of a phenol with an aldehyde. Said products may be used alone or in formulations with other polymers to produce useful coatings.

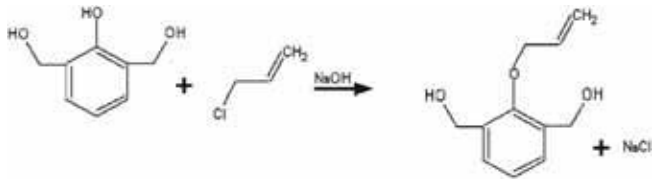

Fig. 1—Modification of resoles with allyl chloride.

carry and bind pigment to a variety of substrates. Over time it was found that "cooking" the oils with various other ingredients improved the performance of the coating made from the oil. This technology developed into what are now known as alkyd resins, which are essentially oil modified polyester resins. Modification of alkyd resins with phenolic resins held the promise of improving performance of the alkyd resin-based coatings, but the compatibility of early phenolic resins with the oil-based alkyd resins was not good and found limited application. Once technology advanced to the production of phenolic resins from alkylated phenolic monomers, the higher aliphatic content provided by the alkylated phenolic monomers greatly improved the compatibility with the oil-based alkyd resins. A variety of improvements in performance was observed for the phenolic resin modified alkyds, including greater abrasion resistance, better high temperature performance, improved chemical resistance, and improved adhesion to metallic substrates. Early phenolic resin modified alkyds were made from resole resins based on alkylated phenolic monomers that had to be cooked into the alkyd resins during manufacture of the alkyd resins. Later, higher molecular weight phenolic resins that could be "cold cut" into the alkyd resins were developed. Both technologies are still in use today [2]. The use of alkylated phenolic monomers to produce phenolic resins with improved compatibility with other coating ingredients led to a wide range of new products that took advantage of the improved heat resistance and hardness of the phenolic resins and the good film-forming properties of the drying oils and the alkyd resins derived from them. One of the areas that depended strongly on this developing technology was electrical insulation coatings where phenolic resins were alloyed with other coating resins to upgrade the performance of both primary and secondary electrical insulation coatings where products with much better performance allowed manufacturers to build electrical motors with improved performance and durability [9].

The development of other new synthetic polymers with potential applications in the coatings industry also created new opportunities for the use of phenolic resins in a wider range of coating applications. Particularly significant was the development of epoxy resins. When cured, epoxy resins exhibit a level of flexibility far higher than the phenolic resins. Also, the similarity in structure between phenolic resins and the predominant commercial epoxy resins makes them compatible across a wide range of blending ratios giving the coatings formulator the opportunity to balance the flexibility of the epoxy resin with the chemical resistance of the phenolic resin for each given application. Further, the aromatic hydroxyl group present throughout the phenolic resin structure is reactive with the oxirane group characteristic of the epoxy resins. When fully reacted the blend of the two polymers becomes one homogeneous film.

Use of phenolic/epoxy alloys in coatings has been employed in a variety of coating applications. One area where they have found wide acceptance is the formulation of coatings for metals, particularly in the packaging coatings industry. In this industry, the ability of phenolic resole/epoxy alloys to provide very good chemical resistance allows packaging of food stuffs and beverages in metal cans coated with very thin film weight coating. These coatings take advantage both of the reaction between the epoxy and the phenolic resin as well as the homopolymerization of the phenolic resole, both of which occur when the coating is baked onto the substrate. Phenolic resole/epoxy alloys are also used in wash or pretreatment coatings. In these applications, a very dilute coating is applied during the wash process and in preparation for painting for the purpose of preventing flash rust formation and/or to improve adhesion of the permanent coating to the substrate.

Phenolic novolak/epoxy alloys have also found use in coating applications. Powder coating formulations take advantage of the relatively low melt viscosity, the good friability, and film forming of the phenolic resin. In addition, the thermally induced reaction of the phenolic hydroxyl with the oxirane encourages the use of the novolak resins as cross-linkers for the epoxy resins to make chemically resistant powder coatings. This addition reaction has the added benefit that no volatiles need to be released, which is especially important in powder coatings where no solvent is present to facilitate the release of volatile components from the film without pinhole formation (Fig. 2).

In addition to being used in alloys to produce epoxy and alkyd based coatings, phenolic resins have proved useful as modifiers at low levels for a variety of other synthetic resins for coating applications. Some examples are the use of phenolic resins as adhesion promoters for a variety of synthetic polymer-based coatings, These include SBR, NBR, and poly-(vinyl chloride) resins, to name a few. In addition the resole phenolic resins are often added as a cross-linking agent to formulations based on polyvinyl butylral or polyvinyl alcohol resins.

PHENOLIC RESINS AS PHOTO-IMAGABLE COATING

Phenolic novolak resins have also found application in the area of photo-imagable coatings. For this application, a coating of phenolic novolak mixed with a photo-sensitive base is applied to a substrate. The coated article is partially exposed to an image and the photo-sensitive base forms a salt with the phenolic novolak where the light activates the base. The phenolic resin salt has a distinct solubility difference from the phenolic novolak that has not reacted with base and so may be selectively removed, exposing the substrate below. The article is then able to be further processed and the exposed portion of the substrate may be selectively reacted while the unexposed substrate is protected by the remaining phenolic resin coating. This technology is used commercially on silicone wafers to make semiconductor chips and on aluminum plates to make planographic printing plates.

PHENOLIC RESIN CHEMISTRY

The reaction between phenols and aldehydes to produce resinous products was difficult to understand in the early years because many of the products were insoluble or

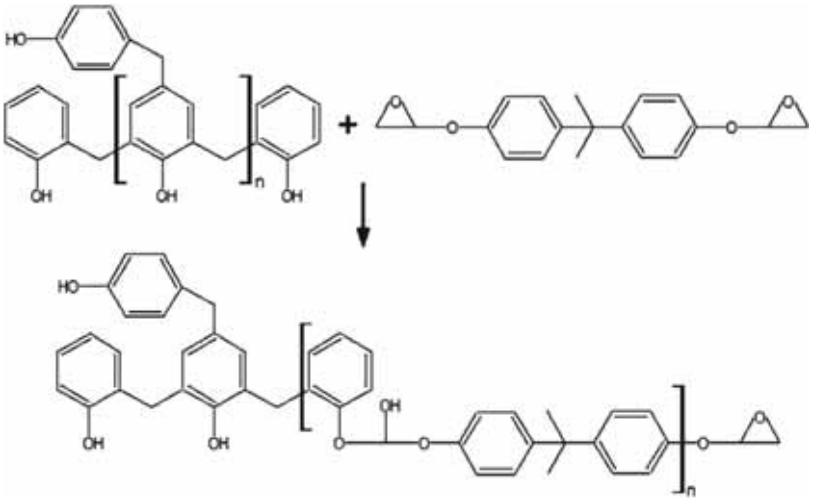

Fig. 2—Reaction between epoxy resin and phenolic resin.

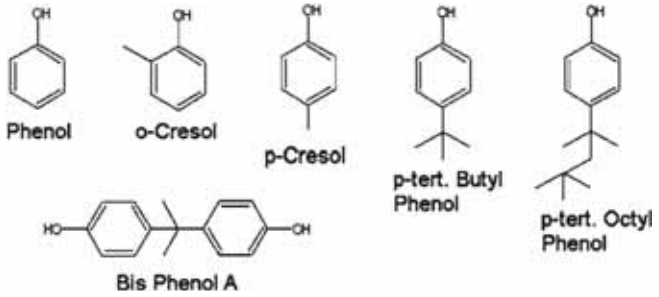

Fig. 3—Typical phenolic starting materials.

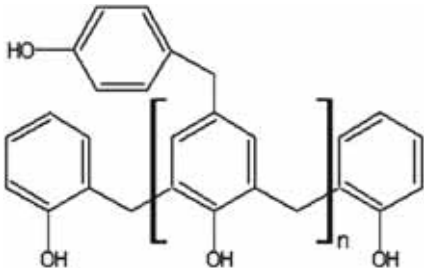

Fig. 4—Typical phenolic novolak structure.

infusible. With the advent of modern analytical tools, the chemistry of the reactions has been more fully defined by various workers. [10–12].

Raw Materials

The commercially important phenols used in coatings resins are shown in Fig. 3. While phenol is the most common, the substituted phenols are also used to vary the solubility, reactivity, and physical properties of resins. The cresols, alkylated phenols and bisphenol-A, are widely employed in various coating applications. Phenolic resins based on other phenolic monomers are used but have limited or specialty uses.

Phenol has three ring positions that are active for reaction with aldehydes; the two and six carbon atoms (ortho) and the four position (para). Phenols with substitution in the above positions have lower functionalities and are frequently used to modify resin properties.

The aldehyde co-reactant of choice for reaction with the phenols is formaldehyde, the most reactive of those commercially available. Formaldehyde is a gas but is conveniently handled as an aqueous solution (formalin), as an alcohol solution (formcel), or in a solid polymeric form known as paraform. Formaldehyde in aqueous solution exists as hydrated glycols or low-molecular-weight glycol ethers, which are easily broken down into formaldehyde under normal reaction conditions. Alternative aldehydes and other bridging agents are employed in the production of phenolic resin, but these alternatives comprise a minute minority of the commercially available phenolic resins.

Acid Catalysis

Acid-catalyzed phenol-formaldehyde reaction proceeds through an unstable addition intermediate to form condensed, methylene-linked phenolic rings (Fig. 4). Acid catalyzed phenol-formaldehyde oligomers and polymers are generally referred to as "novolaks." Novolaks are thermoplastic and require the addition of other materials to further polymerize. When phenol is used, highly branched novolaks are obtained. However, when substituted phenols are used, the functionality of the phenolic monomer is reduced to two and linear resins or cyclic calixarenes are formed [13]. Most novolak resins are produced as solids but are readily soluble in a variety of solvents.

Base Catalysis

The use of base to catalyze the reaction between phenol and formaldehyde produces initial reaction products such as the methylolated phenols, as shown in Fig. 5. Further reaction causes the methylol groups to condense with other ring positions to form a methylene link or to etherify with other alcohol groups to form dibenzyl ether links (Fig. 6). Base catalyzed phenol-formaldehyde oligomers and polymers are

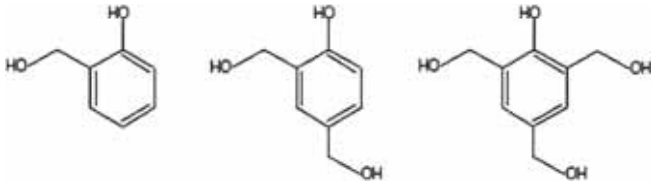

Fig. 5—Methylolated phenols.

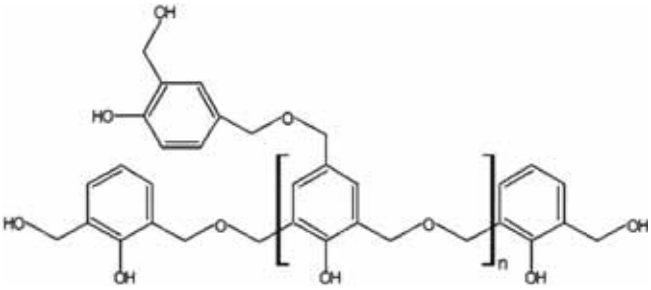

Fig. 6—Typical phenolic resole structure.

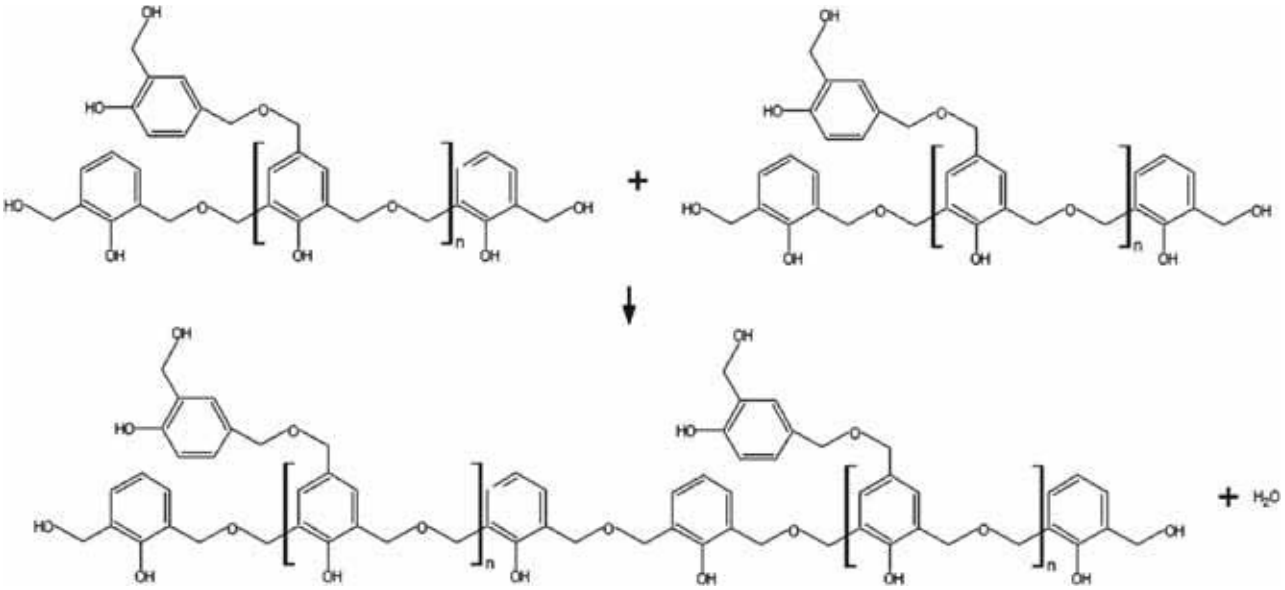

Fig. 7—Homopolymerization of phenolic resole resins.

generally referred to as "resoles." Unlike novolaks, resoles are thermosetting and will further polymerize upon heating (Fig. 7). Additional reaction raises the molecular weight of resoles. As with novolaks, phenol is poly-functional towards formaldehyde and will form highly branched polymers. These highly branched polymers will ultimately reach a highly cross-linked "gelled" state with continued exposure to heat. Phenolic resins produced with substituted phenols will have lower functionality if the reactive ortho or para-sites are blocked. Resins produced using substituted phenols will chain extend or form cyclic calixarenes upon continued exposure to heat. Resole resins are typically produced as solutions in solvents, but some are available as solids.

TESTING OF PHENOLIC RESIN PRODUCTS

Typical quality control tests for phenolic resin products may include the following:

1. Gel time [ASTM Test Method for Determining Stroke Cure Time of Thermosetting Phenol-Formaldehyde Resins (D4640-86)] (heat-reactive resins).
2. Viscosity (solution).
3. Color (Gardner).
4. Specific gravity.

Other tests to characterize resins may be used:

1. Molecular weight distribution by gel permeation chromatography.
2. Structure analysis—NMR and IR.
3. Thermal analysis—TGA, DSC, and TMA (curing curves).
4. Free residual formaldehyde by various methods.
5. Free residual phenols by gas chromatography.

Polyamides

Robert W. Kight[1]

POLYAMIDES

POLYAMIDE RESINS ARE POLYCONDENSATION products of dimerized fatty acids and polyamines. Reactive liquid polyamide resins are oligomers designed primarily for use in the manufacture of two-component epoxy/polyamide coatings and adhesives. The two-component coatings are generally labeled Part A and Part B, with the liquid polyamide resin usually (though not always) contained in Part B. The polyamide resin may function as the curing agent, core-actant, or hardener for epoxy resin. Polyamide resins should not be considered as catalysts although they may initiate the reaction; the polyamide resin reacts with the epoxy resin and becomes part of the polymer. The majority of polyamide resins used in coatings are viscous liquids that are usually supplied by the coatings manufacturer as a solution in organic solvents. The solution may be a clear amber liquid or may contain pigments in colored systems.

Current trends in the coatings industry are toward higher solids, lower volatile organic compound (VOC)-containing products. These products require lower viscosity reactants, such as liquid epoxy resins cured with amidoamines rather than polyamides. Amidoamines are condensation products of monobasic fatty acids and polyamines and are therefore lower in viscosity. These products are less compatible with epoxy resins so commercial examples are adducts of amidoamines. Adduction improves compatibility, though generally increases viscosity, so high boiling, compatible solvents, such as benzyl alcohol, are commonly used to reduce viscosity. Benzyl alcohol becomes trapped in the cured film due to its structural similarity to epoxy resins based on bisphenol A and does not migrate through the film to the surface. Many commercial high-solids curing agents are amidoamine adducts containing benzyl alcohol.

ACIDS

The dibasic fatty acids of commercial importance used to manufacture polyamide curing agents are prepared by dimerizing unsaturated C_{18} fatty acids from linseed, soya, or tall oils. Linseed and soya fatty acids are extracted from flax and soybeans, respectively. Crude tall oil is a by-product from the Kraft process for papermaking and is a mixture of fatty acids and rosin acids, from which the fatty acids are separated by distillation. The tall oil fatty acids are a mixture of C_{18} isomers with a variable number of double bonds. Some of the isomers combine via Diels–Alder addition and other mechanisms to form C_{36} dibasic acids or dimer acids. The dimer acids produced may be acyclic, monocyclic, or polycyclic in structure, depending on the location and number of double bonds in the feedstock. Many isomers are present in commercial dimer acids, most of which are difunctional carboxylic acids [1]. Examples of three possible isomer types follow: acyclic (Fig. 1), monocyclic (Fig. 2), and polycyclic (Fig. 3).

AMINES

The dimer acids are reacted with various polyamines to form polyamide resins and a variety of other useful products. The liquid polyamide resins commonly used in industry are polyethylene polyamines of various chain lengths that are linear, branched, or cyclic. The linear polyethylene polyamines are characterized as secondary amine groups separated by ethylene chains, terminated on either end by primary amine groups. Diethylenetriamine is an example of a simple linear polyethylene polyamine (Fig. 4).

The cyclic and branched polyamine isomers contain tertiary amine groups in addition to the primary and secondary amine groups. Longer chain length polyethylene polyamines available commercially, such as triethylenetetramine and tetraethylenepentamine, are mixtures of linear, branched and cyclic polyamine isomers. Aminoethylpiperazine is an example of a cycloaliphatic polyamine (Fig. 5).

The reaction between dimerized fatty acids and polyamines yield amide oligomers with amine group termination. These amide oligomers are used as coreactants with epoxy resins in high-performance coatings, as well as components of a variety of other useful commercial compositions including two-component adhesives.

EARLY HISTORY

Polyamide resins were commercialized in the late 1950s for use with epoxy resins in the manufacture of two-component adhesives and high-performance coatings. The early commercial epoxy/amine coatings contained aliphatic amines, primarily diethylenetriamine, which had several negative features, such as requiring critical mix ratios and toxicity. The introduction of liquid polyamide resins allowed the coatings manufacturer to produce high-performance coatings characterized by convenient mix ratios, such as 1:1 or 2:1, with very low toxicity.

Epoxy/polyamide coatings find utility in a wide variety of applications, such as industrial maintenance coatings, machinery and equipment enamels, and marine applications. The presence of the long fatty chains gives coatings with much better flexibility as well as better wetting and adhesion than was obtained with the earlier aliphatic amine cured systems.

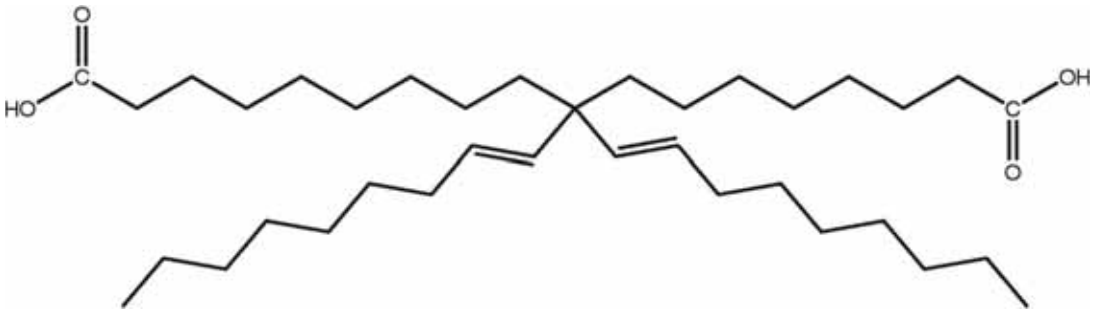

Fig. 1—Acyclic dimer acid.

SYNTHESIS OF POLYAMIDES

Polyamide resins are polycondensation products of difunctional fatty acids and polyfunctional amines. In a typical commercial example, 1 mol of dimer acid is reacted with 2 mol of diethylenetriamine. During this condensation reaction, 2 mol of water are evolved. As the reaction proceeds, an interesting side reaction occurs: An additional mole or so of water evolves from a secondary reaction. One of the primary amine groups reacts with the dimer acid to form an amide linkage, which is a nitrogen bonded carbonyl. In addition, the ethylene chain next to the amide function and the secondary amine nitrogen are incorporated into a five-membered ring, known as an imidazoline ring. This condensation reaction, which also evolves water, eliminates an active hydrogen to yield a tertiary amine group. The degree of cyclization obtained is controlled to yield a product with specific useful properties, such as improved solubility and compatibility and longer pot life. Similar reactions occur at the other carboxylic acid group of the dimer [2]. If 50 % of the diethylenetriamine present in the polyamide is cyclized to imidazoline, a total of 3 mol of water of reaction is evolved. These products are shown in the following structures: the polyamide (Fig. 6) and the imidazoline (Fig. 7).

Commercial products range from about 35 % to more than 80 % imidazoline to allow the coating formulators latitude in customizing the properties of their products.

Other properties of the polyamide resin that are important to the coatings formulator are the amine value, which is related to active hydrogen equivalent weight, and the viscosity level of the polyamide resin in organic solvents. Amine values range from about 100 to about 400, with active hydrogen equivalent weights of about 550-125, respectively. The active hydrogen equivalent weight is used to calculate the amount of polyamide resin required to react with a given amount of an epoxy resin of known epoxide equivalent weight. The ratio of these values, known as the stoichiometric mix ratio, is most often only a starting point for the formulator. By varying the mix ratio of the polyamide resin to the epoxy resin, certain properties of the cured coating are enhanced (and others are sacrificed) to obtain specific application properties.

CHEMICAL PROPERTIES

The total amine value of liquid polyamide resins is determined by potentiometric or colorimetric titration using dilute hydrochloric or perchloric acid to neutralize the amine base. Generally, 0.1*N* hydrochloric acid dissolved in an alco-

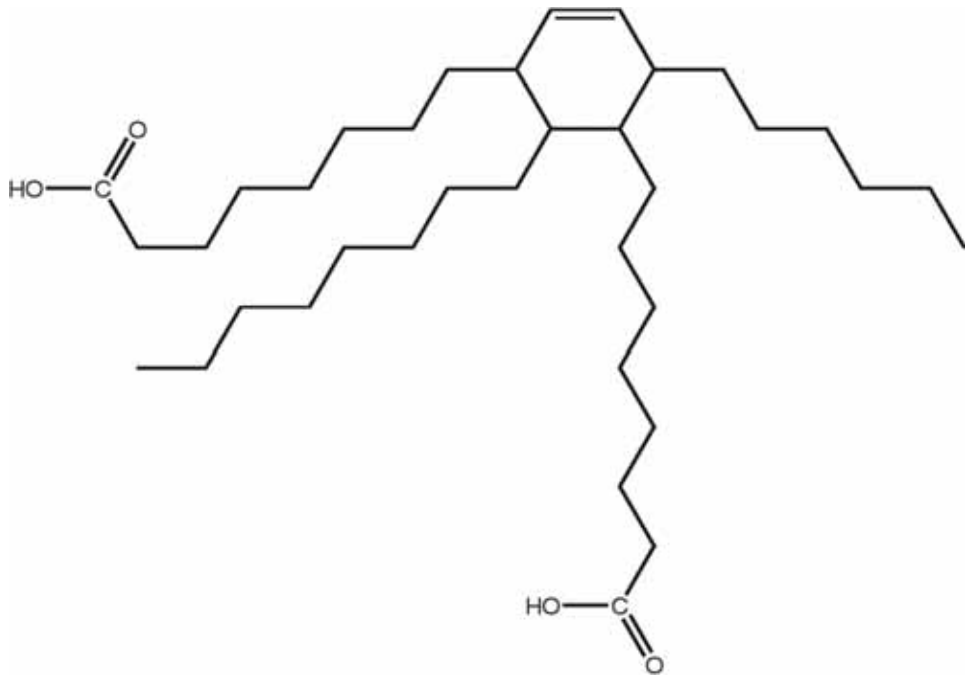

Fig. 2—Monocyclic dimer acid.

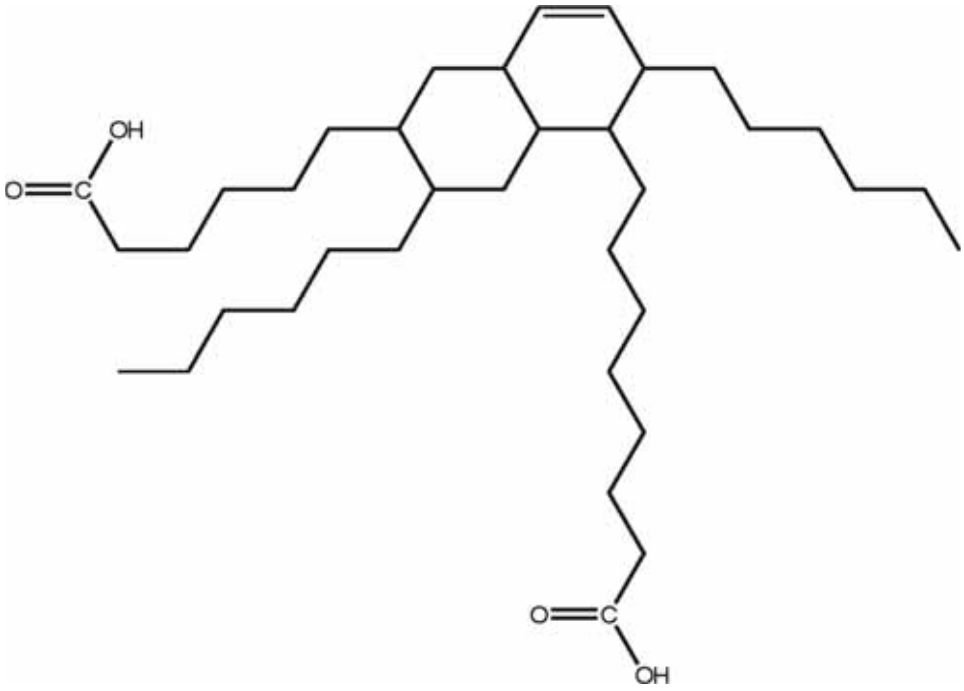

Fig. 3—Polycyclic dimer acid.

hol is used to titrate liquid polyamide resins having < 100 amine value and 0.1*N* perchloric acid dissolved in glacial acetic acid is used to titrate liquid polyamide resins having > 100 amine value. The amine value is commonly listed in the specification properties of commercial liquid polyamide resins and is defined as the number of milligrams of potassium hydroxide equivalent to the basicity in 1 g of sample.

The acid value, generally less than 5, which is also specified in commercial liquid polyamide resins, is defined as the number of milligrams of potassium hydroxide required to neutralize 1 g of sample. The acid value may be determined using ASTM Test Method for Acid Number of Naval Stores Products Including Tall Oil and Other Related Products (D465-05).

The imidazoline content is not specified in commercial liquid polyamide resins except in special cases where the level is deemed critical. The level of imidazoline is usually controlled by the polyamide resin manufacturer to provide products with specific compatibility and/or solubility. Imidazoline level can best be measured by scanning the polyamide resin with an infrared spectrophotometer and comparing the absorption at 6.25 µm to the absorption at 6.05 µm. The imidazoline ring absorbs at 6.25 µm, and the nitrogen-bonded carbonyl, or amide, absorbs at 6.05 µm. The result is reported as either a ratio of imidazoline:amide (I/A) or as a percentage. In the example reaction described previously, the imidazoline ratio would be 1.0 and the percentage would be 50 %.

PHYSICAL PROPERTIES

Polyamide resins are supplied commercially in solution or as 100 % reactive liquids depending on the handling and storage requirements of the coatings manufacturer. For ease of handling, they may be supplied in various solvents. Most liquid polyamide resins suitable for coatings applications are quite viscous, and these polyamide resins are soluble in a variety of organic solvents including alcohols, glycol ethers, ketones, and aromatic hydrocarbons. Thus the coatings manufacturer has considerable latitude in selecting specific solvents for optimum applications properties.

The percent nonvolatile content of polyamide resin solutions may be determined in accordance with ASTM Test Method for Nonvolatile Content of Resin Solutions (D1259-06). Commercial liquid polyamide resins are generally supplied in a single organic solvent at between 60 % and 80 % solids, which provides a handleable viscosity. The coatings formulator further dilutes the polyamide resin solution with more of the same solvent, or with a solvent blend, to form one component of the two-component system.

The polyamide component may be clear or may contain pigments in colored coatings formulations. The color of the liquid polyamide resin or polyamide resin solution is determined in accordance with ASTM Test Method for Color of Transparent Liquids (Gardner Color Scale) (D1544-04).

The viscosity of the liquid polyamide resin may be measured at elevated temperature in accordance with ASTM Test Method for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield type) Viscometer (D2196-05). The viscosity of commercial liquid polyamide resins is typically specified at 40 or 75°C. The

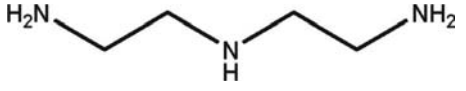

Fig. 4—Diethylenetriamine.

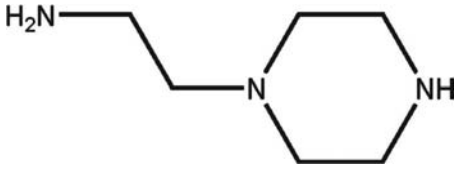

Fig. 5—Aminoethylpiperazine.

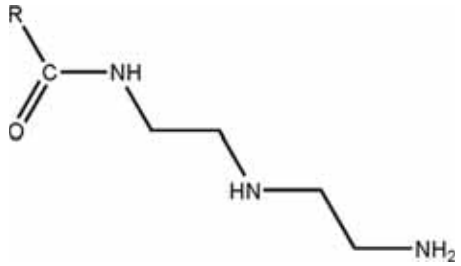

Fig. 6—Polyamide structure.

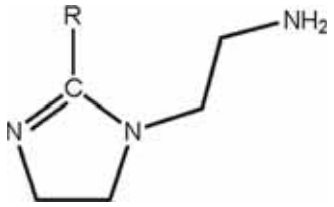

Fig. 7—Imidazoline structure.

viscosity of polyamide resin solutions that may also be measured by this method is generally specified at 25 or 40°C. The viscosity of polyamide resin solutions may also be measured in accordance with ASTM Test Method for Viscosity of Transparent Liquids by Bubble Time Method (D1545-07). A modification of ASTM D1545 is usually used in which the polyamide resin solution is placed in a sample tube, the viscosity is compared to Gardner-Holdt letter standard tubes, and the observation is reported as the alphabetic letter of the tube most closely matching the sample. A plus (+) or a minus (–) is then used to indicate that the viscosity is greater or less than the designated letter.

REACTION OF POLYAMIDE RESINS IN COATINGS

Polyamide resins react with epoxy resins in several stages to form a complex insoluble cross-linked matrix. The initial reaction is between the terminal primary amine groups of the polyamide resin and the oxirane ring of the epoxy resin. The active hydrogen opens the ring and the oligomers join end to end. This initial reaction can be represented by the following simplified structure (Fig. 8).

The reaction of the oxirane ring and active hydrogen, which also occurs at the secondary amine sites in the polyamide resin, is one mechanism for the cross-linking that occurs. A secondary reaction occurs between pendant hydroxyl groups in the epoxy resin molecule and other oxirane rings present, which is another mechanism for the cross-linking reaction [3]. Because of this later reaction, it is desirable to mix the polyamide resin and epoxy resin in less than a stoichiometric ratio to provide coatings with maximum cross-link density. Such coatings will be characterized by excellent impact and chemical resistance but will tend to be less flexible. To provide more flexible coatings with greater elongation, the use of close to or greater than the stoichiometric ratio is recommended.

Epoxy/polyamide coatings contain organic solvents, which when applied appear to dry because of solvent evaporation. This early dry time is not, however, an indication of cure. Cure results from a chemical reaction between the liquid polyamide resin and epoxy resins that generally requires about 8–10 h before the film will resist mechanical deformation. The rate can be accelerated by adding a catalyst, such as 2,4,6-tri(dimethylaminomethyl)phenol, to achieve a 4–6 h cure. Chemical resistance of the coating is not achieved before 3–4 days, and ultimate cure is achieved after about three weeks with ambient curing. Cure rates are faster at elevated temperature and become slower as application temperatures decrease. Below 50°F, liquid polyamide resins cure very slowly, or often will not react with epoxy resins.

Epoxy/polyamide coatings may be applied by any conventional commercial applicator, including spray, brush, or roller. The coatings formulator may design the solvent system for a particular type of applicator. Epoxy/polyamide coatings may be applied to wood, concrete, or steel. For optimum adhesion to the substrate, the surface to be coated should be thoroughly cleaned and degreased. Epoxy/polyamide coatings are not normally applied to wood: When so

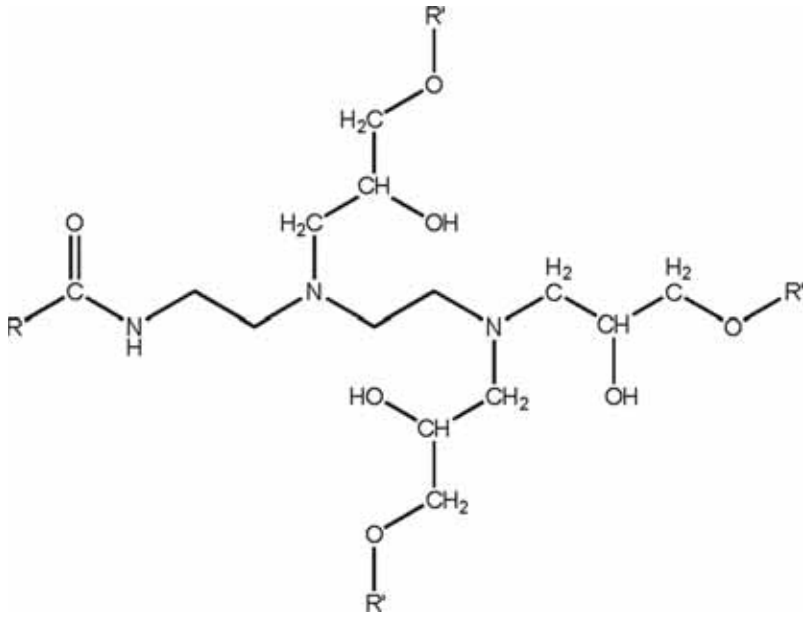

Fig. 8—Polyamide resin reaction with epoxy resin.

used, the wood surfaces should be first cleaned thoroughly and any old loosely adhering paint removed. Concrete surfaces may be chemically acid etched or mechanically brushed. Steel surfaces should be sandblasted, if possible, or at a minimum should be wire brushed and chemically cleaned [4,5].

ENVIRONMENTAL/TOXICITY CONSIDERATIONS

In response to environmental concerns over the emission of organic compounds into the atmosphere, many coatings manufacturers have begun to produce high solids coatings that contain much lower levels of VOCs. The VOC content is measured in accordance with ASTM Standard Practice for Determining VOC Content of Paints and Related Coatings (D3960-05). These products contain low molecular weight polyamide resins or polyamide adducts often dispersed in benzyl alcohol; or amidoamines, products formulated from monomer fatty acid rather than dimer acid [6]. A significant volume of higher VOC epoxy/polyamide coatings continues to be used.

Though liquid polyamide resins are less toxic than aliphatic amines and amine adducts, direct contact exposure with the skin, eyes, and the respiratory system must be avoided. Polyamide resin solutions must also be handled with care to avoid exposure to ignition sources as they contain flammable or combustible solvents and the vapor level from polyamide resin solutions must be monitored in the workplace to avoid overexposure to the organic solvents present.

Polyamide resin manufacturers supply material safety data sheets (MSDSs), which should be consulted for hazard information and guidance on the safe use of the products. The MSDS also contains information regarding procedures to follow if a spill occurs, as well as guidelines for hazardous waste disposal. Those polyamide resin solutions that are classified as hazardous waste due to the presence of organic solvents must be incinerated. Liquid (100 %) polyamide resins are not generally classified as hazardous waste though their disposal may be regulated as an oil because of their liquid nature: These products must be either incinerated or absorbed by a suitable solid absorbent medium, such as a ground clay absorbent product, and placed in a sanitary landfill.

Though liquid polyamide resins are reactive in the presence of epoxy resin, they are quite stable compounds when kept in a cool, dry environment, and they may remain unchanged for a year or more. Liquid polyamide resins may be stored in phosphatized steel drums or tanks constructed of stainless steel or aluminum. Carbon steel tanks should be avoided because of darkening of the product from iron contamination.

Polyurethane Coatings

Han X. Xiao[1] and Joseph V. Koleske[2]

INTRODUCTION

THE CHEMISTRY OF POLYISOCYANATES WAS FIRST described by Professor Otto Bayer in the laboratories of the I. G. Farbenindustry, today's Farbenfabriken Bayer, in Leverkusen, Germany. Polyurethanes are mainly characterized by the linkage –NH–C(CO)–O–, though they may also contain other functional groups such as ester, ether, urea, and amide. The most important commercial route for the synthesis of such polymers is the addition polymerization that occurs when di- or higher functionality isocyanates and di- or higher functionality hydroxyl compounds, such as hydroxyl-terminated acrylics, polyesters, or polyethers, are combined and undergo rearrangement reactions. When di-functional reactants are used, linear or thermoplastic polyurethanes are produced. Cross-linked or thermoset polyurethanes are formed if the functionality of at least one of the reactants is greater than 2. The historical and commercial developments as well as the chemistry and applications of polyurethanes have been reviewed by a number of authors [1–23]. Polyurethanes have found extensive applications in the coating industry due to the fact that they exhibit excellent abrasion resistance, toughness, chemical and corrosion resistance, as well as a wide range of useful mechanical properties.

Polyurethanes are widely used in coatings, adhesives, sealants, foams, elastomers, and RIM (reaction injection molding, composites, fibers, etc.). Excluding coatings, the 1988 United States consumption of polyurethanes was about 2,750 million pounds (1.25 million metric tons). In 1991, the national market for polyurethane coatings was about 209 million pounds (95,000 metric tons) [24, 25].[3] Although the market for polyurethane coatings is large and growing, it is readily apparent that it represents only about 5 %–10 % of the total domestic polyurethane market. The growth in this industry is exemplified by the fact that in 2002 the amount used in the United States was about 5,500 million pounds (2.51 million metric tons), and about 6,390 million pounds (2.90 metric tons) in North America. Reasons for the use of polyurethane coatings include high performance characteristics such as flexibility, toughness, strength, abrasion, chemical, and stain resistance, good light stability when aliphatic isocyanates are used, and good low temperature properties. The latter factor is an important reason for use of polyurethane coatings on plastic substrates.

DEFINITIONS

ASTM [8] in its 2003 document defines *urethane coatings* as "coatings based upon vehicles containing a minimum of 10 % by weight (nonvolatile vehicle basis) of a polyisocyanate monomer reacted in such a manner as to yield polymers containing any ratio, proportion or combination of urethane linkages, active isocyanate groups, or polyisocyanate monomer. The reaction products may contain excess isocyanate groups available for further reaction at time of application or may contain essentially no free isocyanate as supplied." ASTM has further classified such polyurethanes into six general types [8]:

> "*Type I, one-package prereacted*—urethane coatings characterized by the absence of any significant quantity of free isocyanate groups. They are usually the reaction product of a polyisocyanate and a polyhydric alcohol ester of vegetable oil acids and are hardened with the aid of metallic soap driers." The curing cross-linking reaction functions by means of an oxidation of double bonds present in the system, that is, the same reaction that takes place with drying oils. For example, linseed oil and glycerol may be first reacted and then modified with a diisocyanate that reacts with a part or all of the available hydroxyl groups. If any residual isocyanate is present, it is removed by addition of a monofunctional alcohol. Catalysts such as dibutyltin oxide and dibutyltin dilaurate are used to promote urethane-linkage formation. Type I urethane coatings are often used as wood and floor finishes because they provide improved scuff, water, and stain resistance over those of conventional alkyds.
>
> "*Type II, one-package moisture cured*—urethane coatings characterized by the presence of free isocyanate groups and capable of conversion to useful films by the reaction of these isocyanate groups with ambient moisture." The curing mechanism results in mainly urea linkages forming by water molecules reacting with free isocyanato groups. The final coating is a polyurethane/polyurea coating. The rate of cure depends on ambient humidity and the presence of certain tertiary aminecatalysts that accelerate the isocyanato-water reaction. For the most part, type II

[1] *University of Detroit Mercy, Polymer Institute, 8200 W. Outer Drive, Detroit, MI 48219.*
[2] *1513 Brentwood Road, Charleston, WV 25314-2307.*
[3] The purpose of this chapter is not to give current market information, and the data used are used for illustration purposes. The numbers change and are usually quite far behind any current date. Interested readers might consider browsing various websites, particularly national government sites, for detailed information regarding production figures.

Copyright © 2012 by ASTM International

urethane coatings are clear, but pigmented systems are becoming somewhat popular. They are often used as sealers for concrete and wood as well as floor and deck finishes.

"*Type III, one-package heat cured*—urethane coatings that dry on cure by thermal release of blocking agents and regeneration of active isocyanate groups that subsequently react with substances containing active hydrogen groups." Because of the mechanism of cure—release of blocking agents—these urethane coatings are stable at room temperature. The deblocking reaction takes place at elevated temperatures that usually are greater than 150–160°C, releasing active isocyanato groups that react with active hydrogen groups contained in the formulation. Type III coatings will also cure at lower temperatures and at short times if a catalyst is included in the formulation. The coatings are often used in coil coatings and electrical wire coatings.

"*Type IV, two-package catalyst*—urethane coatings that comprise systems wherein one package contains a prepolymer or adduct having free isocyanate groups capable of forming useful films by combining with a relatively small quantity of catalyst, accelerator, or cross-linking agent such as a monomeric polyol or polyamine contained in a second package. This type has limited pot-life after the two components are mixed." Two groups of catalysts are usually utilized with these coating systems. One group is reactive in nature and is comprised of molecules that contain hydroxyl groups such as alkanolamines. The other group are nonreactive catalysts, such as tertiary amines and metal salts of carboxylic acids. These coatings are not widely used.

"*Type V, two-package polyol*—urethane coatings that comprise systems wherein one package contains a pre-polymer or adduct or other polyisocyanate capable of forming useful films by combining with a substantial quantity of a second package containing a resin having active hydrogen groups with or without the benefit of catalyst. This type has limited pot-life after the two components are mixed." The compounds containing an active hydrogen group are usually low to medium molecular weight polyols with, for example, a polyester, polylactone, polyether, or polyacrylic backbone. These coatings, which are usually high-solids in nature, are used in high performance areas, such as automobile re-finish coatings, original automotive equipment clear coats over pigmented decorative coatings, aircraft, bus, and bus coatings, and industrial-structure maintenance coatings.

"*Type VI, one-package, nonreactive lacquer*—urethane coatings characterized by the absence of any significant quantity of free isocyanate or other functional groups. Such coatings convert to solid films primarily by solvent evaporation." Basically, these urethane coatings are solutions of high molecular weight polyurethanes (weight-average molecular weight of about 40,000–100,000) with thermoplastic properties. They are characterized by the absence of nil or essentially nil free isocyanato groups, and properties are developed by controlled solvent evaporation. In addition, they are low solids, about 10 %–15 %, in nature because of the high molecular weights involved and concomitant high viscosity of such molecules in solution. The films resulting from type VI urethane coating solutions have very high gloss and are used in the textile and furniture industries to achieve the "wet look" that was popular in the late 1970s. They are currently used in the cast transfer-process fabric coatings as well as other fabric coatings.

There are other polyurethane coatings besides these six types included in the ASTM classifications. They may be described as follows.

Two-package polyurea and poly(*urethane-urea*) *coatings*, which are composed of one package that contains amines along with fillers, pigments, and additives and a second package that contains monomeric multifunctional isocyanates and/or prepolymeric adducts of diisocyanates [26–33]. If the second package contains no pre-polymers, it will produce polyurea coatings after the two packages are blended and reaction takes place. If there are prepolymers in package 2, the resultant coatings will be poly(urethane-urea) in nature. In these systems, the isocyanates react very rapidly with amines to form urea groups, which have very good adhesion and mechanical properties. The success achieved when preparing this type of coating depends on the following alternatives:

1. The use of hindered aromatic amines to slow down the reaction that forms the urea groups.
2. The use of aliphatic isocyanate-based prepolymers or adducts followed by reacting with aromatic amines or long-chain aliphatic amines to slow down urea formation that takes place when or if aromatic isocyanates are used in prepolymer preparation.
3. The use of especially designed spray systems in which a small, powerful mixing chamber with high efficiency and very short residence time is employed.

A solvent-free, 100 % solids polyurea can be formulated by proper selection of a low viscosity, multifunctional isocyanate such as polyarylpolyisocyanate, often termed PAPI, or the adduct/trimer of hexamethylenedisocyanate (HDI). In addition, to achieve such a goal, an amine with low viscosity such as polypropylene diamines is needed.

Waterborne polyurethane coatings, which are mainly anionic and cationic in nature, though nonionic types are available [33–59]. Most commercial waterborne polyurethane coatings or waterborne polyurethane dispersions (WPUDs) are anionic in nature and a few are cationic in nature. The anionic WPUDs are made in the following manner:

1. Preparation of isocyanate-terminated and carboxyl-containing prepolymers from polyols, diisocyanates and dimethylolpropionic acid (DMPA).
2. Neutralization of the above prepolymers with an organic base such as triethylamine to form the pendant, internal hydrophilic salt groups.
3. Dispersion of the above neutralized isocyanate-terminated prepolymers with water.
4. Chain extension of the above prepolymer dispersion to introduce urea groups.

A large number of anionic WPUDs with extensive mechanical properties can be produced by changing the type of polyols, diisocyanates, neutralizing agents, and chain extenders as well as the acid group concentration from DMPA. If desired, the anionic WPUDs can be cross-linked with melamine compounds, azeridine, polyisocyanates, and blocked polyisocyanates. These could be made as one- or two-package systems.

Cationic WPUDs are prepared in a similar manner as the above with the following changes:

1. A tertiary amine-containing diol such as N-methyldiethanolamine is used to replace DMPA. This introduces a tertiary amine group into the polymer backbone.
2. Inorganic or organic acidic compounds are used to neutralize the tertiary amines and form the internal hydrophilic salt group.
3. In the chain extension step, care should be taken to avoid destroying the hydrophilic internal salt groups.

Various cationic WPUDs can be produced by changing the nature of the raw materials and the concentration of tertiary amine groups.

Nonionic WPUDs are also used. They have a preparation procedure that is similar to that of the anionic/cationic WPUDs except that an internal hydrophilic nonionic group is introduced to replace the internal ionic groups. In comparison to the anionic/cationic WPUDs, nonionic WPUDs have excellent stability in any reasonable range of *p*H values and are commercially available.

WPUDs are suitable for a variety of applications including automotive, furniture, textile, wood, leather, paper, nonwoven fabrics, and construction coatings.

Polyurethane powder coatings [33,60,61], are finely divided, powdered polyurethanes prepared from polyols, difunctional isocyanates, urethane-modified polyesters, and hydroxyl-containing polyacrylics. They are usually cured with melamines or blocked isocyanates. When polyurethanes are prepared for this industry, factors such as ability to convert the polymer to a finely divided state, the final flexibility or impact strength, glass transition temperature, and sintering characteristics are factors that need to be considered. High glass transition temperatures, which might enhance powdering characteristics, may have a deleterious effect on impact strength. In contrast, a low glass transition temperature might result in good impact strength but have a negative effect on powdering factors and cause sintering difficulties. The key to successful powder coatings, polyurethane or other, is related to the ability to balance molecular weight and its concomitant effect on melt viscosity, glass transition temperature, and a cross-linking mechanism that is stable under storage conditions and that is not affected to any significant degree until flow and leveling takes place at the curing temperature. The major end uses for polyurethane powder coatings are the major appliance markets and automotive.

Interpenetrating polymer network (*IPN*) *coatings* [62–77] are a relatively novel type of polymer alloys that consist of two or more cross-linked polymers, which in the general case of IPNs need not be polyurethanes. They are more or less intimate mixtures of two or more distinct cross-linked polymer networks held together by permanent entanglements and with only accidental covalent bonds between two networks—for example, they are polymeric "catenanes." IPNs are produced either by swelling a cross-linked polymer with monomer and cross-linking agent of a different polymer and curing these compounds in situ or by blending the linear polymers, prepolymers, or monomers in some "liquid" form—solution or bulk—together with cross-linking agents and simultaneously curing the component polymers. Combination of various chemical polymer types into IPNs results in different compositions that have controlled morphologies and synergistic behavior. Xiao and Frisch et al. [67–77] have prepared many different types of IPN coatings. Sperling et al. [64,65] have developed two-layer coating systems termed "silent paint," which is capable of attenuating noise and vibration over a broad temperature range.

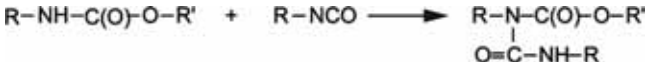
CHEMISTRY AND REACTIONS

Basic Urethane Chemistry

The high reactivity of the isocyanate, especially with nucleo-philic compounds, has always been of intriguing interest for the organic chemist. However, multifunctional isocyanates only gained technical importance through polyaddition chemistry. The reactivity of the —N=C=O group is mainly determined by the pronounced positive charge of the carbon atom in the double bond sequence that consists of nitrogen, carbon, and oxygen. The positive charge on this carbon atom becomes obvious if one considers the resonance structure as shown below [33]:

$$R-N=C=O \rightleftharpoons R=N=\overset{+}{C}-\overset{-}{C} \rightleftharpoons R-\overset{-}{N}-\overset{+}{C}=O \rightleftharpoons \overset{-}{R}=N-\overset{+}{C}=O$$

With R an aromatic radical, the negative charge can be localized into it as described. This also explains that aromatic isocyanates have higher reactivity than aliphatic isocyanates. In the aromatic isocyanates, the electron-donating substituents lower reactivity of the isocyanato (NCO) group. Therefore, the major chemical reactions of the isocyanato group are as follows.



URETHANE

Hydroxyl-containing compounds can be reacted with NCO groups to form the major and important urethane structure, which is the main structure in polyurethane products.

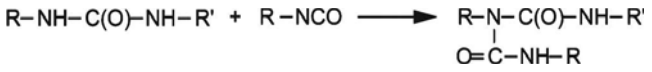
$$R'-OH + R-NCO \rightarrow R-NH-C(O)-O-R'$$

ALLOPHANATE

The urethane that has formed is capable of further reaction with an NCO group to form an allophanate linkage and this results in crosslinking as described below.

UREA

If an amine or water is reacted with an isocyanate, urea groups are formed in the following manner.



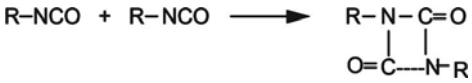
$$R'-NH_2 + R-NCO \rightarrow R-NH-C(O)-NH-R'$$

$$H_2O + R-NCO \rightarrow R-NHCOOH \rightarrow R-NH_2 + CO_2$$

$$R-NH_2 + R-NCO \rightarrow R-NH-C(O)-NH-R$$

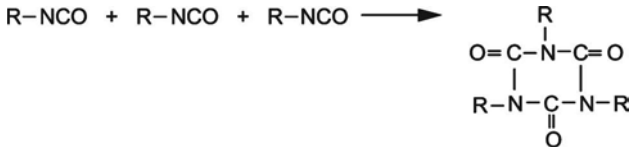
BIURET

If a urea group is reacted with an isocyanate, the biuret compound is formed.



AMIDE

When carboxylic acids react with an isocyanate, amides are formed.

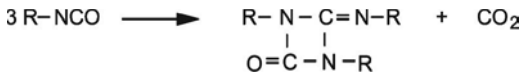


URETDIONE OR ISOCYANATE DIMER

Isocyanates can react with themselves to form isocyanate dimers or uretdione.

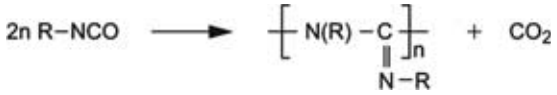
ISOCYANURATE OR ISOCYANATE TRIMER

A six-member ring structure is formed when three isocyanate groups react to form an isocyanurate or isocyanate trimer.



CARBODIIMIDE

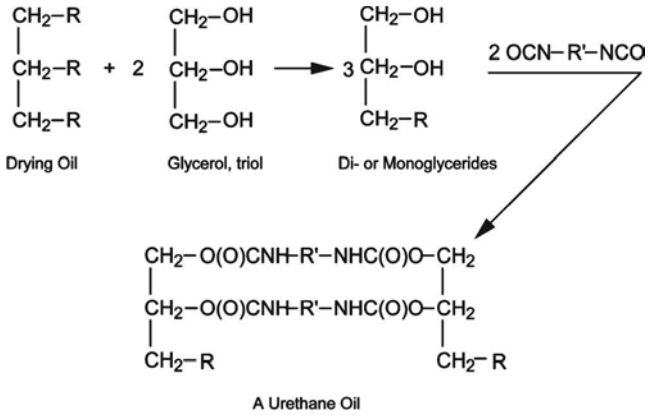
Carbodiimides are formed when two isocyanates groups react and carbon dioxide is eliminated.



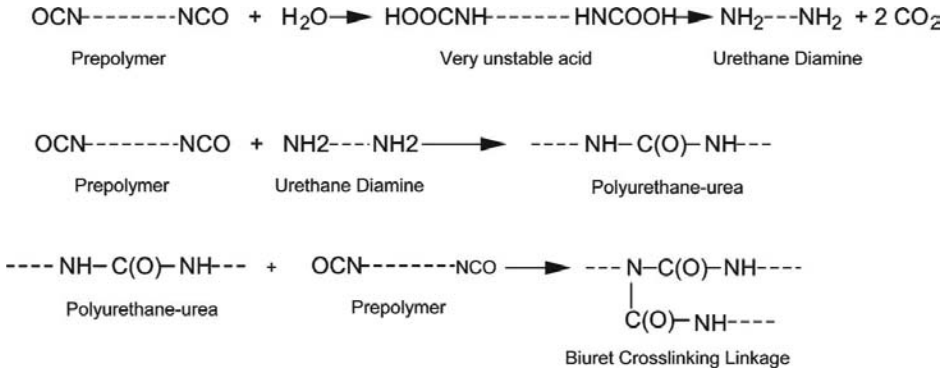
URETONE-IMIME

Three isocyanate molecules can react and form the Uretone-imime molecule.

POLYCARBODIIMIDE



Polycarbodiimide molecules can form when multiple isocyanates react with themselves.

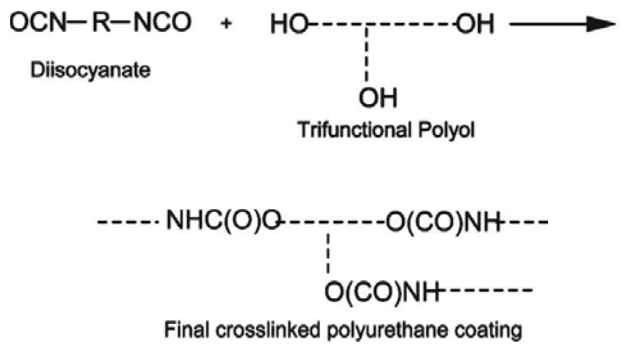


Six ASTM Conventional Type Polyurethane Coatings

The major chemical reactions that take place with the six types of polyurethane coatings that are defined by ASTM [8] are as follows.

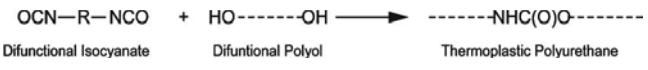
Type I polyurethanes involve a transesterification that introduces the hydroxyl group and yields the di- or monoglycerides that subsequently will be reacted with diisocyanates at NCO/OH ratios equal or greater than 1.0/1.0. This forms urethane modified drying oils—the generalized urethane oil described below wherein R is an unsaturated, aliphatic chain of drying oil and R′ is the aromatic diisocyanate.

Type II polyurethanes involve isocyanate terminated prepolymers that are reacted with moisture (water) in the presence of catalyst to form amines and carbon dioxide. The resultant amines then react with other isocyanate groups to form ureas that also can further react with isocyanate groups to form biuret linkages (crosslinks) as described in the following reactions of prepolymer.



Type III ASTM polyurethanes are prepared by blocking the isocyanate groups with a blocking agent that has an active hydrogen atom, BA-H in the following scheme, and then blending this blocked isocyanate with a polyol, fillers, pigments, and additives. The polyurethane system prepared is a stable one-package system that is cured by deblocking and freeing the isocyanato groups at elevated temperature. These freed groups then react with the hydroxyl groups and form the final polyurethane.

$$\underset{\text{Diisocyanate}}{OCN-R-NCO} + \underset{\text{Blocking Agent}}{2BA-H} \rightarrow \underset{\text{Blocked Diisocyanate}}{BA-(O)C-NH-R-NH-C(O)-BA}$$

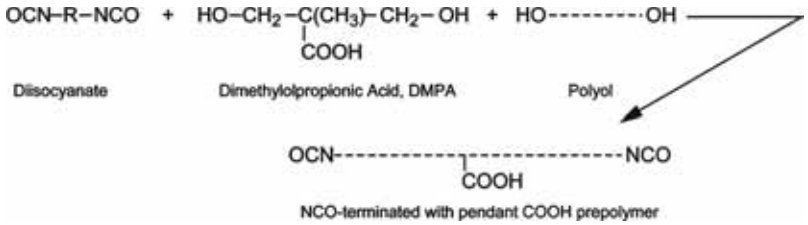


$$BA-(O)C-NH-R-NH-C(O)-BA \xrightarrow{\Delta} \underset{\text{Free NCO for reaction with polyol}}{OCN-R-NCO} + 2BA-H$$

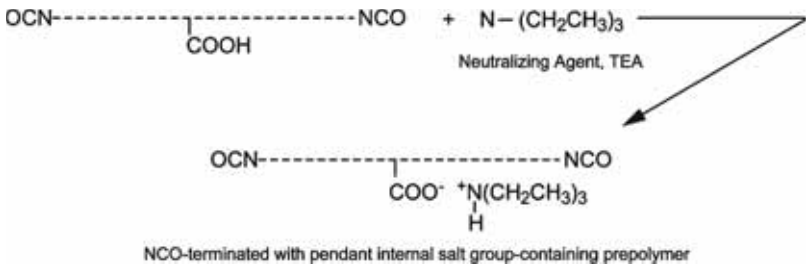
Type IV ASTM polyurethanes are produced with the same chemistry as was used for Type II polyurethanes.

Type V ASTM polyurethanes with or without multifunctionality isocyanates (greater than two) are cured with polyols or urethane/urea linkage-containing polyols with or without multifunctionality (greater than two); however, one of the components with have a functionality greater than 2. The following is one example of the urethane-formation reaction.

Type VI ASTM polyurethanes are high molecular weight, thermoplastic polyurethanes that are formed with an NCO/OH ratio at 1.0 or very close to this value. If this ratio exceeds 1.0 by any amount, there is the possibility of producing a polyurethane that will contain gel particles when dissolved.

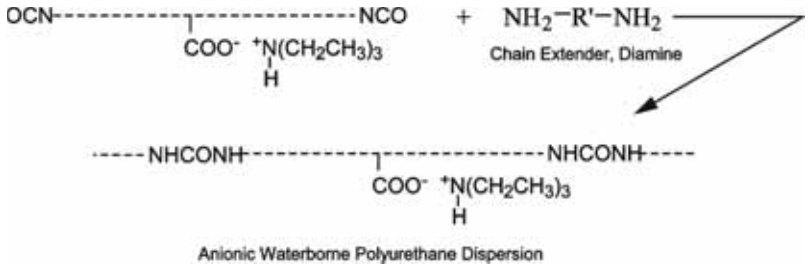


Thermoplastic polyurethanes are used in type VI lacquers as well as in many industrial end uses that require solid polyurethanes. The solid polyurethanes have a similar chemistry except that short chain diol extenders, such as 1,4-butanediol or 1,6-hexanediol, are used and these can form blocks of hard segments with the polyol portion known as the soft segment. In effect, these useful polyurethanes are block copolymers of the $(AN)_n$ type. Thus, one of the blocks is a relatively long, number-average molecular weight of 300 to 3,000, polyether or polyester that forms the soft or flexible segment. The other block is formed by the reaction of a diisocyanate and the chain extender and is termed the hard segment. Again, the overall ratio of isocyanate to hydroxyl is maintained at 1.0 to allow thermal forming. The hard segments act as pseudo cross-links and the result is a tough, strong, elastomeric macromolecule.

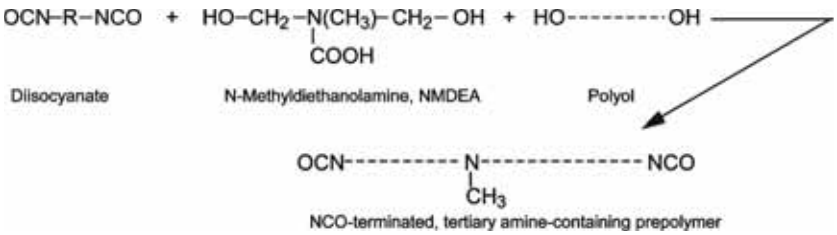


In a mole sense, these polyurethanes can be viewed as polyol/diisocyanate/short-chain extender formed in an equivalents ratio of $1/X/(X-1)$. The number X can vary from 1 or less to as much as 20 or more, though more typically in coatings, X has a value of one or less to about 3 or 4 [32,33,78]. Because of solubility characteristics, a ratio of about 1/2/1 is often used. A small excess of hydroxyl groups is used to keep final free isocyanate content and storage reactivity at a nil level. When the wide range of X values, the types of isocyanates, the types and molecular weight of polyols are considered, it is readily apparent that a myriad of polyurethanes can be prepared and that a broad range of mechanical and chemical properties can be achieved. The chemistry is basically that of isocyanates reacting with hydroxyl groups to form urethane linkages.

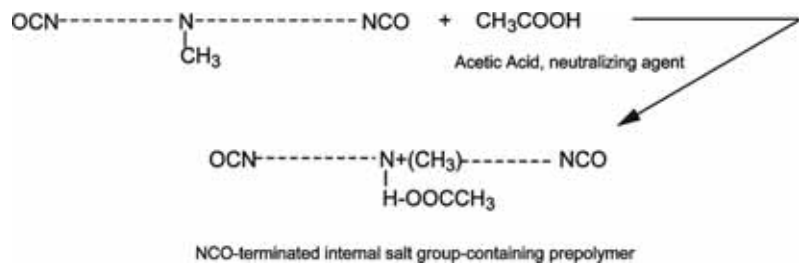
Waterborne Polyurethane Coatings

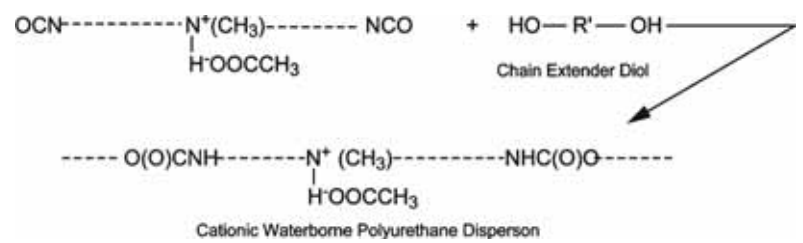


Anionic waterborne polyurethane coatings or WPUDs [34–59,78] are prepared by means of four main chemical reactions as described below. Preparation of NCO-terminated and pendant COOH-containing prepolymer:



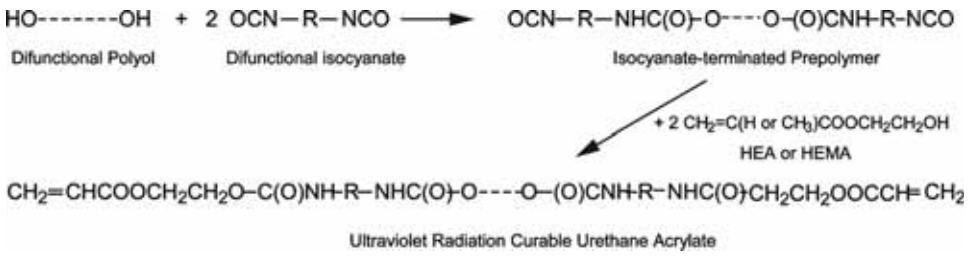
NEUTRALIZATION WITH TRIETHYLAMINE (TEA)





DISPERSION WITH WATER FOLLOWED BY CHAIN EXTENSION WITH DIAMINE

The chemistry involved in cationic WPUDs is similar to that used for anionic WPUDs except that dimethylolpropionic acid is replaced with N-methyldiethanolamine followed by neutralization with an acid such as acetic acid. The prepolymer is then dispersed in water and chain extended with a diol.



Radiation-Curable Coatings

Radiation-curable polyurethane coatings, in particular the ultraviolet radiation-curable polyurethane-acrylate coatings, are prepared by combination of urethane and acrylate chemistry [79–90]. Acrylate-terminated polyurethanes are used in a number of ultraviolet radiation and electron beam curable formulations. The products are commonly termed "urethane-acrylates" or "acrylated urethanes." They are prepared by first forming an isocyanate terminated prepolymer from a difunctional polyol, and then end-capping the prepolymer with a hydroxy acrylate such as 2-hydroxyethyl acrylate or 2-hydroxyethyl methacrylate.

Powder Coatings

Polyurethane powder coatings are usually urethane-modified polyesters and polyacrylates that cure at high temperatures [40,41]. High temperatures are required for the powdered polymer to flow and level to the extent needed for a particular end use. The key to successful powder coatings is related to a balance between molecular weight and related viscosity as well as a cross-linking mechanism that is stable under storage conditions and not effected to any significant degree until flow and leveling have taken place at the cure temperature. Another requirement is that the glass transition temperature be sufficiently high that the powder does not block during shipping and storage. The polyurethanes used as powder coating are usually of the ASTM Type III. The main end use for powdered polyurethanes is in the major appliance market—refrigerators, dryer drums, range cabinets, etc.

These reactions that lead to urethane acrylates are almost always carried out in an inert solvent. The reactions, as depicted above, have been idealized. In all commercial and laboratory preparations, there is a significant amount of reaction between the ingredients and as a result chain extension and accompanying molecular weight increases take place. This causes the final products to have a markedly higher than expected viscosity. Oligomeric compounds such as these are formulated with triacrylates such as trimethylolpropane triacrylate and various multifunctional acrylates to provide cross-linking, with monomeric acrylates, N-vinyl pyrrolidone and other low molecular weight compounds to provide viscosity reduction. In effect, 100 % solids systems that will rapidly cure when exposed to actinic radiation. In most formulations, the urethane acrylate is considered as the main ingredient that contributes to mechanical properties in the cured film. When the actinic radiation is ultraviolet in nature, a photoinitiator (for example, 2,2-diethoxyacetophenone or benzophenone in combination with an amine synergist) is added as a free-radical source. Electron beam curable formulations do not require a photo-initiator.

Acrylated polyurethanes can be prepared as water-based coatings [88]. The anionic and cationic oligomeric materials are prepared by introducing an internal salt in the backbone similar to the procedures described above for conventional waterborne polyurethane dispersions.

Radiation-cured polyurethanes are often used on plastic substrates that will tolerate only low or moderate temperatures such as clear overprint lacquers on vinyl decals, electronic circuit boards, "no wax" vinyl flooring, tile, wood flooring, packaging, and a host of other end uses. Although radiation-cured, colored, and pigmented coatings and inks are widely used in the marketplace, it should be readily appreciated that radiation penetration is more difficult than in clear coatings.

RAW MATERIALS

Isocyanates

Two types of isocyanates are used to prepare polyurethanes for coating end uses—aliphatic and aromatic [33]. Polymers prepared from either type of isocyanate have excellent chemical and physical properties. Aromatic isocyanate-based products are used in places where weathering resistance, particularly sunlight or ultraviolet radiation resistance, is not important, since these isocyanates will cause discoloration, which almost always manifests itself as yellowing. Yellowing in itself causes a loss of an aesthetic property, but its cause and result do not deleteriously affect mechanical properties. Ultraviolet radiation attacks the labile hydrogen atoms on the aromatic ring structure. When non-yellowing polyurethanes are required, it is necessary to use an aliphatic isocyanate since their structure yields excellent sunlight and ultraviolet radiation resistance. However, it should be kept in mind that aliphatic isocyanates are less reactive and more costly than aromatic isocyanates, and while these factors should be considered, aliphatic isocyanates are very widely used for both interior and exterior applications.

The two main aromatic isocyanates currently used are 4,4′-diphenylmethane diisocyanate (MDI) and toluene diisocyanate (TD), which is a mixture of 2,4- and 2,6-isomers. Moisture-cure urethanes and urethane alkyds usually employ TDI, though MDI has some use due to its low vapor pressure. The extensive use of TDI has been gradually, but markedly, reduced because of its toxicity. Xylylene diisocyanate (XDI) is a mixture of aromatic and aliphatic structures in which there are methylene groups between the aromatic

ring and the isocyanate groups. It is used to some extent, but mainly in Japan. MDI has been modified into a liquid form that has a functionality between 2.0 and 2.5, and it has been used in some coating areas [75]. Recently, Dow Chemical Co. has produced a liquid isomer of MDI that comprises a mixture of 4,4′- and 3,4′-diphenylmethane diisocyanate, and it also has been used in coatings. Crude MDI, polyarylpolyisocyanate (PAPI) that has functionalities between 2.0 and 2.7, is dark brown in color and is low in cost. PAPI in combination with poly(oxypropylene) diamines (Jeffamine™) is used for two-package, solvent-free polyurea coatings. Other aromatic diisocyanates, such as naphthalene diisocyanate, have also been used.

Aliphatic isocyanates are more costly than aromatic isocyanates, and they are used for urethane coatings that require excellent sunlight resistance with no discoloration. These coatings are used on plastics, automobile signs, and similar outdoor end-use products. The main aliphatic isocyanates are hydrogenated MDI (4,4′-dicyclohexylmethane diisocyanate, H_{12}MDI), HDI particularly in a biuret or trimer form for improved vapor pressure, tetramethylxylylene diisocyanate (TMXDI), isopropenyldimethyltoluene diisocyanate (TMI), mixtures of 2,2,4- and 2,4,4-trimethyl hexam-ethylene diisocyanate (TMHDI), 1,4-cyclohexane diisocyan-ate, and isophorone diisocyanate (3-isocyanatomethyl-3,5,5-trimethylcyclohexyl isocyanate (IPDI) [9]. The HDI trimer and adducts are major raw materials together with acrylic polyols for two-package, solvent-based polyurethane coatings used in automobile applications. The three significant isocyanates in the above listing are H_{12}MDI, IPDI, and TMXDI.

BLOCKED ISOCYANATES

ASTM Type III polyurethane coatings, including powder coatings, employ blocked isocyanates that provide room-temperature-stable, one-package systems that are activated at elevated temperatures. At such temperatures, the molecules dissociate and the blocking agent leaves freeing the isocyanate functionality that then readily reacts with available active hydrogen-containing molecules. The reaction is rapid due to its nature and to the kinetic effect of elevated temperature. Blocking groups are proton donors such as ε-caprolactam, malonic and acetoacetic esters as well as other enolizable esters, ketoximes, phenol, etc. For example, trimethylolpropane (TMP) can be reacted with a diisocyanate and then blocked by reacting the free isocyanate group with a blocking agent, BA-H, such as phenol.

ACTIVE HYDROGEN-CONTAINING COMPOUNDS

Isocyanate functionality readily reacts with active hydrogen-containing groups such as OH, NH2, NH, COOH, and SH [33]. Polyfunctional compounds such as glycols, triols, tetraols, polyester polyols, polylactone polyols, polyether polyols, acrylic polyols, and hydrocarbon polyols usually supply hydroxyl groups. Low molecular weight compounds or short-chain extenders, such as 1,4-butanediol, in combination with isocyanates, are termed "hard segments" that function as pseudo cross-links in the final polyurethane [13]. In high molecular weight polyurethanes, such as those used for ASTM Type VI products, these chain extenders represent only a few percent of the total polymer molecular weight yet play a significant role in final physical properties. Glycols and low molecular weight triols require relatively large amounts of isocyanates, usually the most costly ingredient, and impart hardness and rigidity to the coating. The long chain polyols function as "soft segments" and impart flexibility.

There are four major types of polyols—polyether, polyester, polyacrylic, and hydrocarbon. Polyether polyols are of three many types—poly(ethylene glycol), poly(oxypropylene) glycol, and poly(tetramethylene oxide) glycol with different functionalities and molecular weights. Copolymeric glycols of ethylene oxide and propylene oxide are also available and used. The polyester polyols are aliphatic (both diol and dimer acid used are aliphatic), aliphatic from ε-caprolactone via ring opening of the cycloaliphatic ring, or aromatic (either diol or dimer acids or both are aromatic). These polyols are also available with different functionalities and a variety of molecular weights. Acrylic polyols are various acrylates copolymerized with 2-hydroxyethylmethacrylate or 2-hydroxyethylacrylate. The equivalent weight based on hydroxyl functionality is dependent on the concentration of hydroxy-acrylate used, and in addition to a distribution of molecular weights, these polyols have a distribution of hydroxy-functional acrylate within the various molecules. Hydrocarbon polyols are homopolymers or copolymers of butadiene, isobutene, and isopentadiene with special initiators. Coatings based on these polyols have excellent water resistance and electrical insulation, but they have lower adhesion to polar surfaces because of their very low backbone polarity than the other classes of polyols. However, hydrocarbon-based polyols may have potential as intermediates for primers on thermoplastic polyolefins used in the automotive industries.

As would be expected, primary hydroxyl groups react much more rapidly than secondary hydroxyl groups and tertiary hydroxyl groups react slower than either other type. For example, primary hydroxyl groups reacted about 3.5 times faster with phenyl isocyanate than secondary hydroxyl groups and about 200 times faster than tertiary hydroxyl groups [11]. It was also found that n-butanol reacted five times faster with the isocyanate group in the para- or 4-position than with the isocyanate next to the methyl group in 2,4-toluene diisocyanate. This demonstrated that neighboring groups can significantly affect isocyanate reactivity.

Polyfunctional amines, which form urea linkages with isocyanates, are also used as chain extenders. Low molecular weight compounds, such as ethylenediamine, are used for this purpose when waterborne polyurethane dispersions are prepared. Amine terminated oligomers based on alky-lene oxides such as poly(oxypropylene)diamine are also available.

Catalysts

There are two main types of catalyst used to promote the urethane formation reactions. One type is tertiary amine-containing compounds and the other is metal salts or metal oxides—in particular organic metal salts. These catalysts most often are used to promote the reaction between isocyanates and active-hydrogen-containing compounds. Only small amounts, on the order of 10 to 100 parts per million, are needed to cause marked increases in reaction rate. Popular catalysts that have been used are dibutyltin dilaurate, stannous octoate, diaza(2.2.2)bicyclooctane, dibutyltin diacetate, bismuth stearate, and zirconium octoate [91].

Additives

Many additives are used in polyurethane coating formulations, and the particular ones used depend on the final

TABLE 1—Examples of polyurethane end uses	
Home Furnishing	Optical Fibers
Drum Dryers	Printed Circuit Boards
Furniture	Sheet Molding Compound
"No Wax" Flooring and Tile	TPO Bumpers
Range Cabinets	Recreational Products
Refrigerators	Baseball Bats
Wood Flooring	Golf Balls
Industrial Maintenance	Golf Clubs
Bridge	Gym Floors

Shoes	Automotive, Refinish
Vinyl Decal Overprints	Bed Liners
Wire Coatings	Golf Carts
Plastic Substrates	Motorcycles
Fascia	Railroad Cars
Electronic Parts and Equipment	Vans

applications. Some of the important additives include are anti-oxidants, UV absorbers, wetting agents, anti-sagging agents, dispersants, defoamers, thixotropic agents, adhesion promoters, flatting agents, etc. [92].

MARKETS

The various types of polyurethanes are used in a number of market areas and end uses [33]. A number of these have been mentioned above. Two features of polyurethane coatings that often have been looked on as disadvantages are cost and special handing of the potentially hazardous isocyanates that are used in manufacturing or as curing agents. However, various industry segments have been able to develop safe handling and use methods that overcome one objection. The very high performance characteristics of polyurethanes, their ability to cure at low baking temperatures, and improved total coating solids, i.e., decreased volatile-organic-compound content, that can be obtained are factors that offset cost factors. For example, polyurethanes are replacing poly(vinyl chloride) plastisols as undercoatings and sealants in the automotive and other transportation markets. The ability to use lower coating thickness at equivalent or improved performance makes the applied cost of polyurethane competitive with the vinyl plastisols [93].

The textiles represent a moderate growth area for thermoplastic polyurethane lacquers with their excellent combination of properties as the main driving force for use. These include good elasticity at low temperatures, abrasion resistance, solvent and water resistance, dry cleansability, machine washability, and an ability to be manufactured with a broad variety of tensile/elongation properties [94]. In addition, high performance can be achieved with very thin coatings that do not markedly increase fabric weight or change styling factors such as drape. To decrease volatile organic content, new low viscosity, aliphatic isocyanates [95] and polyurethane polyols [96] are being developed. Although it is not a complete listing, Table 1 is a summary of many end uses for polyurethane coatings.

Silicone Coatings[1]

D. J. Petraitis[2]

UNIQUE PROPERTIES OF SILICONES THAT MAKE THEM USEFUL AS COATINGS

SILICONE-BASED COATINGS ARE AMONG THE MOST useful materials for a wide variety of applications. Because the basic bond energies of Si–C and Si–O bonds are high, the chemical processes usually associated with aging of coated surfaces are often much slower and in many situations virtually eliminated for silicone coatings. Also, because the Si–C and Si–O bonds are not present in the natural organic world, biocompatibility and resistance to degradation via biochemical and biophysical processes are significantly reduced. In a similar manner, some silicone polymeric coatings and fluorosilicone-based coatings, in particular, have excellent solvent resistance.

Silicone coatings based on trifluoropropylmethyl polysiloxanes have resistance to swelling from such agents as gasoline, jet fuel, solvents, and various other reagents. Chemically, highly branched polymeric silicone coatings begin to approach the properties of silica surfaces as the organic pendant content is reduced. As the organic pendant groups are reduced, the $SiO_{4/2}$ content increases and the chemical resistance increases. Such polymeric coatings can provide physical scratch resistance as well as chemical resistance. Elastomeric silicone coatings, however, do not provide good resistance to strong acids and/or bases. Strong acids or bases, in particular at elevated temperatures, can cause depolymerization of the siloxane backbone, resulting in failure or, in the case of silicone elastomeric coatings, dissolution of the coating.

In a similar manner, silicone coatings are resistant to virtually all frequencies of the electromagnetic spectrum. For compliant coatings, silicones are unsurpassed in resistance to hard radiation, such as that from a Cobalt-60 source for doses in excess of 20 Mrd, as well as from the ultraviolet, visible, and infrared frequencies. When combined with their hydrophobicity, oxygen, and ozone resistance properties, silicones provide excellent weatherability characteristics, and when these properties are combined with the resistance to atomic oxygen encountered in low earth orbit conditions, silicone coatings provide protection for organic substrates in various spacecraft applications.

Coating various medical devices is another applications area that utilizes the high quality chemical and biochemical performance characteristics associated with silicone coatings. Such coatings are used to encapsulate and seal permanent implants such as heart pacemakers. They have also been used to coat temporary implants such as catheters and surgical drains. Thin elastomeric silicone coatings are used to provide soft tissue replacements by forming an envelope to encapsulate gels and/or normal saline solutions. Recent applications for biocompatible silicone coatings include drug delivery devices for both transdermal and long-term implantable, controlled-release drug delivery.

A final characteristic that makes silicone coatings useful is their inherently low or nonflammability. Typically, silicone elastomeric coatings have been rated SE-l when tested via Underwriters' Laboratories Flame Test (UL-94). This property makes silicone coatings ideal for conformal coating of various electrical circuits and devices. In the event of catastrophic thermal degradation, the silicone coatings can and do provide a SiO_2 "ash" coating that may permit the emergency operation of the electrical device on a short-term, temporary basis. Lynch et al. [1] have investigated silicone and other coatings as thermal barrier coatings. They found that the only system that met their requirements of protecting a thin steel plate during a direct flame impingement test and withstanding low temperature flexure tests was a fiberglass-polysilicone composite. Other investigators have studied the effect of silicone fabric coatings on mechanical properties when used in glass fabric/polyester composites [2] and on water absorption of such fabrics [3].

FORMS OF SILICONE COATINGS

Silicone coatings are available in various forms ranging from hard, rigid polymers, to compliant elastomeric products, to soft, almost gel-like, character materials. The rigid polymers are typically supplied in a solvent solution and are mixed with curing agents prior to application. Lead and zinc octoates are among the most common curing agents used. The cure process usually requires approximately 1 h at 250°C to attain complete cure. The cross-linking mechanism involves the condensation of silanol groups

$$\equiv SiOH + HOSi\equiv \rightarrow \equiv Si - O - Si\equiv + H_2O$$

Specific coating applications include jet engine components, furnace parts, incinerators, high-temperature appliances, and missile coatings. In addition, specific silicone polymers have been designed to mix with organic coatings and paints, providing improved performance under moderate heat environments than are realized by the organic materials alone.

By varying the R-group to Si ratio, the hardness of the final coatings can be changed. As the R:Si ratio is decreased, the cross-link density of the polymeric mass effectively increases. Similarly, variation of the R group itself can result in somewhat different flexibility and other physical properties. Properly designed and condensed resins can be formulated to provide hard, silica-like, abrasion-resistant coatings. Such coatings often involve the condensation of alkoxy groups with silanol groups as well as condensation between silanol groups alone. Technology to minimize shrinkage and maximize adhesion during the cure needs to be incorporated to prevent cracking and subsequent flaking of the coating from the substrate. Amino-functional alkoxy silanes are often incorporated into the formulation to simultaneously optimize cure rate and adhesion.

Silicone elastomeric coatings incorporate the use of polymeric siloxanes with appropriate cross-linking agents to provide compliant, flexible coatings. Among the cure mechanisms that result in elastomers are the following:

1. $\equiv SiOH + HSi\equiv \rightarrow \equiv Si–O–Si\equiv + H_2$ (Sn catalyst)
2. $\equiv SiOH + CH_3COOSi\equiv \rightarrow \equiv Si–O–Si\equiv + CH_3COOH$ (Sn catalyst and presence of water)
3. $\equiv SiOH + ROSi\equiv \rightarrow \equiv Si–O–Si\equiv + ROH$ (Sn catalyst)
4. $\equiv Si–CH=CH_2 + HSi\equiv \rightarrow \equiv SiCH_2CH_2Si\equiv$ (Platinum catalyst)
5. $\equiv SiOH + R_2NOSi\equiv \rightarrow \equiv Si–O–Si\equiv + R_2NOH$ (Sn catalyst and presence of water)

These elastomeric coatings can range from extremely tough, high-strength elastomers to soft gel-like coatings. Typically, the elastomers will have properties within the following ranges:

Durometer:	Type 00 = 10
	Type A = 70
Tensile strength:	0.34 to 13.8 MPa
Elongation:	50 % to 1500 %
Tear strength:	0.88 to 43.8 kN/m

The properties and the cure systems that are chosen for these elastomeric coatings depend, to a large extent, on the end use and the method of application. For instance, the SiOH + HSi (reaction 1) mechanism is often used to provide release coatings for backing paper used with pressure-sensitive adhesives. The actual coating itself has poor strength but attains its properties by simply impregnating the substrate and imparting its nonadhesive properties. Such coatings are repellent to tacky substances and a high level of repellency is achieved when the coating contains a considerable proportion of diorganosilicone units. Depending on particular end uses, various degrees of repellency are needed and this can be achieved by replacing methyl groups with alkenyl groups in the cross-linked coating [4]. Systems with slight adherent qualities have been developed using radiation-cure systems [5–7].

The acetoxy cure system (reaction 2) is used where one-package convenience is desired, where relatively slow cure is acceptable, and where the acetic acid given off during the cure is not a problem.

The oxime (reaction 5) cure system provides many of the properties of the acetoxy cure system, but results in an oxime-leaving group instead of an acetic acid-leaving group. Among the applications for the oxime cure systems are coatings for electronic components and protection for organic composites to prevent atomic oxygen degradation, and coating of quartz blankets to provide adequate emissivity and reflectivity characteristics for certain thermal protection surfaces on the space shuttle. The alkoxy 2-part (reaction 3) cure system, when combined with certain thermal enhancing fillers, such as iron oxide, glass microballoons, and various fibers, is often used to provide ablative and thermally insulating coatings. Various products incorporating the alkoxy two-part cure system are used to protect surfaces and components exposed to plume radiation from various rocket motors and jet engines.

The addition cure system (reaction 4) has characteristics that permit rapid heat-accelerated cure, tough physical properties, virtually nil shrinkage; and, due to the platinum catalyst, the best overall flame resistance. Applications include solar cell protection, particularly for satellites, and bum-through protection for the liners of solid rocket motors. The only negative characteristic of the addition cure system is its susceptibility to inhibition. Because the system contains parts-per-million levels of platinum catalyst, it can be readily "poisoned." Among the most common inhibitors are sulfur-containing organic rubbers and organo-tin compounds that are often used as plasticizers in plastics and also as catalysts for other silicone coatings.

There are other silicone elastomeric cure systems, and one of the most significant applications is to coat fiberglass blankets for fire resistance. Spark protection welding blankets are a common application for peroxide-cured silicone coatings. Since peroxide-cured silicones require higher temperature cures, their usefulness is constrained by the substrate upper temperature limits. Also, selectivity of the specific peroxide is critical to prevent poor cures due to the oxygen inhibition; a characteristic of many peroxides.

Another novel silicone elastomeric coating that has been developed is a combination cure involving the ultraviolet photoinitiation via free radical formation to provide cross-linking. This ultraviolet radiation mechanism is often combined with a standard cure mechanism to provide a combination cure. This system provides quick surface cure followed by a slower room temperature cure of unexposed, shadowed areas to ultimately provide a fully cured conformal coating important to the electronic applications area. Processes using the combination cure can be used to minimize the time and space required to hold the coated parts until cure is completed before downstream assemblies can take place.

Other cure systems have been developed for silicone elastomers, but they find limited use as coating materials and were generally developed for specific applications such as building sealants or glazing compounds. ASTM C1564, Standard Guide for Use of Silicone Sealants for Protective Glazing Systems, deals with the use of the sealants for building construction. Protective glazing includes applications that are subject to natural disasters, such as earthquakes, hurricanes, and windstorm, as well as forms of forced entry, such as blasts, burglary, and ballistic attack.

The most common form for silicone coatings is a dispersion of the silicone in an organic liquid. If the coating is based on a tough elastomeric silicone, the uncured elastomer base is most commonly described as a "dispersion" because it contains insoluble components such as

high surface area fumed silica for reinforcement and often other solid components such as titanium dioxide pigments for coloration or reflectivity properties. The carrier liquid for these dispersions may include chlorinated hydrocarbons, fluoro-chlorohydrocarbons, and both aromatic and aliphatic hydrocarbons. The dispersions also often include organic liquid blends to provide the proper combinations of flow, evaporation, and application ease. Among the most common liquids for silicone dispersions are 1,1,1-trichloroethane, VM&P naphthas, and xylene. Low-molecular-weight alcohols, such as ethanol and isopropanol, and ketones, such as acetone, are not suitable because silicones are generally incompatible with these lower-molecular-weight oxygen-containing solvents. Fluorosilicones require the use of such solvents as methyl ethyl ketone and methyl isobutyl ketone for adequate dispersion. Fluorosilicone-dimethyl copolymer-based silicones can be dispersed adequately in 1,1,1-trichloroethane for thin layer application.

True solutions can be made if the silicone contains no insoluble components. For example, true solutions can be made for unfilled silicones or for silicones that are polymer reinforced. These coatings have limited use, however, because the final cured elastomeric coating lacks the overall toughness of filled materials.

Recent developments have resulted in silicone coatings that have not involved the use of solvents. Because of environmental concerns, the use of solvent carriers for dispersions and solutions has become less desirable. In particular, fluorochlorocarbons and chlorinated hydrocarbons, despite their low toxicity and nonflammability, are being phased out because of international agreements. Similarly, hydrocarbon solvents are undesirable because of their flammability, toxicity, and environmental effects. Silicone-based conformal coatings have been developed without solvent carriers. However, thin layer applications are difficult unless the viscosity is low enough to permit proper coating. Unfortunately, the technology for high-strength, low-viscosity, 100 % solids silicone coatings does not exist. The current products, therefore, when cured, are very low strength and do not provide coatings that are resistant to handling. Research is ongoing to develop water-based dispersions, but to date, the demonstrated physical properties, although higher than the 100 % solids coatings, are significantly less than the solvent-based silicone coatings.

METHODS OF APPLICATION

The method used for application of silicone coatings to substrates depends on the article being coated and the specific type of silicone being used. Dipping, spraying, and brush painting are the most common types of application. The thinnest coatings result from spraying of two-solvent dispersions utilizing standard aerosol spray guns. Needless to say, experience involving aerosol spraying is critical for acceptable coatings. Among the variables to consider are viscosity, solvent, percent solids, pot life, and cure system choices.

The most securely sealed surface layer is accomplished by dip coating. Again, variables including solvent, bath life, and cure systems must be optimized. Additionally, the evaporation of solvent during the dip processing needs to be compensated for by periodically or continuously adding make-up solvent to maintain optimal dip-bath viscosity. If a one-part, humidity-actuated cure system is used for film formation, consideration must be given to provide a dry, inert blanket over the bath to prevent a partially cross-linked elastomeric skin from forming. Dry argon is often utilized to prevent moisture in the air from reacting with the silicone base coating. Another consideration for the dip coatings is the possibility of air bubble inclusion. Again, several variables need to be considered. Low viscosity, controlled immersion and withdrawal rates, and vibration of the bath and/or object to be coated can be used to minimize bubble entrapment. Similarly, two distinct liquids with different rates of evaporation are often used to ensure uniform coating with minimal drip regions and minimal bubble formation.

Painting or brush coating substrates is yet another method to apply a uniform silicone coating. Painting, however, is usually not applicable for either large areas or mass production coatings. For brush application, virtually all of the variables discussed in the above dipping and spraying also apply.

Regardless of the methods of application, the cure parameters demand significant considerations. Vacuum exposure may be used to remove air bubbles and to ensure flow under surface irregularities or impregnation of porous substrates. Vacuum treatment may also be used to enhance removal of the solvents, but care should be taken to prevent evaporation of the reactive volatile components that would prevent cure even after removal from the vacuum. Of course, most commonly, the vacuum removal of solvent is unwarranted and therefore solvent is merely evaporated at ambient pressures. The solvent evaporation can also be enhanced by air circulation and by the use of thermal energy. However, the application of heat should be limited or applied in a step-wise manner to prevent solvent entrapment below the surface resulting in bubble formation. Also, for one-part silicone coatings that are cured through moisture activation, it is ineffective to use heat acceleration because humidity is obviously reduced in a normal air circulating oven. If accelerated cure is required for one-part coatings, a steam autoclave may be used, but only after all of the carrier solvent is removed.

TESTING CONDITIONS

The test requirements for silicone coatings include MIL-I-46058C, Insulating Compound, Electrical (for Coating Printed Circuit Assemblies), for qualifying silicone coatings as insulating compounds for electrical coating applications of printed circuit board assemblies. MIL-I-46058C includes the following tests:

Curing Time and Temperature
Appearance
Coating Thickness
Fungus Resistance
Insulation Resistance
Dielectric Withstanding Voltage
Leakage Current Testing
Q Resonance
Q Resonance after Immersion
Thermal Shock
Flexibility
Thermal Humidity Aging
Flammability

Materials are used in spacecraft applications are evaluated by means of ASTM E595, Standard Test Method for

Total Mass Loss and Collected Volatile Condensable Materials from Outgassing in a Vacuum Environment. This test is used to determine the amount of collected volatile condensable material and total mass loss that leave the specimen from a material when exposed to 125°C for 24 h at a vacuum less than 7×10^{-3} Pa (5×10^{-5} torr) and condense on a collector set at 25°C. Basically, the maximum CVCM value for coatings intended for space applications is 0.1 % and the maximum TML is 1.0 %. The coatings intended for satellite applications require these high levels of purity to prevent the contamination of solar cells, optical surfaces, and other sensitive instrumentation. For most silicone materials, extended devolatilization is required for the polymeric components prior to compounding into the finished product.

For silicone elastomeric coatings, the physical properties of the cured elastomer are critical parameters. The tensile strength, elongation, and modulus are defined in ASTM D412, Standard Test Methods for Vulcanized Rubber and Thermoplastic Elastomers-Tension. Kim et al. [8] have investigated the interaction of thickness, modulus, and shear rate on adhesion forces involved in silicone coatings. Durometer and tear strength measurements are defined in ASTM D2240, Standard Test Method for Rubber Property-Durometer Hardness, and ASTM D624, Standard Test Method for Tear Strength of a Conventional Vulcanized Rubber and Thermoplastic Elastomers, respectively. The viscosity, nonvolatile content, and specific gravity tests are defined in ASTM D1084, Standard Test Methods for Viscosity of Adhesives, ASTM D2288, Standard Test Method for Weight Loss of Plasticizers on Heating, and ASTM D792, Standard Test Methods for Density and Specific Gravity (Relative Density) of Plastics by Displacement, respectively.

Other tests have been developed for silicone coatings to meet the requirements of specific applications. Included among these is the "blocking" test to determine the propensity of silicone coatings to cause "sticking" to contacted surfaces after application and cure. This test involves contact between the silicone-coated surface and the surface to be tested by subjecting the interface to an applied pressure for a fixed time followed by measurement of the force needed to separate the surfaces. A variety of tests have been developed to measure the adhesive force of the coating on the substrate. Again, a number of tests that are oriented toward the specific application have been developed and revised.

SPECIFIC APPLICATIONS FOR SILICONE COATINGS

Among the various applications for silicone coatings is the conformal coating of electronic circuit boards. Because of their previously described stability properties, silicones make ideal conformal coatings. Silicone coatings typically have stiffening points of 65°C, and can be formulated with stiffening points as low as 115°C. This makes them ideal for electronic device protection under extreme environmental conditions.

Investigators have developed a thermoformable coating comprised of a thermoplastic film containing microencapsulated silicone that can be vacuum formed onto an object as a removable protective coating for packaging electronic components or equipment [9]. During vacuum forming or melting onto, say, a printed circuit board, there is a release of the silicone from the microcapsules and a film of silicone with a protective thermoplastic top layer is formed. If desired, as in repair, the protective films may be removed by peeling. Removal is complete since the silicone will adhere more tightly to the thermoplastic film than the electronic equipment.

Recently, there have been a number of studies that deal with ship-hull and other fouling [10–14] and how silicone coatings can play a role in alleviating the problem. The studies are concerned with the release properties of silicone coatings and how these can eliminate or reduce fouling by barnacles, barnacle larvae, and other organisms or materials that cause fouling.

Silicone coatings are used almost exclusively to provide protection from atomic oxygen degradation in low earth orbit (approximately 100–500 miles high). Atomic oxygen degradation is sufficiently significant to cause rapid erosion and degrade organic substrates including epoxides, urethanes, and polyester-based thermoset coatings. Coating protection permits the use of composite materials in space applications where the advantages of high strength and low weight associated with composite materials would be unusable due to their atomic oxygen degradation.

The high-temperature stability and excellent dielectric properties of silicone polymers make them ideal impregnate coatings for high-energy capacitors used in jet engine ignitions. The inherent stability of silicone coatings when combined with specific fillers including zinc oxide, titanium dioxide, and zinc orthotitanate are often used to provide the specific emissivity and reflectance required for thermal-control coatings. Similarly, silicone elastomeric coatings that provide ablation protection are produced by the addition of iron oxide, glass or ceramic microballoons, or graphite fibers to the polymeric matrix. Launch vehicles launch equipment, and thrust reversers are often coated with specially formulated silicone ablative coatings. The incorporation of phenyl siloxanes into the basic silicone polymeric species provides increased ablative properties, and various copolymers—including silicone-boranes and silylphenylenes—have been and are being evaluated to provide protection from impingement of high-energy lasers.

As previously discussed, the biocompatibility of silicones makes them ideal for medical applications. Coating permanent implants as well as temporary implants with silicones provides improved safety and efficacy. Foley catheters coated with silicone elastomers result in less patient discomfort and reduced infection rates. For similar reasons, temporary pressure-sensitive silicone adhesive coatings are used to provide adhesion directly to the skin. Combinations of silicone coatings are being investigated for use in various drug delivery devices. Specifically layered coatings of silicones impregnated with drugs can be used for transdermal drug delivery. When combined with a silicone pressure-sensitive adhesive, a complete system of controlled drug delivery devices can be fabricated.

NEW REQUIREMENTS FOR SILICONE COATINGS

Research and development efforts continue to provide silicone coatings with even more stringent requirements and specifications. Electrical coatings with semiconducting properties for electronic applications and elastomeric coatings with volume resistivities in the 10^4–10^5 Ω cm range have been studied. Silicone coatings with variable electric properties are also being researched.

Similarly, silicone coatings that provide specific biological properties are also being developed. Specifically, hydrophilic silicone coatings are being developed for reduced

thrombogenicity, and microporous coatings are under development for controlled tissue in-growth response.

Vinyl Polymers for Coatings

Joseph V. Koleske[1]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CONTENTS of the 14th edition of this manual were drawn upon. The author acknowledges the author of the chapter in the 14th edition, Richard J. Burns. The current edition will review, alter, and update the topics as addressed by the previous author and ensure that any ASTM documents cited are current.

VINYL POLYMERS FOR COATINGS

Definition

The vinyl polymers used in solvent-based coatings, inks, and adhesives are low to- medium molecular weight copolymers of vinyl chloride, vinyl acetate, or other monomers to improve solubility. Functional monomers contribute specific properties; thus, carboxylic acid-containing monomers provide adhesion, while hydroxyl-containing monomers contribute to reactivity, compatibility with other polymeric species, or adhesion to specific surfaces. These modified vinyl chloride copolymers are most often used as thermoplastic, solvent-soluble lacquers, though by formulating with appropriate cross-linking agents and modifiers, air-dry or baking finishes can be produced having thermoset-like properties.

Special techniques have been developed that enable the use of high molecular weight vinyl chloride homopolymers as dispersions in organic media called plastisols or organosols that require a heat fusion step to form films or coatings. Vinyl chloride homopolymers and copolymers are also compounded for use as powder coatings that can be applied by either electrostatic spray or fluidized bed techniques. Water-based vinyl chloride polymers and copolymers include high-molecular-weight polymer latexes that require heat to fuse, and also aqueous dispersions of low-molecular-weight polymers that utilize coalescents to form films at room temperature.

General

Important characteristic features of vinyl polymers/coatings are: (1) relatively high glass transition temperature; (2) excellent resistance to water, alcohols, aliphatic hydrocarbons, vegetable oils, dilute acids, and alkali; and (3) inertness in contact with foods [U.S. Food and Drug Administration (FDA)-listed polymers or copolymers only]. Vinyl copolymer films can be degraded by exposure to high temperatures or by long-term exposure to ultraviolet radiation, with a resultant change in color from clear to amber, red, and, with sufficient exposure, black. Suitable thermal stabilizers are employed to permit the processing of vinyl coatings at high temperature, and proper pigmentation helps to protect vinyl coatings from attack by ultraviolet radiation. Some stabilizer systems can provide limited protection to clear vinyl chloride copolymer films.

History

Between 1912 and about 1929, Ostromislensky pioneered investigations into the polymerization and properties of vinyl polymers, and he also made other valuable contributions to the development of poly(vinyl chloride) [1–4]. Early studies with this polymer showed that it was difficult to process and is thermally unstable. These factors hindered its early commercialization, and it was the development of thermal stabilizers as well as internal (comonomeric) and external plasticizers that opened the commercial door and has led to the wide usage of vinyl chloride polymers. Reid invented the copolymers of vinyl chloride and vinyl acetate [5,6]. In 1933, Davidson and McClure described various applications for vinyl polymers and copolymers including their use as swimming pool coatings [7].

Commercial production of vinyl chloride–vinyl acetate copolymers began in 1936. Carboxyl-modified copolymers were introduced in 1939 and hydroxyl-modified copolymers in 1945. The first commercial use of these vinyl copolymers was in 1936 as a coating used as the sanitary interior lining of beer cans.

In general, the above described copolymers are of relatively low to moderate molecular weight. The viscosity requirements of spray and roll coating applications do not permit the use of very high molecular weight vinyl chloride polymers. In about 1943, organosol and plastisol coating technology that allowed use of such very high molecular weight polymers was developed [8,9].

Polymerization

Vinyl chloride monomer is a gas at standard conditions with a boiling point of –13.9°C. Polymerization is carried out in an autoclave under moderate to high pressure. The reaction is typically initiated by free radical-generating compounds such as peroxides. The polymerization is exothermic, and reaction temperature regulation is necessary to control the growth (molecular weight increases) of the polymer. The use of high pressure and low temperature generally favors the formation of very high molecular weight polymers. To control molecular weight, chain transfer agents are commonly employed. The number-average molecular weight (M_n) of commercially available solvent-soluble vinyl chloride homopolymers and copolymers ranges from a low of a few thousand to about 45,000. The M_n of vinyl chloride

[1] *1513 Brentwood Road, Charleston, WV 25314.*

polymers used for plastisol and organosol coatings ranges between about 60,000 to 110,000 [10].

Manufacture

Vinyl polymers manufactured for the coatings market are made by several processes. Polymerization by the solution and suspension processes is used to make solvent-soluble polymers, while emulsion or dispersion polymerization is used to make much higher molecular weight polymers for plastisols and organosols. Some solvent-soluble grades are also made by the emulsion process. Post-polymerization processes are applied to some copolymers to achieve special properties. The following are brief descriptions of the manufacturing processes. Detailed information is available in many books dealing with vinyl and in particular vinyl chloride-containing polymers In addition, a relatively detailed, but still concise, description of the processes including flow diagrams is available in a government publication [11].

Bulk Process

In the bulk polymerization of most monomers, the monomer acts as a solvent for the initiator and the forming polymer with the end product being a solid mass of polymer. However, in the case of vinyl chloride, polymerization takes place in solution only during the early stages. As the polymer particles grow and reach a sufficient size, they precipitate as a fine powder and polymerization continues in the solid phase of these particles. A slurry results and when the reaction is about 50 % completed, it becomes necessary to separate and remove the polymer particles from the slurry. If this is not done, an extremely rapid, dangerous reaction takes place because of poor heat transfer and autoacceleration [12].

Solution Process

Polymerization is carried out in a solvent in a batch or continuous process. The viscosity of the reaction medium increases as monomer is converted to polymer, and the extent of polymerization can be monitored and controlled by viscosity measurements. When the appropriate viscosity is attained, the autoclave polymer solution is stripped of unreacted vinyl chloride monomer, and the polymer is precipitated in a controlled manner by the addition of water, water/alcohol mixtures, or other precipitant. The slurry is next centrifuged to remove most of the liquid, and the co-polymer is dried in fluid-bed dryers. The particle size of the dried polymers produced by this process ranges from about 75 to about 200 μm. Final particle shape is irregular in nature.

Suspension Polymerization

Suspension polymerization involves the mechanical dispersion of monomer in an aqueous medium. High-molecular-weight, water-soluble colloidal polymers are used in small amounts to stabilize the droplets of suspended monomer(s) and to control particle size. The stabilizer used remains with the polymer during and after polymerization and final polymer recovery. The monomers and associated materials (initiator, stabilizer) exist as discrete, small droplets before and during polymerization and form the final polymer particles after polymerization. The initiator is soluble in the monomer mixture.

Usually, when solutions of suspension vinyl polymers are prepared, mild heating is required to achieve maximum solution clarity at minimum viscosity. Particles of suspension vinyl polymers are characterized as spherical in shape with a size between 100 and 300 μm.

Emulsion Polymerization

Like the suspension process, emulsion polymerization is also carried out in aqueous media, but in place of water-soluble polymers as stabilizers, surfactants are normally used to form and stabilize the very small monomer droplets associated with this process during polymerization. Another differentiation from the suspension process is that in the emulsion process the initiator is soluble in the media rather than in the monomer droplets. A special form of emulsion polymerization called "dispersion polymerization" uses an oil-soluble rather than water-soluble initiator and produces polymer particles that range from about 0.2 to 2 μm in size. These high molecular weight powdered products are used in plastisol and organosol coatings.

Post-Polymerization Process

Some vinyl-alcohol modified polymers are prepared in a two-step process. The first step consists of the preparation of a vinyl chloride-vinyl acetate copolymer by either a solution or suspension process. Next, the copolymer is dissolved in a suitable solvent and a reactant is added to partially hydrolyze the pendant acetoxy groups and yield a vinyl alcohol moiety.[2] The modified polymer is then precipitated from solution and dried as described for the solution process. The vinyl chloride/vinyl alcohol/vinyl acetate or vinyl chloride/vinyl alcohol copolymer thus formed has only secondary hydroxyl groups. These polar groups account for the copolymers' unique solubility/compatibility properties.

These vinyl-alcohol-containing polymers differ from those prepared directly using other hydroxyl-containing monomers in their compatibility with alkyds and in the rate of reactivity with co-reactants such as polyfunctional isocyanates or amino-formaldehyde cross-linking agents.

Applications for Vinyl Chloride-Based Copolymer Coatings

The main solvent-soluble vinyl chloride copolymers available in industry are described in Table 1. These copolymers produced by the solution polymerization process are based on vinyl chloride/vinyl acetate copolymers, and they have the following generalized compositions.

1. Vinyl chloride/vinyl acetate copolymers.
2. Carboxyl-modified vinyl chloride/vinyl acetate copolymers.
3. Hydroxyl-modified copolymers of two types:
   a. Hydroxyalkyl acrylate modified vinyl chloride/vinyl acetate copolymers via direct polymerization.
   b. Vinyl alcohol-modified copolymer derived from vinyl chloride-vinyl acetate copolymer in a post-polymerization reaction process.
4. Carboxyl/hydroxyl modified vinyl chloride/vinyl acetate copolymers
5. Sulfonate modified vinyl chloride/vinyl acetate copolymers.

[2] It is well known that vinyl alcohol does not exist as a monomer and thus its use in a direct polymerization step is not possible.

TABLE 1—Typical (i.e., not specifications) properties of vinyl chloride copolymers for coatings [13,14]. Specific Gravity of the copolymers vary from 1.34 to 1.39 [determined by ASTM D792, Standard Test Methods for Density and Specific Gravity (Relative Density) of Plastics by Displacement].

Soluble polymers similar to those described in Table 1 and prepared by either a solution or suspension process are available from various suppliers.

Food and Drug Administration Considerations

FDA regulations for various end uses list vinyl chloride copolymers by chemical identity. Designations for adhesives and coatings used on food contact surfaces are listed in Table 2. Particular copolymers are listed in these documents by chemical identity are for use on metal and paper substrates that are used as food contact surfaces of articles used in processing, manufacturing, packing, producing, heating, packaging, holding, or transporting food, or as components of closures with sealing gaskets for food containers. Vinyl chloride/acetate copolymers, hydroxyl-modified vinyl chloride-acetate copolymer, and several other vinyl chloride copolymers made with monomers having acid or ester functionality are commercially available. Regulations such as these are subject to change or expansion, so users should always search for up-to-date FDA information.

Vinyl Chloride Copolymers—Analysis

There are many references to chemical methods for identifying and characterizing vinyl chloride copolymers [15]. Infrared spectra of vinyl polymers are very useful for qualitative and quantitative purposes. Spectra of neat vinyl polymers can be found in a variety of sources such as atlases, encyclopedia of plastics, or specific papers dealing with the subject [16–18]. Also, several ASTM documents deal with the identification and characterization of vinyl polymers used in coatings materials.

ASTM D2621, Standard Test Method for Infrared Identification of Vehicle Solids From Solvent-Reducible Paints, details the qualitative characterization of separated paint vehicle solids by infrared spectroscopy. An analysis spectrum for an ortho-phthalic alkyd, vinyl chloride-acetate modified vehicle is detailed.

ASTM D2124, Standard Test Method for Analysis of Components in Poly(Vinyl Chloride) Compounds Using an Infrared Spectrophotometric Technique, presents methods through which vinyl systems can be separated into components including polymers, copolymers, plasticizers, stabilizers, and fillers. Each component can then be analyzed by infrared techniques.

A particularly useful document was ASTM D4368, Standard Guide for Testing Poly(Vinyl Chloride) Resins. Unfortunately, this standard guide was withdrawn in 2005. The ASTM website indicates that a working document

TABLE 2—United States Food and Drug Administration (FDA) regulations [14]	
FDA Regulation[a]	**Intended Use**
21CFR 175.105	In adhesives used in articles intended to be used for holding, packaging, or transporting food
21CFR 175.300(b)(3)(XV)	In polymeric coatings used as continuous films for food contact surfaces intended for use in heating, holding, manufacturing, packaging, packing, processing, producing, or transporting food.
21CFR 175.320	As coating components for coatings to be applied as a continuous film on one or both sides of a base polyolefin film that is in compliance with 21CFR 177.1520.
21CFR 176.170(b)	Component of coatings on food contact surfaces of paper and paperboard used to package aqueous and fatty foods.
21CFR 176.180	Component of coatings on food contact surfaces of paper and paperboard that will be in contact with dry food.
21CFR 177.1210	Components of coatings used on closures with sealing gaskets used for food containers.
[a] Regulations such as these are found in the Code of Federal Regulations (CFR) and users should be aware that they can be and are revised from time to time.	

exists, so there may be a replacement in the future. ASTM D4368 described methods for testing homo- and copolymer vinyl chloride-containing polymers to determine important characteristics such as total chlorine content of the composition, dilute solution viscometry to assess polymer molecular weight, and high and low shear viscosity measurements to characterize vinyl dispersion polymers that are used for plastisols and organosols.

Formulation of Solution Coatings

Typical vinyl coatings formulations consist of copolymer, solvent(s), plasticizer, pigments (required for exterior exposure), and optional ingredients such as stabilizers, modifying polymers(s), and cross-linking agent(s).

The polymer, almost always a copolymer, is normally selected on the basis of its ability to provide adhesion to the substrate. While, in most cases, strong adhesion is desired, there are special coatings such as strippable or peelable coatings where adhesion is not wanted. Table 3 contains the relative adhesion of a few vinyl copolymers to various polymers and substrates. The copolymer selection may be made on the need for reactive functionality to produce cross-linked coatings that change the nature of the coating from thermoplastic to thermoset a factor that is characterized by improved solvent and/or stain resistance in the final coating.

Solubility

Variation in the ratio of vinyl chloride to vinyl acetate, the degree of polymerization, and the modifying third monomer results in a wide variety of vinyl copolymers with different solubility characteristics. Highest solubility is favored by low vinyl chloride content and low molecular weight. This relationship in terms of copolymer solution viscosity is apparent from the viscosity data given in Table 1.

Vinyl solution-polymerized copolymers can be dissolved in ketones, esters, certain chlorinated solvents, and some nitroparaffins. As a class, ketones are the best solvents in terms of the ability to dissolve large amounts of solids with minimal solution viscosity. Hydrocarbons are chiefly used as diluents primarily to lower cost. Both aromatic and aliphatic hydrocarbons can be used as diluents. Aromatic hydrocarbons, particularly toluene and xylene as well as higher boiling fractions such as Aromatic 100 or 150, are preferred because they can be used at high levels, in the range of 50 %–65 % of the solvent blend depending on the copolymer composition, molecular weight, and desired solids. The Aromatic 100 and 150 are usually used only in baking finishes.

Aliphatic hydrocarbons can be used in limited amounts, up to about 30 % of the solvent blend. Higher levels can lead to viscosity instability, and only low boiling aliphatic hydrocarbons, those with boiling points up to 117°C, are suitable. The use of higher boiling aliphatic hydrocarbons can cause

precipitation of the copolymer during film formation and final drying. Alcohols are strong precipitants for vinyls and generally are not used in unmodified vinyl copolymer lacquers. However, in some cases vinyl copolymers, usually hydroxyl-modified versions, are readily formulated with other polymers, oligomers, or copolymers that are alcohol soluble. With these, up to 15 %–20 % alcohol may be used in the solvent blend. Careful attention must be paid in vinyl coating formulations that contain alcohols to ensure that problems do not develop during application and drying of the coatings. Glycol ethers and glycol ether esters are sometimes used in vinyl coatings to improve "flow out" of baked coatings.

In response to regulations restricting the type and amount of solvents used in coatings, such as the early forerunner regulation known as the "Los Angeles Rule 66" and later versions,[3] vinyl coatings were reformulated as compliant systems by reducing the amount of branched ketones and aromatic hydrocarbons and making up the difference with esters and aliphatic hydrocarbons [19]. Though it was necessary to use more oxygenated solvents, the performance requirements of compliant coatings remained the same. Table 4 has some typical solvent blends that had been used for spray applications and the reformulated compliant systems. These particular mixtures are for demonstration purposes to illustrate how regulations can markedly change formulations.

Solution Characteristics

From the time a vinyl polymer is dissolved, the viscosity of solutions increases with time until equilibrium is reached, after which the viscosity remains constant. This behavior is believed to be due to the formation of regions of microcrystallinity or other strong association between polymer molecules in solution. The extent of the viscosity increase is dependent on (a) polymer molecular weight, (b) solids content of the solution, and (c) the "strength"[4] of the solvent blend. The viscosity increase may be small or so large that the solution sets to a gel. Properly formulated vinyl polymer solutions usually reach an equilibrium viscosity in about 3–5 weeks. Guidelines for the preparation of viscosity-stable solutions for polymer of varying molecular weight are shown in Table 5.

Vinyl chloride copolymer solutions also exhibit what is known as the "memory effect." When a vinyl chloride copolymer solution is heated to about 60°C, the effect of microcrystallinity is eliminated. If the solution is then cooled to its original temperature, the viscosity will not immediately return to its original value because of the time lag needed for the effect of the microcrystallinity to redevelop. With time, the viscosity of the solution will return to the same value as it had before the heating process. The converse relationship holds when vinyl chloride copolymer solutions are cooled below the original storage temperature and then returned to the original condition. A graphical representation of the memory effect is given in Fig. 1.

Plasticizers

Internal plasticization of vinyl chloride polymers is achieved by copolymerization of vinyl chloride with monomers such as vinyl acetate. The comonomer reduces softening and processing temperatures and markedly improves solubility. However, such copolymerization often cannot achieve all of the desired physical flexibility and toughness characteristics required in many end uses. Plasticizers are often used with vinyl chloride copolymers to improve flexibility, formability, and impact resistance of the coating. Monomeric as well as polymeric plasticizers or compatible polymers with low glass transition temperature (T_g) may be used to plasticize a vinyl coating.

Phthalate, phosphate, and glycol ester plasticizers are typically used. Plasticizers are selected to meet the requirements of the coating that may include low-temperature flexibility, resistance to extraction by solvents, resistance to migration, to humidity, etc. Blends of plasticizers may be required to meet specific requirements. FDA regulations as well as other health considerations must be taken into account when selecting these additives.

Table 6 presents a listing of plasticizers that have been commonly used with vinyl copolymers.[5] Care must be exercised in choosing the level of plasticizer since excessive amounts tend to make the film soft and prone to dirt retention and can lead to oozing from the surface under certain conditions. Ordinarily, a level of 25 phr (parts per hundred

[3] See chapters in this manual that deal with regulations and with solvents.

[4] "Strength" in this case refers to the quality of the solvent and its ability to alter the size, configuration, and conformation of the dissolved molecules.

[5] Also see the chapter in this manual that deals with plasticizers in general.

parts polymer) plasticizer is considered about maximum for use with coating polymers.

Pigmentation

Vinyl copolymer coatings are pigmented (1) to achieve the desired colors and other aesthetic characteristics and (2) to prevent degradation of the vinyl copolymer caused by ultraviolet radiation when they are to be used outdoors [20]. Most organic and inorganic pigments can be used. However, basic pigments must be avoided with carboxyl-modified copolymers since these pigments can and probably will react with the copolymer to form irreversible gel and may alter the desired color.

Prime or color pigments that absorb ultraviolet radiation must be used at a level sufficient to protect the vinyl copolymer. Extender pigments or fillers do not absorb ultraviolet radiation and can only be used in combination with an ultraviolet-radiation adsorbing pigment, such as titanium dioxide (TiO_2). A minimum level of about 75 phr TiO_2 is required to provide resistance to ultraviolet radiation. Other inorganic pigments can be used to replace TiO_2 by substituting on an equal volume basis. Organic pigments that are manufactured with very small particle size are used at a lower concentration, and blends of inorganic

Di-2-ethylhexyl phthalate (DOP)	Di-2-ethylhexyl adipate (DOA)
Di-isooctyl phthalate (DIOP)	Di-isononyl adipate (DINA)
Di-isononyl phthalate (DINP)	Di-2-ethylhexyl azelate (DOZ)
Di-isodecyl phthalate (DIDP	
Citrates	Phosphates
Acetyl tri-n-butyl citrate	Tri-2-ethylhexyl phosphate (TOP)
	Isodecyl diphenyl phosphate
Epoxides	Polymerics
Epoxidized soybean oil (ESO)	Adipic acid polyesters
2-Ethylhexyl epoxytallate	Azelaic acid polyesters

and organic pigments are often used to achieve the desired color. Excessively high pigment concentrations can lead to early chalking.

Organosols and Plastisols

A plastisol is a dispersion of discreet particles of high molecular weight vinyl chloride homopolymer in plasticizer. The combination almost always contains a low level of thermal stabilizer in sufficient quantity to prevent degradation during the baking or fusing process. Plastisols normally require a minimum amount of about 55–60 parts plasticizer per hundred parts of polymer to form a fluid mixture. The viscosity of the dispersion is dependent on particle packing effects, the volume of dispersed polymer relative to the volume of liquid plasticizer, the size and shape of the suspended particles, solvating or swelling effect of the plasticizer on the polymer particles, and the viscosity of the liquid plasticizer. The relatively high levels of plasticizer needed to produce a flowable liquid mix results in the formation of fused films that are too soft for use as coatings.

Plastisol coatings are usually formulated from the addition of coarse particle-size poly(vinyl chloride) called extenders to the mix. These extenders are obtained from suspension or bulk (mass) polymerization and allow the use of less plasticizer and useful films with improved hardness result. Additionally, small amounts of thinner, usually aliphatic hydrocarbon are used (up to about 10 wt %) to reduce viscosity and provide better flow and leveling of the plastisol coating. Plastisol coatings do not adhere well to most substrates and most often require the use of a suitable primer before application.

An organosol differs from a plastisol in that much lower levels of plasticizer are used. Combinations of weak solvents that are termed "dispersants" in combination with hydrocarbon solvents, termed "diluents," are used to provide sufficient liquid to make a fluid dispersion. Because lower levels of plasticizer are used, films with much greater hardness can be obtained.

Commercial organosols are usually modified with a solvent-soluble polymer to prevent mud cracking or film splitting during the bake used to fuse the film. The modifier polymer at times contains carboxyl functionality to make the coating self-adherent. In other instances, it may be a hydroxyl-containing copolymer to provide functionality for reaction with cross-linking agents, such as amino or phenol/formaldehyde oligomers and thus achieve a degree of thermoset properties. Though vinyl chloride copolymers are usually the preferred modifier for organosols, other polymers, such as acrylic polymers, are used.

Careful consideration must be given to the selection of the solvent/diluent mixture for organosols, if one is to attain the highest solids coupled with good viscosity stability. Commercial organosols of 50 %–55 % non-volatiles by weight are typical.

Plastisols and organosols require a high baking temperature of about 350°F (177°C) to fuse the films. At elevated temperatures, the plasticizer or plasticizer diluent mixture exerts a strong solvating or swelling effect on the dispersed poly(vinyl chloride) particles. At fusion, the polymer no longer exists in discreet particle forms, but rather as a continuous homogeneous film. Films of plastisols or organosols need to only reach fusion temperature, and they do not need to be held at the fusion temperature for a long time period to form the final film. Undercuring or baking at temperatures lower than that required for fusion will yield films deficient in tensile strength, elongation, abrasion resistance, and other properties.

Plastisols and organosols also require the use of thermal stabilizers to protect the vinyl polymer against degradation during the fusion/bake operation. Thermal stabilizers are usually combinations of metal salts of organic acids in combination with epoxidized oils or liquid epoxy compounds. Special attention must be given to the selection of thermal stabilizers for organosols modified with solvent-soluble polymers, especially when carboxyl-modified polymers are used. In such cases, metallic salts must be avoided as these will usually cause gellation; typically, mercapto tin or tin ester compounds are used in combination with an epoxy stabilizer.

The type pigment and pigment concentration used in pigmented organosols follow the guidelines given for solution vinyl copolymers. It is, however, more difficult to prepare pigmented plastisols because there is generally little solvent used to control viscosity. Low oil absorption pigments must be used to avoid excessively high viscosity and difficult-to-work-with formulations.

Primers for Plastisols and Organosols

To develop good adhesion when used on metal substrates, plastisol coatings require a primer. An organosol coating may also require a primer if it is not modified with an adhesion-promoting modifier. Suitable primers can be formulated from carboxyl-modified vinyl copolymers and may require employing thermoset technology for best results. This is accomplished by using cross-linking agents such as amino-formaldehyde or phenolic compounds to provide resistance to excessive softening from highly plasticized plastisol or organosol coatings.

MAJOR MARKET AREAS FOR VINYL COPOLYMER COATINGS

Rigid Packaging

LINERS FOR INTERIOR SURFACE COATINGS, CANS, CAN ENDS, CLOSURE/CAPS AND CROWNS

The first commercial use for vinyl chloride copolymer coatings was as the topcoat lacquer used on the inside of beer cans. As beverage cans evolved from three- to two-piece construction, the vinyl coating also changed from lacquer to hydroxyl-functional vinyl chloride copolymers in combination with amino-formaldehyde cross-linking agents. Thermoset coatings, such as these, were needed to meet the need for greater corrosion conditions encountered. Thermoset coatings of epoxy-modified vinyl chloride copolymers with carboxyl-modified vinyl copolymers were used to coat coil stock. The coated coil stock is then formed into the stay-on-tab can ends, an application that requires excellent mechanical properties to withstand the forming steps without cracking. Organosol coatings containing a solution vinyl copolymer component, usually carboxyl-type for adhesion, have also been used on precoated stock for can ends. Vinyl organosols are further modified with amino-formaldehyde or phenolic compounds to upgrade chemical resistance and permit the use of such coatings for packaging food that will be autoclaved to sterilize the contents [21].

Vinyl lacquer and vinyl thermoset coatings are used as size coats for metals that are formed in caps and closures for jars or as crowns for beverage bottles. These systems serve as the primer coat for gasketing compounds made with plastisol or vinyl copolymer dry blends.

Flexible Packaging

Solvent-soluble carboxyl-modified vinyl chloride copolymers have good adhesion to most materials used in flexible or semi-rigid packaging including aluminum foil, paper, and plastic films, such as poly(ethylene terephthalate), polycarbonate, poly (vinyl chloride), and cellophane. This type copolymer is used for its adhesion characteristics, ease of heat sealing, and resistance to attack by the packaged product. The vinyl copolymer may be used alone or modified with plasticizers or other compounds and polymers to formulate heat-sealable coatings for applications requiring varying degrees of force needed to open the container. This could range from applications such as blister packaging where the bond needs to be strong enough to cause substrate failure when the package is opened, to items such as jellies or cream containers found in restaurants where a tight but readily peel-able bond is required.

Vinyl coatings are also used to coat collapsible metal tubes for packaging materials such as pharmaceutical preparations, toothpastes, and the like where the need is for a very flexible coating that will not crack nor be attacked by the contents of the package even though high stresses from collapsing and rolling up the tube are encountered multiple times.

Other applications include decorative coatings for aluminum foil/paper laminates used in cigarette packaging, food wrappers for fast food restaurant items, for butter, margarine, soups, and so on. Decorative foil for floral wrappings, decorative labels, and coatings for aluminum foil used on vapor barrier insulation in construction applications are also coated with vinyl copolymers.

Inks and Overprint Coatings

The major markets for vinyl copolymer-based inks are for products that have a vinyl surface such as floor and wall coverings, swimming pool liners, vinyl upholstery, and garment fabrics. The main reason for use on these substrates is related to excellent adhesion as well as the toughness, elongation, and stain resistance that are obtained with overprint lacquers—usually transparent wear layers. Other areas of importance include treated poly(ethylene terephthalate) and polyolefin films, aluminum, paper composites, and metalized substrates. Ink formulation is quite similar to that used when formulating coatings except solvent choices are somewhat narrowed and higher pigment or other colorant loadings are needed to achieve hiding in the thin films typical of inks.

Vinyl inks are often reverse printed on a clear vinyl or other polymeric film, and the printed film is then laminated to substrates such as wood or metal to make articles having simulated wood finish. Vinyl inks are also printed by the gravure or screen process because these presses are compatible with the strong solvents needed for vinyls. Flexographic printing is not suitable for vinyls because the plates are susceptible to solvent attack. Inks for highly plasticized vinyl surfaces are usually formulated with ester solvents to avoid excessive softening of calendered films and puckering of the films.

Dry Film Printing (Hot-Stamp Transfer Process)

Dry film printing involves printing vinyl inks onto a carrier film such as poly(ethylene terephthalate), polyethylene, polypropylene, or other suitable surfaces to which the ink will not strongly adhere. The inks are applied and dried usually in web form. When ready for use, the printed carrier film is placed with the inked side on the surface to be decorated. A heated die presses the composite to make intimate contact with the surface so that when the die is removed, the ink is firmly bonded to the substrate and the carrier is cleanly peeled away.

Maintenance and Marine Finishes

Heavy duty marine finishes were developed in the mid-1940s. These systems were comprised of a poly(vinyl butyral) wash primer, vinyl chloride copolymer red lead anti-corrosive intermediate coatings (based on vinyl alcohol modified copolymers, which were needed to provide adhesion to wash primer), and vinyl copolymer/wood rosin/cuprous oxide anti-foul top coats. Such systems have become the subject of numerous specifications. Many United States government agencies as well as agencies of other governments have written specifications with such a coating system specified for use below the waterline of marine vessels.

Because of their good water resistance, weathering qualities, flexibility, fast drying characteristics, ease of application, and repair, vinyl chloride-based copolymers quickly became established as maintenance finishes. This application area includes coatings for locks, dams, appurtenant structures for waterways, interior linings for potable water tanks, steel structures such as bridges, electrical towers, equipment in chemical plants, dams and locks, storage tanks, and the like. Many specifications have been written that require the use of vinyl copolymers as maintenance paints [22,23].

Air atomizing spray guns at low solids were used for application of vinyl maintenance and marine coatings in the early usage days. The low solids required several coats to attain coverage sufficient for good corrosion protection. High-build airless spray-applied vinyl coatings were developed in the 1970s to fill the need for coatings systems that could be applied in fewer coats at less expense [24].

Wood Finishes

Reactive heavy-duty vinyl finishes, coatings and sealants for wood have been developed. These consist of a hydroxyl-modified vinyl chloride copolymer cross-linked with amino/formaldehyde compounds. Alkyd copolymers were often added to improve film build. Such finishes became established as the standard for kitchen cabinets because of their retention of excellent adhesion and water resistance, particularly when the coated wood becomes wet from high humidity or water splashing. These finishes also have excellent resistance to a variety of household chemicals, solvents, and stains and have been used as fine furniture finishes [25].

Magnetic Recording Media

Vinyl chloride copolymers, especially hydroxyl-modified copolymers, have been used as binders for magnetic iron oxide tapes since the beginning of the development of tape recording. The vinyl copolymers are used because of their good adhesion, abrasion resistance, and pigment wetting properties. The early binder formulations used alkyd

copolymers as plasticizers, and later polyesters were used. The polyesters were followed by polyurethanes as the plasticizer as the technology of tapes advanced and placed more stringent requirements on the performance of magnetic tape for audio and video [26].

Powder Coatings

Vinyl powder coatings are formulated with vinyl chloride homopolymers and copolymers for application by fluidized bed, powder spray, or electrostatic powder spray. Powder coatings are prepared by dry compounding the polymers, plasticizer, pigments, and additives in ribbon blenders followed by attrition or dispersion to powder in mixers such as a Henschel mixer. Some powder coatings are prepared by a melt mix technique followed by cryogenic grinding. This latter technique produces powders of smaller particle size [27].

Powder coatings prepared by dry compounding are usually applied by fluidized bed or by spray techniques. For fluid bed powder application, the metal parts are heated so that the powder will adhere to the part, begin to coalesce, and start film formation. An oven bake after the powder application is needed to complete the film-forming process by fusion or melting.

Cryogenically ground powder coatings are applied by electrostatic powder spray. With the electrostatic method, it is not necessary to preheat the parts, but an oven bake is necessary after application to fuse the powder to a coherent film. The finer particle size allows deposition of and thinner and smoother films than is attainable from the fluidized bed process.

Poly(vinyl chloride) powder coatings are used to coat products such as metal pipe, fencing, and metal furniture.

Poly(Vinyl Chloride) Latex

Emulsion polymerized vinyl chloride homopolymers and copolymers are used in the latex form not so much to make finished coatings, but rather as substance coated onto a base or support and thereby providing the substrate for items such as wall coverings, backing for carpeting, and the like. In a sense, such use could be considered analogous to a waterborne version of an organosol coating. The vinyl chloride homopolymers need to be modified with a substantial loading of plasticizer, and some grades are sold as preplasticized latexes. These water-based materials require a high temperature bake to fuse the polymer plasticizer mix into a continuous film.

By varying the type and amount of co-monomer used to make emulsion polymerized copolymer latexes, products with a decreased glass transition temperature and lower film-forming temperature are available. These allow lower temperature bakes for film formation.

Waterborne Vinyl Dispersions

Waterborne vinyl dispersions made from solution-polymerized vinyl copolymers became available in the 1980s. These colloidal aqueous vinyl dispersions are of medium molecular weight and have high glass transition temperatures of about 80°C. Coalescents are needed with these products to form a film. Some dispersions are available with a glycol-ether coalescent already present in the product, and a co-solvent free variety is also available. With the latter, the formulator can choose whichever coalescent, glycol-ether, glycol-ether ester, plasticizer, or blend of coalescents that best meets performance requirements.

Waterborne vinyl dispersions are used in many adhesive, ink, overprint lacquer, industrial coating, and heat-sealable coating applications where solvent-based vinyl coatings had been used and still are used.

Trends in Vinyl Coatings

New and modified regulations of concern to vinyl chloride copolymers have been requiring improved volatile organic solvent content—that is, lower volatile organic content (VOC). Studies over the recent past have centered on high solids and waterborne systems. In the case of high solids formulations, reductions in copolymer molecular weight have allowed viscosity stable solution at twice and more the solids content. While higher solids can be achieved, the reductions in molecular weight have affected the performance of coatings made from such copolymers—decreases in chemical resistance and physical properties were noticed in films formed from low molecular weight lacquers.

To overcome such decreases in properties caused by lower molecular weight copolymers, the copolymers designed for high solids vinyl copolymers are modified to contain hydroxyl functionality and to allow for reaction with added co-reactant materials to build molecular weight through the thermoset process of cross-linking. Here difficulties can be encountered in trying to achieve a minimum of one functional group on each oligomeric molecule. Thus, the high solids lacquer designed copolymers can be used alone for applications that do not have very demanding requirements, but the copolymers are best used when they contain functionality for cross-linking with amino-formaldehyde or isocyanate cross-linking agents or as modifiers for alkyds, polyester-isocyanate, or epoxy-amine coatings to improve initial drying or set-to-touch rate, or to improve recoatability [27]. Modification of the vinyl copolymers to improve specific characteristics such as the copolymer containing sulfonate groups for improved pigment dispersion provides new tools for formulators [28].

The waterborne vinyl dispersions previously described represent an alternative to high solids vinyls as a way to formulate low VOC coatings. The waterborne vinyls are compatible with a wide variety of other waterborne polymers that have low VOC content, such as acrylics, alkyds, urethanes, and amino-formaldehyde cross-linking agents. Investigators are looking into the interactions that take place between poly(vinyl chloride) and poly(vinyl acetate) in various solvents [29]. The results indicate that the solvent has a marked effect on the interactions that take place in solution and these in turn have an effect on films prepared from the mixtures. There may be ramifications from these studies with homopolymers as to copolymer interactions.

Although this chapter deals with polymers and oligomers prepared from vinyl chloride, it should be pointed out that vinyl chloride (that is, the monomer) is a hazardous chemical and a known human carcinogen. Thus, precautions should be taken by anyone who comes in contact with the monomer. It is beyond the scope or intent of this chapter to deal with all of the details and ramifications of the health hazards associated with vinyl chloride monomer and readers are directed to information available from organizations such as the United States

Occupational Safety and Health Administration, from Europe's Restriction on Hazardous Substances (RoHS), from Waste Electronic and Electrical Equipment, as well as other groups. Of course, manufacturers' Material Safety Data Sheets, for both the monomer and polymers derived from it, should always be consulted when dealing with these materials. The internet contains an abundance of information about these and other organizations, vinyl chloride monomer, and polymeric species derived from vinyl chloride.

Miscellaneous Materials and Coatings

Joseph V. Koleske[1]

THIS CHAPTER IS CONCERNED WITH A VARIETY OF products that are not discussed elsewhere in the manual. Some topics are mentioned only briefly to indicate that the area has not been forgotten and that the topic is not within the scope of the manual.

POLYOLS

Polyols, or polyalcohols as they are sometimes known, are compounds containing one or more, but usually two or more, free hydroxyl groups. Most definitions, and particularly those over 10 years old, list typical polyols as compounds such as ethylene glycol, propylene glycol, neopentyl glycol, glycerol or glycerin, trimethylolpropane, pentaerythritol, and sorbitol that were used in the preparation of alkyds and polyesters. Today the word "polyols" is far more encompassing and more often than not refers to alkylene oxide [1] and ∈-caprolactone [2] adducts of the above-mentioned and other monohydric or polyhydric alcohols, low-molecular-weight polyesters prepared from the above mentioned as well as other polyhydroxyl compounds and dicarboxylic acids (particularly adipic acid) [3–5], polytetrahydrofurans prepared by a cationic ring-opening polymerization of tetrahydrofuran [6,7], and low-molecular-weight polycarbonates [8–10]. Ortho-phthalate based polyesters used in the manufacture of polyurethanes have hydrolytic stability advantages based on the aromatic ingredients in high solids and cationic photocure systems, as well as in a number of other end uses including elastomeric fibers, dentistry, artifact preservation, and pharmaceutical preparations. The two main classes of polyols used in coatings are the polyether polyols, which are typified by the poly-(propylene oxide) polyols (PPO), and the polyester polyols, which include both poly(glycol adipates)(PEA) and poly-∈-caprolactone polyols (PCP). Both classes of polyols are available as difunctional and trifunctional hydroxyl compounds though the adipates are almost always difunctional in nature. Higher functional polyols are known and available, but their usage is less common than that of the di- and trifunctional products. In the above structural formulas, R and R′ may be the same or different and –O–R–O– and –O– R′–O– are the residues of the polyhydric alcohol initiators.

Difunctional and trifunctional PPOs are usually initiated with 1,2-propylene glycol and glycerol, respectively. The adipate polyols are usually prepared with an excess of diol, so most end groups are hydroxylic rather than carboxylic in nature. Since these polyols are prepared by a condensation reaction, there is no need for an initiator. Caprolactone polyols are initiated with a variety of diols and triols such as diethylene glycol, ethylene glycol, 1,4-butanediol, trimethylol propane, glycerol, etc. The above structure for PPO indicates that the hydroxyl

$$HO—[CH(CH_3)—CH_2]_a—O—R—O—[CH_2—CH(CH_3)_b—OH$$

Poly(propylene oxide)Polyol

$$H—[O(CH_2)_4O—CO(CH_2)_4CO]_u—O(CH_2)_4O—[CO(CH_2)_4CO—O(CH_2)_4O]_v—H$$

Poly(1,4-butanediol adipate), a Polyester Polyol

$$H—[O(CH_2)_5CO]_s—O—R'—O—[CO(CH_2)_5O]_t—H$$

Poly-∈-caprolactone Polyol

substitution pattern within the polyol [11,12]. There are other compounds that meet the above definition, but they are not usually termed polyols. Compounds such as these are certain acrylic oligomers [13], vinyl chloride copolymers, hydroxyl-containing glycidyl ether compounds, vinyl alcohol copolymers, and so on. This chapter will not be concerned with these latter compounds since they are dealt with elsewhere in the manual.

Polyols are important compounds used in the manufacture of alkyds and polyurethane coatings, of intermediates used in radiation curable formulations, as copolymerizable groups are both secondary, which is the usual case. However, from time to time, a primary hydroxyl group will be found due to an unexpected opening of the propagating 1,2-epoxide. The subscripts *a*, *b*, *u*, *v*, *s*, and *t* in the above structural formulas can be the same or different, and they can take on a wide variety of values with the number average molecular weight ranging from about 150 to 3,000 for polyols usually used in coatings. Details about preparation of urethane coatings based on polycaprolactone polyols for rigid substrates [14] and flexible substrates [15] are available.

A variety of other specialty polyols also exist, such as poly(butylene oxide) and polybutadiene polyols, which are useful when very high levels of barrier hydrophobicity are needed [16]. Poly(tetramethylene oxide) polyols also have good hydrophobic character. New polyols are also being developed, including polyols based on lactose that have flame-retardant characteristics as well as polyols with different end capping, etc. [17]. Poly(phenylene ether) has been made into low-molecular-weight polyols that are effective in enhancing high temperature performance of products [18]. Hydroxyl terminated, low-molecular-weight polysulfides have been prepared by splitting a relatively high-molecular-weight polysulfide in aqueous latex form with a dithiodialkylene glycol and sodium sulfite [19]. Such polyols have been used as polysulfide-based polyurethane glass sealants. Although new polyols such as these are often designed for use in the manufacture of polyurethane foams and elastomers, they can be and are used in coating formulations.

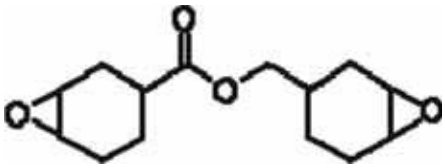
Recently, there has been a noticeable interest in highly branched and highly functional polyols that are hyperbranched or dendritic and polydisperse in nature [20–22]. Perfect dendrimers have a uniform distribution of branches and functional groups around a central core molecule and are monodisperse or substantially monodisperse in character [23]. At present, such molecules are more of academic than practical interest due to the multistep procedures required for their preparation. In contrast, hyperbranched dendritic polyols, which contain a nonuniform distribution of branches and functional groups around a central core, have a certain or definite degree of polydispersity that can have a M_w/M_n ratio of about 1.5 or more [24]. Such polyols are of commercial interest since they can be prepared by a one-step process. The polyols are most conveniently prepared from glycerol in molecular weights of about 1,000 to 35,000 g/mol. The molecules have a functional group on the end of every branch, and a molecule with a molecular weight of about 5,000 has about 68 hydroxyl end groups and a 1,500 molecular weight product will have 24 functional groups. With such high degrees of branching the compounds are amorphous in nature and soluble in a variety of organic solvents as well as with water in the case of polyglycerol. They have low solution viscosities because chain entanglements are nil, low vapor pressure, and high reactivity. The polyglycerol polyols have been further reacted by copolymerization with glycidyl ethers [25] and propylene oxide [26], esterification [27], and condensation with suitable acrylates to form radiation-curable products [28]. The hyper-branched polyols can be cross-linked with a variety of cross-linking agent and formed into useful products such as high solids, thermoset binders [29] and radiation-curable printing inks [30]. Such cured products have improved scratch and abrasion resistance, adhesion, hardness, and flexibility.

End capping polyols can provide adducts with different properties. For example, poly(propylene oxide) polyols, which contain terminal secondary hydroxyl groups, can be end-capped with ethylene oxide to provide polyols with more reactive primary hydroxyl groups [1,7]. Ways to apply nuclear magnetic resonance to measure the ethylene oxide content of these and other propylene oxide/ethylene oxide copolymers are detailed in ASTM D4875, Test Methods of Polyurethane Raw Materials: Determination of the Polymerized Ethylene Oxide Content of Polyether Polyols. Also described in the literature [1,7] are polyols modified to have amine, allyl, carboxyl, cyano, and vinyl ether end groups. Glycols that are solid and/or that have subliming characteristics, as 2,2′-dimethyl-3-hydroxypropyl 2,2′dimethyl-3-hydroxypropionate, can be modified with a few ethylene or propylene oxide groups to yield new polyols that are liquid, have low viscosity, and do not sublime with even a few molecules of ethylene oxide having nil or very little effect on moisture resistance [31]. Polyols can be end-capped with an anhydride to form adducts that have free carboxylic acid functionality or a mixture of it and hydroxyl functionality as has been done with the poly-∈-caprolactone polyols [32] or the alkylene oxide capped glycols [33]. In other instances, poly(propylene oxide) polyols have had carboxyl groups grafted to their backbone with acrylic or methacrylic acid. These grafted polyols retain their original hydroxyl end groups and are used in coating formulations [34].

Polyols can be incorporated into alkyds, made into moisture-curing urethanes, can be cross-linked with aminoplasts, and can be cross-linked with cycloaliphatic epoxides when terminated with carboxylic acid end groups. In using the polyols, the hydroxyl number [35] is their most important physical characteristic to be measured and used. Five wet chemical methods and two nuclear magnetic resonance methods for determining the hydroxyl number are given in ASTM D4274, Test Methods for Testing Polyurethane Polyol Raw Materials: Determination of Hydroxyl Numbers of Polyols and in ASTM D4273, Test Methods for Testing Polyurethane Raw Materials: Determination of Primary Hydroxyl Contents of Polyether Polyols, respectively. An infrared method can be found in ASTM D6342. Standard Practice for Polyurethane Raw Materials: Determining Hydroxyl Number of Polyols by Near Infrared (NIR) Spectroscopy. The equivalent weight or combining weight of a polyol is determined from the hydroxyl number by the following relationship

Equivalent Weight = 56 100/Hydroxyl Number

when potassium hydroxide is used as the titrating agent. Of course, if functionality is known, polyol molecular weight can be calculated by multiplying the equivalent weight by the functionality. Manufacturers provide information about hydroxyl number and usually about methods for analytically determining it.



Another important reactivity parameter is the acid number described in ASTM D4662, Test Methods for Polyurethane Raw Materials: Determination of Acid and Alkalinity Numbers of Polyols. Acidity and alkalinity in polyols can affect reactivity, shelf life, color, and hydrolytic stability of coatings prepared from polyols. Polyethers and poly-∈-caprolactone polyols usually have very low acid numbers. However, due to the nature of the condensation reaction coupled with transesterification used to produce polyester polyols, these polyols have relatively high acid numbers. The alkalinity in polyols with low alkalinity content can be determined with ASTM D6437, Test Method for Polyurethanke Raw Materials: Alkalinity in Low-Alkalinity Polyols (Determination of CPR Values of Polyols). Color, which has obvious implications, can be determined with ASTM D4890, Test Methods for Polyurethane Raw Materials: Determination of

Gardner and APHA Color of Polyols. Other factors such as ethylene oxide content, specific gravity, suspended matter, unsaturation content, and water content can be determined with various ASTM Test Methods, D4875, D4669, D4670, D4671, D4672, respectively.

CYCLOALIPHATIC EPOXIDES

Although the topic of epoxides in coatings is the subject of a separate chapter in this manual, that chapter deals with glycidyl or 1,2-epoxides that are not attached to a ring structure. Such epoxides are the largest volume products of all epoxides used, and the main products in this class are the diglycidyl ethers of bisphenol A. However, there is a special class of epoxides, termed "cycloaliphatic epoxides," that are used in specialty coatings and in cationic radiation-cure coatings. These epoxides are characterized by a saturated ring structure that imparts a high degree of weatherability and excellent electrical properties such as dielectric constant, dissipation factor, dielectric breakdown voltage, etc., to coatings and other products made from them. The good weatherability of the cycloaliphatic epoxides is apparent from the fact that they have been used for decades to make the large electrical insulators used in substations [36]. These compounds react well with carboxylic acids, as evidenced by their time-honored use as acid scavengers, and this reactivity often forms the basis for their use in coating formulations.

The main commercial cycloaliphatic epoxide is 3,4-epoxycyclohexylmethyl 3,4-epoxycyclohexane carboxylate that has the structure

Cycloaliphatic Epoxide

This epoxide is well known by the familiar name designation ERL-4221. Table 1 contains the properties of this epoxide and other cycloaliphatic epoxides that are commonly known in the industry. Epoxide equivalent weight can be determined with ASTM D1652, Test Methods for Epoxy Content of Epoxy Resins. Manufacturers can also be helpful in supplying information about methods of analysis for specific products. Usually these epoxides are reacted with polyols that function as flexibilizing agents for the highly cross-linked polymeric network that results. These epoxides polymerize by nucleophilic attack on the epoxide ring to form an ether linkage and a hydroxyl group on the ring. The hydroxyl group that is formed on the ring is quite acidic in character and will readily open other cycloaliphatic epoxide groups.

Recently, a variety of new cycloaliphatic epoxides have been prepared by a transesterification process involving methyl-3,4-epoxycyclohexanecarboxylate and a variety of hydroxyl-terminated compounds [38]. The hydroxyterminated compounds included 1,4-butanediol, 1-8-octanediol, 1,4-cyclohexanediol, and others. The new epoxides provided tougher films when cross-linked with ultraviolet radiation in the presence of cationic photoinitiators than conventional cycloaliphatic epoxides.

In the coatings industry, cycloaliphatic epoxides are used as a major formulating ingredient in cationic, photocurable formulations [39]. Usually they are formulated with polyols, onium-salt photoinitiators, and other ingredients. The onium salts photolyze in the presence of ultraviolet radiation to form strong protic acids that cause rapid polymerization of the epoxides as well as their copolymerization with active hydrogen compounds such as polyols. The presence of alkalinity including even very weak bases can result in neutralization of the protic acids formed by photolysis. Since the protic acids function as initiators, their neutralization will cause a marked decrease in polymerization rate. It may even result in nil reactivity. Coatings such as these are used as conformal coatings [40–42] in the electronics industry because of their excellent electrical (MIL-I-46058C approved, QPL Type ER) flammability (UL QMJU2 at a 2-mil thickness) and water permeability properties, as exterior can and other packaging coatings, overprint varnishes, printing inks for paper and metal, etc.

Cycloaliphatic epoxides have been reacted with the free carboxylic acid groups on anhydride adducts of polyols [43]. Such coatings are characterized by pot lives of less than 8 h, high solids, and low-temperature curing capabilities with very high gloss and depth of image, high hardness, excellent solvent resistance, adhesion, and toughness. In other instances, the epoxides have been reacted with polyols in the presence of triflic acid salts (as diethylammonium triflate, 3M Co.). In this case, shelf lives of more than 8 months have been obtained and the formulated systems have high solids coupled with low viscosity and low temperature-cure characteristics. Cured coatings have an excellent balance of properties similar to those described above.

TABLE 1—Commercial cycloaliphatic epoxides and their physical properties [36,37]

Chemical Name	Viscosity, cP at 25°C	Specific Gravity 25/25°C	Color, 1993 Gardner (max)	Epoxide Equivalent Weight	Boiling Point, °C (mm Hg)	Vapor Pressure at 20°C, mm Hg	Solidification or Glass Point°C

TABLE 2—A partial listing of polymeric films available for coating or other uses [46].

Type Polymer	Available As	
	Conventional Film	Shrink Film
Cellophane	Yes	No
Cellulose acetate	Yes	No
Cellulose acetate-butyrate	Yes	No
Cellulose triacetate	Yes	No
Ethylene/vinyl acetate copolymer	Yes	No
Fluorocarbon	Yes	No
Ionomer	Yes	No
Nylon	Yes	Yes
Polycarbonate	Yes	No
Polyester	Yes	Yes
Polyethylene	Yes	Yes
Polyethylene linear low density	Yes	No
Polypropylene, nonoriented	Yes	No
Polypropylene, oriented	Yes	Yes
Polyurethane	Yes	No
Poly(vinyl alcohol)	Yes	No
Poly(vinyl chloride)	Yes	Yes
Polyvinylidine chloride	Yes	Yes

With the use of cycloaliphatic epoxides in radiation-curable coatings gaining importance, new tests to monitor the photocuring process involving these materials are being developed. In one instance, optical pyrometry is being used as a rapid, reproducible, and inexpensive way to continuously monitor such polymerizations [44]. In another case, in-situ dielectric analysis and real-time Forrier transform infrared spectroscopy are being used to monitor the cure of such systems [45]. In either of these cases, the techniques work equally well for the free-radical cure of acrylate systems initiated with radiation.

COATING FILMS

Films of many different polymers are available in different forms for use as functional and decorative coatings, adhesive backings, and other uses. Some of these materials [46,47] are listed in Table 2. A directory of film manufacturers that lists the manufacturer product name or number and a short description of the product is available [48]. Full description of these films and their uses is beyond the intent and scope of this manual.

METALLIC COATINGS [47,49,50]

Metallic films are used in a variety of ways. Some metallic coatings are described elsewhere in this manual. The previously described coatings are formulations wherein powdered or flaked metals [51] are combined with a binder. However, solid metallic films are used as coatings in other ways familiar to us. Such films are both functional and decorative in nature, and they form a layer that changes the surface properties of the substrate to those of the metal being applied. The coated product becomes a new material that has a corrosion-resistant outer layer provided by the metal while the load-bearing characteristics are provided by the core material. A variety of metals are used and these include aluminum, cadmium, chromium, copper, gold, nickel, silver, and zinc.

Metals can be applied to plastics and glass by a variety of processes including the physical vapor deposition processes known as vacuum metallizing by thermal evaporation, cathode sputtering, and ion plating of aluminum, copper, chromium, gold, silver, and silicon monoxide [52]. Many special effects can be produced including multilayers for cost and protection, iridescent effects by using compounds with high (CeO_2, ZnS) and low (MgF_2, SiO) refractive index, dyeing—particularly of aluminum to achieve a gold color and other colors—and glass coatings on plastic optical parts. Coatings formed by such vacuum deposition processes are most often applied to plastic substrates with end uses for the coated parts including automotive parts; plastic and paper webs for decorative and functional packaging of cosmetics, drugs, clothing, foods, etc.; household fixtures; data storage systems; optical components; semiconductor devices; and glass for automotive and architectural applications. As indicated above, the packaging industry has a very large use for thin metallic films on paper and plastic substrates.

A plasma technique [53] known as unbalanced magnetron sputtering (UBM) has advantages over conventional balanced magnetron sputtering, which is usually used to metallize silicon wafers and architectural glass. In such techniques, an argon plasma is used to remove atoms from a negatively charged target, and magnets are then placed at the outer edges of the target, which is made the cathode. Each of the magnets produces a field of the same strength, and because of this the system is termed "balanced." This conventional system works well when the substrate is silicon and the coating is thin. However, in certain end uses, thick, dense coatings with excellent adhesion are required, and it is herein that UBM has significant advantages for applying coatings of hard, wear-resistant alloys, such as TiN, NbN, TiC, CrN, TiNbN, and the like, to metal-cutting saw blades and other tools, cams, and gears.

Metallic and ceramic coatings are also applied to metals by a thermal spray technique in which a metallic or ceramic wire, rod, or powder is melted and driven through air or a vacuum at high velocities [54,55]. The molten material, which can range from soft, abradable nickel-graphite to hard ceramic zirconia, is deposited on a surface of base metal to which it bonds through chemical and mechanical processes. Thermally sprayed coatings are used as abrasion, corrosion, and heat barriers for expensive machined components, castings, and other parts used in hostile chemical, mechanical, and thermal environments encountered in automotive, spacecraft (including aerospace and

aircraft), and industrial applications. The special protection provided by these coatings is needed to improve reliability and durability.

Other metal deposition processes for protective, cost savings and/or decorative coating metal, glass, and plastics include electrodeposition by electroplating (Cu, Ni, Cr) and electroless plating (Ni, Cu), galvanizing (Zn), and pack cementation (Al). Electroplating is carried out by passing an electrical current through a solution of the dissolved metal that is to be plated. In this process, the object to be plated functions as the cathode of an electrochemical cell. It attracts metal ions from the solution, and they are deposited as a metallic film on the substrate. Process control is achieved by controlling factors such as additives, amperage, applied voltage, bath solution purity, residence time, and temperature. Additives, often trade secrets, can play an important role in development of smooth, adherent films. Cleaning and rinsing are important process steps. The metals that can be plated include Al, Cd, Cu, Ch, Fe, Ph, Ni, Sn, and Zn. The index in the Annual Book of ASTM Standards (Section 0.0) lists in the neighborhood of 100 standards that deal with electrodeposition. Those that deal with specifications for particular metal deposition are listed in Table 3.

Electroless plating involves similar steps as electroplating except there is no use of an external or applied electrical current. Nickel is the primary metal deposited by this process. Basically, it is a chemical reduction process in which dissolved nickel ions are chemically reduced by means of a chemical reducing agent present in the plating bath. Since the driving force for deposition is constant within the bath when agitation is proper, the metal deposits are very uniform in nature even over complex-shaped objects such as screws, internal areas such as holes, and the like.

Hot dip galvanizing is the process in which an iron or mild steel product is zinc coated by dipping it into a molten zinc bath. It is widely used in the automotive and transportation industry where it imparts corrosion protection to the coated parts. The zinc coating acts as a sacrificial material and thereby provides cathodic protection to the ferrous, strength-providing substrate. Various ASTM standards for galvanizing technology are listed in Table 4.

Pack cementation in which diffusion coatings are formed by simultaneously depositing aluminum, chromium, or silicone and heat-treating the metal to be coated. Shaped ferrous substrates are packed into the appropriate metal powder and heated. The process takes place in a furnace over a programmed time and temperature period during which there is migration of the aluminum (or other metallizing element) and the substrate metal atoms as they diffuse into each other. As a result, oxidation resistance is given to ferrous alloys. In the aluminizing process, a chemical activator is used to facilitate the diffusion process. ASTM documents dealing with aluminum and chromium diffusion coatings applied by this process are ASTM B875, Standard Specification for Aluminum Diffusion Coating Applied by Pack Cementation Process, and ASTM B874, Standard Specification for Chromium Diffusion Coating Applied by Pack Cementation Process.

The Association of Industrial Metallizers, Coaters and Laminators, AIMCAL, is a global, nonprofit, trade association that represents converters of metallized, laminated, and coated flexible substrates as well as their suppliers (www.aimcal.org). They provide a Source Book that is a useful guide for those in the metallized products area. It provides information about the capabilities of the

SPECIALTY ORGANIC COATINGS

Polysulfides

Polysulfide coatings [56] have excellent barrier properties due to low permeability, good abrasion, chemical, and weather resistance, good adhesion, low shrinkage, and low-temperature flexibility coupled with good stress relaxation characteristics. These coatings are based on polysulfide polymers prepared

$$HS—(C_2H_4O—CH_2OC_2H_3—S—S)_xC_2H_4OCH_2OC_2H_4SH$$

from bis(2-ethyl)formal, 1,2,3-trichloropropane and sodium polysulfide. The polymers are available in a molecular weight range of 1,000–8,000. The thiol or mercaptan end groups of this polymer provide sites for curing in an oxidative manner with manganese dioxide, dicumene hydroperoxide and organic peroxides in general, *p*-quinonedioxime, by reaction with glycidyl epoxides in the presence of tertiary amines, or by reaction with multifunctional isocyanates. The polymers are used as rubbery coatings and sealants in buildings and civil engineering projects requiring excellent ultraviolet radiation resistance and other general weatherability properties. Polysulfide coatings have been commercially used for over 50 years. The most recent use of the polymers is to provide chemically resistant barrier coatings on chemical-containment storage-tank dikes that protect the environment from chemicals that could cause serious pollution problems. Their elongation properties make them especially useful for bridging of concrete cracks.

Studies with polysulfides include development of roofing compositions that comprise bituminous materials that have crumb rubber and an elastomeric polysulfide as major components [57]. Anther roofing systems involve a glass filter-fiber roofing mat that is coated with an elastomeric polysulfide and crumb rubber composition [58]. Non-slip, non-abrasive coatings have been prepared from polysulfide compositions [59]. Such coatings maintain sufficient traction in wet and dry environments as are encountered around swimming pools and similar wet areas. Polysulfides have also been used as toughening agents in primer and topcoat coating compositions that provide durable, non-skid surfaces as are needed on aircraft carrier and other ship decks as well as on oil well drilling platforms [60]. As mentioned in the section dealing with polyols above, polysulfides have been converted into polyols, and these have been used to make polyurethane insulated glass sealants [19].

The odor level of polysulfides has been reduced by contacting the polysulfide with a hydrocarbyl acrylate or methacrylate [61]. Both mono(meth)acrylates and poly-(meth)acrylates have been used for this purpose. Although a wide variety of these inhibitors can be used, the preferred inhibitors are n-dodecyl acrylate and glycidyl methacrylate or mixtures of these compounds.

It is worth pointing out that poly(phenylene sulfide) is used as a high performance engineering thermoplastic. Its utility is derived from its excellent heat and flame resistance, good mechanical properties, and chemical resistance coupled with easy processability. The polymer's high temperature performance properties make it useful as a thermo-set phenolic replacement in electrical/electronic applications.

ASTM B866, Test Method for Gross Defects and Mechanical Damage in Metallic Coatings by Polysulfide Immersion and ASTM E1773, Standard Practice for Sealing Rigid Wall Tactical Shelters with Polysulfide Based Sealants are useful for examining particular aspects of polysulfide materials.

Phenoxy

Polyhydroxyethers, which are commonly known as phenoxy polymers or merely phenoxy, are high-molecular-

weight, high-performance thermoplastic materials that are similar in character to the diglycidyl ethers of bisphenol A that are described in Fig. 1 of Chapter 10 in this manual, entitled "Epoxy Resins in Coatings." However, there are significant differences that make the phenoxy polymers separate and unique polymers [62–64]. These polymers have the structure

$$—[O—C_6H_4—C(CH_3)_2—C_6H_4—O—CH(OH)—CH_2]_n—$$

where n is about 100, indicating a molecular weight of about 30,000 compared with a molecular weight of about 300–10,000 for the diglycidyl ethers of bisphenol A. In addition, phenoxy polymers do not have active epoxide end groups and are thermally stable materials with no limit on shelf life, are tough and ductile, and can form useful, resistant films by solvent evaporation without cross-linking. The hydroxyl functionality associated with phenoxy polymers provides a site for cross-linking with isocyanates, epoxides, or aminoplasts. Films from these polymers are considered to have excellent physical and chemical resistance properties when the polymer is in a thermoplastic form, but if improved resistance to certain solvents is needed, the polymers may be cross-linked. The high molecular weight of these polymers results in relatively low solids (~ 20 %) coating systems, and this might be a restriction to their use in today's climate for high solids. The excellent properties of these polymers has led researchers into investigations of ways for advancing molecular weight of the diglycidyl ethers of bisphenol A during the curing stages [65].

Phenoxy is still used in a variety of ways with and without powdered zinc or other metals in the composition. Coatings that withstand substantial deformation without losing continuity have been compounded from compositions comprised of phenoxy and modifier, polymeric materials [66]. The modifier polymeric materials are softer than phenoxy and are, for example, poly(alkylene oxides), polyesters, caprolactone polyols, polyester urethanes, and polyether urethanes. Phenoxy has found utility on steel that is coated with zinc or zinc-based alloy and used as fuel tanks [67]. Tin-plated steel that is used in the manufacture of gas tanks can be coated with a mixture containing phenoxy and powdered tin and zinc dust to provide corrosion resistance [68].

Parylene Coatings [69,70]

Parylene coatings are applied by exposing a substrate to a gaseous atmosphere of *p*-xylylene. The gaseous monomer is stable, but when it is condensed on a substrate it spontaneously polymerizes to form high-molecular-weight, linear, poly(*p*-xylylene), which is commonly known as parylene [71]. The resultant coating of crystalline polymer provides a pinhole-free coating with an outstandingly uniform thickness and conformance even over pointed objects such as a needle. The polymer has excellent electrical properties, including high dielectric breakdown voltage, low dielectric constant and dissipation factor, and high-volume resistivity due to low moisture absorption and freedom from ionic impurities. Parylene is used for coating printed wiring assemblies, semi-conductors, capacitors, electrets, contamination and corrosion control, medical and surgical devices, medication delivery devices, solder masks for printed circuit boards, as well as similar end uses that require an inert coating that can be uniformly applied in an extremely thin film [72–76].

Part 4: Plasticizers

17

Plasticizers

Peter Tan[1] and Leonard G. Krauskopf[2]

PAINT AND COATING FORMULATIONS OFTEN incorporate high boiling fluids as plasticizers where rigid or brittle resins fail to meet toughness and flexibility requirements. The primary function of the plasticizer is to impart flexibility to the resin, thus minimizing film cracking. Depending on resin and other ingredients used in the system, plasticizer choice may affect compatibility, toughness, flammability, smoke generation, heat and light stability, and other aging or permanence-related performances. Plasticizers are primarily employed in heavy gage coatings and/or when improved toughness is required for industrial, automotive, and appliance applications.

Plasticizers function by reducing the glass transition temperature of the resin to a point below its application temperature. The chemical mechanism of plasticization involves a strong polar association of polymer-plasticizer molecules, but not a chemical reaction between them. Plasticizers fundamentally reduce van der Waals forces between polymer-polymer molecules in the amorphous regions and do not penetrate crystallites [1–3]. The plasticized morphological phase is then of a different nature than that of the neat polymer and has unique mechanical properties.

The absence of a chemical bond between the plasticizer and the polymer impairs permanence; plasticizer molecules are free to leave the polymeric coating by means of extraction and volatility. Plasticizer loss, however, is minimal in most applications except for very low molecular weight plasticizers and/or exposure to very severe thermal conditions. Thus, plasticized coatings products have high durability and long service life in most applications. Plasticizers are liquids of molecular weight greater than that of solvents—to limit volatility—but are not solids, such as alloying polymers, etc. It should be noted that cross-linked resinous coatings significantly reduce plasticizer loss due to diffusibility and volatility. Several thousand high boiling fluids are potential plasticizers for coatings applications. The choice of plasticizer is dependent on compatibility with the resin in use, cost, and other desired attributes.

Plasticizers may be classified by both chemical structure and performance characteristics, as shown in Table 1 [4]. Typical plasticizers are liquid esters of molecular weight between about 200 to 800, with specific gravities between 0.75 and 1.35 at 20/20°C, viscosities between 50 to 450 cSt, vapor pressure of less than 3.0 mm of mercury at 200°C, and flash points greater than 120°C (248°F). They are generally stable and innocuous and should not be considered a significant threat to humans or the environment [5,6].

Plasticizer extenders are commonly used in extruded or molded flexible plastic shapes. Extenders are low-cost organic oils that may be subdivided as groups of aliphatic, aromatic, or chlorinated hydrocarbons. They are seldom used in coatings due to their relatively high volatility and limited compatibility in polar resins.

This chapter lists the basic properties of plasticizers and methods for their determination. Methods for the isolation, identification, and quantitative determinations of these plasticizers are also included.

PHYSICAL AND CHEMICAL PROPERTIES

Acidity

Plasticizer acidity may be due to improper processing, degradation during storage, contamination, presence of byproducts, or residual catalyst. ASTM D1613, Test Method for Acidity in Volatile Solvents and Chemical Intermediates Used in Paint, Varnish, Lacquer, and Related Products, may be used for determination of acidity. Either ethyl or isopropyl alcohol may be used as diluent for the plasticizer, which is titrated with aqueous sodium hydroxide or potassium hydroxide to the phenolphthalein end point. Results may be expressed in weight percent, as weight equivalents of acetic acid, acid number (milligrams potassium hydroxide consumed per gram of sample), or if the plasticizer is an ester, as weight percent of the parent acid of the ester (see section entitled "Ester Value").

Color

The majority of plasticizers are colorless. As a class, esters are very stable chemical reagents. However, exposure to abnormal conditions, such as high thermal or ultraviolet energy, moisture, or chemically active surfaces, may induce development of color bodies and/or chemical decomposition of the plasticizers. Higher molecular weight phthalates, polymeric plasticizers, and chlorinated paraffins may range in color from light to bright yellow. Although ASTM D1209, Test Method for Color of Clear Liquids (Platinum-Cobalt Scale), has been a standard color measurement method for plasticizers, it was withdrawn by ASTM in 1987. However, the test method can be obtained from a third party. ALPHA is a scale that is likewise used for liquids of low color. The standards are based on platinum solutions without cobalt

and are described in ASTM D2849, Standard Method of Testing Urethane Foam Polyol Raw Materials.

ASTM D1 544, Test Method for Color of Transparent Liquids, employs the Gardner Color Scale for amber and dark-colored plasticizers, which cannot be read on the platinum-cobalt (Pt-Co) or APHA scales. Gardner standards are colored disks held in a "Hellige" gage. Gardner values of "1" and "2" are approximately equivalent to 250 and 400, respectively, on the APHA scale. The Gardner scale goes up to "18" for use with increasingly darker amber and brownish color liquids.

The platinum-cobalt scale is also known as the Hazen scale, but readers should be aware of potential confusion with APHA; APHA adopted a version of this scale in which a hazel color of one is the same as APHA 100. To avoid confusion, it is recommended that only the Pt-Co scale be used when referring to Procedure D1209.

The APHA color scale in ASTM D2849 (see Footnote 3) reflects a slightly greenish hue for APHA versus the Pt-Co scale, which is slightly yellowish. The scale readings are similar in the 25 to 50 range, but in the vicinity of 100 Pt-Co, the APHA scale (Pt only) reads 10 to 20 units lighter (lower). Both the Pt-Co and APHA scales cover a range from "3" up to "500," but are recommended for use for liquids having colors ≤250 units.

An instrumental method (Hunter Colorimeter) that is five to seven times more precise may also be used for color measurement, replacing the subjective comparisons of the above methods using Nessler tubes; while commonly used in commercial practice, the Hunter Colorimeter is not yet defined as an ASTM method.

Copper Corrosion

ASTM D130, Test Method for Corrosiveness to Copper from Petroleum Products by the Copper Strip Test, and ASTM D849, Test Method for Copper Strip Corrosion by Industrial Aromatic Hydrocarbons, which is normally applied to hydrocarbon solvents, may be used to evaluate the copper corrosive tendencies if suspected to be sourced in plasticizer. The appearance of a copper strip, which has been immersed in the test fluid, under standard conditions, is compared with twelve special standard strips classified as follows:

1. Slight tarnish (1a,b) light orange, dark orange.
2. Moderate tarnish (2a,b,c,d,e) claret red, brassy, or gold.
3. Dark tarnish (3a,b) magenta, multicolored.
4. Corrosion (4a,b,c) transparent black, jet black.

The historical application of copper corrosion testing to plasticizers was an attempt to measure effects contributed by residual sulfur compounds due to sulfur-based catalysts, which may hydrolyze to acidic *p*H in the presence of moisture. Current commercial grade plasticizers do not typically contribute to copper corrosion. Commercial grade alkyl sulfonate esters of phenol [7] are plasticizers in which the sulfur is organically "combined" and not readily susceptible to hydrolyses.

Distillation Range

Most plasticizers have high boiling points or boiling ranges. This property can be used as a measure of its degree of permanence or resistance to loss through volatilization. Presence of lighter components can also be detected. The measurement of vapor pressure is a costly and time-consuming procedure. Thus, commercial liquids of high molecular weight—low vapor pressures—are typically characterized by boiling ranges in which one determines initial, mid, and final (or dry point) boiling point temperatures. For fluids with dry point >140°C, ASTM D86, Test Method for Distillation of Petroleum Products at Atmospheric Pressure, is used. Fluids with dry point <140°C are measured using ASTM D1078, Test Method for Distillation Range of Volatile Organic Liquids. For very high boiling fluids or where decomposition may occur, distillation may be done under vacuum regulated at 5 mm Hg. The initial and final boiling points or the mid boiling point are typically reported.

Gas chromatographic (GC) techniques are commonly applied as a fundamental measure of plasticizer chemical purity and isomer distribution. Direct relationships between GC traces and boiling ranges have not yet been established for plasticizers.

Both distillation range and GC analyses are means to relate vaporization characteristics of plasticizers to practical needs. The fundamental characteristic of vapor pressure may be measured by ASTM D2879, Test Method for Vapor Pressure-Temperature Relationship and Initial Decomposition Temperature of Liquids by Isoteniscope. The log of plasticizer vapor pressure varies linearly with the reciprocal absolute temperature (Kelvin) according to the Clausius-Clapeyron equation [8]

[3] ASTM withdrew this method in 1987 and it cannot be downloaded from the ASTM website. However, the document can be obtained from a third party.

$$\ln \frac{P_1}{P_2} = \frac{\Delta H}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) \quad (1)$$

where

P_1 and P_2 = vapor pressure, g cm^2 s^{-2},
T_1 and T_2 = respective temperatures, K,
ΔH = molar heat of vaporization, cal—g^{-1}, and
R = gas constant, 1.99 cal°C^{-1} mol.

Vapor pressure values are useful to estimate normal boiling points at 760 mm mercury and solubility parameters [1]. Sears and Darby have reported that the vapor pressure of binary plasticizer blends may be expected to fall between the values of the neat plasticizers, but cannot be predicted from knowledge of the blend ratio and the neat vapor pressures.

Ester Value

Esters are the largest group of materials that are commercially useful as plasticizers. This is a result of reasonable costs and broad utility in a wide range of polymers having moderate to high polarity characteristics. Ester value can be used to estimate the purity or ester content of the plasticizer. ASTM D1617, Test Method for Ester Value of Solvents and Thinners, or ASTM D1045, Test Methods for Sampling and Testing Plasticizers Used in Plastics, may be used for this determination. The methods involve saponification of the ester in a known excess amount of KOH. The excess amount of KOH is then determined by titration with standard sulfuric acid. The amount of KOH consumed in the saponification process is a measure of the ester content of the plasticizer.

A gas chromatography method, ASTM D3465, Standard Test Method for Purity of Monomeric Plasticizers by Gas Chromatography, may also be used to determine the purity of monomeric plasticizers. The GC method does not provide "ester values." It is useful to characterize major isomers present versus known standards and to ascertain trace quantities of nonparent organic compounds. GC instrumentation is costly and requires comparison of output traces against a library of known materials that have been characterized under a specific set of conditions using specific GC instruments and columns.

Flash Point

Most plasticizers are high flash materials. Either ASTM D92, Test Method for Flash and Fire Points by Cleveland Open Cup Tester, or ASTM D93, Test Methods for Flash Point by Pensky-Martens Closed Cup Tester, may be used. Preference should be for the closed cup method; this yields a more conservative number and is consistent with Department of Transportation (DOT) regulations in the United States. DOT has revised the definitions and classifications of hazardous materials, effective 1 Oct. 1993, as follows:

Flash Point	
Not Regulated	≥93°C (200°F)
Combustible	61–92.5°C (142–199°F)
Flammable	≤60.5°C (141°F)

The "flash point" is defined as the minimum temperature at which a liquid gives off vapor within a test vessel in sufficient concentration to form an ignitable mixture with air near the surface of the liquid as determined by ASTM D56, Test Method for Flash Point by Tag Closed Cup Tester, or ASTM D3278, Test Methods for Flash Point of Liquids by Small Scale Closed-Cup Apparatus. In industry, all four methods are used for flash point determination.

Flash point values are reported for commercially significant monomeric plasticizers in E. J. Wickson's *Handbook on PVC Formulating* [7]. While not a very good analytical tool, flash points will reflect presence of nonparent, low-flashpoint contaminants.

Pour Point

Due to the high molecular weight and isomeric mixtures of plasticizers, few have distinct freezing points. The pour point can be useful information for handling plasticizers during cold seasons. Method of measurement is described in ASTM D97, Test Method for Pour Point of Petroleum Products, and ASTM D5950, Standard Test Method for Pour Point of Petroleum Products (Automatic Tilt Method). Plasticizer pour point temperatures may also be estimated from viscosity/temperature plots as the temperature at which kinematic viscosity is 50,000 cSt. Most plasticizers have pour points of less than –30°C [7]; no known relationship exists between pour point and plasticizer performance properties in polymers under low-temperature conditions [9].

Refractive Index

The refractive index of a plasticizer is measured using ASTM D1218, Test Method for Refractive Index and Refractive Dispersion of Hydrocarbon Liquids. Refractive index is often thought of as a means of identifying the plasticizer. This is an erroneous assumption. It may be used, however, to differentiate between classes of plasticizers, as, for example, between phthalates and adipates [10]. When used with other physical measurements, refractive index may be used as a supplemental test. Refractive index can also be used to check for product contamination, but it is only useful to distinguish commercial materials having very widely different refractive indices.

Residual Odor

Residual odor may be contributed by reaction by-products from manufacturing or by residual raw ingredients, which are often more volatile and odorous than the plasticizer. When ASTM D1296, Test Method for Odor of Volatile Solvents and Diluents, is used, tests at elevated temperatures (about 150°C) can be considered to improve detection. Since odor is a subjective characteristic, generalizations for plasticizers are limited to terms such as "mild and characteristic." ASTM D6165, Guide for Comparison, Detection, and Identification of Odors of Paints, Inks, and Related Materials, is also useful for ascertaining and differentiating odors.

Sampling

To obtain representative samples of plasticizers for evaluation, ASTM D1045, Methods for Sampling and Testing Plasticizers Used in Plastics, may be followed. ASTM E300, Standard Practice for Sampling of Industrial Chemicals, can also be used.

Density and Specific Gravity

Density is an important characteristic for design engineering of plasticizer storage and building facilities. Specific gravity is the density of the given reagent relative to that of water at the specified temperature; it is generally used in the characterization of plasticizers or as a means to detect gross contamination. Specific gravity at 20/20°C is measured with ASTM D891, Test Methods for Specific Gravity, Apparent, of Liquid Industrial Chemicals, and is commonly employed in industry. Commercial plasticizers typically fall within the range of 0.92–1.50 sp gr at 20/20°C. ASTM D4052, Test Method for Density and Relative Density of Liquids by Digital Density Meter, is the recommended procedure to measure specific gravity of fluids that lie between 0.68 and 0.97; this method is applicable to hydrocarbons that are commonly used as plasticizer extenders. Another standard method used in the paint and coatings industry is ASTM D1475, Density of Liquid Coatings, Inks, and Related Products.

Viscosity

Viscosity measures the fluid's resistance to flow; the thicker the fluid, the higher its viscosity and the greater its resistance to flow under gravity. In ASTM D445, Test Method for Kinematic Viscosity of Transparent and Opaque Liquids (and Calculation of Dynamic Viscosity), time is measured in seconds for a fixed volume of the fluid to flow under gravity through the capillary of a calibrated viscometer at constant temperature. The kinematic viscosity of a plasticizer varies as a log log function versus the log of absolute temperature according to the following equation

$$\log\log\eta \cong A - B\log T \tag{2}$$

where

η = kinematic viscosity, centistokes,
T = temperature, degrees Kelvin, and
A and B = constants.

This reflects the tremendous influence of temperature on viscosity and allows one to interpolate viscosity values at specified temperatures. The kinematic viscosity (centistokes) can be converted to its dynamic viscosity (centipoise) by multiplying by the true density of the fluid at the specified temperature: dynamic viscosity, cP = kinematic viscosity, cSt, times density.

Water

Residual water from manufacturing processes and moisture absorbed from the atmosphere can affect the quality and clarity of coatings. Water content can be measured using ASTM D1364, Test Method for Water in Volatile Solvents (Karl Fischer Reagent Titration Method). Plasticizers are hydrophobic liquids and typically have a limited capacity to take up water and/or be dissolved into water. Higher-molecular-weight phthalates are practically insoluble in water with solubilities in the 0.1 to 1.2 mg/L (ppm) range with even less solubility in salt water [6].

Typical Properties

As shown in Table 1, commercial plasticizers fall into about seven chemical family groups (eight if we were to add a "miscellaneous" grouping). The major plasticizer types in use are phthalates, trimellitates, and aliphatic dibasic esters such as adipates. The families of esters are formed by reacting the parent acid with monomeric alcohols ranging from C4H9OH (butanol) to $C_{13}H_{27}OH$ (tridecanol); the alcohol may also vary in isomeric structure ranging from normal (un-branched) to very specific and/or randomly branched structures. Two alcohols have found wide usage in synthesis of commercial plasticizers—2-ethylhexanol and isononanol—a mixture of randomly branched (primarily methyl branched) nonyl isomers. Table 2 is a summary of typical properties of plasticizers derived from these two alcohols with the major parent acids—phthalic, trimellitic, and adipic [11].

METHODS OF IDENTIFICATION

A plasticizer may initially be characterized by its functional groups. While absolute identification is complicated without sophisticated chemical or instrumental methods, it is possible to identify the type of plasticizer by functional groups or presence of elements associated only with the plasticizer by the use of infrared analyses or wet chemistry. Most plasticizers are a member of one of the following families:

Plasticizer Type/Functional Group
Adipates
Chlorinated compounds
Epoxides (oxirane)
Phosphates
Phthalates
Polyesters
Trimellitates

Isolation of Plasticizers

Plasticizers may be separated from a lacquer or dried film by solvent extraction if it is to be analyzed. The lacquer is first dried to remove all solvents present. The dried solid is then solvent extracted (in an appropriate apparatus) with hot ethyl ether or another appropriate solvent that will extract the plasticizers while leaving most of the resins behind. The extractant is concentrated, and a small amount of methyl or ethyl alcohol is added. This will cause some of the dissolved resin to precipitate out. Next, filter and concentrate the extractant. ASTM D494, Test Method for Acetone Extraction of Phenolic Molded or Laminated Products, may be applied.

Instrumental Methods

Modern instrumental analytical methods are able to separate, identify, and quantify components in composite mixtures. Rapidly falling costs of such instruments have enabled instrumental methods to be more widely available. These include gas chromatography (GC), high-performance liquid chromatography, infrared spectroscopy (FTIR), and other emerging analytical instruments such as supercritical fluid chromatography, GC/FTIR, and GC/mass spectrometry.

Infrared Spectrophotometry

An infrared scan of the isolated plasticizer is by far the best way to identify the functional groups in the molecule. Mixtures of plasticizers can present problems due to masking effects. If one or more of the component plasticizers is known and its IR scan available, subtracting it from the IR scan of the mixture may aid in identification of the other component. Other chromatographic techniques could be used to separate the components before scanning.

TABLE 2—Selected physical properties of plasticizers prepared with 2-ethylhexyl (2-EH) and i-nonyl (iso-N) alcohols. Note: Health information about these and other plasticizers can be found by searching the CAS number on the Internet.

Liquid Chromatography

Column chromatography involves distribution of substances between liquid (mobile phase) and substrate (solid phase). Column and thin layer chromatography can be used. Instrumental methods using high-performance liquid chromatography with ultraviolet detection can be used for separation, identification, and quantification of plasticizers that possess a suitable chromophore.

Gas Chromatography

By comparing relative retention times and peak shapes with known samples, a plasticizer or mixture can often be identified and quantified. When coupled with IR (i.e., GC/FTIR), the IR spectrum of each chromatographic peak can assist in the identification of functional groups and hence plasticizer identity, ASTM D3465, Standard Test Method for Purity of Monomeric Plasticizers by Gas Chromatography.

Qualitative Methods

For the detection of nitrogen, chlorine, sulphur, or phosphorus, the sample needs to be fused with metallic sodium. This preparation should be carried out in a fume hood and caution observed when handling metallic sodium. A small amount (about 3 mm^3) of metallic sodium is placed in a dry 6 in. (15.24 cm) test tube. The test tube should be held vertically by clamping it at the open end. The test tube is then heated until a cloud of sodium vapor begins to form. Remove the flame immediately. Add two to three drops of the plasticizer sample directly to the sodium vapor. When the test tube is cold, carefully break off the end containing the sodium in a mortar. Add several milliliters of alcohol to destroy unreacted sodium. Add about 20 mL of distilled or de-ionized water, grind up the sample, transfer to a beaker, bring to boil, and filter. The filtrate is then used for the chemical detection of the elements.

Sulfur

Add two to three drops of 10 % solution of lead acetate to 2 mL of a 10 % solution of sodium hydroxide. Add this mixture to 5 mL of the filtrate. A black precipitate of lead sulphide indicates the presence of sulphur. Positive identification suggests that the sample is either a sulphonamide or sulphate.

Nitrogen

Bring 2 mL of the filtrate to boil in a test tube. Add five drops of a 10 % solution of NaOH and five drops of 10 % ferrous sulphate solution. When cold, add, drop wise, a 10 % solution of hydrochloric acid until the solution is acidic and the precipitate of ferrous hydroxide has dissolved. Avoid using an excessive amount of acid. A blue or green color or blue precipitate indicates presence of nitrogen. A positive test suggests that the plasticizer could be an amide.

Chlorine

Acidify 5 mL of the filtrate with several drops of dilute sulfuric acid and bring it to boil. Cool and acidify with nitric acid. Add several drops of a 10 % silver nitrate solution. A white precipitate indicates the presence of a chlorinated compound.

Phosphorous

Boil 5 mL of the filtrate with 3 mL of concentrated nitric acid for 1 min. Cool and add twice the volume of 10 % ammonium molybdate solution. Heat to about 60°C and set aside to cool. A yellow precipitate indicates the presence of phosphorous. Phosphate plasticizers will result in a positive test.

Phthalates

Add about 0.05 g of resorcinol and 0.05 g of phenol to separate 6 in. (15.24 cm) test tubes. Add to each test tube two to three drops of the isolated plasticizer and a drop of concentrated sulfuric acid. Heat the contents in an oil bath at 160°C for several minutes. Cool and add 2 mL of distilled water and 2 mL of 10 % sodium hydroxide solution and stir. The presence of phthalate is indicated by a pronounced

PERFORMANCE PROPERTIES

Compatibility

Compatibility is the ability of two or more substances to mix together without objectionable separation [12]. In the case of plasticizers, it is primarily a measure of the solvency or strength of positive interactions between the plasticizer and the polymer that attract them together.

Solvency is the extent (or amount) of interaction of plasticizer or solvent molecules at the surface of a polymer particle; a solid solution results when the polymer and plasticizer—and possibly additional reagents—become molecularly homogeneous. The degree to which a homogeneous solution, or miscibility, is stable is a function of the plasticizer/polymer interactions when in the presence of other reagents employed in the coating formulation; it must be recognized that the presence of these additional reagents can compete with the polymer/plasticizer interactions. The rule of thumb "like dissolves like" applies, but more specific knowledge is required to avoid results that appear to be anomalous.

Dried polymeric coatings may be considered as solid solutions; the limits of miscibility are impacted by all of the reagents that become components of the coating—those intentionally added, as well as inadvertent contaminates and/or degradation products formed in the coating process. When plasticizers are employed, they have a major effect on compatibility, primarily due to the level, or concentration, used in the polymer. If we accept the definition of a solution as a homogeneous mixture of two or more types of molecules, then "solvency" is a measure of a given solvent or plasticizer to homogenize and interact with a given polymer. Quantification of this "interaction" has been elusive; scales that have been devised are capable of measuring only gross differences. Observations of phase separation of plasticizer/polymer have been more finite than that predicted in many cases; while on the other hand, observations of symptoms (compatibility) are incapable of separating "solvency" from other interfering mechanisms that are concurrent, such as diffusibility.

Hansen publications [13, 14] define the total solubility parameters of polymers, solvents, and other reagents as a function of three component parameters:

$$\lambda_T = (\lambda_d^2 + \lambda_p^2 + \lambda_h^2)^{1/2}, \quad (\text{cal/cm}^3)^{1/2} \tag{3}$$

where

λ_T = total solubility parameter,
λ_d = dispersion parameter,
λ_p = polarity parameter, and
λ_h = hydrogen bonding parameter.

The location of polymers and other nonionic reagents may be defined on this three-dimensional grid. Hansen states that it may be assumed that the closer a plasticizer lies to the center of the polymer solubility space of a polymer, the more compatible it will be with the given polymer. Many materials have been characterized in this fashion. Exxon Chemical Company has developed a computerized capability to define the location of various solvents and plasticizers relative to that of various polymers; it is called the CO-ACT® program and contains information on more than 1,200 resins, solvents, and plasticizers [15].

Compatibility data for different plasticizer resin systems are available in various publications [1, 16, 17]. The plasticizers are usually presented as compatible, incompatible, or partially compatible with the resins. These data are often not useful due to incomplete description of the resin or a lack of standard approach in the test and reporting of observations. Where Hansen parameters are available for the plasticizers and resins, comparison of three-dimensional Hansen solubility parameters provide a better measure of compatibility as described earlier. Table 3 lists generalized examples of plasticizers and their compatibility with various coating resins.

Permanence

"Reactive" plasticizers are specialty types designed to self-polymerize or graft onto the polymeric resin during the curing process. But, in most cases, plasticizers do not chemically react with the polymer. They function by an overall solvating action that is less strong than that of a good solvent, but stronger than that of incompatible reagents such as lubricants. This interaction imparts a slight effect on plasticizer "permanence," or more properly "transience." One of two factors are generally the controlling influence over loss of plasticizer:

- Rate of diffusion of plasticizer from the resin bulk to the surface.
- Rate of loss of plasticizer from the surface.

The slowest rate of the two is the controlling factor under any specific set of conditions. Volatility and extraction by aqueous reagents are generally surface-controlled losses, while rate of diffusion controls loss under oil immersion and similar tests. The subject is very complex [1,2], but one may consider plasticizer vapor pressure as a key predictor of volatile loss, while diffusion-controlled losses are improved with plasticizers of higher molecular weight and branchiness in the chemical structure.

Resistance to washing is typically characterized as a function of thermal and/or humidity cycling exposures. This is a measure of the aging resistance of the plasticized polymeric coating.

Low-Temperature Properties

Some applications require flexibility and impact resistance at low temperatures. This property may be significantly improved at increased plasticizer levels, as well as being a function of the plasticizer type [1]. For example, at approximately 50 PHR, plasticizer in poly(vinyl chloride) phthalates of linear alcohols impart about –10°C improvement in low-temperature brittleness over branched, DOP-type, phthalate plasticizer. Dialkyl adipates, however, impart about –25°C improvement over the brittleness value of DOP-plasticized PVC as measured by ASTM D746, Test Method for Brittleness Temperature of Plastics and Elastomers by Impact. Commercial coatings require the optimum choice of plasticizer type and concentration to meet required costs, hardness or modulus, permanence, and low-temperature properties.

Part 5: Solvents

18

Solvents

Stephen A. Yuhas, Jr.[1] and Rey G. Montemayor[2]

SOLVENTS ARE SUBSTANCES, USUALLY LIQUIDS, which are capable of dissolving other substances to bring them into liquid form. In the paint and coating industry, solvents dissolve the solid or semisolid film-forming resins and reduce viscosity so that the paint can be applied as a uniform, thin film to a surface. Although solvents are transient components of a paint, they significantly affect not only the application characteristics of a paint, but also the appearance, physical properties, and durability of the coating.

The two most important performance requirements that must be considered in selecting the proper solvent for any coating end use are solvency and evaporation rate. These key properties control initial paint viscosity during application, coating viscosity at various stages of drying, and final coating appearance. Solvents must evaporate relatively quickly during initial drying to prevent excessive flow and sag, but they must evaporate more slowly in the later stages to provide good leveling and adhesion.

Solvency and evaporation rate are often measured indirectly since direct measurements are not always feasible or convenient. In addition, there are numerous other solvent properties that must be considered for specific applications. These are often listed as requirements in the solvent specifications and include measures of purity, uniformity, safety, and compliance with air pollution regulations.

There are many different solvents used by the coatings industry. To facilitate their review and comparison, it is convenient to classify them chemically into three general categories: Hydrocarbon solvents, oxygenated solvents, and other solvents. Each category will be discussed separately in the sections that follow.

Solvents may also be classified according to the function they perform: Active, latent, and diluent. An active solvent is a true solvent for the film-forming resin and has the major role in dissolving it. A latent solvent alone will not dissolve the resin, but behaves as an active solvent or has a synergistic effect when used in conjunction with an active solvent. A diluent usually has no solvency for the resin, but is tolerated by it in blends. Diluents are added to reduce cost and vehicle viscosity through dilution.

CLASSIFICATION BY CHEMICAL TYPE

Solvents can be broadly classified by chemical type into three categories:

1. *Hydrocarbon solvents*—organic compounds comprised of molecules consisting of hydrogen and carbon atoms.
2. *Oxygenated solvents*—organic compounds comprised of molecules consisting of hydrogen, carbon, and oxygen atoms.
3. *Other solvents*—organic compounds consisting of hydrogen, carbon, and atoms other than oxygen, such as chlorine or nitrogen, or inorganic compounds such as water or supercritical carbon dioxide.

Hydrocarbon Solvents

The vast majority of hydrocarbon solvents are derived from petroleum, although a few are of vegetable origin. Therefore, hydrocarbon solvents may be regarded as being "natural products." Most are physically separated from petroleum by distillation and other refining processes. As a result, hydrocarbon solvents tend to be mixtures of organic compounds (rather than individual chemicals), and they may vary in composition depending on feedstock source.

Solvency of hydrocarbons is relatively weak compared with oxygenated and other solvents. Being of natural origin, they are good solvents for natural resins and natural-modified resins, such as drying oils, varnishes, alkyds, asphalt, rosin, and petroleum resins. However, they are generally poor solvents for synthetic resins such as vinyls, epoxies, urethanes, acrylics, and nitrocellulose. Hydrocarbon solvents are usually used as low-cost diluents in solvent blends. Other distinguishing characteristics of hydrocarbon solvents are low specific gravity and complete water immiscibility.

Hydrocarbon solvents may be further subclassified into four subcategories: aliphatics, aromatics, naphthenes, and terpenes.

ALIPHATIC HYDROCARBONS

Most aliphatic hydrocarbon solvents are manufactured by distilling the appropriate boiling range fractions from crude oil and subsequently treating them to improve odor and color stability. These saturated organic molecules are generally mixtures of straight chain or *normal-paraffins* and branched chain or iso-paraffins, with perhaps some cycloparaffins [1].

Unique, distinguishing characteristics of commodity aliphatic hydrocarbons are very weak solvency, low odor, low specific gravity, and cost. Although they are active solvents for some varnishes and alkyds, they are used primarily as low-cost diluents in solvent blends. Weak solvency is not necessarily a disadvantage of aliphatic hydrocarbons. They are preferred as carrier solvents in vinyl organosols and as

reaction diluents in certain polymer syntheses because of their low tendency to dissolve or swell polymers.

Examples of some typical aliphatic solvents used by the coatings industry are shown in Table 1 together with their ASTM specification references. Others are commercially available as aliphatic naphthas having producer-defined distillation ranges. The fastest-evaporating solvents—hexane, heptane, and lacquer diluent—are often used as the diluent component of fast-drying lacquers, where one of their important functions is to reduce cost.

Mineral spirits is the most commonly used aliphatic solvent. (Outside the United States, mineral spirits is often called white spirits.) It is the common "paint thinner" sold in retail stores and is used in architectural paints, varnishes, and stains. It has the right combination of moderate solvency and moderately slow evaporation rate to impart proper brushability, leveling, and wet edge.

Mineral spirits is a distillation fraction boiling between 300°F (149°C) and 415°F (213°C), with a minimum flash point of 100°F (38°C). Four types are defined in ASTM D235, Specification for Mineral Spirits (Petroleum Spirits) Hydrocarbon Drycleaning Solvent [2]. "Low dry point" mineral spirits, referred to as Stoddard solvent, has a faster evaporation rate and is used as a dry-cleaning solvent.

VM&P naphthas have about the same solvency as mineral spirits, but have a much faster evaporation rate. They are distillation fractions having boiling ranges between 235°F (113°C) and 310°F (154°C). ASTM D3735, Specification for VM&P Naphthas [2], defines four types. They are used primarily in spray-applied, industrial finishes.

Several hydrocarbon solvent producers also manufacture and market complete lines of pure, isoparaffinic solvents that are synthetically produced from petroleum components. Unique characteristics of the isoparaffins are that they have very weak solvency and are virtually odorless. Examples are odorless mineral spirits and odorless VM&P naphtha.

AROMATIC HYDROCARBONS

Aromatic hydrocarbons, which are cyclic, unsaturated compounds, are also made from petroleum. However, their manufacture requires additional processing steps. To manufacture aromatic solvents, an aliphatic naphtha distillate from crude oil is typically processed through a catalytic reformer to rearrange the molecules into cyclic and

[a]Specification withdrawn 1995.

polycyclic compounds, which are further dehydrogenated to aromatic hydrocarbons. The aromatic hydrocarbons are typically concentrated and refined through an extraction process and thus separated by distillation [1].

There are four aromatic solvents commonly used by the coatings industry: Toluene, mixed xylenes, and two high-flash aromatic naphthas. Evaporation rates of these four aromatic solvents range from fast to very slow. ASTM specification references and key properties are summarized in Table 2. Distinguishing characteristics of aromatic solvents, relative to hydrocarbon solvents, are stronger solvency and odor, high specific gravity, and higher cost.

Toluene is a pure chemical, methylbenzene. It is a fast-evaporating solvent used as an active solvent for certain resins, as a lacquer diluent, in spray paints, aerosols, and in a variety of industrial coatings.

Mixed xylenes are used as paint solvents and in thinners. Xylene is a mixture of three isomers: *ortho-*, *meta-*, and *para*-xylene, plus ethylbenzene. Xylene solvents from different producers may vary in composition, resulting in slight differences in properties and performance [3]. Xylene has a moderate evaporation rate and is used primarily in industrial coatings.

The individual components of mixed xylene solvent are also isolated and marketed separately as chemical intermediates, which are used by the coatings and chemical industries. Phthalic anhydride, used in the manufacture of alkyd resins, is produced from *ortho*-xylene. Terephthalic acid, also used in the manufacture of resins, is produced from *para*-xylene. Styrene is produced from ethylbenzene.

Two *high-flash aromatic naphthas* as specified in ASTM D3734, Specification for High-Flash Aromatic Naphthas [2], round out the aromatics most commonly used by the coatings industry.

Type I—Aromatic 100 has a flash point not less than 100°F (38°C).

Type II—Aromatic 150 has a flash point not less than 142.5°F (61°C).

Aromatic 100 consists mainly of C, aromatics, while Aromatic 150 is a mixture of predominantly C_{10} aromatics. Both are slow evaporating and are used in baked industrial coatings.

NAPHTHENIC HYDROCARBONS

Most of the aliphatic hydrocarbon solvents contain minor amounts of naphthenes, i.e., cycloparaffins or cyclic aliphatics. Properties of naphthenes, with respect to solvency, odor, and specific gravity, are intermediate between aliphatics and aromatics.

Purely naphthenic hydrocarbon solvents currently have very limited commercial availability. Cyclohexane, a pure naphthenic hydrocarbon, finds applications not as a solvent but as a chemical intermediate in the manufacture of nylon fiber and engineering resins, plasticizers, polyurethane, polyester, and epoxy resins. Properties are summarized in Table 3.

TERPENES

Terpene solvents are obtained from pine trees and to a much lesser extent as a by-product of the citrus industry. They are the oldest solvents used in coatings, predating ancient Egyptian civilization [1,4]. The main solvents in this group

TABLE 3—Typical properties of cyclohexane

ASTM specification	D5309; D7266
Specific gravity, 60/60°F	0.782
Distillation range, °C	79–81
Evaporation rate, n-butyl acetate=100	1000 (estimated)
Flash point, °F (°C)	–4 (–20)
Kauri-butanol value	52
Mixed aniline point, °F (°C)	93 (34)

are turpentine, dipentene, and pine oil. Chemically, they are mixtures of C_{10} unsaturated hydrocarbon compounds. A good review of terpenes may be found in ASTM D804, Terminology Relating to Naval Stores, Including Tall Oil and Related Products [5].

Terpene solvents have volatilities similar to mineral spirits. However, they have only minor commercial significance today because they are more expensive than hydrocarbon solvents. Although their solvency is greater than that of aliphatic hydrocarbons, they have a much narrower range of solvency and evaporation rate and a stronger odor. Furthermore, because of their unsaturated structure, they are restricted in some areas by air pollution regulations.

There are four kinds of *turpentine,* as specified in ASTM D13, Specification for Spirits of Turpentine [5], depending on the source and method of production [1,6].

Gum turpentine or *gum spirits* is produced by distilling the crude gum or oleoresin collected from living pine trees. It contains mostly α-pinene with lesser quantities of β-pinene and small amounts of other terpene hydrocarbons.

Steam-distilled wood turpentine is obtained from oleoresin within the wood of pine stumps or cuttings, either by direct steaming of the mechanically disintegrated wood or after solvent extraction of the oleoresin from the wood. It consists primarily of α-pinene, with small quantities of dipentene and other terpenes.

Sulfate wood turpentine is recovered during the conversion of wood to pulp by the sulfate (Kraft) papermaking process. It is a mixture of α- and β-pinene, with small amounts of other terpene hydrocarbons.

Destructively distilled wood turpentine is obtained by fractionation of certain oils recovered from the destructive distillation of pine wood. It is a complex mixture of a wide variety of aromatic hydrocarbons with only moderate quantities of terpenes being present.

Standard methods of sampling and testing turpentine are described in ASTM D233, Methods of Sampling and Testing Turpentine [5].

Dipentene is obtained by fractional distillation from crude oils recovered in the several commercial methods of processing pine wood during the production of turpentine. It has somewhat stronger solvency and a slower evaporation rate than turpentine. Standard test methods for sampling and testing dipentene are described in ASTM D801, Methods of Sampling and Testing Dipentene [6].

Pine oil is a unique material separated during the four commercial turpentine production methods. Unlike the other hydrocarbon solvents, pine oil consists mainly of terpene alcohols, with a variety of small quantities of other oxygenated terpenes. Pine oil has strong solvent power due to the oxygen functionality. However, its evaporation rate is very slow. Pine oil is generally used in additive quantities, i.e., 5 wt % of the total solvent, to provide good coating flow out and wetting properties. Standard methods for sampling and testing pine oil are described in ASTM D802, Methods for Sampling and Testing Pine Oil [5].

d-Limonene is a relatively new commercial terpene hydrocarbon solvent recovered and purified from by-products of the citrus industry.

Typical properties of some selected terpene solvents are summarized in Table 4 [7,8].

Oxygenated Solvents

Oxygenated solvents contain oxygen in the molecule. Unlike hydrocarbon solvents, oxygenated solvents are synthetically produced; as a result, they are somewhat higher in cost. Most are pure, single-component chemical compounds compared with hydrocarbon solvents, which tend to be complex mixtures. Oxygenated solvents generally have very narrow distillation ranges, some as narrow as 1°C.

Relative to the hydrocarbons, oxygenated solvents have much stronger solvency and are used as active solvents for most synthetic resins. Their strong solvency, together with the wide range of volatilities available, makes them an extremely important group of solvents for the coatings industry. Other distinguishing characteristics include higher specific gravity and partial to complete water solubility.

There are four principal types of oxygenated solvents widely used in coatings: ketones, esters, glycol ethers (ether alcohols), and alcohols. Through blending, almost

any desired combination of performance properties can be obtained.

KETONES

Ketones are characterized chemically by a carbonyl group (—C═O) bonded to two carbon atoms or alkyl groups in the molecule. This versatile class of solvents has powerful solvency and a wide range of evaporation rates, from very fast-evaporating acetone to slow-evaporating isophorone. Ketones are further characterized by their strong, sharp odors. They have narrow distillation ranges because of their high purity. Acetone is completely water miscible, while other ketones have varying degrees of water solubility. Properties of selected ketones, with their ASTM specification references, are summarized in Table 5. (Diacetone alcohol is included in this category since this ketone alcohol functions more as a ketone than an alcohol.)

Acetone is a very fast-evaporating solvent. It is often used in aerosols and sprayed coatings, particularly in nitrocellulose and acrylic lacquers, to effectively reduce viscosity for spray application and then quickly flash off during the spraying process. Methyl ethyl ketone (MEK) has a fast evaporation rate, and methyl isobutyl ketone (MIBK) exhibits a moderate evaporation rate. MEK and MIBK are extensively used as active solvents in synthetic resin lacquers and paints. The very slow evaporation rate of isophorone makes it useful in baked industrial coatings.

ESTERS

Esters used as solvents are alkyl acetates and propionates and glycol ether acetates. Several other types of ester solvents are also commercially available as specialty products. The alkyl esters cover a wide range of volatilities, mainly methyl through hexyl esters. Glycol ether acetates are slow-evaporating solvents, and they are used as retarder solvents in solvent-based coatings and as coalescents in latex paints.

Esters have strong solvency, although generally slightly weaker than ketones of similar volatility. They are characterized by their pleasant, sweet, fruity odors. All esters have narrow distillation ranges since they are relatively pure compounds.

Typical properties of the most common ester solvents are summarized in Table 6. As with ketones, their solvencies follow a general pattern, diminishing with increasing molecular weight and with increasing branching of the molecule. Evaporation rate also decreases with increasing molecular weight, but increases with increased branching. n-Butyl acetate, one of the most important ester solvents, has a medium evaporation rate. It is used as a reference for expressing evaporation rates of other solvents.

GLYCOL ETHERS

Glycol ethers are ether alcohols having both ether and alcohol functionality. The ethylene glycol ethers, derived from ethylene oxide and alcohols, have been widely used in coatings. However, because of health hazard concerns associated with certain ethylene glycol ethers, they are being replaced in many applications by propylene glycol ethers, which are derived from propylene oxide.

Glycol ethers have a truly unique combination of properties: Strong solvency, slow evaporation rate, complete water miscibility, high flash point, and mild odor. They are often used in small percentages in lacquers and lacquer thinners as retarder solvents to maintain coating flow and leveling after most of the other solvents have evaporated. In these applications, their water miscibility is beneficial in reducing moisture blush. Glycol ethers are also widely used as coupling solvents in water-based coatings to solubilize the water-reducible polymers.

Chemical terminology for the glycol ethers is cumbersome. For example, 2-ethoxyethanol is also referred to as ethylene glycol monoethyl ether. Therefore, they are often identified by their commercial brand names. Typical properties of selected glycol ethers are summarized in Table 7.

ALCOHOLS

Alcohols are chemically characterized as organic compounds having a single hydroxyl group (–OH). This structure imparts some degree of water solubility to alcohols, complete for the low molecular weight compounds, methanol, ethanol, and propanol, and partial for the higher molecular weight compounds. Alcohols are further characterized physically as having mild, pleasant odors. Typical properties of selected alcohols are summarized in Table 8.

By themselves, alcohols are very poor solvents or non-solvents for most polymers. There are few exceptions; ethanol is a solvent for shellac, poly(vinyl acetate), poly (vinyl butyrate), some phenolics, and natural resins. Alcohols find applications as latent solvents or co-solvents for nitrocellulose lacquers, melamine-formaldehyde and urea formaldehyde resins, and certain alkyds. They are also useful coupling solvents, with glycol ethers, to solubilize water-reducible resins. In addition to their use as solvents, latent solvents, and coupling solvents, they are

used as chemical raw materials for the manufacture of other solvents (e.g., ketones and esters), monomers, and synthetic polymers.

Methanol is the fastest evaporating alcohol. It is the only alcohol that has some solvency for nitrocellulose. Methanol, historically known as wood alcohol, is now rarely used as a solvent because of its relative toxicity.

Pure ethyl alcohol (ethanol) is restricted in use by law to beverages and to scientific and analytical purposes. It cannot be used without a federal government permit. Commercial ethyl alcohol, for solvent and chemical intermediate use, is denatured with any of a large number of government-approved substances to make it unfit for use in beverages. There are close to 100 approved denatured formulations available in both 95 vol % (190 proof) and anhydrous (200 proof) grades. Because of the large multiplicity of grades, ASTM specifications have not been established for ethyl alcohol. Isopropyl alcohol can replace ethyl alcohol in most coating solvent applications.

Butyl alcohols (butanols) differ in volatility and solvency among the four isomers, which are normal, secondary, iso-, and tertiary. All have moderate volatility. Branching increases volatility and decreases solvency. n-Butanol is by far the most widely used isomer. t-Butanol is a solid at room temperature.

The higher-boiling alcohols are used in relatively small amounts in solvent blends, and they find applications mainly in baked industrial coatings.

OTHER OXYGENATED SOLVENTS

Specialty oxygenated solvents include furan solvents and organic carbonates. Currently, they are not specified by ASTM standards. Information about them may be obtained from their suppliers.

Furan solvents of commercial interest include furfuryl alcohol, tetrahydrofuran (THF), and tetrahydrofurfuryl alcohol. These solvents have a cyclic ether structure and are characterized by exceptionally strong solvency for some synthetic resins, especially vinyls.

Ethylene and propylene carbonates are cyclic organic esters, which are good solvents for many organic and inorganic materials. The former is a solid at room temperature. Characteristics of these carbonates include high flash point, very slow evaporation rate, high specific gravity, and very low odor.

Other Solvents

CHLORINATED HYDROCARBONS

Chlorinated solvents contain chlorine atoms in the molecules. This gives them unique features of nonflammability, i.e., most have no flash point, and very high specific gravity. Several chlorinated solvents specified by ASTM standards are summarized in Table 9.

Methylene chloride has long been the active ingredient in many paint removers. It has strong solvency to soften and swell cured paint films and has a very fast evaporation rate.

1,1,1-Trichloroethane (methylchloroform) found solvent applications in coating formulations because it was considered to be nonphotochemically reactive by many regulatory agencies, and therefore did not have to be included in measuring volatile organic compound (VOC) content [1]. However, in the recent Montreal HAZOP accord, it has been banned and is no longer manufactured.

Trichloroethylene is widely used for metal cleaning in vapor degreasing operations. (See ASTM D3698, Practice for Solvent Vapor Degreasing Operations [9].)

Use of chlorinated solvents is declining due to (a) global concerns about their damaging effects on the Earth's protective ozone layer and (b) concerns about the toxicity and carcinogenicity of many chlorinated solvents.

NITRATED HYDROCARBONS

Nitrogen-containing hydrocarbon solvents include nitroparaffins and N-methyl-2-pyrrolidone (NMP). These are not currently specified by ASTM standards.

There are four nitroparaffinic solvents commercially available: nitromethane, nitroethane, 1-nitropropane, and 2-nitropropane (2NP). Of these, 2NP is of most interest to

[a] Specification was withdrawn in 1993.

the coatings industry. It has an evaporation rate similar to that of *n*-butyl acetate, and it is reported to have fast solvent release from coating films.

NMP is a specialty solvent having strong solvency, high flash point, complete water solubility, and high specific gravity. It is reported to be biodegradable and have a low order of toxicity. Applications include paint strippers, water-based coatings, printing inks, and reaction solvent for high-temperature resins.

SUPERCRITICAL CARBON DIOXIDE [10]

It has long been known that certain gases under supercritical temperature and pressure conditions can behave as solvents. They have become useful in a variety of industrial and analytical separation processes, such as extraction, polymer fractionation, chromatography, and catalyst regeneration, and as a reaction medium.

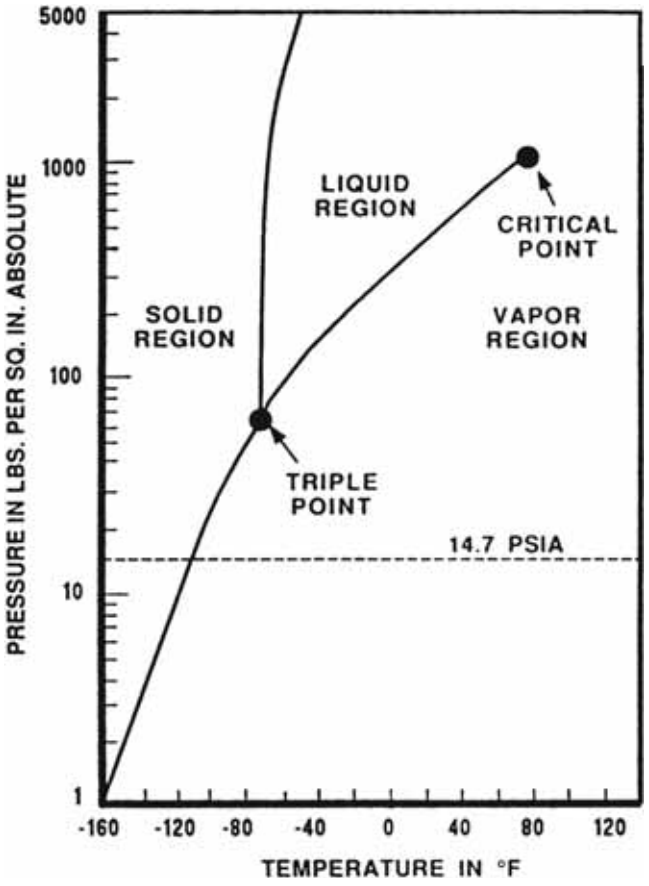

Fig. 1—Phase diagram for carbon dioxide [10].

Supercritical fluids have properties intermediate to those of normal liquids and gases. The supercritical fluid region on a phase diagram corresponds to temperatures and pressures near or above the critical point of the fluid where the properties of the liquid and gas are similar or identical, so that in effect only one fluid phase, which is simultaneously liquid like and gas like, exists (Fig. 1).

Supercritical carbon dioxide has many useful attributes, which make it attractive as a diluent for spray-applied coatings. Carbon dioxide is environmentally compatible because it is not regarded as a VOC. It acts as a hydrocarbon diluent and replaces organic solvents to the extent of 10-30 vol % of a formulation. Low VOC coatings can be formulated with existing high-performance polymer systems, and 70-80 % reductions in VOC are achievable. Using carbon dioxide as a coating solvent effects a net reduction in the amount of "greenhouse" carbon dioxide that is otherwise produced as a result of coating operations.

The UNICARB™[3] process has been developed to utilize supercritical carbon dioxide in airless sprayed coating operations. It has numerous advantages in this application. The temperatures and pressures necessary to use supercritical carbon dioxide are well within the capabilities of present hot, airless spray systems.

Carbon dioxide has low toxicity, is nonflammable, inert, inexpensive, and readily available. Supercritical carbon dioxide has high solubility in most coating formulations, and it is a good viscosity reducer for polymer solutions. In the actual spraying process, it behaves as a highly volatile solvent, producing vigorous atomization that can remedy many of the defects of airless spraying, thereby achieving high quality coatings.

CLASSIFICATION BY FUNCTION

Solvents can be classified according to the function they perform in an end-use application: active solvents, latent solvents, and diluents.

Active Solvents

Active solvents are sometimes called "true solvents." They are the ones that really do the work to dissolve resins and

[3] Union Carbide Corp., a subsidiary of Dow Chemical Co.

other film formers. Active solvents are usually the more expensive ones with strong solvent power: ketones, esters, and glycol ethers. They are essential for dissolving film-forming polymers and for effectively reducing the viscosity of paints, varnishes, and lacquers for application.

Relative solvency of active solvents, particularly for lacquers, may be determined by ASTM D1720, Method for Dilution Ratio of Active Solvents in Cellulose Nitrate Solution [2], and expressed in terms of toluene dilution ratio. Stronger solvents will tolerate more hydrocarbon diluent and still keep resins in solution. High toluene dilution ratio values indicate strong solvency. Typical values for selected active solvents may be compared in Tables 5–7.

Latent Solvents

By themselves, latent solvents are either poor solvents or nonsolvents for most coating resins. However, they possess a hidden or latent solvency that manifests itself when they are used in combination with active solvents. Latent solvents then behave as if they were strong active solvents. This synergism is used to advantage in formulating nitrocellulose lacquers in particular. Latent solvents are often alcohols that are intermediate in cost.

Diluents

Diluents are generally nonsolvents if used alone with synthetic resins. Their function is to participate in solvent blends to provide viscosity reduction through dilution of lacquers and paints and to reduce the cost of thinners and coating solvent blends. Diluents are usually low-cost hydrocarbon solvents.

There is usually a limit to how much diluent will be tolerated by coating resins in a solvent blend. If the limit is exceeded, the resins will start to gel or precipitate from solution. Aromatic hydrocarbon solvents are usually tolerated in greater amounts than are aliphatic hydrocarbons.

ASTM D1720 may be used to determine the relative tolerances for hydrocarbon diluent when *n*-butyl acetate is used as the reference active solvent. In the test, the maximum ratio of hydrocarbon diluent to *n*-butyl acetate that will be tolerated by a solution of 8 g of nitrocellulose in a total of 100 mL of solvent and diluent is determined. This provides a measure of the suitability of the diluent for lacquer solvent fromulations. For example, the toluene dilution ratio of n-butyl acetate is 2.8, while the VM&P naphtha dilution ratio is only 1.2, indicating a much greater tolerance for toluene than for VM&P naphtha.

Solvent Balance

In formulating coating solvents and thinners, careful attention must be paid to the proper balance of solvency and evaporation rate. Generally, expensive active solvents are kept to a minimum amount that is sufficient to provide adequate solvency and viscosity reduction. Diluent content is usually maximized to keep cost low.

Evaporation rate of each component must be considered in selecting appropriate active solvents and diluents depending on the method of coating application. As the applied coatings dry, the balance of active solvents and diluents remaining in the wet coating must be such that solvency for the coating resin remains sufficiently strong throughout the drying process. Otherwise, resin blush, i.e., precipitation or separation of the resin, can occur, resulting in loss of gloss, incompatibility, haze, or other serious coating defects.

KEY PERFORMANCE REQUIREMENTS

Solvency

Solvency is the foremost performance requirement of a solvent. From a practical perspective, the term "solvency" to a coatings formulator refers to the ability of a solvent to (a) dissolve resins, (b) hold those resins in solution in the presence of diluents, and (c) efficiently reduce viscosity of resin solutions, lacquers, and paints. In general, relative solvency is measured indirectly by determining compatibility of specified resins or a chemical reagent with the solvent under test.

Three test methods are most often used for measuring and expressing relative solvent strength: Kauri-butanol value, aniline point, and diluent ratio. The first two test methods are used exclusively for hydrocarbon solvents and the latter test for only oxygenated solvents. Although these methods are somewhat archaic, the values obtained have been found to be useful in estimating general solvency for many coating resins.

Another method, a viscosity reduction test, provides a means of direct measurement of solvent power when a specific resin under consideration is employed. Solvents are directly compared by measuring the viscosities of solutions at different resin concentrations and plotting viscosity versus resin concentration.

KAURI-BUTANOL VALUE

Kauri-butanol value (KBV) is one measure of the solvent power of hydrocarbon solvents. High KBV indicates relatively strong solvency and often relatively high aromatics content as well. Comparative KBVs for selected materials are found in Tables 1–4.

KBV is a continuous scale and is sometimes used as an indicator of aromatics content; low aromatic (aliphatic) hydrocarbons have low KBVs and weak solvency, while highly aromatic hydrocarbons have high KBVs and relatively strong solvency. For example, odorless mineral spirits at the low end of the scale have a KBV of about 27, regular mineral spirits about 37, and aromatic hydrocarbons close to 100.

KBV is defined in ASTM Method D1133, Method for Kauri-Butanol Value of Hydrocarbon Solvents [2], as the volume in milliliters of the solvent at 25°C required to produce a defined degree of turbidity when titrated into a specified quantity of a standard clear solution of kauri resin in *n*-butyl alcohol; Kauri resin, a natural product, now archaic, was once used as a coating polymer. Standard test solutions are available from chemical supply companies. The kauri resin solution is standardized against toluene, which has an assigned value of 105, and a mixture of 75 % *n*-heptane and 25 % toluene on a volume basis has an assigned value of 40.

The procedure is to accurately weigh 20 g of standardized kauri-butanol solution into an Erlenmeyer flask and bring the flask and its contents to 25°C in a water bath. It is then titrated with the solvent being tested to a turbidity end point that occurs when the sharp outlines of ten-point print on a sheet placed under the flask are obscured or blurred but are not illegible. Turbidity at the end point is caused by precipitation of the kauri resin at incipient incompatibility.

This test is not applicable to oxygenated solvents.

ANILINE POINT

Aniline point (or mixed aniline point) is another measure of solvency of hydrocarbon solvents. In addition, it is often used to provide an estimate of the aromatics content of hydrocarbon mixtures. Aromatic hydrocarbons (strong solvents) exhibit the lowest aniline points and aliphatics (weak solvents) the highest. Naphthenes have values between those for aromatics and aliphatics. In homologous series, the aniline point increases with increasing molecular weight, i.e., decreasing solvency.

Aniline point is defined in ASTM Method D611, Aniline Point and Mixed Aniline Point of Petroleum Products and Hydrocarbon Solvents [11], as the minimum equilibrium solution temperature for equal volumes of aniline and solvent. The reagent for this test is aniline, a clear liquid at room temperature. The procedure requires that equal volumes of aniline and hydrocarbon solvent be placed in a jacketed tube and mechanically mixed. The basic apparatus is shown in Fig. 2, although ASTM D611 also describes alternative variations in the manual apparatus and an automatic apparatus as well.

Hydrocarbon solvents containing less than 50 % aromatics will generally form an incompatible, turbid mixture at room temperature [12]. Therefore, the stirred mixture is heated at a controlled rate until the two phases become miscible and clear. The stirred mixture is then allowed to cool at a controlled rate until it suddenly becomes cloudy throughout. The temperature at this end point is recorded as the aniline point of the solvent.

Hydrocarbon solvents containing more than 50 % aromatics will generally form clear, miscible solutions with aniline at room temperature [12]. When this occurs, the stirred mixture must be cooled below room temperature at a controlled rate until the cloudy transition point suddenly appears. The temperature at this cloud point is the aniline point.

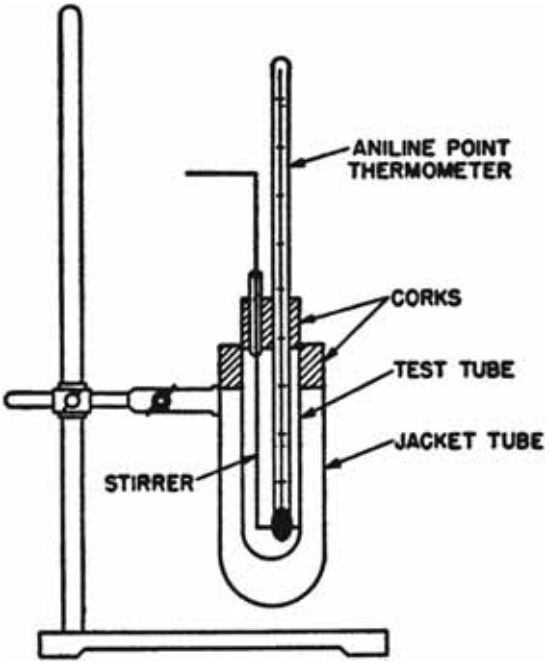

Fig. 2—Basic aniline point apparatus.

With hydrocarbons having high aromatics content, the aniline point may be far below room temperature and below the temperature at which aniline will crystallize from the aniline-sample mixture. To treat this circumstance, it becomes necessary to perform a "mixed aniline point" test. Instead of using equal volumes of aniline and sample, a mixture containing two volumes of aniline, one volume of sample, and one volume of n-heptane of specified purity is made. The test is then performed as described above, and the result is reported as the mixed aniline point. Again, low values indicate strong solvency (the opposite of kauri-butanol values).

Unlike the continuous KBV scale, a disadvantage of the aniline point and mixed aniline point is that the two scales are not continuous. Therefore, it is difficult to directly compare high- and low-aromatic content solvents [12].

This test is not applicable to oxygenated solvents.

DILUENT RATIO

The diluent ratio test measures the solvency of oxygenated (active) solvents by determining their ability to hold in solution a difficult-to-dissolve resin, nitrocellulose, in the presence of hydrocarbon diluent. The test measures the maximum ratio of hydrocarbon diluent to oxygenated solvent that can be tolerated by the nitrocellulose solution. Strong oxygenated solvents provide a high tolerance for diluent and have high diluent dilution ratios. Typical values may be compared in Tables 5–7.

ASTM D1720 defines diluent ratio as the maximum number of unit volumes of a diluent that can be added to a unit volume of solvent to cause the first persistent heterogeneity (precipitation) in the solution at a concentration of 8 g of cellulose nitrate per 100 mL of combined solvent plus diluent at 25°C.

The procedure is to dissolve dried nitrocellulose in the oxygenated (active) solvent, and with stirring, add hydrocarbon diluent by titration. The end point occurs at the first persistent appearance of resin precipitation or gelation. Additional active solvent is then added to redissolve the resin, and titration is continued to a second end point. The data are plotted to determine the ratio of diluent to active solvent at exactly 8 g of cellulose nitrate per 100 mL of total solvent.

Most often, toluene is used as the diluent in the test, and the result is expressed as the "toluene dilution ratio." However, other hydrocarbons, e.g., VM&P naphtha, may also be used, thereby producing different (lower) values expressed as "naphtha dilution ratios." Although cellulose nitrate is used as the "reagent" in this test, and the results are most meaningful for formulating nitrocellulose lacquers, it has been found from experience that the solvency ranking of oxygenated solvents according to their diluent dilution ratios applies to other coating resins as well.

As described in the section entitled "Diluents," ASTM D1720 may also be applied to compare and measure the suitability of specific diluents for use in lacquer solvent and thinner formulations by using *n*-butyl acetate as the reference active solvent in the test.

DILUTION LIMIT

Some resins are soluble at high concentrations in a solvent but become incompatible and precipitate when diluted below a critical concentration, which is termed the dilution

limit. Sometimes, this concentration is within the range of practical formulations. Therefore, it is important to know whether a dilution limit exists for a particular resin. To determine the dilution limit, a known weight of resin is dissolved in the solvent. Solvent is then added until precipitation, the first persistent cloudiness, appears. Dilution limit is expressed as the percent by weight of resin at the end point [12].

VISCOSITY REDUCTION

The relative solvency of different solvents for a given resin may be compared with each other or with a reference solvent by measuring the viscosities of different concentrations of the given resin in each of the solvents. The viscosities are then plotted as a function of resin concentration. An example is shown in Fig. 3 [1].

Viscosities of resin solutions can be measured precisely by ASTM D445, Method for Kinematic Viscosity of Transparent and Opaque Liquids [11], or by ASTM D1725, Method for Viscosity of Resin Solutions [5]. A simpler, more widely used, but less precise, method for determining resin solution viscosities is ASTM D1545, Method for Viscosity of Transparent Liquids by Bubble Time Method (Gardner-Holdt Viscosity) [5].

At high resin concentrations, solution viscosity will depend on solvency of the solvent and solubility of the resin. However, at low resin concentrations, the solution viscosity becomes more influenced by viscosity of the pure (neat) solvent. Viscosities of selected solvents are listed in Table 10 [13].

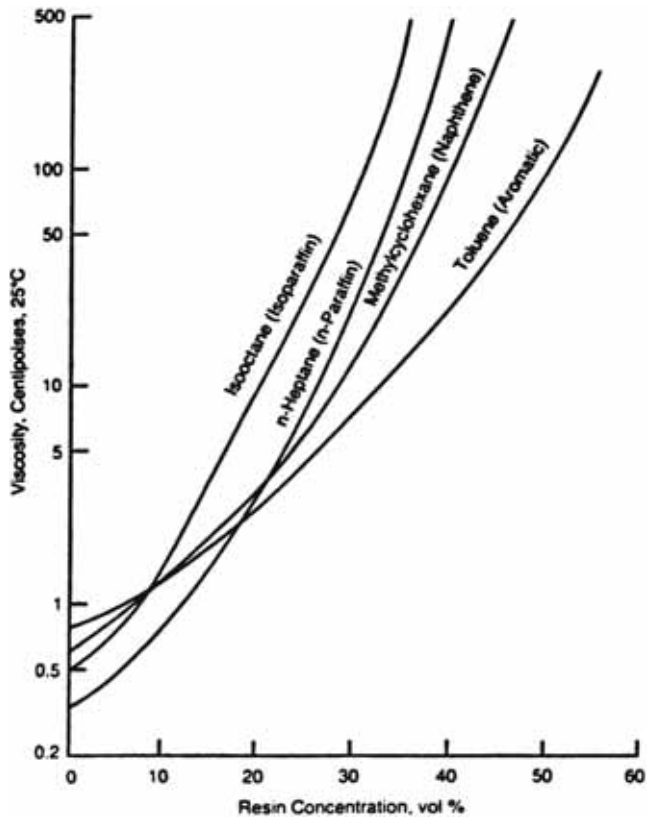

Fig. 3—Effect of solvent type on solution viscosity (medium oil alkyd in four hydrocarbon types) [1].

SOLUBILITY PARAMETERS

Great strides have been made in developing theoretical models to describe solvency and to predict the capacity of a pure solvent or solvent blend to dissolve a given resin. The concept of solubility parameters was first proposed by Hildebrand [14,15], and it was applied to practical

applications in the coatings industry by Burrell [16]. Further refinements and enhancements to the solvency model made by Burrell [17], Crowley [18], Hansen [19,20], and others have resulted in the evolution of a model that is workable, reasonably accurate in its predictions, and useful as a formulating tool.

The three-dimensional solubility parameter is the most widely used method for predicting miscibility/solvency between solvents and polymers. In this method, each polymer and each solvent is characterized by three solubility parameters: δ_d representing dispersion forces, δ_p representing polar forces, and δ_h representing hydrogen bonding forces. Therefore, polymers and solvents can be represented by points in a three-dimensional plot using the three solubility parameters.

Each polymer point may constitute the center of a sphere, the so-called "sphere of solubility," of radius *R*, known as the radius of interaction. Solvents whose points lie at a distance less than *R* from the center of the polymer's sphere, i.e., within the sphere, should dissolve the polymer. Conversely, solvents whose point coordinates lie outside of the sphere are not expected to dissolve the polymer [21]. A more thorough discussion of solubility parameters can be found in Chapter 35 of this manual.

A very comprehensive source of solubility parameter information and data is the "CRC Handbook of Solubility Parameters and Other Cohesive Parameters" by A. F. M. Burton [22]. A simpler, two-dimensional approach to solubility parameters, employing only the dispersion and hydrogen bonding parameters, is described in ASTM D3132, Test for Solubility Range of Resins and Polymers [5]. Most major solvent suppliers have developed computer programs, based on the solubility parameter concept, to aid in formulating solvent blends to optimize solvency, obtain desired performance requirements, and minimize cost.

Volatility

Volatility of a solvent describes its inherent tendency to transform from a liquid to a vapor. The fundamental controlling property is vapor pressure. Volatility is manifested by such properties as evaporation rate, boiling point, and flash point.

VAPOR PRESSURE

All liquids have a tendency to vaporize and become gases, depending upon their relative vapor pressures. A solvent's liquid vapor pressure is the pressure exerted by molecules at the liquid surface in their attempt to escape the liquid phase and penetrate their gaseous environment. In a physical sense, vapor pressure is the force exerted on the walls of a closed container by the vaporized portion of the liquid. Conversely, it is the force that must be exerted on the liquid to prevent it from vaporizing further. For a given liquid solvent, vapor pressure is a function purely of temperature. The more volatile a solvent, the higher the liquid vapor pressure at a specified temperature and the faster the vaporization, i.e., evaporation rate. A knowledge of the vapor pressure/temperature relationship is important in the safe design of solvent storage and distribution equipment to minimize solvent losses by vaporization.

Relative vapor pressures of pure solvents and blends are measured at 100°F (38°C) by ASTM D323, Method for Reid Vapor Pressure (RVP) [11]. The RVP apparatus consists of a double-chamber bomb fitted with a pressure gage. The lower chamber, which has one quarter the capacity of the upper chamber, is filled with the liquid solvent sample. The sample and its chamber are chilled to 0°C (32°F) to reduce premature evaporation, the bomb is sealed, and it is immersed in a 100°F (38°C) water bath. To assure full opportunity for vaporization, the bomb is removed from the bath periodically for a brief vigorous shaking. When an equilibrium temperature is reached and when the bomb pressure gage (which initially registered zero) has stabilized at maximum value, the pressure is recorded. After applying appropriate correction factors, the pressure is reported as the Reid vapor pressure at 100°F (38°C).

Alternatively, vapor pressure of a solvent can be measured over a wide range of temperatures by ASTM Method D2879, Method for Vapor Pressure by Isoteniscope [23]. This procedure utilizes a differential manometer, one leg of which is exposed to saturated vapor while the other is evacuated. Measurements are reported in absolute units. Absolute vapor pressures of selected solvents at 20°C are listed in Table 11 [8,13].

In the last 15 years, the use of automatic instruments for measuring vapor pressure have grown. ASTM D5190, Method for Vapor Pressure of Petroleum Products (Automatic Method) [49]; ASTM D5191, Method for Vapor Pressure of Petroleum Products (Mini Method) [49]; and ASTM D5482, Method for Vapor Pressure of Petroleum Products (Mini-Method-Atmospheric) [49] are all automatic vapor pressure test methods. Although primarily used for gasoline and reformulated gasoline, the performance of the various automatic vapor pressure instruments are checked using pure hydrocarbon liquid materials.

EVAPORATION RATE

Evaporation rate of a solvent is second only to solvency in its importance to the coatings industry. Although solvents are transient ingredients of a coating, they perform vital functions but must ultimately leave the coating film by evaporation. During application of a coating, solvents play a role in controlling flow characteristics as the film forms. If solvent evaporation is too fast, the coating film will not level and flow out to form a smooth surface, the result being a rough, "orange peel" effect in spray-applied coatings, or brush marks if brush applied. Conversely, if solvent evaporation is too slow, the coating may run and sag on vertical surfaces, or solvents may become trapped in the film as it cures, thus impairing performance properties of the coating.

For proper solvent balance, the ratio of active solvent to diluent is important. If this balance becomes upset as a result of composition changes during evaporation, resin precipitation can occur, thereby causing a loss of film integrity. Therefore, solvent evaporation rate is a key factor in the formulation of coatings. Relative evaporation rates of selected solvents of various types may be compared in Fig. 4 and in Tables 1–9.

Evaporation rates of solvents are always expressed on a relative basis. They are not absolute values in practical situations because evaporation rates are dependent upon numerous environmental factors including temperature, airflow, humidity, exposed surface area, and the presence of resin and pigment. Humidity has no effect on the evaporation of hydrocarbon solvents, but it can significantly retard

TABLE 11—Vapor pressures of typical commercial solvents

evaporation of oxygenated solvents, which are completely or partially water miscible.

It is common practice to express evaporation rates relative to *n*-butyl acetate, a widely used, medium-evaporating solvent as a reference. The evaporation rate of *n*-butyl acetate is arbitrarily assigned a value of 100 (or sometimes 1.0 depending on the scale used). Solvents evaporating faster than *n*-butyl acetate have higher values for evaporation rate; while those solvents evaporating slower have lower numerical values. Use of a reference standard compensates for differences in test procedure and environmental factors.

Numerous techniques have been used for measuring relative evaporation rates, some of them gravimetric, some volumetric. The ones currently most widely used are based on a gravimetric procedure and instrumentation (or some variation thereof) described in ASTM D3539, Method for Evaporation Rates of Volatile Liquids by Shell Thin-Film Evaporometer [24]. In this method, a measured volume of liquid solvent is spread on a known area of filter paper that is suspended from a sensitive balance in a controlled environment cabinet. Weight loss of the filter paper/solvent liquid is measured as a function of time as the solvent evaporates.

Early models of the apparatus use a Jolly spring as the gravimetric measuring device and require manual measurement of weight and time (Fig. 5). More recent models employ an electrobalance and automatically record weight loss versus time (Fig. 6). The Shell Thin-Film Evaporometer and the Chevron Research Evapograph operate under similar principles.

The basic procedure with both the manual and automatic instruments is similar. The evaporation chamber and sample are conditioned to 25°C (77°F). Airflow rate (21 L/min) and relative humidity (less than 5 %) in the chamber are set. A filter paper, 90 mm in diameter, is horizontally suspended in the evaporation chamber from the weight-sensing device. The solvent sample (0.7 mL) is added from a hypodermic syringe and distributed over the entire area of the filter paper within a period of 10 s. Data are reported as time in seconds for 10 % solvent weight increments through the evaporation cycle, and they are plotted as percent solvent evaporated versus elapsed time (for example, see Fig. 7)[12,25].

The procedure is repeated using n-butyl acetate as the reference standard. Elapsed time for 90 % evaporation of specimen and standard are determined. Evaporation *rate* of the solvent specimen is calculated as the ratio of 90 % evaporation time for *n*-butyl acetate standard divided by the 90 % evaporation time for the solvent specimen and normalized so that the evaporation rate of *n*-butyl acetate is 100 (or 1.0). The 90 % evaporation time is generally used since some curvature of the plot usually occurs above that data point. Evaporation plots for pure solvents are nearly straight lines. Solvent mixtures or blends produce curved plots, the curvature becoming more extreme as differences in the evaporation rates of individual blend components become greater. Several solvent suppliers have developed computer programs to model and predict evaporation rates of solvent blends [26–30].

The information presented so far has dealt with the evaporation of neat (pure) solvents. The presence of resin solute, e.g., in a lacquer or paint, retards solvent evaporation, as illustrated in Fig. 8. In addition, some solvents are preferentially retained more than others by certain polymers due to solvent/polymer interactions arising from factors such as polarity and hydrogen bonding.

As solvent evaporation from a coating film progresses, it slows down markedly. The evaporation rate-limiting factor changes from neat solvent volatility to diffusion through

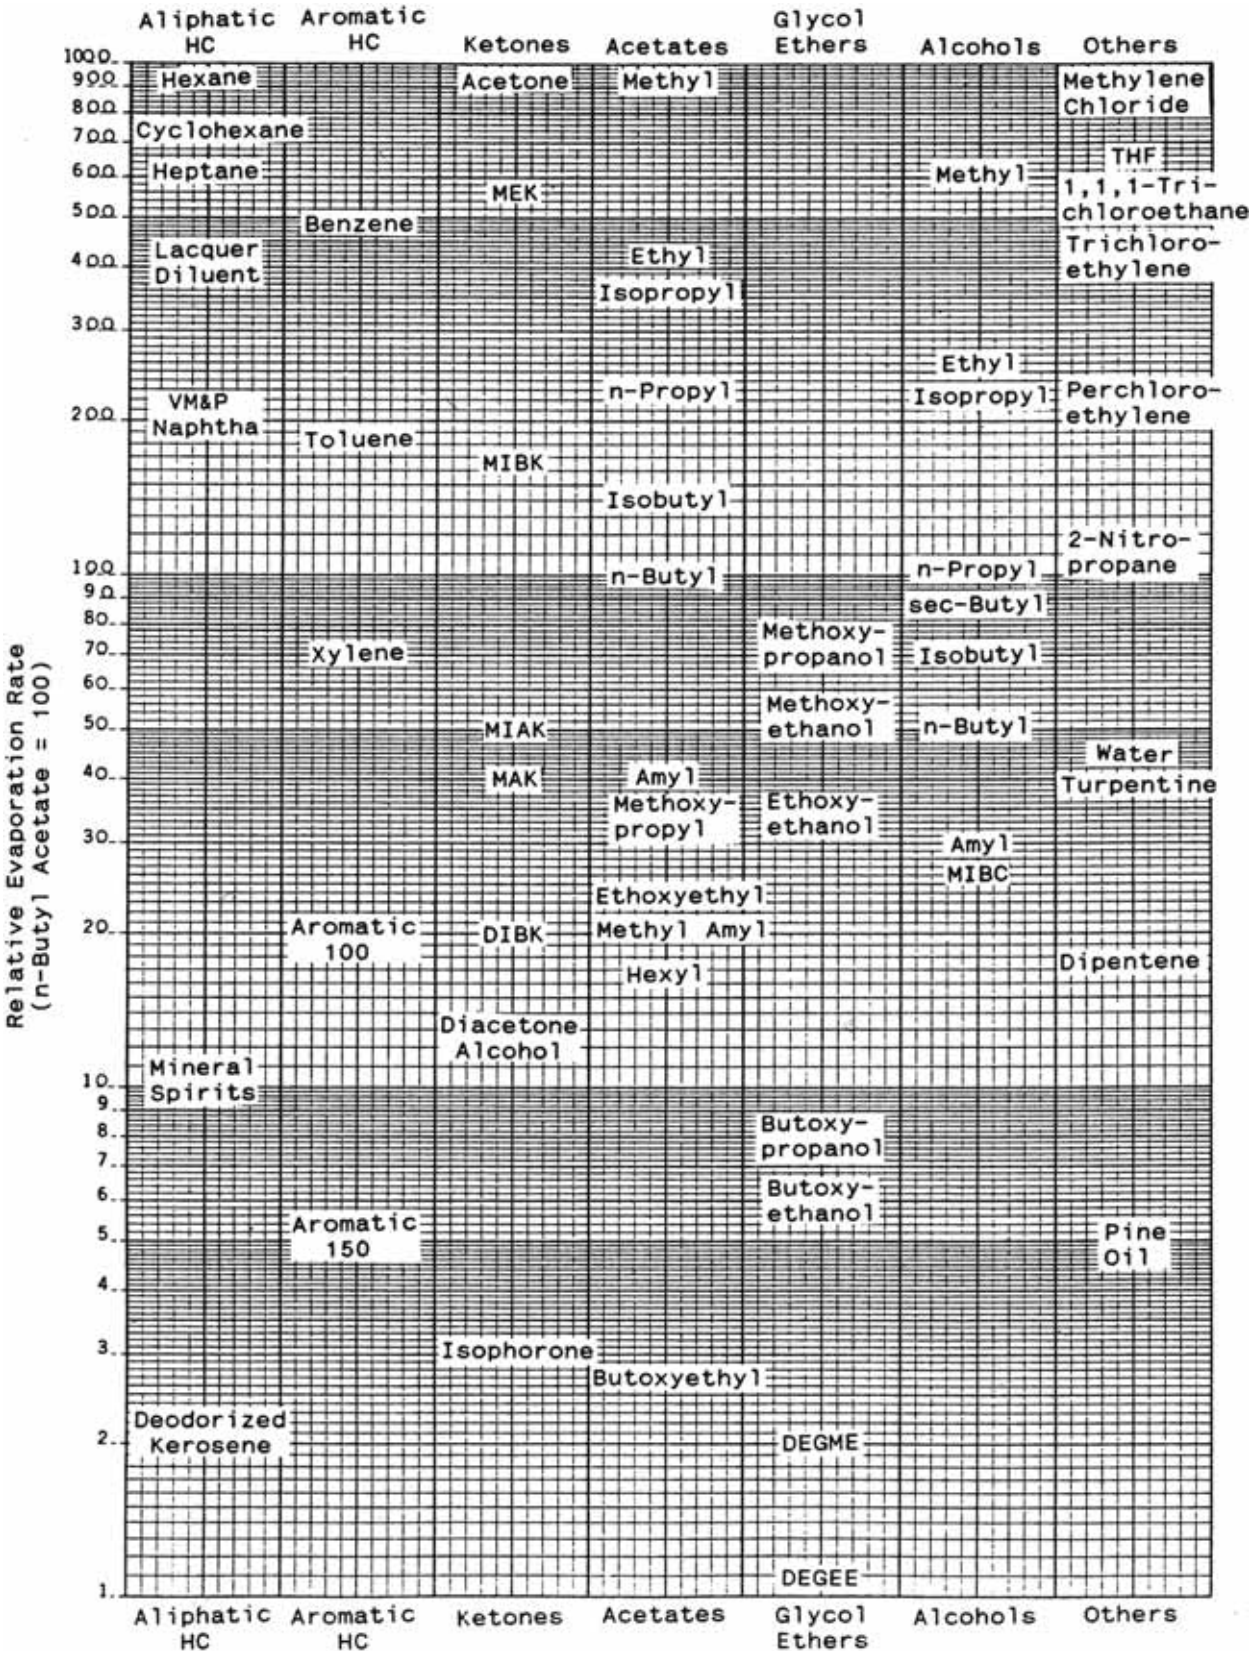

Fig. 4—Relative solvent evaporation rates.

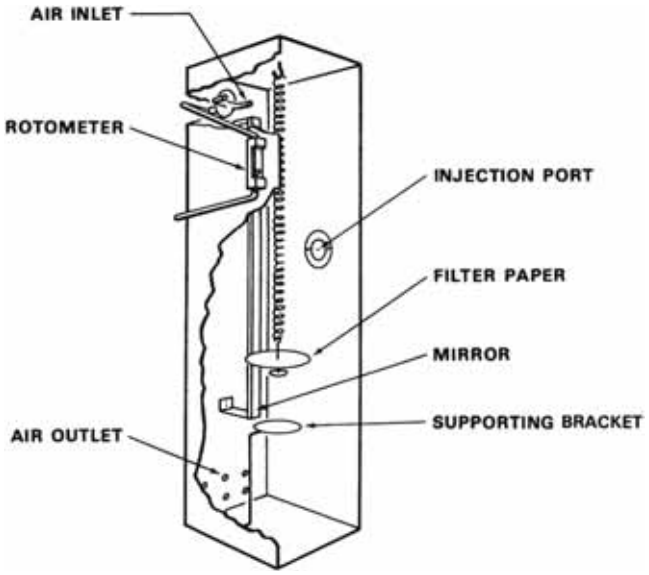

Fig. 5—Thin-film evaporometer.

Fig. 6—Automatic thin-film evaporometer.

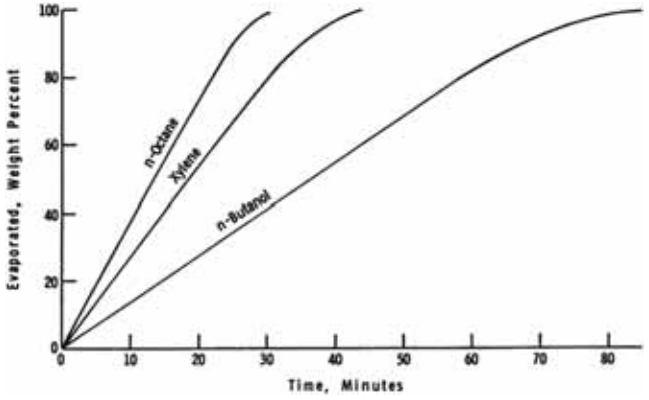

Fig. 7—Evaporation rates of typical solvents (Chevron Research Evapograph at 80°F).

the coating film. Diffusion-limited evaporation is much slower [31].

Actual evaporation of solvents from polymer films must be determined empirically. Although there are no standard test methods for doing so, various experimental procedures are reported in the literature [12]. Murdock

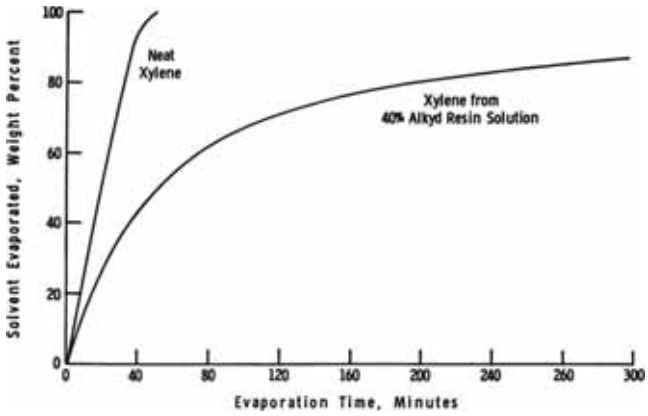

Fig. 8—Evaporation rate of xylene Neat, and from a 40 % solution of medium oil alkyd (Chevron Research Evapograph at 80°F).

and Wirkus [32], as well as Hays [33], tagged solvents with carbon-14 and measured residual radioactivity after the bulk of the solvent had evaporated. More recently, gas chromatography has been used effectively. Sletmoe modified a Shell thin-film evaporometer to permit sampling and subsequent analysis of evaporating vapor [34]. Lesnini evaporated the solvent from a series of solution aliquots and used a gas chromatograph to determine the type and amount of solvent remaining [35]. He dissolved the resin solution in a carrier solvent to ensure that a representative sample of the retained solvent was recovered for analysis.

A similar empirical procedure was used by a major solvent supplier to develop a database and appropriate algorithms for a solvency/evaporation rate computer program [36,26]. The program models solvency and evaporation rates of solvent blends from coating films, taking into account specific resin/solvent interactions. It calculates evaporation data for solvent blends evaporating from coating films and the compositions and solvency interaction radii of the solvent blends remaining in the film at any time.

BOILING POINT/DISTILLATION RANGE

Vapor pressure of a solvent increases as its temperature increases, as illustrated in the generalized graph in Fig. 9. If a solvent is heated to a high enough temperature, its vapor pressure will eventually rise to a value equal to 1 atm (e.g., 760 mm mercury pressure at sea level). At that point, the solvent will vaporize not only from the surface of the liquid, but vapor bubbles will form within the body of the liquid. This phenomenon is called "boiling," and the corresponding temperature at which it initially occurs is the "boiling point" [37]. When a solvent consists of a mixture of chemical components, as is the case with most hydrocarbon solvents, boiling occurs over a range of temperatures referred to as the "boiling range" or "distillation range." Single-component, pure solvents have single, unique boiling points or very narrow distillation ranges.

Distillation temperature or range is an important physical property, which is listed in all solvent specifications. It is useful as an identification test (in combination with other tests, such as specific gravity), but will not differentiate between solvents of similar boiling point or range. Distillation range also gives an indication of solvent purity. This is particularly true for oxygenated solvents,

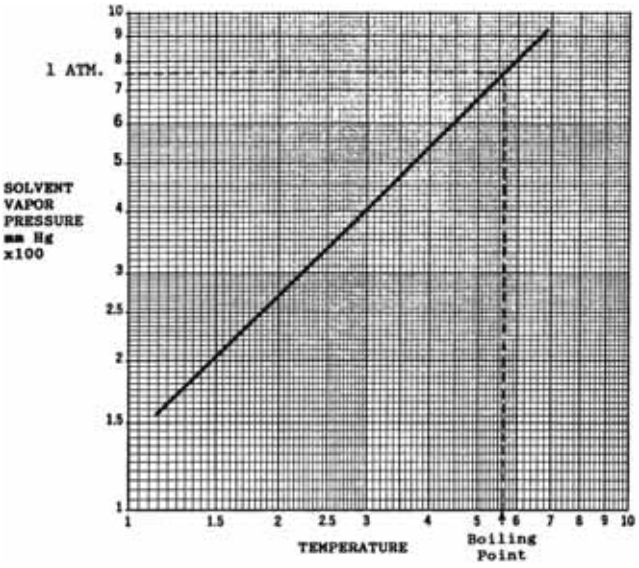

Fig. 9—Solvent vapor pressure versus temperature (idealized representation) [37].

which are relatively pure compounds. The more narrow the distillation range, the more pure is the solvent. Therefore, it is a useful test for detecting the presence of impurities or contaminants.

In addition, distillation temperature may be used to approximate the relative evaporation properties of one solvent versus another, although it does not provide precise information about evaporation rate. Evaporation/distillation temperature comparisons should not be made between dissimilar types of solvents since such predictions would be erroneous. However, for similar types of solvents, distillation data can be used effectively as a first approximation or gross measure of relative evaporation rate. For hydrocarbon solvents, the 50 % distillation point (i.e., the temperature at which 50 % of the solvent has distilled) has been found to have a good correlation with evaporation rate [12].

The McArdle-Robertson evaporation index is based on the 50 % distillation temperature [38]. It is intended primarily to apply to straight-run paraffinic naphthas having distillation ranges of not more than 40°C and to compare their relative evaporation times.

There are three ASTM distillation test methods, which are used for different kinds of solvents:

1. ASTM D86, Method for Distillation of Petroleum Products [11], is intended to be used for wide-boiling hydrocarbon solvents such as VM&P naphthas and mineral spirits.
2. ASTM D850, Method for Distillation of Industrial Aromatic Hydrocarbons and Related Materials [2], is in tended for narrow-boiling aromatic solvents such as toluene, ethylbenzene, and xylenes.
3. ASTM D1078, Method for Distillation Range of Volatile Organic Liquids [2], is intended for narrow-boiling solvents, oxygenated solvents in particular, and also for certain hydrocarbon solvents, chlorinated solvents, and others.

The same solvent sample, tested by each of the three ASTM methods, may produce different distillation data due to variations in the equipment and procedures. It is important, therefore, when presenting distillation data or solvent specifications, to indicate the test method used.

The basic test procedure described in all three test methods is similar, although there are differences as noted in Table 12. The sample is heated in a glass distillation flask until it boils. Solvent vapors are cooled and condensed by passing them through a jacketed, water-cooled tube. Condensate is collected in a calibrated receiver. Distillation temperatures are read from a thermometer immersed in the vapor in the neck of the distillation flask. Distillation temperatures are usually recorded at the initial boiling point, and when 5, 10, and each additional 10 % up to 90 %, and 95 % of the sample have distilled over, and at the dry point. Observed distillation temperatures are corrected to standard barometric pressure. Typical distillation temperatures of selected commercial solvents are listed in Tables 1–9.

The basic assembly of the manual distillation apparatus is illustrated in Fig. 10. Automatic distillation equipment (Fig. 11) employing the same basic principles is available. The automatic equipment uses a thermocouple or RTD probe for temperature measurement, and an automatic moving photocell sensing device to measure liquid level in the receiver. Required distillation rate is also accurately controlled in automatic apparatus compared to manual units. In older versions of automatic distillation apparatus,

TABLE 12—Comparison of ASTM distillation test methods for solvents

Sample Type	ASTM D86, Wide-Boiling Hydrocarbons	ASTM D850, Narrow-Boiling Aromatics	ASTM D1078, Narrow-Boiling Oxygenated (and others)
Sample size, mL	100	100	100

[a] Varies depending on boiling point and range of sample.			

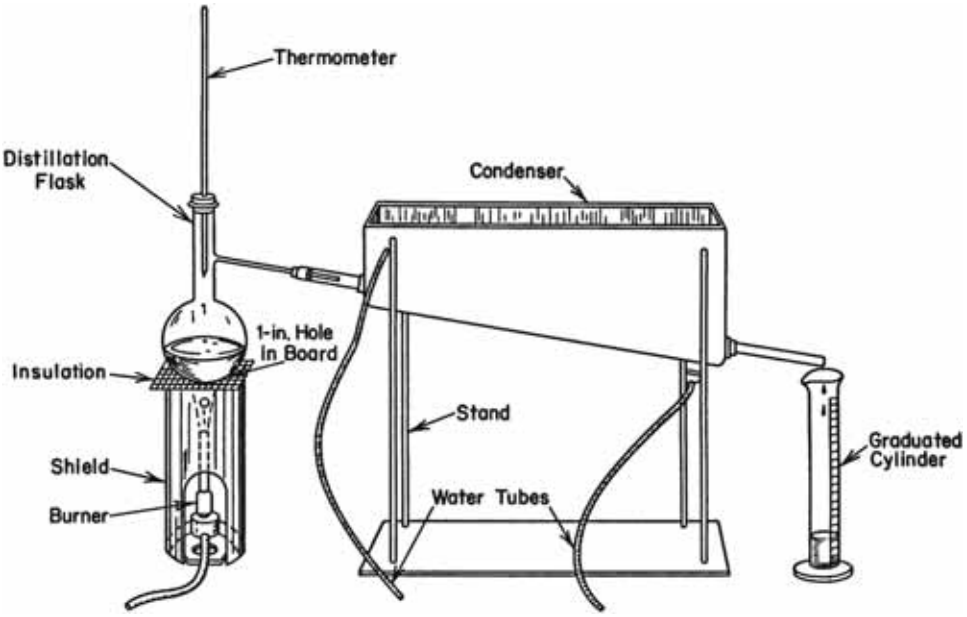

Fig. 10—Manual apparatus assembly for distillation test.

a recorder charts the volume of distillate recovered versus temperature. However, in current models of automatic units, distillation results are reported automatically by data processors. The distillation curve can be reported if desired. Automatic barometric pressure correction is available in most models of automatic distillation apparatus.

There are specific terms to describe key temperatures in all ASTM distillations:

1. *Initial boiling point*—The temperature indicated by the distillation thermometer at the instant that the first drop of condensate falls from the condenser tube into the receiver.
2. *Dry point*—The temperature indicated at the instant that the last drop of liquid evaporates from the lowest point in the distillation flask.
3. *End point, final boiling point,* or *maximum temperature*—The maximum thermometer reading obtained during the test. This usually occurs after the evaporation of all liquid from the bottom of the distillation flask. If there are "heavies" in the sample, and there is no clean dry point, the end point is taken as the thermometer reading 5 min after the 95 % distillation point.
4. *Decomposition Point*—The temperature reading that coincides with the first indication of decomposition of the liquid in the flask. Decomposition, if it occurs, is evidenced by smoke and fumes in the flask; the temperature ceases to rise and begins to fall.

Two common sources of error or bias in distillation data are (a) improper placement of the thermometer in the distillation flask and (b) failure to make appropriate corrections for barometric pressure. The thermometer must be positioned exactly as shown in Fig. 12. Higher placement will result in consistently lower temperature readings; lower placement may give higher readings.

Fig. 11—Typical automatic distillation apparatus (Courtesy of Petroleum Analyzer Co.).

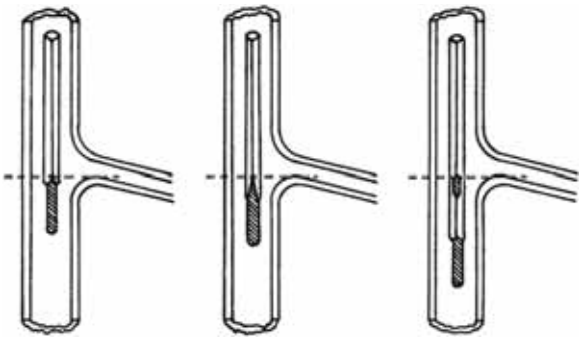

Fig. 12—Position of thermometer in distillation flask.

Distillation temperature readings must be corrected for deviations from standard sea-level barometric pressure. Otherwise, tests run at high altitude or low barometric pressure will result in inaccurate, low distillation temperatures, while high barometric pressure will cause high distillation temperatures. Correction factors appropriate for specific solvents are listed in the ASTM test methods.

FLASH POINT

Flash point is another indicator of volatility. The flash point of a liquid is defined as the lowest temperature at which the liquid gives off enough vapor to form an ignitable mixture with air to produce a flame when a source of ignition is brought close to the surface of the liquid under specified conditions of test at standard barometric pressure (760 mmHg, 101.3 kPa). Appropriate corrections must be made for barometric pressure deviations from standard pressure since flash point is dependent on vapor concentration, which is governed by vapor pressure.

Similar to the vapor pressure/temperature relationship, solvent vapor pressure *concentration* in air is also a function of temperature, as shown in the generalized illustration in Fig. 13 [37]. At low temperatures, there is insufficient vapor concentration (fuel) available to ignite and produce a flame. In this temperature region, below the flash point temperature, the solvent vapor cannot be ignited by a spark, gas flame, or other ignition source.

As the temperature of the solvent is gradually increased, there is an accompanying increase in vapor concentration above the surface of the liquid. At a certain temperature, there will be sufficient vapor (fuel) to form a flammable (or explosive) mixture, and a flame is observed if a spark, a gas flame, or ignition source is introduced. The temperature of the liquid at this point is called the "flash point," and the concentration of vapor at this temperature is called the "lower flammable limit" or "lower explosive limit" (LEL). Typical flash points of selected commercial solvents are listed in Tables 1–8.

At temperatures above the flash point, a flammable mixture of solvent vapor and air is present above the surface of the solvent. While the flash point represents the lower temperature limit for ignition, there is also an upper limit beyond which the vapor/air mixture is too rich to ignite and burn. The vapor concentration at the upper temperature limit is called the "upper flammable limit" or "upper explosive limit" (UEL). *It must be emphasized that these phenomena apply only to equilibrium, closed systems.* For hydrocarbon solvents, the LEL is usually about 1 vol % solvent vapor in air, and the UEL is about 7 vol %, but for oxygenated solvents, these values can vary over a wide range.

Flash point is one indicator of the relative flammability hazard of solvents and solvent-containing products. Within the United States, the U.S. Department of Transportation (DOT) and the U.S. Department of Labor (OSHA) designate "flammable liquids" as those having flash points below 100°F (38°C) [39]. These require special packaging and handling. International cargo regulations specify a 140°F (60°C) flash point as the upper limit for flammable liquids. In addition to being used to classify materials in government regulations, flash point limits are often listed as one of the requirements in solvent specifications and for hydrocarbon solvents in particular. Flash point may also be used to indicate the presence of impurities or contaminants in a

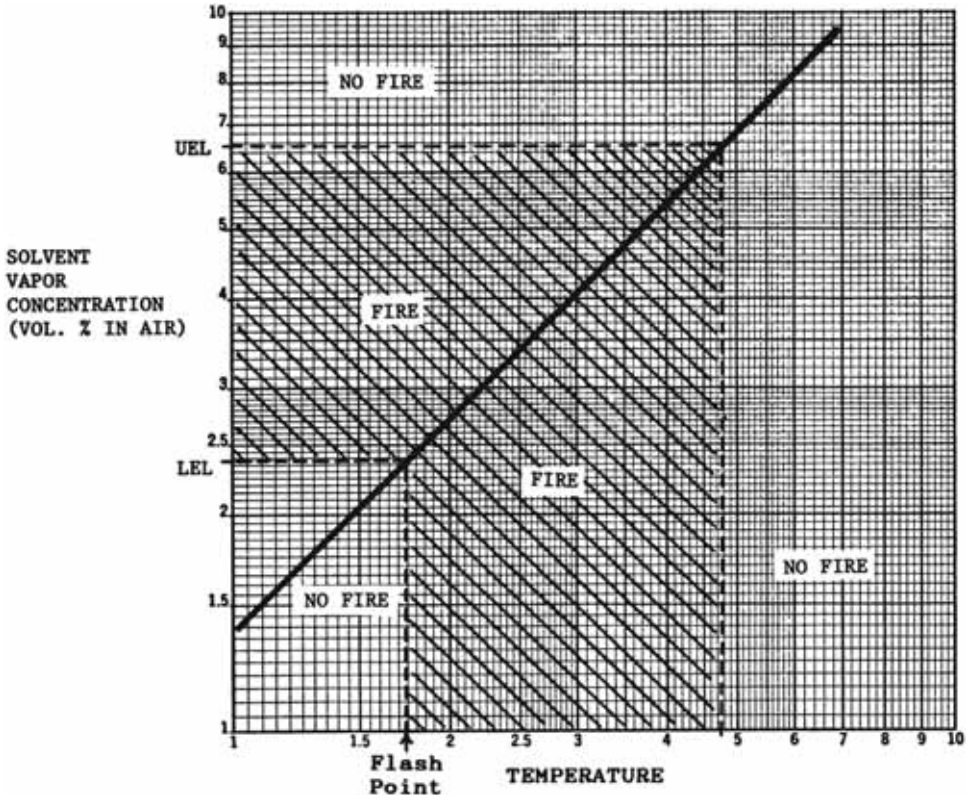

Fig. 13—Solvent vapor concentration versus temperature (idealized representation) [37].

given liquid, such as the presence of residual solvents in solvent-refined drying oils.

Flash point is roughly inversely proportional to volatility. The most volatile solvents tend to have the lowest flash points, which are indicative of the greatest fire hazard. With mixtures of miscible solvents, the component having the lowest flash point largely determines the flash point of the mixture when that component is present in substantial proportion, e.g., 5 % or more. Mutually miscible mixtures of flammable/nonflammable liquids exhibit a direct, though often complex, relationship between flash point and the concentration of the flammable component, e.g., alcohols and water.

Chlorinated solvents, most of which are nonflammable, will have various effects in mixtures with flammable solvents. Some will suppress (i.e., raise or prevent) the flash point of flammable liquids because of the high vapor pressure of the nonflammable chlorinated solvent. Some mixtures of chlorinated solvents and flammable liquids will lower the flash point below that of the flammable liquid, e.g., mineral spirits and methylene chloride [40].

It is good practice to actually measure the flash point of solvent blends because of the uncertainty of making predictions. There are several test methods commonly used.

Tag Open Cup—ASTM D1310, Method for Flash Point and Fire Points of Liquids by Tag Open-Cup Apparatus [24], may be used for determining the *open cup* flash points of liquids having flash points between zero and 325°F (–18 and 165°C). The sample is cooled to at least 20°F (11°C) below the expected flash point, and it is placed in an uncovered cup jacketed by a heat transfer fluid. The sample cup is filled to a depth of approximately 1/8 in. below the rim of the sample cup, and it is heated at a slow, constant rate. Temperature is measured by a thermometer immersed in the sample. A small test flame is passed at a uniform rate across the surface of the cup at 2°F (1°C) intervals of temperature rise until a flash of flame is observed. The sample temperature corresponding to the instantaneous propagation of a flame across the surface of the sample is the flash point. Fig. 14 shows a graphical sketch of a Tag open-cup flash point tester.

"Fire point" can be determined with the same apparatus by continuing the test. Fire point is defined as the lowest temperature at which sustained burning of the sample takes place for at least 5 s.

Although the Tag Open-Cup Flash Point test may appear to represent real-life situations of open containers or accidental solvent spills, the test results could be misleading, especially for solvent blends. As the sample is slowly heated, the lightest, most volatile component in the blend may escape without being ignited. Therefore, *closed-cup* test methods are now preferred by most regulatory agencies.

Tag Closed Cup—ASTM D56, Method for Flash Point by Tag Closed-Cup Tester, uses an apparatus that confines solvent vapors in a closed-cup apparatus (manual unit is shown in Fig. 15). It is intended for testing liquids (a) which contain no suspended solids, (b) which do not form a surface film under test conditions, (c) with viscosities below 9.5 mm^2/s (cSt) at 77°F (25°C) or below 5.5 mm^2/s (cSt) at 104°F (40°C), and (d) with flash points below 200°F (93°C).

The 50 mL sample, cup, and heat transfer fluid in the cup jacket are cooled to 20°F (11°C) below the expected

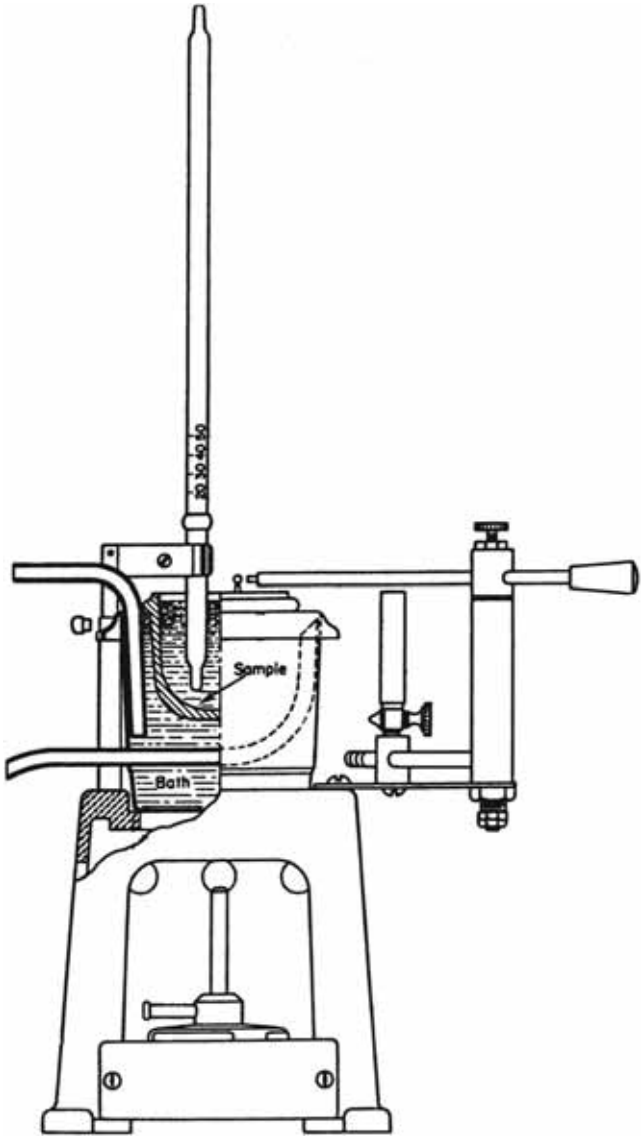

Fig. 14—Tag open-cup flash point tester.

flash point. With the cup lid closed, the sample is heated at a specified slow, constant rate, as measured by a thermometer immersed in the sample. A small test flame of specified size is momentarily directed into the cup through an opening in the lid that is simultaneously opened at regular intervals of temperature rise; after each 1°F (0.5°C) for samples with flash points below 140°F (60°C) or 2°F (1°C) for samples with flash points above 140°F. The flash point is taken as the lowest temperature at which application of the test flame causes the vapor in the cup to ignite.

The advent of automatic Tag closed-cup flash point testers, which can provide more accurate heating rate control and automatic detection of flash points, has led to a movement away from the manual apparatus. Flash point detection mechanisms other than visual observation, such as flame ionization and temperature differential, provide more efficient measurement of flash points. Some automatic instruments also correct for barometric pressure automatically. An example of a typical automatic Tag closed-cup flash point tester is shown in Fig. 16. There are newer models of Tag closed-cup flash point tester utilizing

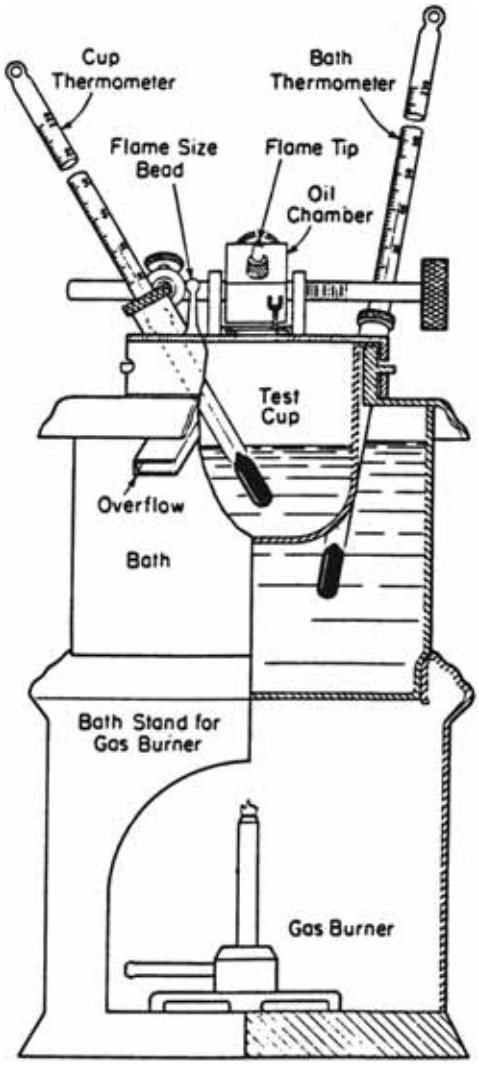

Fig. 15—Manual Tag closed-cup flash point tester.

Peltier technology for cooling samples and can determine flash points to lower temperatures.

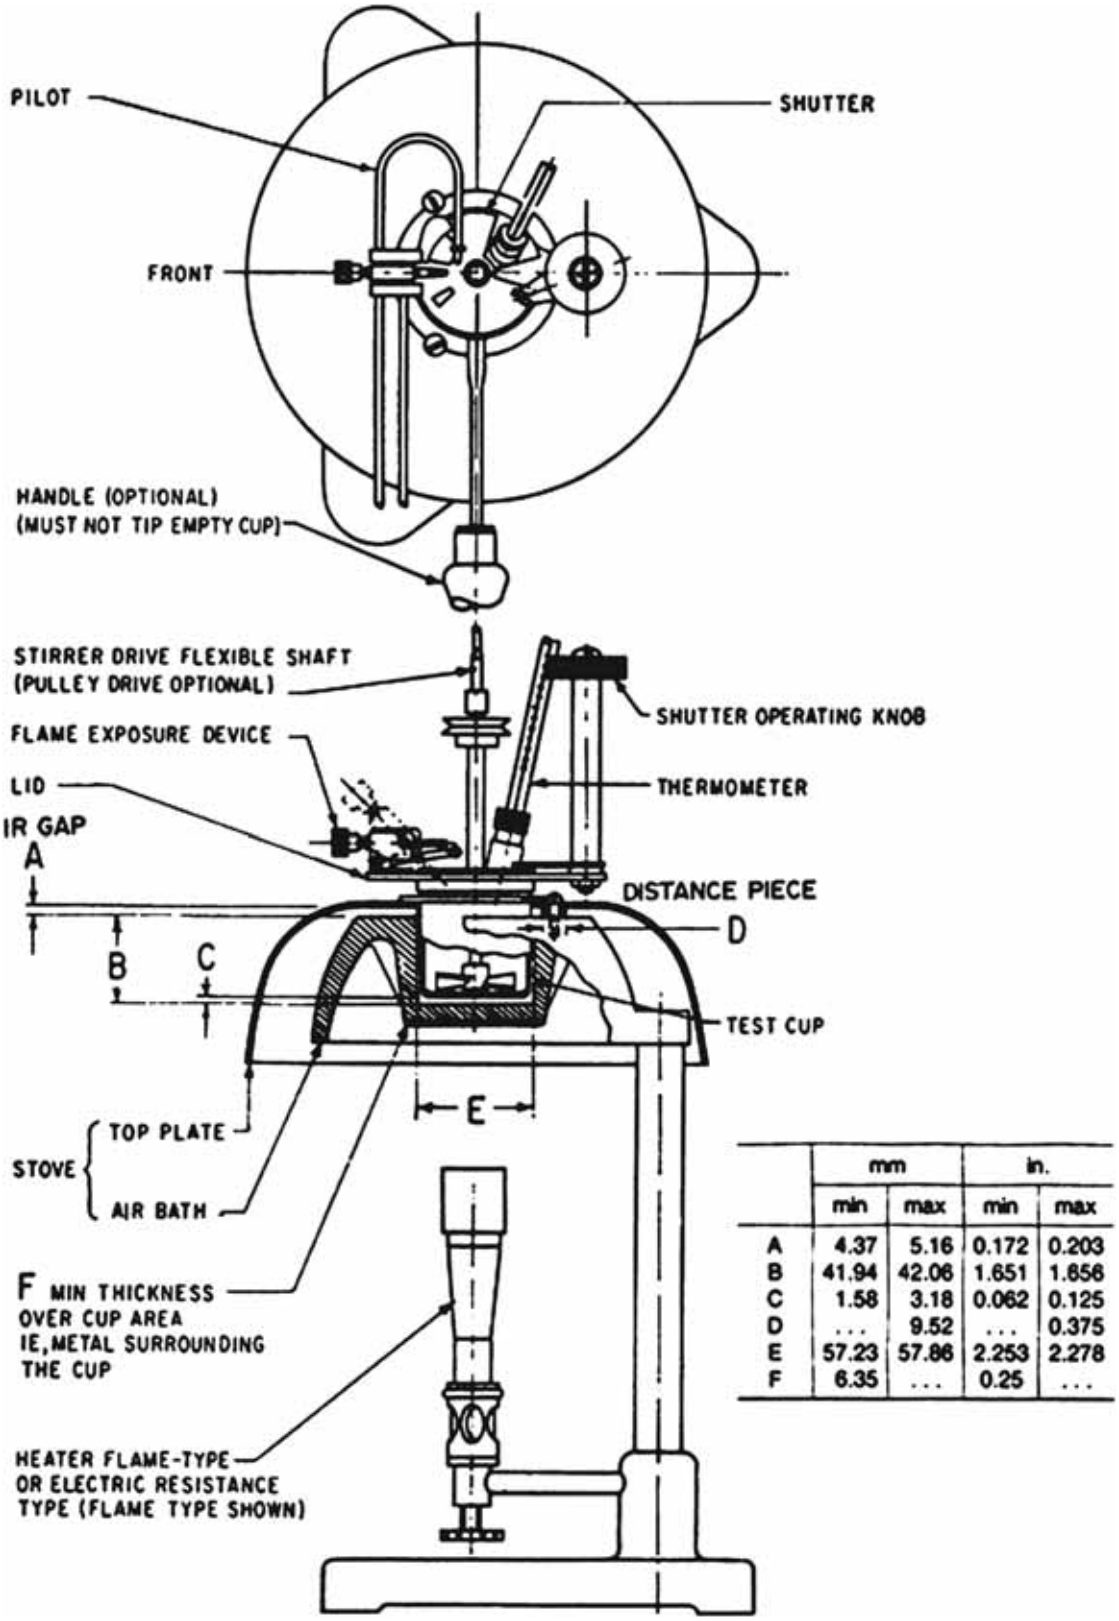
Pensky-Martens—ASTM D93, Method for Flash Point by Pensky-Martens Closed-Cup Tester [11], is used for the measurement of flash points of homogeneous liquids as well as for viscous liquids, suspensions of solids, and liquids that tend to form a surface film under test conditions.

Fig. 16—Typical automatic Tag closed-cup flash point tester (Courtesy of Petroleum Analyzer Co.).

It differs from the Tag Closed-Cup Test in that (a) it employs an air bath device instead of a liquid jacket around the test cup, and (b) the sample is mechanically stirred during the test (Figs. 17 and 19). This test method is particularly suited for samples such as resin solutions, paints, varnishes, lacquers, printing inks, and certain adhesives. Materials with flash points as high as 698°F (370°C) can be tested.

The sample and test cup are first brought to a temperature of 60°F (15°C) or 32°F (18°C) below the expected flash point, whichever is lower (see test method for exact details). The sample is then heated at a slow, constant rate with continual stirring to provide uniform temperature throughout and to prevent formation of a surface film, which would otherwise retard solvent vaporization. A small test flame is momentarily directed into the cup through a shuttered opening in the lid at regular temperature intervals with simultaneous interruption of stirring. The flash point is the lowest temperature at which application of the test flame causes vapor in the cup to ignite.

Automatic Pensky-Martens closed-cup testers have gained popularity over the manual equipment. A typical example of an automatic Pensky-Martens flash point tester is shown in Fig. 18. More accurate heating rate control, and unattended flash point detection are advantages of the automatic apparatus. Some automatic apparatus correct for barometric pressure automatically (Fig. 19).



Small-Scale—ASTM D3278, Method for Flash Point of Liquids by Small-Scale Closed-Cup Apparatus [24] (formerly known as Setaflash), describes procedures for (a) determining whether a material does or does not flash at a specified temperature, or (b) determining the lowest finite temperature at which a material does flash. The procedures are applicable to paints, enamels, lacquers, varnishes, and related products having a flash point between 32 and 230°F (0 and 110°C) and viscosity lower than 150 St at 77°F (25°C). These test methods are similar to international standards ISO 3679 and ISO 3680. The Small-Scale apparatus requires only a 2 to 4 mL sample instead of 50 to 70 mL (Figs. 20 and 21).

To perform a "flash/no flash" test, 2 mL of sample is introduced by means of a syringe through a leakproof entry port into the tightly closed Small Scale tester or, with very viscous materials, directly into the cup that has been brought to the required test temperature. As a flash/no flash test, the expected flash point temperature may be a specification or other operating requirement. After 1 min, a test flame is applied inside the cup and note is taken whether or not the specimen flashes. A fresh specimen must be used if a repeat test is necessary.

For a finite flash point measurement, the temperature is sequentially increased through the anticipated range, the test flame being applied at 9°F (5°C) intervals until a flash is observed. A true determination is then made using a fresh specimen, starting the test at the temperature of the last interval before the flash point of the material and making tests at increasing 1°F (0.5°C) intervals.

Semi-automatic Small-Scale testers are now available (Fig. 21).

Equilibrium Flash Point—The Tag Closed-Cup and Pensky-Martens flash point test methods depend on a definite rate of temperature increase to control the precision of the test method. However, the rate of heating may not in all cases give the accuracy expected because of the low thermal conductivity of some liquids such as paints, resin solutions,

	mm		in.	
	min	max	min	max
A	4.37	5.16	0.172	0.203

D	...	9.52	...	0.375
E	57.23	57.86	2.253	2.278
F	6.35	...	0.25	...

Fig. 17—Manual Pensky-Martens closed-cup flash point tester.

and related viscous materials. To reduce this effect, ASTM D3941, Method for Flash Point by the Equilibrium Method with a Closed-Cup Apparatus [24], uses a slow rate of heating to allow temperature equilibrium between the vapor and the sample specimen.

The specimen is heated in a closed cup of standard design in a suitable water bath at a rate of 1.0°F (0.5°C) in not less than 1.5 min so that the difference in temperature between the specimen in the cup and the bath never exceeds 3.5°F (2.0°C). Flash determinations are made at

Fig. 18—Typical automatic Pensky-Martens closed-cup flash point tester (courtesy of Petroleum Analyzer Co.).

intervals of not less than 1.5 min. Since the specimen is heated at a reduced rate, a longer time interval between each determination is necessary to re-establish the temperature equilibrium of vapor in the air space above the specimen after each flash test.

Equilibrium Flash/No Flash—ASTM D3934, Method for Flash/No Flash Test—Equilibrium Method by Closed-Cup Apparatus [24], does not determine a finite flash point, but it verifies whether or not flashing occurs at a single

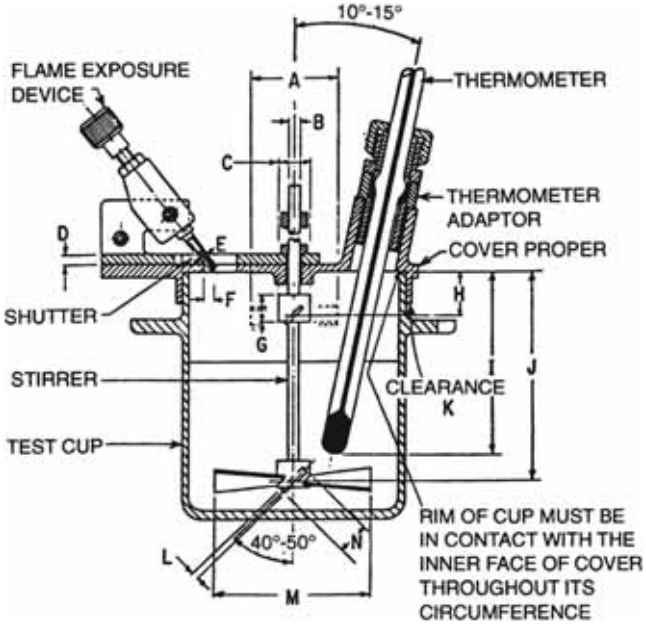

Fig. 19—Pensky-Martens flash point test cup and cover assembly.

Fig. 20—Manual small-scale (Setaflash) flash point tester.

specified temperature, which may be a product specification or agency requirement. The determination is made more accurate by ensuring that the flash test is carried out only when the material under test and the air/vapor mixture above it are in approximate equilibrium at the specified temperature.

Standard closed cups are used, i.e., Tag, Pensky-Martens, or Setaflash, and this test is run such that the air/vapor space above the specimen to be thermally equilibrated with the specimen before the test flame is applied. The specimen is held at the specified temperature for at least a 10 min period before the test flame is applied. This test method does not provide for the determination of the actual flash point, but only whether a specimen does or does not flash at a specified temperature.

Continuously Closed-Cup Flash Point—a new automatic flash point measurement method using pressure differential detection mechanism is described in ASTM D6450, Method for Flash Point by Continuously Closed-Cup (CCCFP) Tester [50]. Only 1 mL sample is required for the test, and an arc of defined energy is used as the ignition source. The specimen and the cell temperatures are brought to 18°C below the expected flash point. The temperature is increased at a prescribed rate and the ignition source is introduced at 1°C interval. The sudden change in pressure within the specimen cell when the flash point is reached is used as the mechanism for flash point detection. Not much data is known in the use of this test method for paints and coatings, but it should be applicable to resin solutions, paints, solvents, varnishes, and similar materials.

PHYSICAL PROPERTIES

Density and Specific Gravity

SIGNIFICANCE

Specific gravity is an inherent property that is listed as a requirement in most solvent specifications and is often used to set specifications. It is a good, simple, qualitative test when used with other tests can establish or confirm the identity of a solvent. In addition, it is useful for quality control, to provide a check on product uniformity, and to detect gross contamination.

Accurate specific gravity values are essential for the calculation of the volume occupied by a product whose weight is known or of the weight of a product when the volume is known. This information is necessary for accurately surveying large shipments of materials by vessels, barges, railroad tank cars, or tank trucks to calculate costs and freight rates, and for inventory measurement and control.

It is customary to buy and sell hydrocarbon solvents on a volumetric basis (e.g., gallons, liters), converting measured values to volume at a standard temperature of 60°F (15.56°C). International transactions, however, are made on a gravimetric basis (e.g., metric tons) calculated at a standard 15°C temperature.

For oxygenated and other solvents, commercial transactions are customarily made on a gravimetric basis (e.g., pounds, kilograms, tons) converting measured values to weight at a standard temperature of 20°C (68°F). However, there is a trend toward changing the standard temperature to 25°C (77°F).

Finally, a knowledge of specific gravities of solvents and other paint components is important for the formulation of paints, varnishes, and lacquers. It is often necessary to make conversions between weight and volume bases and to calculate parameters such as pounds per gallon or kilograms per liter.

Typical specific gravities of selected commercial solvents are listed in Tables 1–9.

DEFINITIONS

The terminology relating to density and specific gravity is often confusing: Density and apparent density, specific gravity and apparent specific gravity, and mass and apparent mass versus weight. Definitions for these terms as they are applied in ASTM standards are contained in ASTM E1547, Terminology Relating to Density and Specific Gravity of Solids, Liquids, and Gases [41]. Key definitions pertaining to liquid solvents are as follows.

density—the mass of a unit volume of a material at a specified temperature. The units shall be stated, such as grams per milliliter, grams per cubic centimeter, pounds per cubic foot, or other. The form of expression shall be

"density at *x*"

where *x* is the temperature of the material.

density, apparent—the weight in air of a unit volume of a material at a specified temperature. The units shall be stated. The form of expression shall be

"apparent density at *x*"

where *x* is the temperature of the material.

specific gravity—the ratio of the mass of a unit volume of a material at a stated temperature to the mass of the same volume of gas-free distilled water at a stated temperature. The form of the expression shall be

"specific gravity *x*/*y*°C"

where *x* is the temperature of the material and *y* is the temperature of the water. The term "relative density" with the same meaning as specific gravity is becoming more widely used than "specific gravity."

specific gravity, apparent—the ratio of the weight in air of a unit volume of a material at a stated temperature to the weight in air of equal density of an equal volume of gas-free distilled water at a stated temperature. The form of expression shall be

"apparent specific gravity *x*/*y*°C"

where *x* is the temperature of the material and *y* is the temperature of the water.

API gravity—a special function of relative density (specific gravity) 60/60°F (15.56/15.56°C) represented by

$$\text{API Gravity, deg} = \left(\frac{141.5}{Sp.Gr.60°\text{F} / 60°\text{F}} \right) - 131.5$$

No statement of reference temperature is required, since 60°F is included in the definition. API gravity applies specifically to crude petroleum and to petroleum products such as hydrocarbon solvents. Gravities are determined at 60°F (15.56°C) or are converted to values at 60°F by means of standard tables. These tables are *not applicable* to nonhydrocarbons nor to essentially pure hydrocarbons such as the aromatics.

A brief discussion of these definitions may be useful. In scientific terminology, *mass* is a measure of the quantity of material in a body, and it is constant regardless of geographical location, altitude, or atmospheric conditions as long as no material is added or taken away. *Weight* is the force with which a body is attracted to the earth, and it varies from place to place with the acceleration of gravity.

When an equal-arm balance is used to compare an object with standards of mass ("weights"), the effects of variations in the acceleration of gravity are self-eliminating and need not be taken into account, but the apparent mass of the object is slightly different from the true mass because of the buoyant effects of the surrounding air. Mass can then be computed from apparent mass by applying a correction for air buoyancy. When a spring balance is used, an additional correction accounting for the local value of the acceleration of gravity is required for the computation of mass.

For many commercial and industrial processes the scientific distinction between mass, apparent mass, and weight is of no practical consequence and is therefore ignored. The term weight in general practice has been accepted as being the value secured when an object is weighed in air. This weight or "weight in air" is often converted to "weight in vacuo" by the application of an air buoyancy correction, and it is then considered synonymous with mass.

All of the definitions listed above are based on either "mass" or "weight in air," with the distinction being that air buoyancy corrections have been applied in the former case and not in the latter. Density and specific gravity are

based on mass and should be similarly constant. Apparent density and apparent specific gravity are based on weight in air, and therefore they are subject to change with atmospheric conditions, locality, and altitude. These changes may be negligible, depending on the accuracy required for the particular application.

HYDROMETER METHODS

Hydrometer methods are the quickest, simplest means for measuring density, specific gravity (relative density), and API gravity, especially in the field. These methods are based on the principle that the specific gravity of a liquid varies directly with the depth of immersion of a body floating in it. The floating body, called a hydrometer, is graduated in units of density, specific gravity, or API gravity units. Hydrometers are useful when accuracy to three decimal places is adequate.

The sample is brought to the prescribed temperature, and it is transferred to a clear glass or plastic cylinder, which is at approximately the same temperature. The appropriate hydrometer, having the scale of interest, is lowered into the sample and is allowed to float freely and settle. After temperature equilibrium has been reached, the hydrometer scale is read. Note is made of the hydrometer scale graduation nearest to the apparent intersection of the horizontal plane surface of the liquid (Fig. 22). Temperature of the sample is read from a separate thermometer or from a thermometer integrated into the design of the hydrometer.

Detailed descriptions of test methods for the proper use of hydrometers can be found in ASTM D891, (Method A), Specific Gravity, Apparent, of Liquid Industrial Chemicals [9]; ASTM D287, Method for API Gravity of Crude Petroleum and Petroleum Products (Hydrometer Method) [11]; and ASTM D1298, Method for Density, Relative Density (Specific Gravity), or API Gravity of Crude Petroleum and Liquid Petroleum Products by Hydrometer Method [11].

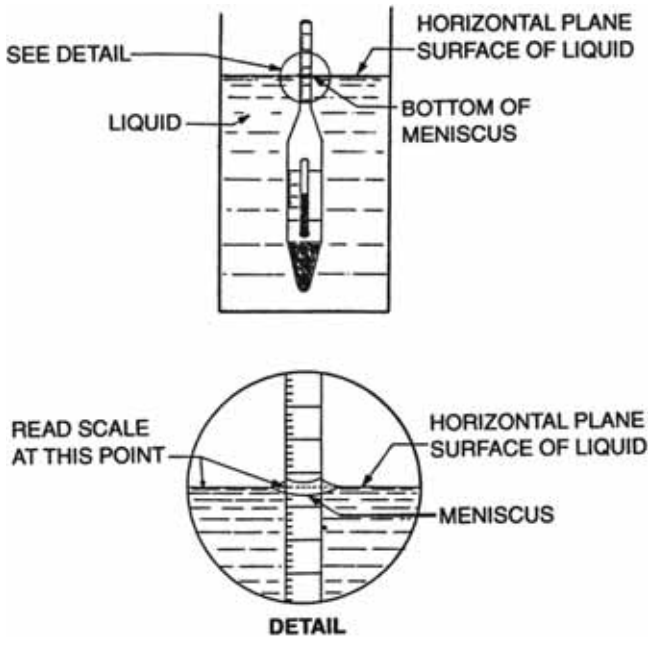

Fig. 22—Hydrometer and meniscus detail.

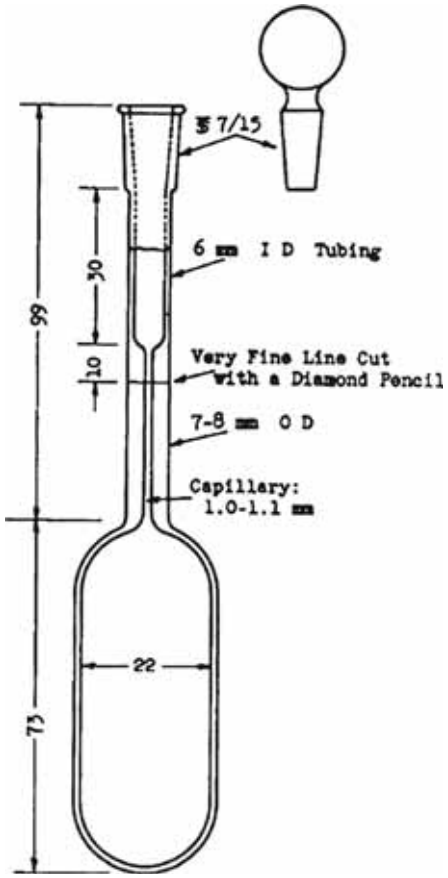

Fig. 23—Bingham-type pycnometer.

For hydrocarbon solvent naphthas, values can be measured on a hydrometer at convenient temperatures, the readings of density may then be reduced to 15°C, and readings of relative density (specific gravity) and API gravity at 60°F are obtained by means of international standard tables. By means of these tables, values determined in any one of the three systems of measurement are convertible to equivalent values in either of the other two systems so that measurements may be made in the units of local convenience.

PYCNOMETER METHODS

Pycnometer methods for measuring specific gravity are more accurate and precise than hydrometer methods. They are used when accuracy to four or more decimal places is required. ASTM D891, (Method B), Specific Gravity, Apparent, of Liquid Industrial Chemicals [9], describes the general test method for using a pycnometer.

A pycnometer is a tared vessel which is filled with water and weighed. It is then filled with the sample and weighed. Water, sample, and pycnometer are at a specified temperature. The ratio of the weight of sample to weight of water in air is the apparent specific gravity.

Bingham Pycnometer—A Bingham-type pycnometer may be used when density or specific gravity needs to be determined to five decimal places (Fig. 23). Its use is described in ASTM D1217, Method for Density and Relative Density (Specific Gravity) of Liquids by Bingham Pycnometer [11].

The pycnometer is first carefully calibrated by determining the weight of freshly boiled and cooled distilled water (distilled from alkaline permanganate through a tin condenser) held by the pycnometer when equilibrated to volume at the bath temperature to be used for the determination. The liquid sample is introduced into the tared, clean, dry pycnometer, equilibrated to the desired temperature, and weighted. The relative density (specific gravity) or density is then calculated from this weight and the previously determined weight of water required to fill the pycnometer at the same temperature, both weights being corrected for the buoyancy of air.

Lipkin Bicapillary Pycnometer—The Lipkin bicapillary pycnometer is another type that is capable of high accuracy and precision when density or specific gravity needs to be determined to five decimal places [42]. Its use was described in ASTM D941, Method for Density and Relative Density (Specific Gravity) of Liquids by Lipkin Bicapillary Pycnometer, but this test method was discontinued in 1993.

The liquid sample is drawn into the pycnometer and weighed. It is then equilibrated at the test temperature, and the positions of the liquid levels in the capillaries are observed (Fig. 24). The density or relative density of the sample is then calculated from its weight, a calibration factor proportional to an equal volume of water, and a term that corrects for the buoyancy of air. NOTE: This test method has been discontinued and is included for historical purposes.

DIGITAL DENSITY METER

A rapid, direct-reading, instrumental method for measuring density or specific gravity is by means of a digital density meter. Its use is described in ASTM D4052, Method for Density and Relative Density of Liquids by Digital Density Meter [23]. A small amount of sample (several milliliters) is introduced into a oscillating quartz tube in the instrument at a preset temperature. Operation of the instrument is based on the principle that the period of oscillation of the quartz tube is affected by the density of the sample within it. The instrument provides a digital readout of either density or specific gravity at the specified temperature.

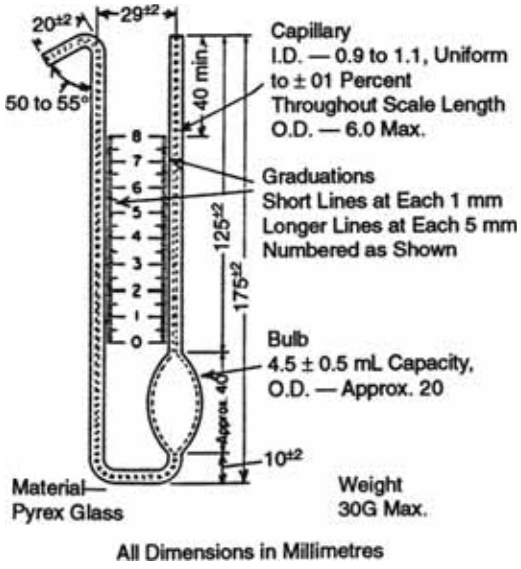

Fig. 24—Lipkin-type pycnometer.

CALCULATIONS AND CONVERSION TABLES

ASTM D1250, Guide for Petroleum Measurement Tables [11], is a description of the tables that comprise Chapter 11, Section 1, of the *API Manual of Petroleum Measurement Standards* [43]. These are distributed in three basic systems of measurement: °API, °F, 60°F; relative density, °F, 60°F; and kilograms per cubic meter, °C, 15°C. These tables apply to crude petroleum and to all normally liquid petroleum products derived therefrom, which includes hydrocarbon solvent naphthas. They do *not* apply to oxygenated and other solvents nor to pure hydrocarbon solvents such as the aromatics.

ASTM D1555, Method for Calculation of Volume and Weight of Industrial Aromatic Hydrocarbons [2], contains tables for use in calculating the weights and volumes of the following solvents: benzene, toluene, mixed xylenes, *o*-, *m*-, p-xylene, cumene, ethylbenzene, high-flash aromatic naphthas, and cyclohexane. A method is given for calculating the volume at 60°F from an observed volume at any convenient temperature.

ASTM D3505, Method for Density or Relative Density of Pure Liquid Chemicals [2], describes the measurement of density or relative density using a Lipkin-type pycnometer, and it provides methods for reporting results in the following units:

Density, g/cm^3 at 20°C
Density, g/mL at 20°C
Relative density, 20°C/4°C
Relative density, 60°F/60°F (15.56°C/15.56°C)
Commercial density, pounds (in air)/U.S. gal. at 60°F
Commercial density, pounds (in air)/U.K. gal. at 60°F

Tables of factors versus temperature are presented for benzene, toluene, mixed xylenes, *o*-, *m*-, *p*-xylene, and cyclohexane.

ASTM D2935, Method for Apparent Density of Industrial Aromatic Hydrocarbons [2], describes the measurement of apparent density in pounds (in air) per U.S. gallon at convenient temperature using a hydrometer and reporting values at any specified temperature. This method contains tables of "pounds in air per U.S. gallon" versus temperature. It applies only to the following solvents: benzene, toluene, mixed xylenes, *o*-, *m*-, p-xylenes, ethylbenzene, and cyclohexane. NOTE: This test method has been discontinued and is included for historical purposes.

ASTM E201, Method for Calculation of Volume and Weight of Industrial Chemical Liquids [9], presents tables for use in calculating the volume and weight of the following solvents: acetone, ethyl acetate (85-88 wt%), ethylene dichloride, ethylene glycol monomethyl ether, isobutyl alcohol, isopropyl alcohol (anhydrous), isopropyl alcohol (91 vol %), methyl ethyl ketone, methyl isobutyl ketone, and perchloroethylene.

A method is given for calculating the volume at 60°F from a volume observed at another convenient temperature. (Tables at 20°C can be calculated from the data and information provided.)

Also, a method is given for determining the weight in pounds per U.S. gallon (in air) at 60°F from an observed specific gravity and to compute therefrom the weight in pounds of a given volume of the liquid in U. S. gallons at 60°F. NOTE: This test method has been discontinued and is included for historical proposes.

Color

Most solvents are "water-white" or clear and essentially colorless. Color is an important specification requirement. If a solvent has color greater than the specification limit, it may be an indication of (a) inadequate processing, (b) contamination that might have occurred during storage and distribution, e.g., pickup of rust from tanks or pipes or color extracted from improper tank linings or loading hoses, or (c) oxidative degradation as a result of aging.

The property of color of a solvent varies in importance with the application for which the solvent is intended, the amount of color that can be tolerated being dependent on the color characteristics of the material in which it is used. For example, solvent color may undesirably contribute color to white paints or to fabrics if it is used for dry cleaning. Solvents that are off-specification in color are often found to be off-specification in other properties as well.

There are two visual test methods used for measuring the color of solvents; platinum-cobalt color and Saybolt Color. Table 13 compares the approximate color values of the two scales.

PLATINUM-COBALT COLOR

ASTM D1209, Method for Color of Clear Liquids (Platinum-Cobalt Scale) [2], describes a procedure for the visual measurement of the color of nearly colorless liquids. It is used for oxygenated solvents and is gradually being used also for hydrocarbon solvents, where Saybolt Color still predominates.

For a number of years the term water-white was considered sufficient as a measurement of solvent color. Several expressions for defining water-white gradually appeared, and it became evident that a more precise color standard was needed. This was accomplished in 1952 with the adoption of ASTM Test Method D1209 using the platinum-cobalt (Pt-Co) scale.

This test method is similar to the description given in "Standard Methods for the Examination of Water and Waste Water" [44] and is sometimes referred to as "APHA Color." The properties of these platinum-cobalt color standards were originally described by A. Hazen in 1892 in a paper entitled, "New Color Standard for Natural Waters" [45]. He assigned the number 5 (parts per ten thousand) to his platinum-cobalt stock solution.

Subsequently the American Public Health Association (APHA) in their first edition (1905) of "Standard Methods for the Examination of Water" used exactly the same concentration of reagents as did Hazen, and they assigned the color designation 500 (parts per million) to the same stock solution. (The parts per million nomenclature is not used since color is not referred directly to a weight relationship.)

The terms "Hazen Color" and "APHA Color" should not be used for solvents because they refer primarily to water. The recommended nomenclature for referring to the color of organic liquids is "Platinum-Cobalt Color, Test Method D1209."

The method involves comparing visually the color of the solvent sample with colors of standard dilutions of the Pt-Co stock reference solution in Nessler tubes. The tubes are viewed vertically. The color standards are aqueous solutions of mixtures of cobalt chloride, potassium chloroplatinate, and hydrochloric acid. The scale runs from zero for pure water to 500 for the stock solution of 1.000 g of cobalt chloride, 1.245 g of potassium chloroplatinate, and 100 mL of hydrochloric acid made up to 1 L of solution. Most solvents have color values of less than 5 on the Pt-Co scale.

SAYBOLT COLOR

ASTM D156, Method for Saybolt Color of Petroleum Products [11], is used most often to measure the color of hydrocarbon solvents. This system of color measurement is not commonly employed outside of the petroleum industry.

In this method, a column of sample is viewed vertically, and its color is compared with that of a reference glass disk in the Saybolt chromometer. The height of the column of liquid is adjusted until the observed color intensity is equal to that of the colored glass disk. The depth of the liquid column is a measure of the Saybolt color, which is read directly from a scale on the instrument. The scale runs from +30 for colorless liquids to -30 for dark liquids.

TRISTIMULUS COLORIMETRY

More recently, automatic instrumental color measurements using tristimulus colorimetry has gained acceptance. ASTM D6045, Method for Color of Petroleum Products by the Automatic Tristimulus Method [50], and ASTM D5386, Method for Color of Liquids Using Tristimulus Colorimetry [2], are two test methods that describe automatic color measurements. ASTM D6045 has been used mainly for petroleum products, while ASTM D5386 is used primarily for near-clear aromatic hydrocarbons. Both test methods specify the use of spectro-photometers capable of converting light measured in total transmission through the sample into CIE XYZ tristimulus values using the CIE Illuminant C and the 1931 CIE Standard Observer as per ASTM E308, Practice for Computing Colors of Objects by Using the CIE Systems [23]. D5386 is capable

of reporting equivalent D1209 Platinum-Cobalt color values, while D6045 can report equivalent D156 Saybolt color values.

Odor

Odor is an inherent, characteristic property of most solvents. Evaluation of the *characteristic odor* by a trained person is a quick and simple means of identifying a solvent (when combined with other tests) as well as for determining its suitability for an application from an odor point of view. *Residual odor* can be used to detect the presence of low-volatility materials that may be associated with manufacture, product degradation, or contamination during distribution.

ASTM D1296, Method for Odor of Volatile Solvents and Diluents [2], describes procedures for testing both the characteristic and residual odors of solvents. It involves dipping strips of filter paper into the sample and into a reference standard. To judge characteristic odor, an immediate comparison is made between the odor of the sample and reference standard on the filter paper. Residual odor is judged by permitting the papers to dry in air at room temperature and examining them at suitable time intervals for differences in odor. Because of safety and health concerns, many solvent specifications have made odor an optional specification requirement and subject to the mutual consent between the solvent manufacturer and user.

Electrical Resistivity

Control of electrical resistivity is critical to the application of electrostatically sprayed coatings. It impacts the transfer efficiency (efficiency of paint application), coating appearance, and economics. Electrical resistivity of the paint must be properly adjusted to obtain optimum atomization characteristics and deposition. The adjustment is mainly accomplished through appropriate selection of solvents [46]. Non-polar solvents, such as hydrocarbon solvents, have high electrical resistivity (low conductivity). Polar solvents such as ketones, alcohols, glycol ethers, and esters generally have low electrical resistivity (high conductivity), although some (e.g., higher molecular weight esters) have high resistivity. Typical values for commercial solvents are shown in Table 14.

ASTM D5682, Method for Electrical Resistivity of Liquid Paint and Related Materials [24], describes the use of two different test meters and probes, Ransburg and BYK-Gardner. Electrical resistivity values are often expressed in terms of "Ransburg megohms," which are read from the meter scale. Multiplication of these values by an appropriate cell constant, which is typically about 132, converts Ransburg megohms to specific resistivity in megohm-cm units.

Refractive Index

Refractive index is defined as the ratio of the speed of light through a vacuum to the speed of light through the sample. Although this property may have no fundamental significance to the practical solvent user and is generally not a specification requirement, the test is useful because measurements can be made quickly and precisely. As with specific gravity, refractive index is characteristic (although not uniquely so) of different solvents, and it is very sensitive to differences in composition of solvent blends. Therefore, it is useful for distinguishing between aromatic and saturated hydrocarbon solvents and for checking purity and uniformity of batches.

TABLE 14—Electrical resistance of typical commercial solvents

Solvent or Solvent Class	Ransburg Megohms
Hydrocarbon solvents	>20
Ketones	<1
Alcohols	<1
Glycol ethers	[1]<1
Esters	. . .
Ethyl acetate	6
n-Butyl acetate	16
Hexyl acetate	>20
Ethoxyethyl acetate	3
Methoxypropyl acetate	3

ASTM D1218, Refractive Index and Refractive Dispersion of Hydrocarbon Liquids [11], is designed to measure these properties with high precision. Manual refractometers are used less as automatic refractometers are gaining popularity. Automatic refractometers have the advantage of not requiring a constant-temperature recirculating liquid bath to control the temperature of the cell because of their use of Peltier technology. In addition, automatic refractometers provide digital readout of the refractive indices, thus eliminating the subjectivity in reading the refractive index value. The temperature at which refractive index of a material is determined must be specified since refractive index is affected by temperature.

PURITY AND COMPOSITION

Gas Chromatography

Gas chromatography (GC), also referred to in the past as gas-liquid chromatography (GLC), is commonly used for the analysis of purity and composition of solvents. GC is a powerful analytical tool, very sensitive, rapid and simple in execution. It is capable of furnishing accurate qualitative and quantitative information from extremely small amounts of sample [47].

In this analytical technique, a minute amount of solvent sample (microliters) is injected by means of a hypodermic syringe into a heated injection port in the instrument, where it is instantly vaporized. The solvent vapors are carried into a GC column by means of an inert carrier gas: helium, hydrogen, or nitrogen. The carrier gas is the eluent that transports the solvent components in vapor form through the GC column, which is maintained at a certain constant or programmed temperature.

In older models of gas chromatographs, GC columns consist of a long, coiled tube, typically 1/8 to 1/4 in. inside diameter and made of stainless steel, copper, or glass. The tube is packed with a powdered, porous substrate or support, which is coated with an absorbent, stationary liquid phase. However, in GCs more commonly in use today, the

GC column consists of a long, coiled capillary tube 1/32 in. or less in diameter, which does not contain the powdered packing support. Instead, the interior walls of the capillary tube are coated with the liquid stationary phase.

The stationary liquid phase has the ability to preferentially adsorb certain components of the vaporized solvent sample. It is selected on the basis of the analysis to be performed. The stationary phase can in some cases be a nonpolar liquid, for instance a methyl silicone, but in other cases a better separation of solvent components can be obtained by employing a highly polar liquid such as polyethylene glycol.

Actual separation of solvent components is achieved by a continuously alternating process of adsorption and vaporization as the solvent vapors pass through the GC column. Differences in adsorption characteristics and volatilities cause the individual sample components to pass through the column at different rates. The components are eluted from the column as individual bands or peaks separated by zones of inert carrier gas.

At the end of the GC column, the carrier gas and sample components flow through a sensitive detector, which is capable of indicating the presence of the components qualitatively and quantitatively. The detector may be a thermal conductivity cell, a flame ionization detector, or an electron capture detector. There are also other less-common types of detectors, and element specific detectors like nitrogen or sulfur specific detectors. Any material other than the carrier gas going through the detector will cause a peak to be plotted on a recorder chart or a data processor.

The time required for a component to flow through the column, under a given set of operating conditions, when compared to the time for known compounds, helps to identify the component. The amount of that component is proportional to the area under the recorder chart peak. Modern gas chromatographs often have a digital integrator, which prints out the elution time and the area under the peak. Temperature, column length and size, type and amount of stationary liquid phase, carrier gas pressure and flow rate, and sample size are some of the variables that can be changed to effect desired separations.

Versatility of gas chromatography in solvent analysis is very great. Good ASTM references on gas chromatography include "ASTM Standards on Chromatography," second edition [48]; ASTM E260, Practice for Packed Column Gas Chromatography [41]; and ASTM E355, Practice for Gas Chromatography Terms and Relationships [41]. Specific ASTM GC methods for analyzing the purity and composition of solvents are listed in Table 15.

Liquid Chromatography

There are two test methods that utilize a liquid chromatography procedure for measuring the volume percentages of aromatics, olefins, and saturated aliphatics (paraffins and naphthenes), which comprise a hydrocarbon solvent naphtha. Both methods involve the physical separation of these hydrocarbon types by passing the hydrocarbon sample through a tube packed with silica gel. The technique is based on the principle that polar compounds are adsorbed more strongly by silica gel than are nonpolar saturated compounds.

In a discontinued ASTM method, D936, Method for Aromatic Hydrocarbons in Olefin-Free Gasolines by Silica Gel Adsorption, a hydrocarbon solvent sample is passed through a glass column packed with silica gel. Then, alcohol, which is more strongly adsorbed than any hydrocarbon, follows the sample through the column, desorbing and forcing the hydrocarbons out. Saturated compounds are

TABLE 15—ASTM gas chromatography methods for analyzing purity and composition of solvents

Compound	ASTM Method	Compound	ASTM Method
Benzene	D4492	Mineral spirits (aromatics content)	D3257
n-Butyl acetate	D3545	i-Octane	D2268
i-Butyl acetate	D3545	n-Propyl acetate	D3545
Cyclohexane	D3054	i-Propyl acetate	D3545
Dipropylene glycol monomethyl ether	D4773	i-Propyl benzene	D3760
Ethanol (SD-3A)	E1100	Propylene glycol	E202
2-Ethoxyethyl acetate	D3545	Propylene glycol monomethyl ether	D4773

Methyl isobutyl ketone	D3329	Hydrocarbon solvents	D6229

eluted first, unsaturated compounds next, and then aromatics. Small samples of the emerging sample are periodically collected. The refractive index of each fraction is measured. From this information, the relative percentages of aliphatics and aromatics can be determined. The precision is good, but the procedure is slow. A more modern version of the test method is ASTM D6379, Method for Aromatic Hydrocarbon Types in Aviation Fuels and Petroleum Distillates—High Performance Liquid Chromatography with Refractive Index Detector [50]. In this test method, the peaks due to the eluting components are detected by a differential refractive index detector. A nonpolar mobile phase such as hexane or heptane is used.

ASTM D1319, Method for Hydrocarbon Types in Liquid Petroleum Products by Fluorescent Indicator Adsorption (FIA) [11], is a refinement of the earlier silica gel adsorption procedure. A mixture of fluorescent dyes is added to the hydrocarbon solvent sample before it is put into the silica gel column. When all of the sample has been adsorbed on the silica gel, alcohol is added under pressure to desorb and force the sample down the column. The fluorescent dyes are also selectively separated with the sample fractions, and they make the boundaries of the aromatics, olefins, and saturates clearly visible under ultraviolet light. The zone of aromatics fluoresces violet, and the zone of olefins fluoresces a chartreuse color. The zone of paraffins plus naphthenes remains colorless. Volume percentage of each hydrocarbon type is determined by measuring the length of each zone in a long, narrow extension of the silica gel column.

Purity of Ketones

ASTM D2192, Method for Purity of Aldehydes and Ketones [2], is an alternative to gas chromatography for measurement of the purity of ketone solvents. This is a wet chemical procedure and is applicable for testing ketones having greater than 98 % purity.

The test is based on the reaction of ketones with hydroxylamine to form an oxime. Hydroxylamine hydrochloride is first converted in part to free hydroxylamine by reaction with a known amount of aqueous triethanolamine.

$$H_2NOH \bullet HCI + (HOCH_2CH_2)_3N \rightarrow H_2NOH + (HOCH_2CH_2)_3N \cdot HCI$$

The free hydroxylamine then reacts with the ketone to form an oxime.

$$R_1R_2C = 0 + H_2NOH \rightarrow R_2C = NOH + H_2O$$

where R_1 and R_2 arealkyl groups.

The amount of hydroxylamine consumed, which is determined by titration of the excess base with standard sulfuric acid, using bromophenol blue indicator, is a measure of the ketone originally present. Water, alcohols, saturated esters, and hydrocarbons do not react with the reagent, but large amounts of inert organic solvents are undesirable because of the possible effect on the indicator.

Purity of Esters

ASTM D1617, Method for Ester Value of Solvents and Thinners [2], is an alternative to gas chromatography for the measurement of purity of ester solvents. It may also be used for determining the ester content of lacquer thinners.

This is a wet chemical test and involves the reaction of the solvent sample with a measured excess of aqueous potassium hydroxide, using isopropanol as a mutual solvent if necessary

$$R_1COOR_2 + KOH \rightarrow [R_1COO]^- K^+ + R_2OH$$

where R_1 and R_2 are alkyl groups. The amount of potassium hydroxide consumed, which is determined by titrating the excess with standard mineral acid, is a measure of the amount of ester originally present.

This test method has its greatest application where the solvent or thinner is not a pure ester. The type of ester present must be known to perform the calculations. The test may also be used for assessing compliance with ester specifications.

IMPURITIES

Acidity

Solvents may have residual acidity from manufacturing processes, or acidity may be present as a result of contamination or decomposition during storage or distribution. Acidity is undesirable since it may cause corrosion of storage tanks and lines. Also, it may cause reactions with basic pigments resulting in color changes.

ASTM D847, Method for Acidity of Benzene, Toluene, Xylenes, Solvent Naphthas, and Similar Industrial Aromatic Hydrocarbons [2], expresses acidity in terms of milligrams of sodium hydroxide consumed when 100 mL of sample are titrated using phenolphthalein indicator. If two drops or less of standard 0.1N sodium hydroxide solution produce a persistent pink end point, the sample is reported to contain no free acid.

ASTM D1613, Method for Acidity in Volatile Solvents and Chemical Intermediates Used in Paint, Varnish, Lacquer, and Related Products [2], expresses total acidity in terms of weight percent acetic acid or as milligrams of sodium hydroxide required to neutralize one gram of sample.

The test is performed by mixing 50 mL of sample with an equal volume of water (or with an equal volume of alcohol if the sample is not water soluble) and titrating with aqueous 0.05N sodium hydroxide solution to the phenolphthalein end point.

Acid Wash Color

ASTM D848, Method for Acid Wash Color of Industrial Aromatic Hydrocarbons [2], is a test used for benzene, toluene, xylenes, refined solvent naphthas, and similar aromatic hydrocarbons. Acid wash color is a measure of chemical reactivity reactivity of trace impurities rather than a measure of the color of the sample itself.

The test is performed by agitating a sample with sulfuric acid under prescribed conditions. The color of the acid layer is compared with colors of aqueous reference solutions containing various concentrations of cobalt chloride, ferric chloride, potassium chromate, and potassium dichromate. The color scale ranges from zero for distilled water to 14 for the darkest reference color standard. The color developed in the acid layer gives an indication of impurities in the aromatic hydrocarbon, which when sulfonated, would cause the material to be discolored.

Alkalinity

ASTM D1614, Method for Alkalinity in Acetone [2], specifically covers the determination of alkalinity in acetone

calculated as ammonia (NH_3). The sample is added to an equal volume of water previously neutralized to the methyl red indicator end point. If alkalinity is detected, it is titrated with 0.05N sulfuric acid and is reported as weight percent ammonia.

Benzene Content

Benzene is classed as a toxic and carcinogenic compound. A knowledge of the concentration of benzene may be an aid in evaluating the possible health hazards to persons handling and using solvents, but the ASTM test methods are not intended to evaluate such hazards. In addition, benzene content is an important specification requirement for aromatic hydrocarbons used as chemical intermediates.

ASTM D4367, Method for Benzene in Hydrocarbon Solvents by Gas Chromatography [2], may be used to determine benzene content of hydrocarbon solvents at levels from 0.01 to 1 vol %. An internal standard, MEK, is added to the solvent sample, which is then introduced into a gas chromatograph equipped with two columns connected in series. The specimen passes first through a column packed with a nonpolar stationary liquid phase, methyl silicone, which separates components by boiling point. After octane has eluted, the flow through the nonpolar column is reversed, flushing out components higher boiling than octane. The octane and lighter components then pass through a column with a highly polar phase, 1,2,3-tris(2-cyanoethoxy)propane, which separates the aromatic and nonaromatic compounds. The eluted components are detected by a conventional detector and are recorded on a strip chart. Peak areas are measured, and the concentration of benzene is calculated by reference to the internal standard. A more recent test method for determining benzene down to 1 vppm level in hydrocarbon solvents is ASTM D6229, Method for Trace Benzene in Hydrocarbon Solvents by Capillary Gas Chromatography [2]. It is similar to D4367 but uses capillary columns in series instead of packed columns. The first column is a methyl silicone capillary column, and the second column is a polyethylene glycol capillary column. This test method is an external standard GC method using an automatic injector. This trace level GC method for benzene becomes increasingly important as the maximum benzene content hydrocarbon solvent gets to be more stringent.

ASTM D4534, Method for Benzene Content of Cyclic Products by Gas Chromatography [2], applies to cyclohexane, toluene, individual C_8 aromatics, cumene, and styrene. Benzene may be determined over a range from 5 to 300 mg/kg (5–300 ppm). The test is performed with a gas chromatograph equipped with a flame ionization or other detector and a column containing a polar stationary liquid phase such as tetracyanoethylated pentaerythritol. A reproducible volume of sample is injected. Quantitative results are obtained from the measured area of the recorded benzene peak by using a factor obtained from the analysis of a blend of known benzene content.

Nonaromatic Hydrocarbons in Aromatics

ASTM D2360, Method for Trace Impurities in Monocyclic Aromatic Hydrocarbons by Gas Chromatography [2], covers the determination of total nonaromatic hydrocarbons and trace monocyclic aromatic hydrocarbons at levels of 0.0005 to 1 % by weight in high-purity benzene, toluene, and mixed xylenes by gas chromatography. This inspection is of particular importance when these high-purity aromatics are used as chemical intermediates.

This test method is performed using an internal standard, *n*-butylbenzene, added to the specimen which is then introduced into a gas chromatographic column. The sample passes through the column, which contains a polyethylene glycol stationary liquid phase, and it is separated into nonaromatic and aromatic components. The components are detected by a flame ionization detector as they elute from the column and appear as peaks on the chromatogram. Peak areas are measured, and the concentration of the composite nonaromatics and each trace aromatic component is calculated with reference to the internal standard.

A more recent but similar test method for determining the nonaromatic contents of aromatic solvents is ASTM D5917, Method for Trace Impurities in Monocyclic Aromatic Hydrocarbons by Gas Chromatography and External Calibration [2]. It uses the same column and GC parameters as in D2360, and has the similar applicable range, but uses external standard calibration. Both test methods have comparable precision.

Nonvolatile Residue

ASTM D1353, Method for Nonvolatile Matter in Volatile Solvents for Use in Paint, Varnish, Lacquer, and Related Products [2], describes the analytical measurement of residual matter in solvents that are intended to be 100 % volatile at 105 ± 5°C. Volatile solvents are used in the manufacture and application of paint, varnish, lacquer, and other related products, and the presence of any residue may affect the product quality or efficiency of the process.

Nonvolatile residues may consist of oil contamination, dissolved solids, rust, sand, or dirt. Trace oil contamination, which could cause cleaning solvents to leave an objectionable deposit of oily residue, often will not be detected by any other specification test.

This test is performed by evaporating to dryness 100 mL of solvent in a carefully cleaned, dried, and tared evaporating dish of platinum, aluminum, ceramic, or glass, first on a stream bath and then in an oven at 105±5°C. The weight of any residue remaining in the dish is determined, and the result is reported as milligrams of nonvolatile residue per 100 mL.

Olefins Content

Olefins are undesirable impurities in hydrocarbon solvents. They are unsaturated, reactive compounds that tend to oxidize, causing solvent discoloration and objectionable non-characteristic odor. The level of olefins present can be determined by reacting them with bromine. The amount of bromine that will react is a measure of the olefin content.

ASTM D1159, Method for Bromine Number of Petroleum Distillates and Commercial Aliphatic Olefins by Electrometric Titration [11], is used for testing materials that have fairly high olefin contents. Bromine number is defined as the number of grams of bromine that will react with 100 g of sample.

The test is performed by first dissolving the hydrocarbon sample in a titration solvent composed of specified proportions of glacial acetic acid, dichloromethane,

methanol, and sulfuric acid. The use of 1,1,1 trichloroethane in the titration solvent has been superceded by dichloromethane. The dissolved sample is then titrated at 0–5°C with a bromide-bromate solution. (The titration is run at low temperature since addition of bromine to olefinic molecules proceeds rapidly and completely at temperatures down to or below 0°C, while competing reactions with aromatics and compounds of sulfur, nitrogen, or oxygen, if present, are minimized.) The end point of the titration is indicated by a dead-stop electrometric or potentiometric titration apparatus. Bromine number is calculated from the weight of sample and from the volume of bromide-bromate reagent titrated. Values are generally in the range of 1–100.

Hydrocarbon solvents usually have a bromine number of less than one. For greater accuracy, precision, and discrimination, it is more appropriate to use ASTM D1492, Method for Bromine Index of Aromatic Hydrocarbons by Coulometric Titration [2], or ASTM D2710, Method for Bromine Index of Petroleum Hydrocarbons by Electrometric Titration [23]. A more recent test method for Bromine index of aromatic solvents is ASTM D5776, Method for Bromine Index of Aromatic Hydrocarbons by Electrometric Titration [2]. This test method is very similar to D2710 with the exception that 1-methyl-2-pyrrolidinone is used in place of dichloromethane or 1,1,1-trichloroethane in the titration solvent. Bromine index is defined as the number of *milligrams* of bromine consumed by 100 g of sample (as compared with bromine number, which is expressed as *grams* of bromine consumed by 100 g of sample). Although the test procedures differ, bromine index is the more sensitive test and may be assumed to be numerically equal to 1000 times the bromine number.

In the coulometric titration method (ASTM D1492), the specimen is added to an electrolyte solution consisting of glacial acetic acid, methanol, potassium bromide, and mercuric acetate, and it is titrated with electrolytically generated bromine at room temperature. End point is determined by a dead-stop method when excess bromine is detected. The time of titration and generation current are proportional to the bromine generated and consumed by the sample.

Sulfur Content

Crude petroleum usually contains minor amounts of sulfur compounds, the greater proportion of which are removed during refining since they might otherwise cause objectionable corrosive tendencies and foul odors in refined products such as hydrocarbon solvents. There are several test methods that directly measure sulfur content or which indicate their presence indirectly.

COPPER STRIP CORROSION

ASTM D130, Method for Detection of Copper Corrosion from Petroleum Products by the Copper Strip Tarnish Test [11], indicates the presence of corrosive compounds (such as reactive sulfur compounds) in hydrocarbon solvents and other petroleum products by their effect on a highly polished test strip of copper. The polished copper strip is immersed in the solvent sample in a test tube and heated for 3 h at 100°C. At the end of this period, the copper strip is removed, washed, and compared with ASTM Copper Strip Corrosion Standards. Rating classifications range from "1a—slight tarnish," light orange, almost the same as the freshly polished strip, to "4c—corrosion," jet black.

ASTM D849, Method for Copper Corrosion of Industrial Aromatic Hydrocarbons [2], is similar to ASTM D130 but applies specifically to aromatic hydrocarbons. The sample and polished copper strip are placed in a flask fitted with a condenser and are placed in a boiling water bath for 30 min. At the end of this period, the copper strip is removed and compared with the ASTM Copper Strip Corrosion Standards. Aromatic solvents are reported to pass the test if the copper strip ratings are "1a" or "1b," indicating only "slight tarnish." All other ratings are considered failures.

DOCTOR TEST

ASTM D4952, Method for Qualitative Analysis of Active Sulfur Species in Fuels and Solvents (Doctor Test) [49] is a very sensitive qualitative test for detecting hydrogen sulfide and mercaptan sulfur in hydrocarbon solvent naphthas. It is referenced in section 6.1.10 of ASTM D235, Specification for Mineral Spirits [2]. The test is performed by vigorously shaking together in a test tube the solvent being tested and an aqueous sodium plumbite solution. A small amount of pure, dry flowers of sulfur is added so that practically all of it floats on the interface between the solvent and the sodium plum-bite solution after shaking. If the solvent is discolored or if the yellow color of the sulfur film is noticeably masked or discolored and blackened, the test is considered positive and the solvent is reported as "sour." If the solvent remains unchanged in color and the sulfur film is bright yellow or only slightly discolored with gray or flecked with black, the test is considered negative and the solvent is reported as "sweet."

SULFUR BY LAMP METHOD

ASTM D1266, Method for Sulfur in Petroleum Products (Lamp Method) [11], is an older test method used for quantitatively measuring total sulfur content of solvents. The sample is burned in a wick lamp in an artificial atmosphere of 70 % carbon dioxide and 30 % oxygen to prevent formation of nitrogen oxides. A solution of hydrogen peroxide is used to absorb the oxides of sulfur, which are formed during combustion and to oxidize them to sulfuric acid. After flushing with air to remove dissolved carbon dioxide, the absorbent is titrated with a standard solution of sodium hydroxide. Sulfur is calculated as percent by weight from the weight of sample burned and the volume of sodium hydroxide reagent required to titrate the acid in the absorbent. Alternatively, the sample may be burned in air, in which case the sulfur as sulfate in the absorbent is reacted with barium chloride to precipitate barium sulfate, and the sulfur content is determined gravimetrically.

TRACE SULFUR BY HYDROGENOLYSIS AND COLORIMETRIC DETECTION

There are two ASTM test methods that deal with the determination of trace sulfur in aromatic compounds: ASTM D6212, Method for Trace Sulfur in Aromatic Compounds by Hydrogenolysis and Rateometric Colorimetery [2], and ASTM D6313, Method for Trace Sulfur in Aromatic Compounds by Hydrogenolysis and Sulfur Specific Difference

Photometry [2]. The corresponding test method for petroleum products is ASTM D4045. Method for Sulfur in Petroleum Products by Hydrogenolysis and Rateometric Colorimetry [23]. Both D4045 and D6212 specify a 0.02–10 mg/kg sulfur range, while D6313 claims to be applicable down to 0.005 mg/kg sulfur.

In these three test methods, the sample is injected at a constant rate into an air stream and introduced into a pyrolysis furnace. The sulfur species reacts with oxygen and is converted to SO_2 and SO_3, which in turn are converted to H_2S in a second pyrolysis furnace at 1200 to 1300°C in the presence of hydrogen. The H_2S thus formed reacts with lead acetate, and the rate of color change of the lead acetate paper is proportional to the sulfur content.

TRACE SULFUR BY OXIDATIVE COMBUSTION AND ELECTROCHEMICAL DETECTION

A very recent method for sulfur content in aromatic hydrocarbons is described in ASTM D6428, Method for Total Sulfur in Aromatic Hydrocarbons by Oxidative Combustion and Electrochemical Detection [2]. The sample is injected at a controlled rate into a stream of inert gas (helium or argon) or inert gas mixed with oxygen. The sample is vaporized and carried into a high temperature zone (>900°C) where oxygen is introduced. Sulfur compounds, present in the specimen, are converted to sulfur dioxide, which react with the sensing electrode in a three-electrode electrochemical cell. The reaction produces a measurable current that is directly proportional to the amount of sulfur in the original material.

TRACE SULFUR BY GAS CHROMATOGRAPHY AND SULFUR SPECIFIC DETECTION

ASTM D5623, Method for Sulfur Compounds in Light Hydrocarbon Liquids by Gas Chromatography and Sulfur Selective Detection [49], describes a test method for determining individual sulfur species concentration as well as total sulfur concentration. The sample is injected into a gas chromatograph equipped with a capillary column that can separate the individual sulfur species. A sulfur specific detector such as the atomic emission detector or the sulfur chemiluminescence detector gives equimolar responses to different sulfur species in the sample. The total area of all the sulfur species peaks can be summed up to give a measure of the total sulfur concentration. This is the only sulfur test method that can determine the concentration of individual sulfur species. This test method can detect below 1 wppm of total sulfur in various hydrocarbon solvents.

Water Content

Dissolved water can have adverse effects on solvent end-use applications. For example, it can reduce solvency. Water can cause reactions with isocyanates during polyurethane preparation and with moisture-cure polyurethane paints and varnishes causing polymerization and gelation during storage. Metallic pigments can react with water to generate hydrogen gas, which can expand and burst paint cans. Dissolved water can act as a catalyst poison when a solvent is used as a reaction diluent for polyolefin polymerization.

KARL FISCHER REAGENT METHOD

ASTM D1 364, Method for Water in Volatile Solvents (Fischer Reagent Titration Method) [2], is a quantitative test. It is based on reactions involving the reduction of iodine by sulfur dioxide in the presence of water. These reactions can be used quantitatively when pyridine and an alcohol are present to react with the sulfur trioxide and hydroiodic acid produced in the reagent.

$$H_2O + I_2 + SO_2 + 3C_5H_5N \rightarrow 2C_5H_5N \cdot HI + C_5H_5N \cdot SO_3$$
$$C_5H_5N \cdot SO_3 + ROH \rightarrow C_5H_5N \cdot HSO_4R$$

To determine water content, Fischer reagent (a solution of iodine, pyridine, and sulfur dioxide in the molar ratio of 1:10:3) dissolved in anhydrous 2-methoxyethanol is added to a solution of the sample in anhydrous pyridine-ethylene glycol (1:4) until all water present has been consumed. This is evidenced colorimetrically by the persistence of an orange-red end-point color or electrometrically by an indication on a galvanometer or similar current-indicating device which records the depolarization of a pair of noble-metal electrodes. The reagent is standardized by titration of measured amounts of water.

Alternatively, automatic instruments are commercially available which operate on a coulometric principle according to ASTM E1064, Method for Water Content of Liquid Organic Chemicals by Coulometric Karl Fischer Titration [9]. A measured quantity of sample is introduced into a titration cell containing reagent, which undergoes the Karl Fischer reactions. Iodine is coulometrically regenerated, the amount of current required being proportional to the water content of the sample.

HEPTANE MISCIBILITY TEST

Oxygenated solvents are capable of dissolving sizable amounts of water. They can be checked qualitatively for water content by ASTM D1476, Method for Heptane Miscibility of Lacquer Solvents [2]. Heptane is water immiscible and has a very low tolerance for water in solvent blends. The test is performed by mixing the solvent sample under test with heptane in a 1:19 proportion and agitating. A clear solution indicates miscibility and low water content (less than about 0.5 wt%) in the solvent sample. A turbid solution indicates immiscibility and the presence of high water content in the solvent sample.

Water Solubility

Certain oxygenated solvents are completely miscible, e.g., methanol, isopropanol, and acetone. This property can provide a qualitative means for indicating the presence or absence of water-insoluble contaminants, such as oils, paraffins, olefins, aromatics, high-molecular-weight alcohols, ketones, etc. Water-insoluble materials in the solvents may interfere with many of their end-uses [50].

ASTM D1722, Method for Water Miscibility of Water-Soluble Solvents [2], covers the determination of the miscibility of water-soluble solvents with water. The sample is diluted with ten volumes of water in a glass graduated cylinder. The resulting mixture is viewed through the length of the column of liquid toward a dark background while being transversely illuminated. The sample is reported to pass the test if there is no evidence of cloudiness or turbidity initially and after 30 min.

Part 6: Pigments

19

White Pigments

Juergen H. Braun[1]

INTRODUCTION

ALMOST EVERYTHING MANMADE THAT IS WHITE or light in color contains white pigment in its surface: houses inside and outside, industrial articles, plastics, glazes, rubber, printed surfaces, many paper products, and even some foods. Only papers and textiles can be white without pigment.

Virtually all this whiteness and lightness is supplied by titanium dioxide (TiO_2) pigments. Void pigments make a minor contribution. The classic white pigments—lithopone, zinc sulfide, and the white leads—have essentially disappeared from commerce because TiO_2 pigments perform much better, are much cheaper, and are nontoxic. Zinc oxide is still added to some paints as a mildewstat, but not for use as a white pigment.

TiO_2 pigments are manufactured by a major, globally distributed industry. Its products are sold for many applications; however, more than half of all white pigment goes into paints. In many coatings, white pigment is the single most expensive ingredient. To select the right pigment grade and use it well is an important challenge to the paint manufacturer.

This chapter will familiarize coating manufacturers with white pigments and help them understand their options for selection, utilization, and testing. Toward this objective, I will first outline the commerce and manufacture of white pigments and then discuss their function, the substances that serve this function, and the commodities available. I will distinguish between product characteristics that describe the pigment itself and product performance, which are properties of paint films, that is, systems composed of pigment and binder.

Commerce

The white pigment market is served almost exclusively by titanium dioxide pigments. Globally, about twelve billion pounds are produced annually at a value of about sixteen billion dollars. The value of TiO_2 pigments exceeds by far the combined value of all color pigments.

Five manufacturers share two-thirds of the world market. Their products are of similar quality. Most of these producers operate several large plants located in industrialized countries. The largest of these plants makes about two million pounds of pigment a day. A few small plants operate in certain countries where they manufacture the pigment for regional consumption.

In the United States and most other countries, one-half of the TiO_2 pigment is used in coatings, one-fourth in paper, and 15 % in plastics. All other end uses, pigmentary (inks, floor coverings, elastomers, roofing granules, fibers, fabrics, sealants, foods, etc.) and nonpigmentary (ceramics, welding rods, etc.), account for the remaining 10 %. In less-developed countries, most of the TiO_2 pigments go into paints and plastics.

Manufacture

TiO_2 particles, the active ingredient of pigment, are made by one of two processes:

1. The old sulfate route dissolves the ore in sulfuric acid, purifies the aqueous solution of titanyl sulfate, precipitates a hydrous titania gel, and calcines the gel to crystallize it into aggregates of pigment particles, which, in turn must be ground.
2. The newer and "greener" chloride route chlorinates the ore and purifies the $TiCl_4$ intermediate by distillation and chemical treatments. $TiCl_4$ is then flame oxidized to pigmentary TiO_2 particles and chlorine. The chlorine is recycled.

Sulfate processes are low-tech, labor-intensive operations that operate in a batch mode. Chloride processes are high-tech, automated, continuous operations. Sulfate and chloride products do not differ much in performance except that chloride TiO_2 is purer and thus brighter in nature.

Waste disposal is a significant factor and constraint. The sulfate process generates vast quantities of dilute sulfuric acid and iron(II) sulfate from its ilmenite ($FeTiO_3$) ingredient.[2] The chloride process makes iron(III)chloride by-product in much lower quantities that are dependent on ore composition: rutile (TiO_2), anatase (TiO_2), leucoxene ($TiO_2/FeTiO_3$), and ilmenite ($FeTiO_3$).

After the primary step, either process manufactures pigment particles, and their surfaces are treated to adapt the pigment to a variety of end uses. These treatments are carried out in aqueous suspension followed by drying, grinding, and dry treatment operations. Pigments are also converted into slurry grades.

By either process, manufacture involves six steps:

1. Digestion of the ore.
2. Purification of the intermediate.
3. Crystallization of pigment particles.
4. Treatment of the pigment surface.
5. A variety of finishing operations.
6. Grinding of pigment aggregates.

Research and Development

For 50 years, the TiO_2 industry has been large, competitive, and profitable enough to dedicate sizable science and engineering resources to product improvement. These efforts have been remarkably successful. Today's TiO_2 pigments are complex structures composed of an optically active core with shells that adapt the pigment to specific end uses. Each feature is carefully designed into each pigment grade, optimizing it for its specific application. Their optical performance approaches the theoretical light-scattering effectiveness calculated from concepts of theoretical physics.

Experts in pigment technology, with the help of specialists in optics, surface chemistry, fine-particle technology, and chemistry have resolved many of the compromises between often-conflicting requirements. End users can contribute to progress by suggesting new opportunities. Solving pigment problems does, however, require expertise in pigment technology.

THE FUNCTION OF PIGMENTS

Most coatings have two functions, aesthetic and protective. More often than not, manufactured surfaces are visually unattractive and therefore coated for aesthetic appeal. The coating hides the substrates' discolors and contrasts and provides a visually pleasing appearance or identification with certain exceptions such as vinyl siding. ASTM D16, Standard Terminology for Paint, Related Coatings, Materials, and Applications, defines pigments as the fine solid particles used in the preparation of paint or printing ink and substantially insoluble in the vehicle.[3]

Pigments supply the hiding and color of a coating. They are incorporated in surfaces to make them look bright or dark, colorful or drab, white or black, either more appealing or more appropriate to whatever the intended service. Toward that end, pigments must hide the unattractiveness of a substrate. Thus, pigments serve the human eye. They interact with visible light and cause surfaces to be seen in colors:[4] chromatic colors such as red, blue, and green, or achromatic colors such as black, gray, and white.

To understand this primary aesthetic function of pigments, let us consider the interactions of visible light with matter at or near surfaces. Involved are two mechanisms of optics: light scattering and light absorption. White or bright hiding is achieved by light scattering, an optical mechanism by which a ray of light is scattered as it impinges on an interface. White pigments are substances selected to scatter light very well.

Hiding also can be achieved by the absorption of light that is involved in colored and black surfaces and pigments. Optical absorption is decisively more efficient than optical scattering. Thus, less color or black than white pigment is required for hiding. Dark and black paint films can therefore be thinner than their white and light counterparts.[5]

Table 1 relates appearance characteristics of surfaces to the optical phenomena that cause them. If all light is absorbed by a surface, none scattered, the surface is perceived as black. If all light is scattered, none absorbed, the surface is seen as white. If a portion of the light is scattered and another portion of it is absorbed, the surface is gray. If the absorption and scattering is wavelength dependent, for example, if red light is absorbed and green light is scattered, the surface is colored by the scattered green portion of the light. Even though common usage refers to objects as colored, i.e., red cars, green mountains, almost always only their surfaces matter.[6]

The return of light from a surface is caused by reflection at the surface and scattering from beneath with pigment causing the scattering. The optical action itself occurs at or in pigment particles, not on the particles but rather within the surface. Light reflected at the surface does not usually change its color.[7]

Light scattered and returned from inside the coatings makes a surface look white or, if color pigments are involved, gives color to the surface. It is the white pigment in the coatings that does most of the light scattering.

Light scattering can be explained quantitatively from optical theories. Geometric optics give a graphic but superficial picture that accounts well for effects of refractive indices of potential pigments but unreliably for effects of pigment particle size. Wave optics and electromagnetic theory provide a more accurate but quite abstract model, accounting for particle size but not for effects of particle shape, orientation, and crowding.

The optimum particle size at which a population of white pigment particles scatters a maximum amount of light is about[8] 0.2 μm for green and white light. Blue light is scattered more efficiently by smaller particles, red light by larger particles. For pigments of high refractive indices, the theoretical curve of optical effectiveness versus particle size

[3] The definition goes on to point out that asphaltic materials are not pigments except when they contain substances substantially insoluble in the vehicle in which they are used. It is worth pointing out that Webster's definition of a pigment is "a substance that imparts black or white or color to other materials."

[4] In most technical contexts of color and colorants, white, gray, and black are considered colors.

[5] The transparency of white clothes, in particular wet, white clothes, illustrates the relative hiding effectiveness of white and color.

[6] This comes about because visible light and thus human vision penetrates pure gasses to a depth of about 10^{-6} m, pure liquids to about 10^{-2} m, dielectric solids to about 10^{-3} m, and metals to about 10^{-9} m, a range of 15 orders of magnitude.

[7] Exceptions are the colored metals—gold, copper, and their alloys—and extremely strong colorants, for example, copper phthalocyanine and hematite.

[8] The uncertainty is not in the optical calculation but reflects difficulties in defining the size of particles other then spheres. What, for example, is larger, a large snake or a small monkey? It depends on the perspective of the observer.

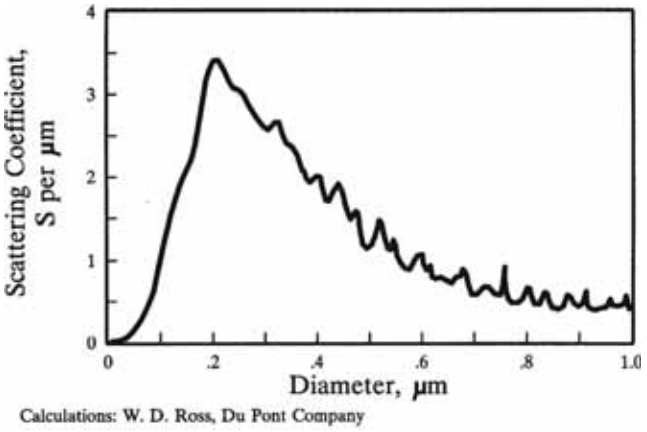

Fig. 1—Scattering by spheres of rutile in polymer. From Braun, J. H., "Introduction to Pigments," Monograph in the Federation Series on Coatings Technology, Federation of Societies for Coating Technology, United States, 1993.

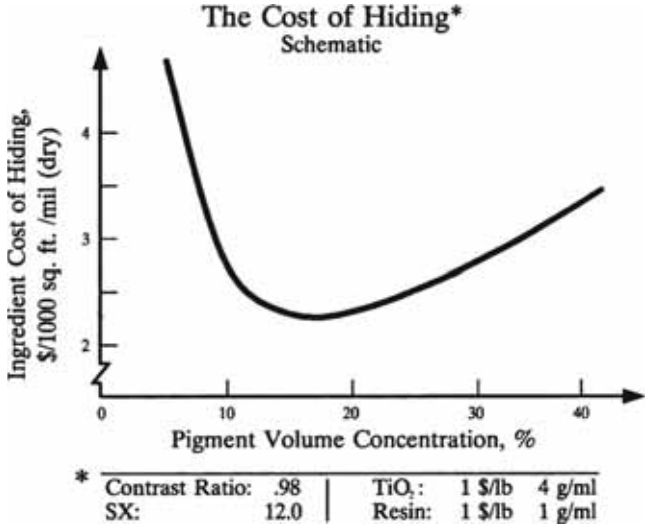

Fig. 2—The cost of hiding, from Braun, J. H., "Introduction to Pigments," Monograph in the Federation Series on Coatings Technology, Federation of Societies for Coating Technology, United States, 1993.

has a sharp peak (Fig. 1). For pigments of lower refractive indices, the peak broadens but the optimal size near 0.2 *μm* does not change much.

The pronounced wavelength dependence of optimum scattering causes a subtle color effect by white pigments in colored coatings. Their color shifts toward red if the white pigment is larger than optimal. Color shifts toward blue if the white pigment is smaller. This "undertone" is visible in colored coatings and in white coatings, at incomplete hiding. In gray coatings, the effect can be quite obvious and at times objectionable in nature.

Pigments can act by themselves, but they are usually used in combinations: White pigment with a small amount of color or black pigment, white pigment with one or more color pigments, combinations of color pigments, color pigments with some black pigment, etc. Some types of pigment particles scatter light and other types absorb it. White pigments deliver white appearance by scattering all light (see Table 1). Black pigments absorb all light. Color pigments create color by absorption of light of specific wave bands. Sometimes, though, the wavelength-specific absorption by color pigments is augmented by wavelength-specific scattering.

Pigments, because they are particulates, can affect surface texture and texture-related appearance characteristics: gloss and sheen.

Pigments do the optical, that is, the aesthetic work; they provide the color and the hiding. Binder keeps the pigment on the substrate and does the mechanical and the chemical work that protects the substrate from the environment. The less effective the pigment in its optical function, the thicker the coating must be to hide and provide the desired color. Thick coatings, however, cost more than thin ones. Since the cost of binder increases proportionally to film thickness, film costs are inversely proportional to the effectiveness of the pigment. Economics discriminate severely against pigments of low optical effectiveness.

Fig. 2 is a plot of the cost of hiding as a function of pigment volume concentration for the case of a typical white paint applied to hide color contrasts of a substrate; it illustrates the economics of hiding. The film is composed of a TiO_2 pigment at $1 per pound and a density of 4 g/mL dispersed in a polymer at $1 per pound and a density of 1 g/mL. Hiding cost has a distinct minimum. At too low a pigment volume concentration, the film must be thick to hide. The cost of hiding increases because additional polymer is required to provide the required film thickness. At too high a pigment volume concentration, the white pigment is used inefficiently, also increasing cost, albeit at a lower rate.

THE SUBSTANCE OF WHITE PIGMENT

White pigments translate light scattering into hiding power, brightness, and opacity of thin films. The films, in turn, hide the color and contrasts of the substrate. To serve as an effective white pigment, a substance must meet requirements that limit the selection to less than one dozen from among the thousands upon thousands of natural and man-made chemicals. A potential white pigment must have an extremely high refractive index.

In addition, the substance must be

- stable,
- almost colorless,
- suitable for manufacture in optimized, colloidal particle size,
- a solid,
- insoluble in water and organic solvents, and
- safe in manufacture, end use, and as a waste.

Of these criteria, the requirement of an extremely high refractive index, larger than 2.0, is essential and is most restrictive. Most materials with high refractive indices are hydrolytically unstable. A combined requirement for extreme refractive index plus stability eliminates all but a few substances.

High density is a disadvantage for a pigment. Pigments function by volume yet are sold by weight. Thus, a high-density pigment contains fewer particles per pound to do its optical work than a low-density pigment. Because of its optical performance, safety, and cost, titanium dioxide has become the only white pigment of commercial

significance. In the foreseeable future, it is quite unlikely that a better white pigment will be found to replace TiO_2 because its performance advantage results from a combination of a uniquely high refractive index with other essential characteristics.

TiO_2 has the highest refractive index of all ordinary, colorless, and stable substances, significantly higher even than diamond. Refractive indices of most compounds such as TiO_2 have been measured and can even be calculated from pure theory. No colorless substance, neither real nor hypothetical, has been found[9] that has a higher refractive index than TiO_2.

Before the commercialization of titanium dioxide, lithopone ($BaSO_4$/ZnS), zinc oxide, zinc sulfide, and white lead [lead(II)hydroxy carbonate] served as white pigments. All have lower refractive indices, scatter less effectively, and are much less cost effective than TiO_2.

Not only particulates but also air voids in coatings scatter light as if they were particles. But air voids are far less effective than TiO_2. Voids thus contribute to hiding but at direct or indirect costs. In coatings below their critical pigment volume concentration, voids scatter light and hide as such. But because they do not hide as well as TiO_2, films must be thicker, which increases binder cost. In coatings above the critical pigment volume concentration, extenders create a network of interconnected voids. These pores enhance the hiding effectiveness of the pigments. This indirect hiding contribution of voids is cheap to achieve in paint but comes at the expense of mechanical and chemical film qualities. Pores (1) concentrate mechanical stresses to where they initiate fracture and (2) conduct aggressive chemicals from the surface into the depth of the paint film. The hiding improvements and the quality detriments of coatings above their critical pigment volume concentration can be quite large.

TIO_2 PIGMENTS

Titanium dioxide has obsoleted all other white pigments because TiO_2 is cheaper to use and much safer than other pigments. TiO_2 pigments are the most effective scatterers of visible light. They hide better and provide more lightness. They are more stable and are less toxic.

Fig. 3 and Fig. 4 are descriptions of what TiO_2 pigments "look" like. Figure 3 is a transmission electron micrograph of an uncoated TiO_2 pigment grade dispersed in a dispersant by conventional techniques of grid preparation. Single crystals, twins, aggregates, and small agglomerates are visible. Weakly bonded agglomerates, though, are not distinguishable from strongly bonded aggregates because micrographs do not show strength of bonding. Fig. 4 is a description of a set of electron scanning micrographs of dry pigment in bulk and as an individual floc. Visible are masses and individual crystallites, single and twinned. At highest magnification, scanning electron microscopy shows crystals significantly more rounded in shape than they actually are.

TiO_2 pigments are made in two crystal phases, rutile and anatase, that differ in lattice structures, refractive indices, and densities. Anatase was the first commercial titanium dioxide pigment but, for the coatings industry, has now been replaced by rutile because, in organic media, rutile has an 18 % scattering advantage over anatase.

[9] Extreme pressure phases of TiO2 could be expected to have higher densities combined with higher refractive indices.

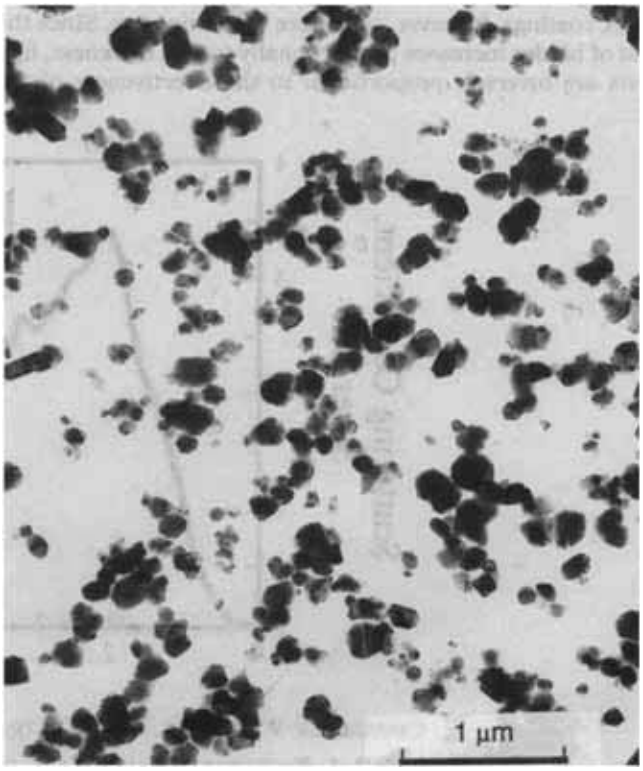

Fig. 3—Transmission electron micrograph of TiO_2 pigment.

For the sake of clarity, I will distinguish between characteristics and performance of a pigment. Composition, for example, is a characteristic of a pigment that is essentially independent of its environment. By contrast, hiding power describes the performance of a system, a pigment within a paint film. Hiding is a film characteristic that depends on pigment volume concentration and a host of formulation and application parameters of the paint in which the pigment was evaluated.

Characteristics are properties of the commodity: composition, density, particle size, etc. They can be measured on the commodity, either dry powder or slurry. Granted, some product characteristics are affected by the ambiance in which they are measured but only in secondary ways. Particle size is an example of a characteristic affected by method of measurement.

At the state of the art, it does not appear possible to establish rigid links between pigment characteristics and performance. Thus, the pigment commodity cannot be defined exclusively in terms of its characteristics. Certain characteristics can be measured reliably. Their results bear on but do not guarantee performance. Clearly, complete specifications for pigments must include both product characteristics as well as product performance measures.

A few generalizations of the connection between pigment characteristics and product performance are appropriate.

- High gloss pigments: (1) Pack densely as indicated by measures of oil absorption, liquid demand, and interstitial space; (2) contain few agglomerates larger than

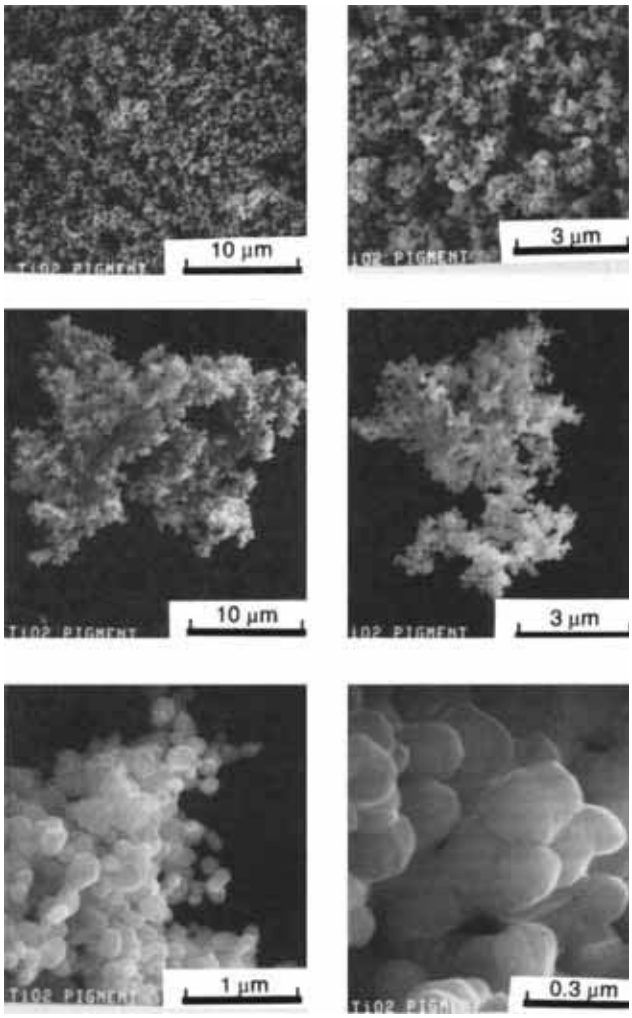

Fig. 4—Scanning electron micrographs of TiO_2 pigment.

about 0.5 μm;[10] and (3) have hydrous oxides contents that are low and TiO_2 contents that are correspondingly high [l].

- Pigments intended for high-pigment volume concentration paints contain up to 20 wt % hydrous oxides be cause fluffy oxides act as very efficient extenders. TiO_2 contents are correspondingly low.
- Satisfactory outdoor durability precludes the presence of more than about 1 wt % anatase phase with the rutile [2].
- Product fractions smaller than about 0.1/lm and larger than about 0.4/lm constitute losses to optical performance because particles that are too large or too small scatter light inefficiently.
- Impurity metal ions within the rutile crystals can de grade brightness dependent on the nature of the metal ion. Certain ions degrade color in concentrations as low as 0.00001 wt %. Effects of ion contaminants on characteristics other than brightness are generally insignificant. Hydrous oxide coatings can tolerate a much higher concentration of impurity metal ions in the coating without having much effect.
- Hydrous oxide coatings on pigment have ion-exchange characteristics. Their exchangeable ion content affects pigment performance in applications that are sensitive to *p*H (acid-catalyzed coatings) or the presence of electrolyte (electrocoatings).
- Pigment surface area affects oil absorption.

Some of these effects are sufficiently well quantified for translation into specifications.

Pigment Characteristics

TiO_2 pigment has to meet stringent specifications of crystal phase, particle size, surface characteristics, and purity. As with all chemicals, every product characteristic has some effect on every performance quality. Some specific characteristics, however, dictate equally specific performance attributes. These crucial relationships are described.

Refractive index and density are paramount to optical function, but they are not subject to manipulation. The crystal phase impacts weathering and light-scattering performance. Particle size controls light scattering and has effects on color. Surface characteristics are designed into the product through chemical treatments reflected by commodity composition. The treatments improve dispersibility, durability, and gloss performance. High purity of the pigment makes for brightness.

TIO_2 CRYSTALLITES

The active ingredients of a TiO_2 pigment commodity are its TiO_2 crystallites. Other components of the commodity affect the commodity density but do not affect the crystallite density or the refractive index of the pigment. Neither the refractive index nor the density of any chemical can be manipulated independently by conventional technology.[11] Two crystal phases of titanium dioxide serve as pigments: rutile and anatase. They differ in refractive indices, densities, and weathering performance because rutile and anatase differ by the arrangement of the titanium and oxygen ions within the crystals (Fig. 5). Rutile crystals are elongated, are denser, and have higher refractive indices.[12] Because of their higher refractive indices, rutile pigments scatter light more effectively than anatase products. They are also much less prone to cause paint films to chalk.

Rutile absorbs slightly more violet radiation than anatase and is slightly more yellow in bulk. However, little, if any, of this yellowness extends into pigment applications.

TiO_2 is an ultraviolet radiation-energized oxidation catalyst of organic polymers. Anatase surface is about ten times more reactive than rutile surface. It takes only 10 % anatase in rutile to reduce to one-half the life expectancy of a paint film. Thus, for all exterior applications, the phase purity of rutile pigments is quite important.

During paint manufacture or usage, titanium dioxide cannot undergo transitions of crystal phase, that is, it cannot change its lattice structure. This contrasts with most organic pigments, many of which phase convert readily and usually with dramatic loss of optical performance.

[10] Particle size measured as Stoke's settling diameters by sedimentation methods.

[11] Density and refractive indices of inorganic oxides can be increased together, but only at extreme pressures and astronomic cost.

[12] Actually, TiO_2 crystals have two principal refractive indices each. These two refractive indices do not differ much. They enter all relevant considerations of pigment as an appropriately weighted average.

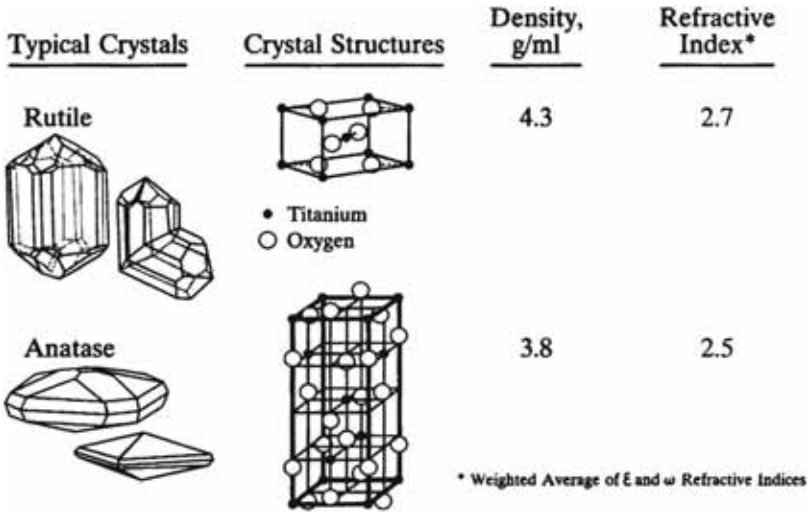

Fig. 5—Titanium dioxide crystals. From Braun, J. H., "Introduction to Pigments," Monograph in the Federation Series on Coatings Technology, Federation of Societies for Coating Technology, United States, 1993.

For example, an unstabilized a-copper phthalocyanine pigment, on exposure to an aromatic solvent, grows into long needles of β-copper phthalocyanine, losing most of its color strength in the process.

PHASE ANALYSIS

1 % or more of anatase in rutile pigment is considered undesirable because it increases the catalytic reactivity of the pigment. Fortunately, the phase analysis of TiO_2 pigment is cheap, convenient, and reliable.

Phase purity of pigment is usually measured by x-ray diffraction, for example, ASTM D3720, Standard Test Method for the Ratio of Anatase to Rutile in Titanium Dioxide Pigments by X-ray Diffraction. Conventional diffractometers can detect 1 % of pigmentary anatase in 99 % rutile by using peak intensity ratios or instrument counts. With careful attention to instrument alignment and sample preparation, a bit less anatase can be detected. Other more complex techniques are more sensitive. However, why bother since less than 1 wt % anatase does not contribute much to the catalytic activity of the pigment.

The hydrous and anhydrous oxides contributed by pigment treatment are not detectable by x-ray diffraction because they are either truly amorphous or subcrystalline in nature and that is too small and/or too disorganized to be disruptive. Their diffraction lines are diffuse and drowned in the TiO_2 signal.

PIGMENT PARTICLE SIZE

TiO_2 pigment particles are submicroscopic. They are so small that one pigment particle is to the size of a man as the size of a man is to the size of the earth. Thus, intuitive judgments based on macroscopic experiences are often misleading.

The particle size of pigment grades is tailored to the required optical performance. Pigment size depends critically on definition of "particle." For paint optics, the particle is the object that a light beam meets in the paint film. Its size is a composite of primary particles, aggregates, agglomerates, flocs, and even of casual contact of any of these assemblies. Primary particles are individual single crystals and crystallographic twins.[13] They average from 0.1 to 0.3 μm in median diameter by weight with a geometric standard deviation of about 1.4.[14] Aggregates are associations of crystallites sharing grain boundaries and are thus strongly bonded. Agglomerates are associations of crystallites and aggregates bonded by relatively weak forces. Flocs are weakly bonded associations of crystallites, aggregates, and agglomerates formed spontaneously in a liquid or even in air.

The shear forces of paint application can disperse flocs. However, they are likely to reassociate. Paint grinding breaks most agglomerates if (1) the mill base is formulated to proper viscosity and (2) the mill is well operated. Aggregates can be broken only by high-intensity mills. Crystallites cannot ordinarily be broken. Aggregates and crystals, once broken, do not reassemble because aggregate bonding and crystal growth require thermal activation to many hundred degrees centigrade. TiO_2 pigments do not degrade in conventional paint and plastics processing operations.

The inclusion of the term "casual contact" in the definition of particle is important because it links size to concentration. At low pigment concentration, the frequency of particle overlap in a beam of light is low and the casual contact contribution to effective size is small. At high concentration, casual contacts are abundant and contribute significantly to the particle size as seen by a light beam penetrating a paint film.

Optimal scattering performance calls for optimal particle size. Particles that are too small, in the extreme, are in molecular dispersions and scatter almost no light; particles too large, macroscopic crystals, are transparent. The particle size at which a population of TiO_2 particles scatters a maximum amount of light is about 0.2 μm for green[15] and white light. Blue light is scattered more effectively by

[13] Two or more single crystals intergrown according to some deducible law of symmetry.

[14] Geometric standard deviation = $\frac{1}{2}(D_{84}D_{50} + D_{50}/D_{16})$, with D = diameter, and 84, 50, and 16 signify the respective percentiles.

[15] For whiteness and brightness, green light matters most because the human eye is most sensitive in the green waveband.

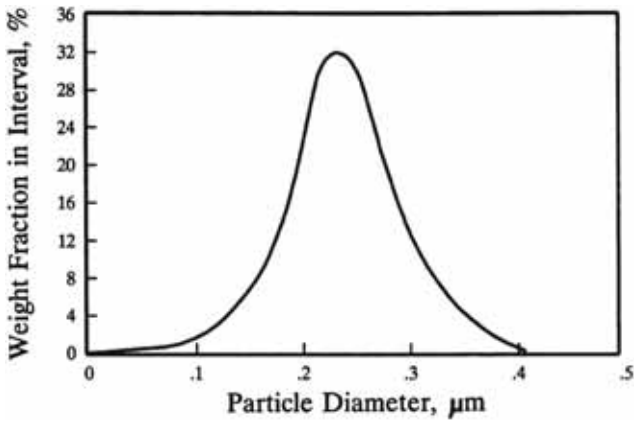

Fig. 6—Particle size distribution of TiO_2 pigment. From Braun, J. H., "Introduction to Pigments," Monograph in the Federation Series on Coatings Technology, Federation of Societies for Coating Technology, United States, 1993.

particles closer to about 0.16 μm, red light by particles of about 0.23 μm. This optically effective particle size is likely to differ from the size measured by analysis.

Particle-size distributions of commercial TiO_2 pigments are narrower than those of many so-called monodisperse particulates (Fig. 6). Population statistics approach "log-normal" character, that is, a logarithmic transform converts the size distribution curve to "normal" or Gaussian probabilities. Appropriately ground, pigment dispersions contain less than 5 wt % of particles smaller than 0.10 μm and larger than 1.0 μm. The mean particle size of pigment grades is tailored to the required light-scattering performance. Pigment grades composed of small particles are made for applications at low-pigment volume concentration.

The pronounced wavelength dependence of optimum scattering results in a subtle color effect caused by white pigments in colored coatings. Their color shifts toward red if the white pigment is larger than optimal or toward blue if the white pigment is smaller than optimal. This "undertone" is visible only in gray and colored coatings and in white at incomplete hiding. In gray coatings, the effect can be quite obvious, sometimes objectionable, sometimes desirable. Small-size TiO_2 grades with blue undertone are used to make colors look "cleaner," i.e., less yellowish.[16]

Large particles in a paint film are detrimental to gloss. Thus, the coarse tail of the size distribution of TiO_2 pigments impacts gloss performance [1]. Fig. 7 shows what particle size range impacts which performance characteristic.

Paint grind gages reveal the presence of minute quantities of grit, which are clumps composed of tens of thousands of primary particles. Grind gages do not respond to pigmentary particle sizes. For TiO_2 pigments, the presence of grit has no detectable optical effects.

Particle size control is one of the manufacturing secrets of the TiO_2 industry. Additives and process conditions during crystallization and grinding operations are crucial to particle size and product performance in both the chloride and the sulfate processes.

[16] Because dirt is colored by iron and thus reddish gray, a reddish or yellowish cast is perceived as "dirty."

PARTICLE SIZE ANALYSIS

An upfront warning: *Particle-size analysis and the interpretation of analytical data calls for specialized expertise.* Potential pitfalls are so numerous that serious misinterpretation is the rule rather than the exception, particularly in the interpretation of electron micrographs.

Problems arise in several ways. Two definitions of particle, be it clump, agglomerate, aggregate, or crystallite, are vitally important: (1) the particle of the analysis and (2) the particle that matters within the intended application. The analytical particle is almost never the same as the particle in a paint film that interacts with light.

- Dispersion is a true grinding operation that reduces particle size. In spite of this, grinding must be an integral part of the analytical procedure. Otherwise, the softest and largest clumps become valid members of population statistics.
- In the process of sample preparation, dispersive work is often expended on minute samples. Such work can add up to enormous energy concentrations that can break crystallites, which cannot be broken *en masse.*
- Sampling statistics is a frequent problem considering small quantities or low concentrations of pigment in samples.
- In microscopy, transmission images bear little resemblance to ordinary visual perceptions based on observation of surfaces. Scanning micrographs, by contrast, correspond to human vision. Differences become apparent when comparing Figs. 3 and 4.
- In light-scattering methods, the extreme refractive index of TiO_2 affects computational interpretation.
- No certified standards are available pertaining to the size range of pigments.

Numerous methods have been applied to the size analysis of pigments: Andreasan pipettes, disk centrifuges, transmission electron microscopy, light-scattering measurements, field flow fractionation, etc., have been used. They are too complex and far too costly for routine analysis.

Lately two methods have advanced TiO_2 technology because reproducible results can be obtained routinely: x-ray sedimentation and the x-ray disk centrifuge. Both methods are usually combined with ultrasonic dispersion.

X-ray sedimentation measures the Stokes' diameters of particles settling in water by gravity. Settling causes density differences in the suspension and these are detected by absorption of x-rays. Brownian motion interferes with settling and distorts the small end of the size distribution curve of the particle population. The x-ray disk centrifuge substitutes centrifugal force for gravity and this avoids misrepresentation of small particle fractions.

COMMODITY COMPOSITION

The TiO_2 in the pigment is its optically active ingredient. Other components adapt it to its end use. The commercial products have compositions that fall into one of three categories: (1) uncoated pigments, (2) coated pigments, and (3) Slurries.

Uncoated pigments contain 98 % or more titanium dioxide; some contain up to about 1 % aluminum oxide (anhydrous), and other products contain less than about 0.5 % aluminum oxide with some other inorganic, anhydrous oxides. Organic additives and their decomposition products may be present in concentrations of fractional weight percentages. Uncoated pigments are used in plastics

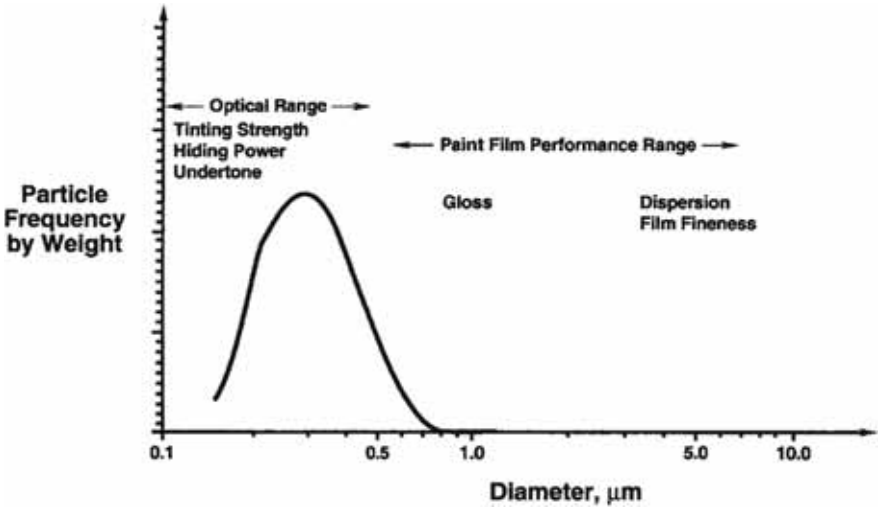

Fig. 7—TiO_2 aggregate size distribution [1].

and paper. In coatings, wet-treated pigments are preferred because they are easier to disperse into liquids of low or moderate viscosity.

Minor constituents, either carried over from the ore or added in the manufacturing process, can be important in determining pigmentary properties because they can control crystallite size. Sulfate pigments retain up to 0.3 % niobium pentoxide and 0.3 % phosphorus pentoxide from the ore. They also contain up to 0.2 % alumina, which is added to compensate for the presence of niobium. Compensation minimizes discoloration by the semiconductor imbalance that pentavalent and trivalent cations can cause in the rutile lattice.

Chloride process pigments contain practically no unwanted impurities because the titanium tetrachloride intermediate can be effectively purified. They contain about 1 % pyrogenic alumina that is added for improved process control and for photochemical stability improvement.

Trace constituents are generally unimportant except for transition metals, such as iron, chromium, vanadium, etc., which degrade color by semiconductor mechanisms.

Besides inorganic constituents, most uncoated and many coated pigments contain up to 0.5 % of an organic grinding aid to improve flow in the fluid energy mill, thereby achieving more uniform grinds. The grinding aids are usually polyhydroxyl compounds (for example, trimethylol propane, triethanolamine, etc.) that can undergo some pyrolytic degradation in the mill.

For use in coatings, i.e., to be dispersible by conventional paint-making equipment, TiO_2 pigments are "coated." In aqueous suspension, hydrous aluminum oxides are precipitated onto the surfaces of pigment particles. Interior grades contain a coating of up to 5 % hydrous alumina for ease of dispersion. Durable grades have another coating that usually consists of about 2 % silica and sometimes also oxides of zirconium, boron, zinc, cerium, and tin, usually in concentrations of less than 1 %.

Rutile pigments are made suitable for extreme exposure by encapsulating individual particles in glassy silica sheaths. Silica surface treatments on TiO_2 pigments were once considered detrimental to gloss performance. Silica on pigment, however, comes in two distinct modifications, either "fluffy" or "dense." Fluffy silica does indeed reduce gloss and is precipitated onto pigments intended for dry-hiding paints to increase oil absorption. Dense silica is used to encapsulate the TiO_2 particle in a distinct shell and thereby make the pigment durable in severe exposure.

Special high oil absorption products are made for paints formulated for dry flat hiding, that is, above the critical pigment volume concentration. They contain fluffy coatings, 5–15 % hydrous silica and 2–6 % hydrous alumina, for better spacing and improved optical efficiency in vehicle-starved formulations. The fluffy silica increases oil absorption and water demand by the pigment. Gloss is reduced.

Slurry products for coatings applications are usually based on coated pigments. In addition to the coated product, they contain organic dispersants and stabilizers. Predispersed pigments, sold as aqueous slurries, contain from 60 to almost 80 % titanium dioxide by weight. They are stabilized with low concentrations of organic chemicals.

Odorless amines are added for *pH* control. Together with preservatives, about 1 % of organic material is present. Pigment loading in slurry products is limited by the concentration at which the slurry becomes too thick to be pumped. Slurries of lightly treated grades are available at higher solids contents than slurries of heavily treated, dry flat grades. The slurries can be shear thickening. Effects can be severe.

The pigment industry describes its products and the hydrous oxides they contain in terms of their analytical equivalents, alumina ($A1_2O_3$), silica (SiO_2), and water (H_2O) or moisture content. Such description does not imply structure or chemical characteristics of the components but reflects analytical results. The actual components of pigment coatings are hydrous oxides: boehmite (γ-AlOOH), diaspor (α-AlOOH), hydrargillite γ-$Al(OH)_3$, etc.

Product descriptions in terms of analytical results are preferred because they can be verified. By contrast, the precise structural analysis of colloidal coatings on pigment surfaces is always difficult and often beyond the capability of even the most sophisticated analytical techniques. Results are usually ambiguous. But because coatings are precipitated from aqueous solution, the alumina coatings on coated TiO_2 pigments contain structural water, i.e., they are hydrous.

Wet treatments have profound effects on dispersibility and durability. In dry hiding paints, they affect hiding through oil absorption and spacing. Brightness is not usually affected. Process details of wet treatment are guarded secrets of the TiO_2 industry. The patent literature provides little guidance because the most and least effective processes can be described by equally factual performance claims.

ELEMENTAL ANALYSIS

Chemical analysis of pigments presents no particular problems. The quality of the data meets the requirements of pigment and coatings technologies. For routine analyses, conventional, wet analytical methods, for example, ASTM D1394, Standard Test Methods for Chemical Analysis of White Titanium Pigments, have been replaced by instrumental techniques for cost savings, not data quality. Aluminum and silicon contents are usually determined by x-ray fluorescence techniques. Water content is analyzed as weight loss of volatiles by thermogravimetric analysis.

PIGMENT SURFACE

Because pigment particles are so very small, their surfaces are enormously large. 1 lb of untreated TiO_2 has a surface of about 1 acre. Thus, surface characteristics have a profound impact on a pigment's interactions with all the other components of paints. Furthermore, pigment surfaces are complex composites reflecting the nature of the commodity.

The rutile component of most TiO_2 pigments contributes up to 10 m^2/g of composite surface area. Inorganic treatments with hydrous aluminas and silicas can more than double the total surface area of a pigment. Most pigment surfaces are composites of Ti—O, Ti—OH, Al—O, and Al—OH groups. Many pigment surfaces include Si—O and Si—OH units. Silica-encapsulated grades have few if any Ti—O and Ti—OH surfaces.

The surface areas themselves are not homogeneous. Usually they are composites to which TiO_2 contributes 0–10 m^2/g $TiO_2$and 5–10 m^2/g pigment, hydrous aluminas with about 200 m^2/g $Al_2O_3 \bullet xH_2O$ and 2–8 m^2/g pigment, silicic acid with about 150 m_2/g $SiO_2 \bullet xH_2O$ and up to 10 m^2/g pigment, silica glass 5–10 m^2/g SiO_2, 5–10 m^2/g pigment, etc. The chemical and physical characteristics of the surface are specific to the component. Granted, the components share important similarities. They are all hydrophilic oxides with high-energy surfaces.

Even the surfaces of titanium dioxide crystallites themselves are not just composed of titanium and oxygen ions. In the sulfate process, while the rutile crystallites grow, insoluble components accumulate on their surfaces. Those components are either impurities present in the ore and not removed in the purification process or additives designed to control crystal structure and growth and to regulate agglomeration. This fortuitous surface is not necessarily suitable for a given end-use application; thus, crystallite surfaces are modified by treatments.

The surfaces of TiO_2 pigments are readily wetted. They are usually hydrophilic and disperse spontaneously into water. The energy of wetting is high, aiding dispersion into organic liquids. The ease of wetting of TiO_2 pigments contrasts with wetting problems of organic color pigments, most of which are hydrophobic and have a low negative free energy of wetting. Water does not wet them without the help of surfactants. Suitable organic solvents may wet organic pigments but often only sluggishly.

Since unmodified pigments tend to cake and flow poorly, they are treated with up to 0.5 % of a grinding aid, usually organic polyhydroxyl compounds, to improve dry flow. These organic materials remain on the pigment surface. Silicone treatment can be used to make dry pigment flow like sand, but the pigment becomes hydrophobic and unsuitable for most coatings applications.

SURFACE ANALYSES

Surface analysis of pigments involves three interrelated subjects: surface area, surface composition, and surface chemistry. For data interpretation, sample density data are also required. Methods and results tend to be more interesting to the scientist than the practitioner.

Instrumental surface area determinations are now routine. Nitrogen adsorption is used widely. Reliability of results is satisfactory. Data are affected by the composite character of pigments and its response to sample preparation.

The modem methods of surface analysis, Microprobe, ESCA, etc., have been used to study pigment surfaces and have yielded interesting results and valuable insights. Costs and technical complexity preclude their widespread and routine use.

Surface adsorption by pigments has been explored extensively by surface calorimetry and in terms of adsorption isotherms, etc. Ambiguities introduced by the composite character of the surfaces have their impacts.

The density of a pigment can be measured precisely and quickly by a helium densitometer. However, for fine powders of known composition, calculated densities are often more reliable than measured values. Density calculation requires knowledge of the pigment composition and the density data for the pure component oxides. It is decisively important to include in the calculation the total water content: absorbed moisture plus the structural water of the hydrous oxides.

PIGMENT PACKING

Pigment particle packing density affects paint film performance. This density is an inverse measure of interstitial volume, a reflection of the way pigment particles aggregate and agglomerate into either stringy assemblies that haystack loosely or compact clumps that pack densely.

Effects of packing density on performance are profound. Packing characteristics determine the critical pigment volume concentration of a pigment. Through the critical pigment volume concentration, pigment packing affects virtually all characteristics of paint films [3]. Fluffy pigments have a low critical pigment volume concentration; particulates that pack densely have high critical pigment volume concentrations. In effect, the critical pigment volume concentration itself is a measure of the interstitial volume of wetted pigment particles. Adsorption layers are also involved, but in most instances their contribution is minor.

Practitioners of coatings technology have long been aware of the importance of packing density. They used oil absorption of a pigment as one of its most important descriptors. Oil absorption is still used today because it reveals so much about the pigment even though linseed oil has lost its importance as a binder.

Oil absorption is primarily a measure of wet packing complicated by the involvement of adsorption layers,

dispersion work, and flocculation. The measure predates the insights of Asbeck/Van Loo into structure and performance of paint films.[17] Thus, the connection between oil absorption—the practical measure—and the scientific concept—critical pigment volume concentrations—is unnecessarily convoluted. Oil absorption of different pigments cannot be compared because the measure is based on weights, not volumes. Critical pigment volume concentration, by contrast, is based on volumes and lends itself readily to comparisons of particulates that differ in densities. At its best, when oil absorptions of similar pigments of identical densities are measured by an experienced individual who uses a standardized procedure to his personal end point, oil absorption values become a reasonably precise measure of the packing of pigment particles in oil.

For wetted particles, pigment packing is not affected much by the nature of the liquid—water, oil, or solvent—provided the particles are not flocculated. In practice, surfactants must be added or be present as a natural component of the system as they are in raw linseed oil. "Liquid absorption" values agree pretty well with each other if they are based on relative volumes of a pigment in a variety of liquids. Incidentally, oil absorption values correlate inversely with the bulk density of a given pigment. The fluffier the pigment packs in air, the more loosely it packs in liquids.

PACKING MEASURES

In spite of its many shortcomings, oil absorption is the only measure of packing that is widely accepted. The test is a titration of raw linseed oil into dry pigment powder to an end point at which the mass cakes. Two procedures are in common use: ASTM D281, Standard Test Method for Oil Absorption of Pigments by Spatula Rub-out and ASTM D1483, Standard Test Method for Oil Absorption of Pigments by Gardner-Coleman Method.

Precision of oil absorption data is poor unless one experienced individual makes all measurements in the data set. For tests by different laboratories, the spatula method has a coefficient of variation of 12 %, with 5.3 % for the Gardner-Coleman method. Data obtained by two analysts tend to differ because the end point of the titration is more difficult to define than to reproduce.

CONTAMINANTS

Extraneous metal ions within rutile crystallites can degrade pigment brightness. Nickel and chromium can be detrimental in concentrations as low as a few parts per million. Semi-conductor mechanisms are involved. Substitution of extraneous ions for Ti^{4+} in the TiO_2 lattices discolors the crystals usually toward gray or yellow. Impurities and coproducts introduced by the treatment chemicals are far less detrimental to brightness. Coproducts can, however, affect specialized performance requirements. Certain ions can, for example, inhibit cure of acid or base-catalyzed coatings or cause film defects in electrocoatings.

Purity and brightness of TiO_2 crystallites are process related. TiO_2 crystallites made by the chloride process are purer and brighter than sulfate products. The coproduct content of a pigment commodity is usually not a matter of poor operating practice but set by complex compromises between conflicting performance requirements.

TRACE ANALYSES

Trace impurities in pigments are analyzed by conventional emission spectroscopic and x-ray fluorescence methods. Results are considered reliable though not particularly precise.

COLOR

Titanium dioxide is a virtually colorless dielectric with some semiconductor characteristics due to small amounts of contaminants. Rutile absorbs in the violet end of the visible spectrum. Fig. 8 is a schematic representation of the reflectances of white, gray, and black paints pigmented with only TiO_2, with TiO_2 and carbon black, and with only carbon black, respectively. Absorption of far violet radiation imparts a slight yellow hue to large crystals. The anatase absorption edge is at a shorter wavelength than rutile, shifted almost completely into ultraviolet wavelengths. Thus, anatase crystals are slightly less yellow than rutile crystals. All this does not matter much in coatings. For high-purity pigment, dry powder color does not correlate with end use color because most polymers contribute far more yellowness than the pigment.

Pigment brightness matters less in most coatings applications than one might presume. Most coatings, even white ones, are toned, that is, their brightness is reduced intentionally by addition of carbon black or color pigments. Purity, thus brightness, is important only for white coatings that are usually not toned: Coatings for light fixtures, many coil coatings, most inks, and ink-similar paints.

Chloride process pigments are intrinsically brighter and whiter than their sulfate counterparts. Typically, chloride process pigments average 99.5 % L*[18] lightness,[19] and 98.5 % sulfate pigments.[20] The difference between chloride and sulfate pigments, an L lightness difference of 1 %, is about ten times larger than the least visible difference.

TiO_2 particle size has a significant effect on the color of tinted coatings and thin white films. Smaller particles scatter blue light more efficiently. As a result, pigment of a smaller average particle size will shade bluer both tinted coatings and white coatings at incomplete hiding. Pigment of a larger average particle size will shade redder in the same systems. Most TiO_2 grades for coating applications are neutral in this particle-size-related undertone. Products intended for very low end-use concentrations are often bluish. Red undertone pigments are not in demand.

COLOR MEASUREMENT

Color measurements of pigments are performed on dry pressed pellets. Modem spectrophotometers provide data with more than sufficient precision for most purposes of pigment quality control. Most of these instruments can

[17] Asbeck and Van Loo recognized that the characteristics of paint films involve volume rather than weight consideration, no small matter when densities of paint film components can range from 0.9 to 6 g/mL.

[18] CIELAB (Commision International de l'Eclairage, 1978) metric of lightness.

[19] Brightness/lightness of a dry pressed pigment pellet.

[20] In very first approximation, a TiO_2 pigment with an L* lightness of 98.5 % contains a three times higher concentration of colorant impurities than a pigment of 99.5 % brightness: 1.5 %/0.5 % = 3.

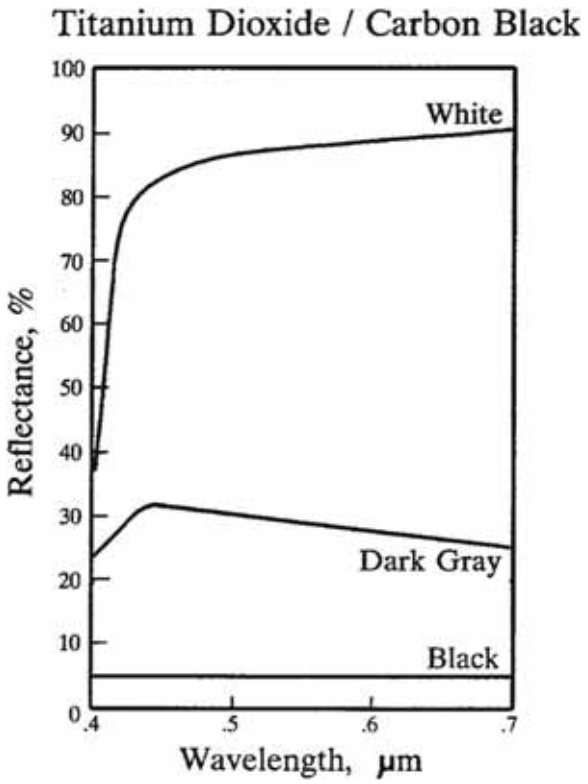

Fig. 8—Reflectance of white, gray, and black paints. From Braun, J. H., "Introduction to Pigments," Monograph in the Federation Series on Coatings Technology, Federation of Societies for Coating Technology, United States, 1993.

report their results in any of several color coordinates. The L**a***b** system[21] seems particularly well suited to describe variations on the theme of white.

HAZARDS

TiO_2 pigment is a benign chemical. Its hazards, and the relative lack thereof, are detailed in Material Safety Data Sheets that must accompany any United States shipment. TiO_2 presents no pronounced health hazards; it is neither corrosive nor acutely toxic and does not appear to be a significant carcinogen nor embryo toxin in the workplace. As a dry powder, TiO_2 can become a nuisance dust that may require control.

TiO_2 pigment cannot burn nor explode, either as a dry powder or as aqueous slurry. Neither the dry pigment nor the slurry is corrosive or reactive. The hazards of pigment dispersions in organic liquids reflect the characteristics of the dispersion liquids.

Pigment Performance

The TiO_2 industry sells light scattering for the price of TiO_2 because there is no better and cheaper way to achieve effective hiding by thin films that are white or light in color. Thus, optical effectiveness is the primary performance characteristic of the pigment. However, TiO_2 pigment is well optimized and functions near its theoretical potential. Between products developed for similar end use, light scattering differences are too small to matter or to be measured. Thus, secondary performance characteristics can be commercially decisive.

[21] CIELAB (Commision International de l'Eclairage, 1978) metric of color.

HIDING AND OPACITY

Pigment sells by weight but scatters light, that is, functions, by its volume. The particle size of TiO_2 for white pigment applications was optimized for the scattering of visible light, first experimentally, later confirmed by theory. Commercial grades perform near theoretical potential. A rutile particle of about 0.2 μm diameter is optimal for green light, the wavelengths of greatest sensitivity of the human eye.

Fig. 1 illustrates the relationship between scattering power and particle diameter. The Mie theory can specify the optimal diameter for the scattering of an electromagnetic wave by a dielectric particle with great precision, but the result is limited to single spheres. This complex and abstract theory must be translated (1) from a sphere into a real particle of elongated, angular shape, (2) from a single, isolated particle to assemblies of massive numbers, and (3) from monosize particles to particle-size distributions. The task is formidable, yet significant progress has already been made.

Fig. 9 is an illustration of the effects of pigment concentration on hiding of a paint film. At first, hiding increases in direct proportion to concentration. Then, the crowding of pigment particles causes the increase to diminish, to reach a maximum, and to decrease toward the critical pigment volume concentration. Beyond the critical pigment volume concentration, dry hiding, that is, light scattering at air/ pigment interfaces, causes hiding to increase again.

Crowding of pigment particles diminishes light scattering substantially [4] (Fig. 10). Effects become apparent at pigment volume concentrations above about 8 vol %. More than half of a pigment's scattering effectiveness can be lost between 8 vol % and the critical pigment volume concentration. A simple optical model explains the effects [5]. Improvements in pigment effectiveness achieved through control of crowding are likely to be fairly insignificant [6].

The optics within paint films are quantified by the Kubelka-Munk theory that combines for thin films the effects of light scattering (usually by white pigment) and light absorption (usually by color pigment). The model serves exceedingly well in spite of some theoretical limitations. Kubelka-Munk equations provide a basis or an explanation for most performance measurements: hiding, opacity, and tinting strength.

MEASUREMENTS OF LIGHT SCATTERING

Until recently, pigments and paint films were evaluated by visual comparisons, for example, ASTM D332, Standard Test Method for Relative Tinting Strength of White Pigments by Visual Observation. The eye was more sensitive than available instruments, and the mathematics of Kubelka-Munk was too complex for routine calculations. Two developments make quantitative evaluation of pigments more appropriate: (1) Optical instruments have become more sensitive and more reliable than the eye, and (2) the least of computers can calculate results on the spot.

Light scattering and light absorption of paint films can be quantified independently using light reflectance or transmission measurements of thin[22] films drawn over black and white substrates. In addition, film thickness or film weight and composition must be measured. ASTM

[22] Thin enough to show obvious contrast between regions drawn over black and white backgrounds but thick enough to look uniform rather than mottled.

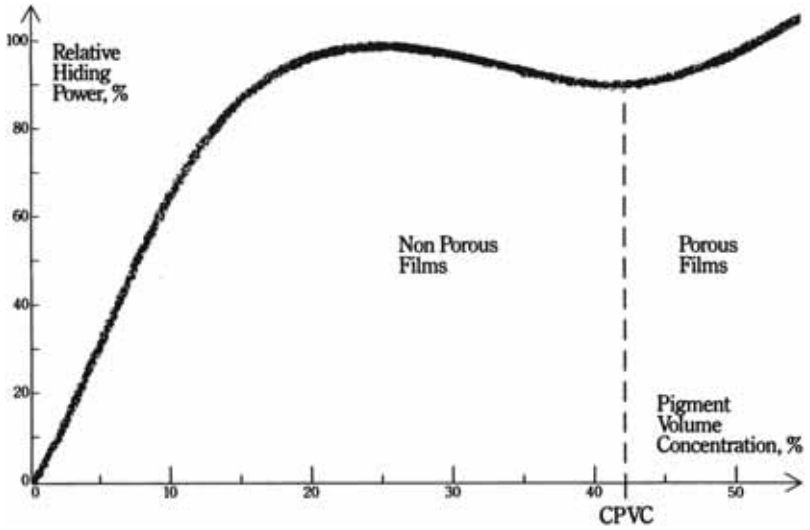

Fig. 9—Hiding power of paint films. From Braun, J. H., "Introduction to Pigments," Monograph in the Federation Series on Coatings Technology, Federation of Societies for Coating Technology, United States, 1993.

D2805, Standard Test Method for Hiding Power of Paints by Reflectometry, describes such a test.

Relatively inexpensive and very reliable spectrophotometers can measure reflectances in any specific and narrow wave band. By measurements, wave band-by-wave band across the spectrum of visible light, applicability of hiding power measurements is extended from black and white to color. Paints of different hues can be compared and results expressed separately for performances of white and color pigments. Computer programs are available for data evaluation.

Tinting strength tests, ASTM D2745, Standard Test Method for Relative Tinting Strength of White Pigments by Reflectance Measurement, measure the relative light scattering of a white pigment by overwhelming the slight intrinsic absorptions of binder and pigment with a massive absorption by a standardized addition of colorant. Measured are thick films of infinite hiding.[23] The same test serves for the evaluation of color pigment. Here, the slight intrinsic scattering of the color pigment is overpowered by the massive scattering from standardized addition of a white pigment.

Absorption of light within the paint film increases the hiding power of the film. The effect is quite pronounced, and either pigment or binder can cause it. When caused by TiO_2 pigment of low brightness, this low-purity product can get undeserved credit for a hiding power advantage over purer products. Also, off-color extenders and colored polymers can boost hiding power incidentally or deliberately. This hiding improvement comes at the expense of brightness.

DISPERSIBILITY

To make paint, dry powder has to be distributed in liquid composed of binder and solvent. The process is called dispersion or paint grinding. The ease with which a powder can be dispersed in a liquid depends primarily on its particle size. As pigments go, TiO_2 at 0.2 μm size is large and easy to disperse, almost as easy as extenders, much easier than most color pigments. For all but glossy coatings, TiO_2 can be stirred into liquids with high-speed agitators. High-gloss finishes require more powerful equipment: media, roll, or ball mills.

Dispersing a pigment involves four distinct stages during which most of the energy of grinding converts to heat:

1. *Liquid replaces air-solid interfaces with liquid-solid interfaces.* The ease of wetting depends on (a) energy characteristics of the surface of the solid and (b) the chemical affinity between solid and liquid. TiO_2's high-energy surface wets well. By contrast, the low-energy surfaces of organic color pigments wet only with difficulty.
2. *Bonds between particles are broken.* TiO_2 crystals are not broken in ordinary mills. Bonds between crystals range in strength from strong within aggregates to weak within agglomerates. Weak aggregates can be broken in the high-energy mills of pigment and plastics technologies, not, though, by equipment common in coating technology. Agglomerates break in high-speed dispersers.
3. *Particles are distributed throughout the liquid.* The more viscous the liquid, the more power that is required to mix and distribute materials and the more effective is the grind.

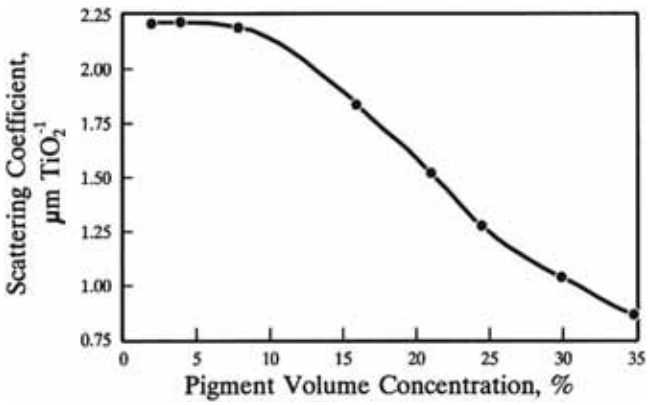

Fig. 10—Scattering coefficient of TiO_2 [4].

[23] Sufficiently thick that a further increase in thickness does not affect reflectance.

4. *The distribution of particles has to be stabilized against reversible flocculation.* Nonaqueous systems flocculate by Brownian motion and are stabilized against flocculation by surfactants that provide steric hindrance. Aqueous dispersions flocculate by (1) electrostatic attraction and by (2) Brownian collisions. They are charge stabilized by ionic dispersants.

Rheology matters decisively. When grinding in a shear-thickening rheology regime, dilatent grinding is highly effective. By contrast, shear-thinning rheology of the grind charge absorbs energy into reversible bonding, wasting much of it as heat. High viscosity helps the energy transfer from mill to particulate. Thus, other parameters equal, grinding "viscous" is more effective than grinding "thin," and grinding "well cooled" is more effective than grinding "hot."

Flocculation degrades optical performance. White pigments can lose only a moderate fraction of hiding, rarely as much as 30 %. By contrast, color pigments can lose most of their color. Excessive or inappropriate grinding does not degrade TiO_2. Optical performance does not improve with grinding because most of the pigment is dispersed very early in the grind cycle. A few parts per million of undispersed grit, however, can degrade film fineness from "excellent" to "inadequate."

MEASUREMENT OF DISPERSIBILITY

This author knows of no reliable and useful measurement of dispersibility. Granted, it is possible to use standardized procedures to establish a ranking of pigment samples against specific performance requirements. Such a ranking cannot be quantified and does not translate from one application to another. In one such scheme, paint is made by a minutely standardized, low-shear dispersion procedure. The paint is then tested for grit by one of several conventional fineness gages.

The "residual grit" aspect of dispersion is usually evaluated by fineness-of-dispersion gages, for example, ASTM D1210, Standard Test Method for Fineness of Dispersion of Pigment-Vehicle Systems by Hegman-Type Gage. The gages are shallow, tapered channels that are precision machined into steel blocks. A paint sample is scraped into the channel. The surface of the paint wedge is then examined to see at what depth the diameters of largest agglomerates exceed the depth of the channel. This point is visible as a transition from smooth to streaked paint surface.

PIGMENT EFFECTS ON PAINT FILM DURABILITY

Durability is the continuance of decorative and protective performance of paint films and their components under the influence of weathering. Lack of weathering resistance manifests itself as (1) oxidation of polymer ultimately to carbon dioxide and water, (2) discoloration and fading of color pigments, and (3) chalking of the TiO_2 with concomitant erosion and gloss loss. Instability of substrates introduces additional degradation effects.

For paint films with TiO_2, concerns involve the weathering resistance of the films themselves. Exposure to sunlight, moisture, and oxygen changes the appearance of paint films. Some films chalk and eventually erode to their substrates; others discolor and fade well before chalking becomes a problem. Degradation of coatings occurs because paint films are slowly oxidized by air. Sunlight triggers the degradation reactions. In the dark, paint films can last for centuries, even millennia. In light, durability depends on binders, pigments, and the conditions of exposure. High humidity, particularly condensation, aggravates degradation.

Only the ultraviolet radiation (UV) portion of sunlight causes degradation directly because it has energy content sufficient to break chemical bonds. The degradation of UV-A and UV-B radiation[24] is irreversible for polymers and for all organic and some inorganic pigments. A few inorganic pigments are thermodynamically stable. Titanium dioxide is stable, but UV above 3.08 eV activates its catalytic characteristics. In effect, the band gap of TiO_2 [25] is within the energy levels present in sunlight. All white pigments share some of this attribute. Extenders are stable and inert. Their band gaps are too large to be activated by the UV components of sunlight.

Titanium dioxide affects the durability of paint films in two distinct and opposing ways. (1) As a strong UV absorber, TiO_2 protects the paint film, and (2) as a UV-activated oxidation catalyst, TiO_2 degrades binders [7].

Three characteristics of TiO_2 are functionally disparate but are manifestations of a single fundamental characteristic of dielectric matter: (1) its unique refractive index, which makes TiO_2 the best white pigment, (2) its extreme UV absorptivity, and (3) UV catalytic activity of the TiO_2 surface.

Radiation of more than 3.08 eV, water, and oxygen are all essential for the TiO_2-catalyzed degradation of binder. Their reactions combine into a cycle that generates two free radicals from each active UV photon [8].

$$H_2O + O_2 + h\nu_{(UV)} \rightarrow \cdot OH + \cdot HO_2 \text{ (in presence of } TiO_2)$$

The hydroxyl and peroxyl free radicals are highly reactive agents that oxidize and thus degrade essentially any organic polymer:

$$2 \cdot HO + 2 \cdot HO_2 + CH_4 \rightarrow CO_2 + 4H_2O$$

The chain of chalking events is cyclic with respect to TiO_2, and it can be disrupted by exclusion of either UV, water, or oxygen.

DURABILITY CONTROL

The TiO_2 industry inhibits the catalytic activity of the TiO_2 surface and improves the weathering resistance of its products by encapsulation in amorphous silica. The shell that forms is a true silica glass precipitated from aqueous solution by technology invented by DuPont in the 1960s [9]. Encapsulation of TiO_2 made it practical to paint automobiles in white and bright colors. Meanwhile, binders were improved so that less effective deactivation of the TiO_2's

[24] UV-A is the UV wavelength region near to visible radiation or light, UV-B is the medium UV region, and UV-C is the far (shortest wavelength) UV light. Sunlight contains little UV-B and essentially no UV-C.

[25] The band gap is the "forbidden" energy gap between the valence band and the conduction band of a semiconductor. In the language of physics: "UV radiation induces semiconductor characteristics in TiO2;" in the language of chemistry: "UV radiation reduces colorless TiO_2 to black Ti_2O_3."

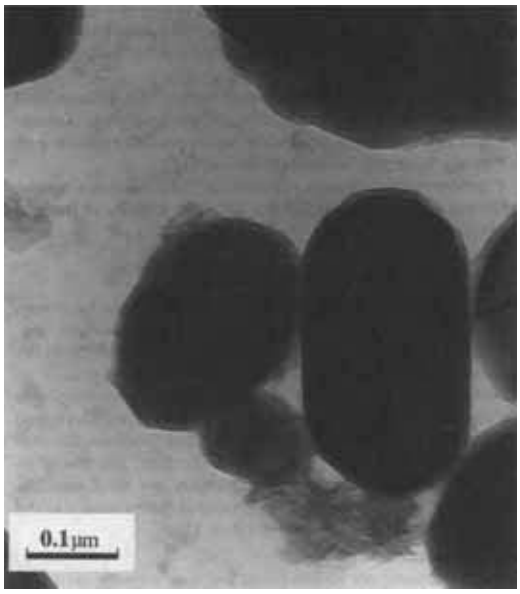

Fig. 11—Encapsulated TiO_2 pigment.

catalytic activity suffices and provides satisfactory performance of automotive finishes in temperate climates.

The SiO_2 glass prevents contact between the catalytic surface of rutile and the organic vehicle and provides a surface for recombination of free radicals. Fig. 11 is a depiction of superdurable pigment particles. Their silica sheaths are barely visible on the transmission electron micrograph. The silica sheaths themselves, after the TiO_2 was dissolved out, are shown in the transmission electron micrographs of Fig. 12. Even the holes are visible through which the rutile cores were dissolved.

Intermediate levels of weathering resistance are attained by partial encapsulation of the rutile in silica and/or alumina with or without zirconia and by bulky coatings of hydrous aluminum and silicon oxides on rutile.

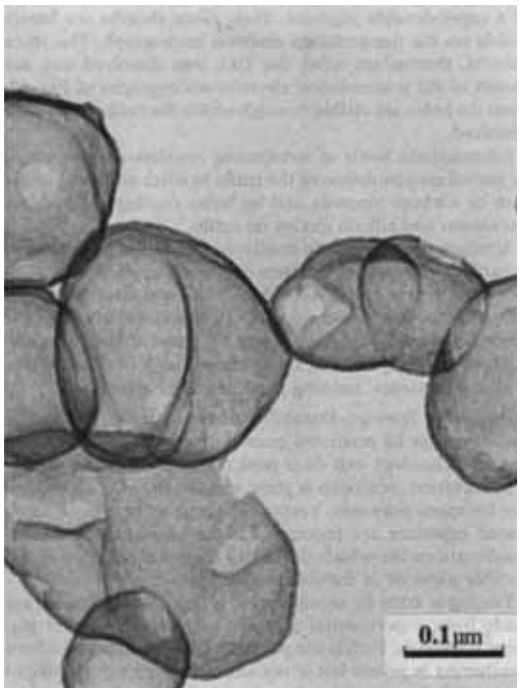

Fig. 12—Silica shells from encapsulated pigment.

Alternate approaches to chalking control are less effective or cause performance problems in coating applications. They involve attempts to (1) recombine holes and electrons at the TiO_2 surface by semiconductor mechanisms whereby the products are slightly yellow and (2) prevent the hydroxylation of the TiO_2 surface, i.e., interfere with one step of the chalking sequence, causing products to be gritty.

DURABILITY TESTING

Durability of coatings can neither be measured nor be predicted quantitatively. The best state-of-the-art technology can do is rank coatings. Costs per sample are exorbitant, precision is poor, and the time lag is prohibitive for many purposes. Years of outdoor or months of accelerated exposure are required for the pigment and binder combinations for which durability is important to yield useful information, that is, for durable pigment in durable binder.

Testing is done by simulation of a "real" world. Paints are made from experimental pigment and usually several pigment standards. Panels are painted. They are exposed where weathering is severe but is not necessarily representative of the intended application. Certain appearance characteristics are regularly measured and often chalk, color, gloss, etc., are noted. Finally, data are reduced, correlated, and compared. Reproducibility is barely sufficient to tell an interior grade pigment from a durable grade without testing replicates. Experimental durability differences within grades are not generally detectable [10].

Results from one binder system cannot be extrapolated quantitatively to binders involving different polymer chemistry, nor can a single acceleration factor predict outdoor performance from accelerated exposures [11]. Pigment manufacturers supplement their exposure testing by science-based analyses of the catalytic activity of the pigment.

PIGMENT EFFECTS ON GLOSS

Powders do not have a gloss; only surfaces can be glossy. Within surfaces, particulates affect gloss, for example, pigments in paint films. They are detrimental, particularly to the dimension of gloss perceived by the human eye. Naturally glossy surfaces occur on liquids and amorphous solids.[26] Particulates in paint film, pigments, extenders, and some additives reduce gloss because they roughen the film surface. The more particulate there is in the film, the lower its gloss. Clear paint films are glossy if they are sufficiently thick. Thin films can telegraph the roughness of the substrate to the surface of the paint film, reducing its gloss.

Since the volume concentration of white pigments in paint films must be much higher for hiding than the concentration of color pigments and blacks, the burden of improvement falls on TiO_2 producers. They have increased gloss performance for grades that serve the automotive and industrial markets.

Gloss matters are complicated because a fundamental difference exists between the measured gloss that guides

[26] Single crystals are an exception, but their surfaces are generally small. Glass is an amorphous solid. Polished surfaces are not "natural." Incidentally, only liquids, amorphous solids, and single crystals can be transparent.

coatings formulation and the perceived gloss that sells automobiles [1]. These two operational definitions of gloss, one based on instrumental measurement of an intensity of image and the other on the human perception of a distinctness of image, differ profoundly in substance. However, they correlate well enough to guide quality control and pigment development by incremental improvement. The fundamental difference between measured and perceived gloss can, however, misdirect the strategy of product development, for example, a development strategy focus on increasing refractive index. A mechanism by which pigment causes the surface roughness that degrades gloss explains [1] that pigments diminish gloss by an interplay between the surface tension of the wet film with the compressive strength of a particulate bed and a gel structure that develops within the film while it cures. While the film is fluid, surface tension maintains the surface at a molecular smoothness that results in "perfect" intensity-of-image gloss. As the film dries, the structure within the wet film strengthens until it overcomes the surface tension that maintains gloss. Shrinkage of the partially cured film continues, but now shrinkage becomes uneven on a microscopic scale because only the binder/solvent combination, not the pigment, shrinks. Thus, micro-roughness develops and diminishes gloss.

GLOSS MEASUREMENT

Gloss measurement has long been routine, and one technique is described in ASTM D523, Standard Test Method for Specular Gloss. Many conventional gloss meters are on the market. Most perform well for coatings pigmented with white and color pigments.[27] They come with measuring heads for three specular angles, generally 20°, 60°, and 85°. High-gloss surfaces are best measured at low (20° specular angle), medium glosses at medium angle, and matte surfaces at grazing angle, 85°. The selection of the proper specular angle improves instrumental precision.

The conventional gloss meters measure the intensity of light reflected by a surface, the intensity-of-image component of gloss. The human eye, by contrast, perceives the distinctness-of-image[28] component of gloss. Thus, haze and so-called distinctness-of-image data are used to supplement the conventional gloss measurements.

COMPATIBILITY

Usually, TiO_2 is used in combination with other pigments. Interactions between pigments can occur and are detrimental to performance. Often, hiding is decreased, color strength is lost, and chroma is reduced; occasionally, the hue shifts slightly.

Most interaction problems involve surface chemistry. The immediate cause of the problem is flocculation. Either the white or one of the color pigments has flocculated. Almost inevitably, the color pigment is at fault.

Most color pigments enter the market as toners, lakes, or dispersions, that is, complex composites that can contain more surfactants and modifiers than colorant. These additives are chemically reactive and can interact detrimentally with the surfactants or additives of the paint formula. Dry TiO_2 pigments,[29] by contrast, contain no surfactants and are inert and chemically less complex with far fewer possibilities of adverse interactions.

Chemical interactions between pigments are problems of the past caused by reactive pigments. White lead, for example, was incompatible with TiO_2 because UV exposure could cause gross, though temporary, discoloration. Few modern pigments are susceptible to these problems.

Problems between TiO_2 pigment and polymers or additives do, however, occur occasionally because many paint films contain much higher concentrations of TiO_2 than of additives or of color pigments. Components of TiO_2 pigment can thus have significant leverage even if present in relatively small concentrations on the pigment. Problems are usually quite specific to the paint formula. Several such problems have been recognized and are resolved through specialized TiO_2 grades made, for example, for electrocoating primers and for acid-catalyzed paints.

Product Types

ASTM D476, Standard Classification for Dry Pigmentary Titanium Dioxide Products, distinguishes four types of TiO_2 pigments (Table 2)—one anatase type and three rutile types: interior, exterior, and pigment for paints formulated above the critical pigment volume concentration. The standard was formulated in 1939 with two classes of pigments. In the years since, the design of pigments has progressed to where the coatings industry can now select the most suitable pigment grade for a specific application from far more than two or four TiO_2 types. Granted, a single TiO_2 grade could serve diverse needs but would do so only moderately well. Optimal performance in any application demands specialized pigment grades that satisfy specific requirements of optics, surface chemistry, and dispersion technology. Some of these requirements can be met only through compromise.

The diversity of products can be described in terms of four specific performance dimensions such as durability, gloss, dispersibility, and undertone. Then there are products aimed at specific applications such as enamel paints, dry hiding paints, pigment slurries, acid-catalyzed coatings, electrocoated primers, etc. Finally, pigment grades are designed for the specific requirements of whole industries such as coatings, plastics, paper, and ink.

These are the products designed to specific performance dimensions in coatings.

- *Durability: Interior—Exterior—Severe Exposure.* Interior grades are unfit for exterior applications except when used underneath top coatings that absorb all radiation with wavelengths below 400 nm. All-purpose pigments are exterior durable in appropriately durable vehicles at moderate severity of exposure and for moderate appearance requirements. Severe exposure grades are intended for satisfactory performance including high gloss at exceptionally severe conditions, for example, at the horizontal position in the humid subtropics. Durability must be manufactured into the pigment surface.
- *Gloss: Conventional—Flashy.* Conventional pigments satisfy the gloss requirements of most architectural and

[27] For coatings that contain flake pigments, the interpretation of angle-dependent reflectance measurements is complicated.

[28] The distinctness-of-image instrument is really an intensity-of-image meter sensitized toward distinctness of image.

[29] Slurry grades do contain some organic surfactant.

TABLE 2—Excerpt from ASTM D476: Specification for titanium dioxide pigments				
	Type 1	**Type II**	**Type III**	**Type IV**
	Anatase Free Chalking	Rutile Medium Chalk Resistant	Rutile Medium Chalk Resistant	Rutile Highly Chalk Resistant
Typical application	White exterior house paint, interior use	Low-medium PVC enamels and lacquers	Medium-high PVC enamels; alkyd and emulsion flat wall paints	Highly chalk-resistant exterior coatings requiring excellent durability and gloss retention
TiO_2, min.%	94	92	80	80

trade-sales applications and of many industrial coatings. High-gloss pigments are aimed at automotive and some flashy industrial finishes. High-gloss applications call for pigments of small agglomerate size and low oil absorption.

- *Dispersibility: Conventional—Low Shear.* Conventional pigments are designed to be dispersed by equipment developing moderate to high shear:[30] media mills, ball mills, roller mills, and high-speed dissolvers at low rates of throughput. Special pigments are available for low-shear, high-rate dispersion by high-speed dissolvers and for stir-in with screening. Dispersibility is promoted by surface treatments at some detriment to gloss. Unlike many color pigments, TiO_2 pigments are sufficiently dispersible to not require predispersion.
- *Undertone: Neutral—Blue.* In coatings applications, the undertone of the pigment, blue, neutral, or red, is rarely an issue. Thus, most coating grades have a neutral undertone. Blue undertone pigments are preferred in applications at very low pigment volume concentration. Red undertone pigments do not appear to be in demand. Undertone is affected by pigment volume concentration and controlled by the size of the primary TiO_2 particle, small for blue, intermediate for neutral, and large for red.

There are also specific coatings applications addressed by special product designs.

- *Grades intended for coatings below the critical pigment volume concentration.* Most TiO_2 pigments, conventional interior and exterior grades, conventional and high-gloss products, conventional and low-shear dispersible pigments, the neutral and blue undertone pigments, are all suitable for applications below the critical pigment volume concentration.
- *Grades intended for applications above the critical pigment volume concentration.* Heavily treated, low-gloss products perform better in dry-hiding paints than grades made for high and moderate gloss. In effect, the pigment contains its own, exceptionally effective ex tender.
- *Slurries intended for waterborne paints.* Aqueous slurries are suited only for waterborne applications. The costs of dispersion operations are borne by pigment manufacturers. For medium- and large-scale operations, savings from the elimination of a process step outweigh the costs of slurry-handling facilities.
- Other specialized grades are made as opportunities are recognized and solutions developed.

[30] High shear within coatings technology. The plastics industry uses several more powerful mills.

Finally, specific products targeted for industries other than coatings.

- *Plastics.* Plastics are pigmented by products most of which are optimized for performance at PVCs of less than 1 vol %. Durability and dry-flow characteristics can be important to the plastics industry. High-gloss and low-shear dispersibility are usually not required.
- *Paper.* The wet-end stage of papermaking uses aqueous slurries. Slurry handling and optics are important: Low-shear dispersibility, high gloss, and durability are irrelevant.
- *Ink.* Inks require pigments that are high in gloss. Compatibility with a wide range of solvents and vehicles is often an important factor.
- *Miscellaneous end uses.* Pigmentary applications (floor coverings, elastomers, roofing granules, fibers, fabrics, sealants, food additives, etc.) and nonpigmentary applications where pigment is used for its TiO_2 content (ceramics, welding rods, etc.) or as a low-cost, mono-disperse particulate (for example, as catalyst support).

Also, the same products can be packaged in different ways, bag, semibulk, or bulk, or analyzed for special purposes, for example, food additive purity. Each such product may enter commerce under its own grade designation.

The wrong grade of TiO_2 pigment for any specific application will still be inert, white, and will hide well. But, the inappropriate pigment will fall short of expectations on secondary performance characteristics such as durability, gloss, or rheology. This is in marked contrast to most color pigments, where a grade inappropriate to an application is likely to fail grossly.

Matters of pigment classification are complicated by interactions among requirements.

1. Certain requirements are mutually exclusive. For example, aqueous pigment slurries are obviously suitable only for waterborne applications.
2. Some industry requirements overlap. Paper coatings resemble dry hiding paints and are served by similar products.
3. Optimal performance in one dimension can come at the expense of performance in another dimension. Flashy gloss can be attained only at the expense of pigment characteristics that promote stir-in dispersibility.
4. Premium performance can require additional process steps, increasing the cost of manufacture. Pigments for severe exposure and grades for flashy finishes are sold at a premium because they are more expensive to make.
5. Identical performance objectives can be achieved by different product designs.

TABLE 3—Commercial TiO_2 pigment grades

Product Type	Intended PVC[a]	Intended Gloss	Intended Exposure	Pigment Delivery	Intended Dispersion
1	Low[b]	Flashy[c]	Indoors	Dry	High Shear[d]
2	Low[b]	Flashy[c]	Indoors	Slurry[e]	Dispersed
3	Low[b]	Flashy[c]	Outdoors	Dry	High Shear[d]
4	Low[b]	Flashy[c]	Outdoors	Slurry[e]	Dispersed
5	Low[b]	Flashy[c]	Extreme[f]	Dry	High Shear[d]
6	Low[b]	Flashy[c]	Extreme[f]	Slurry[e]	Dispersed
7	Low[b]	Discreet[g]	Extreme[f]	Dry	Low Shear[h,i,j]
8	Low[b]	Discreet[g]	Extreme[f]	Slurry[e]	Dispersed
9	Low[b]	Discreet[g]	Extreme[f]	Dry	Low Shear[h,i,j]
10	Low[b]	Discreet[g]	Extreme[f]	Slurry[e]	Dispersed
11	Low[b]	Discreet[g]	Extreme[f]	Dry	Low Shear[h,i,j]
12	Low[b]	Discreet[g]	Extreme[f]	Slurry[e]	Dispersed
13	High[k]	Discreet[g]	Indoors[l]	Dry	Low Shear[h,i,j]
14	High[k]	Discreet[g]	Indoors[l]	Slurry[e]	Dispersed

[a]Pigment volume concentration, pigments plus extenders, in the paint film.
[b]Always below the critical pigment volume concentration.
[c]Application for which gloss is maximized at direct or indirect expense.
[d]Media mills and the like at moderate or low throughput, optimized mill base.
[e]Aqueous slurries.
[f]Including horizontal exposure to tropical and subtropical levels of ultraviolet radiation.
[g]Gloss levels from flat through semi-gloss to high gloss but excluding extremely high gloss.
[h]High shear is generally not required for less than extremes levels of gloss.
[i]High speed dispersers and the like.
[j]The film qualities of low-shear dispersion are generally not satisfactory for flashy finishes.
[k]Above the critical particulate volume concentration.
[l]Coatings above the critical pigment volume concentration are usually not suited for outdoors.

Nevertheless, I have attempted classification of state-of-the-art products in terms of six performance parameters and intended applications: concentration, gloss level, exposure, optics, slurry, and dispersion. Permutations of these requirements make for 72 potential product niches for coatings applications alone. Commercial products occupy 14 of the niches. They are shown in Table 3. All major manufacturers sell at least several of these products as specific grades or by equivalent subclassifications within grades.

About two-thirds of the potential product niches appear to serve no practical purpose. For example, aqueous pigment slurries are not suited for solvent-based paints, and high-PVC paint films are not made to have flashy gloss. Obviously, the multiplicity of grades creates costs and incentives for the development of universal grades. Lately some of these attempts have been partially successful, and a few "universal" products have appeared on the market. Conspicuously absent from this table are anatase pigments. They and the extended TiO_2 grades that used to dominate TiO_2 markets are no longer used in coatings.

OTHER WHITE PIGMENTS

In coatings, only void hiding competes with TiO_2. The classic white pigments—lithopone, zinc sulfide, zinc oxide, and white lead—are far less cost effective. White lead is also too toxic. Pigmentary zinc oxide is still being used in paint, not as a white pigment but as a mildewstat.

Extenders—colorless ground minerals and precipitated particulates—are sometimes described as pigments and are advocated as supplements for true white pigments.[31] Extenders are formulated into coatings to reduce costs by replacing expensive polymer with cheaper mineral. Below the critical pigment volume concentration, that is, in films with excess polymer, extenders do not scatter light because their refractive indices are too low. In films with excess particulates (films above their critical pigment volume concentration), extenders hide indirectly by creating pores. Only in very porous films do extenders scatter light at the particulate/air interface.

In colonial times, calcium carbonate ($CaCO_3$) was used as a white pigment. The pigment was made *in situ* by the reaction of atmospheric carbon dioxide with "whitewash," a brushed-on slurry of calcium hydroxide. The pigment was held together by minimal amounts of binder. Light was scattered at the $CaCO_3$/air interface. Because the service life of the coating was minimal, whitewashing ceased when wages increased with industrialization.

[31] They do not "impart black or white or a color to other materials," thus they do not meet Webster's definition of a pigment.

Void Pigments

Air-filled voids in a paint film can either act as if they were pigment particles or enhance the effectiveness of a true pigment. Both mechanisms have been implemented in coatings.

Pigmentary and subpigmentary voids contribute to hiding of all dry hiding paints films, that is, films starved of binder. Somewhere above the critical pigment volume concentration voids join into an interconnected network of pores. The pores become stress concentrators that degrade the mechanical qualities of the paint film. The network conducts chemical contaminants into the paint film and to the substrate, diminishing the chemical and protective qualities of the film.

It is through the creation of pores that extenders contribute to light scattering. This scattering comes at the expense of film qualities. Problems can be avoided if the voids are sealed and spherical.

Voids of pigmentary size scatter light like particles, about as effectively as pigmentary zinc sulfide but not nearly as well as TiO_2 pigment. Unlike interconnected pores that degrade paint films, sealed spherical voids are not, *per se,* detrimental to mechanical and chemical film qualities.

One commercial product, Rhopaque® (Fig. 13), generates sealed, spherical air voids in paint films from plastic beads that have one concentric void. The beads are added to the paint as an aqueous dispersion of water-filled resin balloons that lose their water as the film dries. These voids are protected by the thickness of their own plastic shells from the crowding that diminishes the scattering effectiveness of conventional white pigment. Their direct light scattering effectiveness is only 12 % of scattering by the same volume of rutile. Immunity to crowding increases the effective light scattering of voids.

Another, less-successful product, Pittment®, generated pigment-sized air voids in paint films by evaporation of droplets of an organic solvent emulsified in the paint. If the voids are of subpigmentary size, small enough to lose their individual optical identity, they do not scatter much light but collectively decrease the refractive index of the matrix. A composite refractive index of polymer and air takes the place of the index of polymer alone. This decrease of matrix refractive index has a potent effect on the scattering of any true pigment present in the paint film.

A product composed of vesiculated and pigmented polymer beads makes use of this effect. The product, Spindrift® (Fig. 14), is suitable only for low-sheen paints because the beads act as a flatting agent. They have to be larger than TiO_2 particles because each bead has to accommodate several pigment particles plus voids and some binder.

A third approach to void hiding, the use of stretched foam, is very efficient. Hiding can be achieved without any pigment with less polymer on the substrate than by any conventional paint. But foam coatings are pressure sensitive.

They are too sensitive for paint applications but are suitable for opacification of textiles, curtain fabrics in particular.

ACKNOWLEDGMENTS

I am indebted to my former colleagues for advice, counsel, and the insights I developed during my career in DuPont's white and color pigments businesses. Special thanks go to A. Baidins and R. E. Marganski, my co-authors in a literature review of TiO_2 technology, and to D. A. Holtzen and R. C. Craft-Tulloch, who helped review and revise the manuscript.

Black Pigments

Frank R. Spinelli[1,2]

BLACK PIGMENTS FALL INTO THREE CLASSES [1] as described in Table 1. The first two classes derive their color characteristics from the element carbon, the third class from ferrous oxide, Fe_3O_4. Class 1 blacks are carbon blacks that are composed of 90 % or more elemental carbon. Class 2 blacks may be referred to as "carbonaceous pigments" and these contain from 8 % to 88 % elemental carbon.

CARBONACEOUS PIGMENTS (CLASS 2)

This class of blacks, perhaps the least important for paints and coatings, is composed of two main types, mineral blacks and bone blacks.

Mineral Blacks

Mineral blacks are finely ground derivatives of coal and shale, and they are mixtures of carbon, aluminum silicates, silica, and iron oxides. They can be characterized as having poor jetness (see later description), very low tinting strength, low oil absorption, very brown undertone, and poor dispersibility. Consequently, they are rarely used in the paint industry.

Bone Blacks

Bone blacks are made by the destructive distillation of solvent-extracted cattle and sheep bones and contain only from 8 % to 17 % carbon with the remainder of the composition mostly calcium phosphate. During the "calcination," thermal treatment for 8 h at 800°C, the organic matter is decomposed and the resulting carbon forms a thin, porous film on the surface of the mineral network, creating a large carbon surface area per unit of weight. Consequently, bone blacks have high color and great adsorptive ability, but they have very weak tinting strength. Oil absorption is quite low, and aqueous dispersibility is excellent. Bone blacks are used only in specialty finishes where high color with low oil absorption is essential.

IRON OXIDE BLACKS (CLASS 3)

Naturally occurring as the mineral magnetite, iron oxide blacks are synthesized by reacting ferrous sulfate, $FeSO_4$, with alkali and then oxidizing to ferrous oxide, Fe_3O_4 (black magnetic oxide). Having the highest density of the black pigments as well as excellent light fastness and chemical resistance, these blacks are chiefly used in the paint industry in metal-protective primers. It should be noted that black iron oxide, Fe_3O_4, will oxidize at high temperatures to red or brown ferric oxide, Fe_2O_3. Iron oxide blacks have very poor color and strength properties compared to carbon blacks.

CARBON BLACKS (CLASS 1)

Carbon black is the most important black pigment for paints and coatings. This unique, strictly manmade material offers great versatility in end use performance. Through variation in key properties, by careful control of manufacturing conditions, a broad range of grades is commercially available. To provide a better understanding of carbon black as a pigment in paints and coatings, the effects of carbon black property variations on its optical functioning in dispersed media are herein defined. This involves some discussion of how carbon black is formed as well as identification of its key parameters. Following is an elucidation of the mechanisms of carbon black's optical function and how they are influenced by variations in each of the key parameters. Based on this knowledge, certain guidelines for selection of a grade of carbon black are enumerated. As a corollary, the subjects of achieving optimal quality dispersion and its importance to end use performance are addressed. Finally, techniques for measurement of carbon black coating's optical performance properties are outlined with reference to the appropriate ASTM tests where applicable.

Carbon Black Optical Function

GENERAL NATURE OF CARBON BLACK

1. *Principles of formation*—The formation of carbon black requires the application of thermal energy to a hydrocarbon, usually by incomplete combustion (limited oxygen supply), which results in the rupture of C—H bonds [2]. This first stage is often called "cracking" [Fig. 1(a)]. The reaction products are aromatic radicals and dicarbon radicals, highly reactive species, which combine to form hexagonal lattices in a planar configuration. Several "layer planes" then tend to stack and form crystallites [Fig. 1(b)]. These crystallites tend to form spherical prime particles that continue to grow, forming primary aggregates that are the characteristic units of carbon black (Fig. 2). Both prime particle and primary aggregate distributions are typically broad since a great number of layer planes and crystallites are going through the described processes, but not in phase. Those particles and aggregates that began formation earlier in the process have longer growth times and would be larger in character. By choice of hydrocarbon feedstock and careful control of reaction conditions, the key properties of prime particle

size, primary aggregate size, porosity, structure, and surface chemistry are varied to create the spectrum of commercial carbon blacks.

2. *Types/processes* [3]—There are five types of industrial carbons that fall in the general category of carbon black. Included are lampblack, channel black, furnace black, thermal black, and acetylene black. Each of these is made by a different process and, consequently, has certain unique properties (Table 2).

Lampblack Process: Oils or resins are burned in shallow pans in an enclosure with a restricted air supply, and the smoke is passed through settling chambers prior to venting. Carbon black deposited on the cool walls of the chambers is subsequently scraped off by motor-driven ploughs. The principal feedstocks are coal tars or petroleum residual oils. Lampblack's major usage in the coatings industry is as a tinting pigment. It exhibits excellent antiflocculation properties and an extremely blue undertone. Although lampblacks have been replaced by furnace blacks to some extent on a tinting strength basis, substantial quantities are still produced for special applications.

Channel Process: Until about 1975, this process was the leading source of carbon blacks for the coatings industry. Its demise was brought about by two principal factors: (1) the escalating cost of natural gas and (2) the increasing stringency of air pollution regulations.

The process (Fig. 3) involves partial burning of natural gas with insufficient air. Small fan-shaped flames from gas burner tips (2,000 or more) are housed in sheet metal buildings or "hot houses" and are arranged so that they impinge

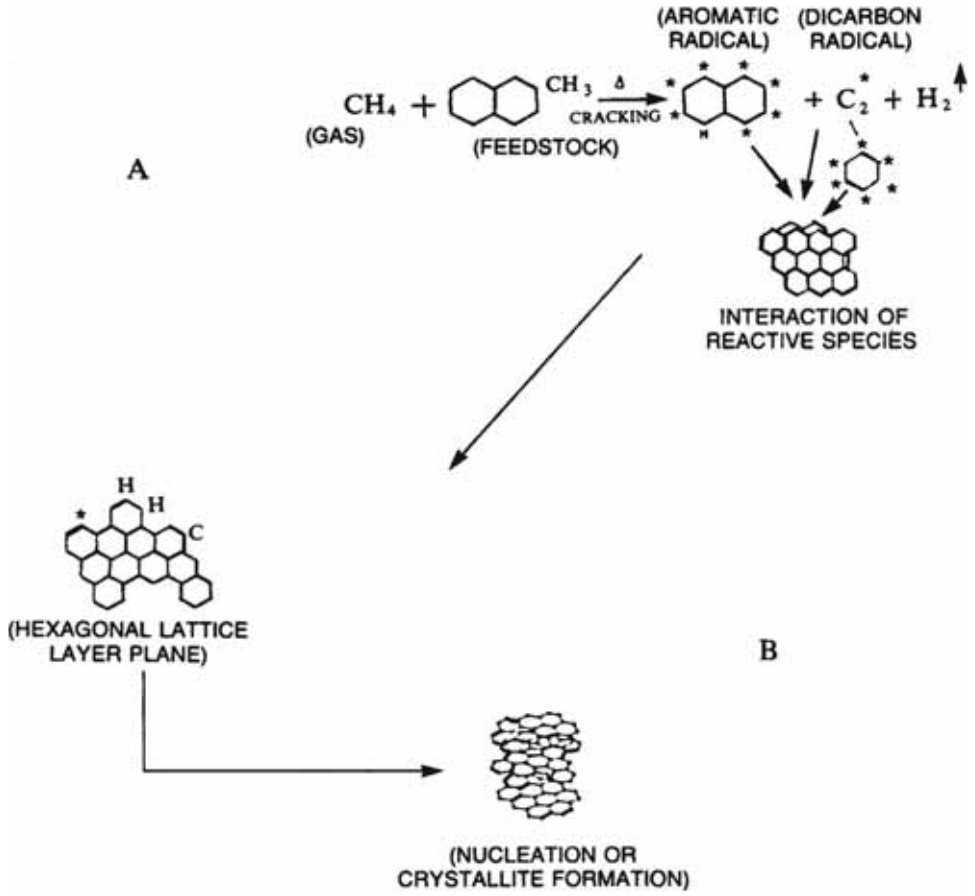

Fig. 1—Formation of carbon black. Asterisks indicate active sites.

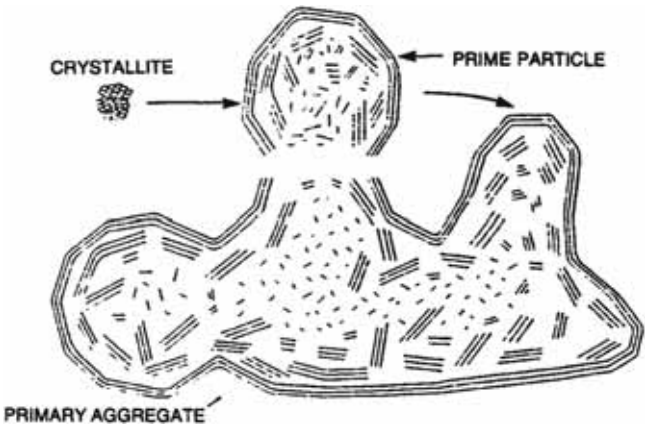

Fig. 2—Growth to particles and aggregates

on channel irons suspended above hoppers. Using scrapers and a reciprocating action of the channel irons, the deposited carbon is collected in the hoppers and passed through a collection system. Yields are characteristically very low, reaching a maximum of about 5 % with the coarser grades. This process can produce carbon blacks with particle sizes ranging from about 30 nm to less than 10 nm. The resultant blacks typically have higher volatile contents (chemisorbed oxygen complexes on the surface) because of the presence of oxygen during formation than other blacks. Though channel blacks have virtually disappeared from industry, a variant called "roller process blacks," made from feedstocks other than natural gas, are still produced in limited quantities in Germany.

Furnace Process Blacks: These products are made by partial combustion of a hydrocarbon in a closed reactor (or furnace) under well-defined conditions. The precursors of modern oil furnace blacks were the gas furnace blacks, which are no longer produced.

Oil Furnace Process: A hot flame is first created by burning gas with air inside a closed furnace, and then a liquid hydrocarbon is atomized into the hot flame zone. Furnace designs and reactor configurations vary considerably, but the principle is the same [Fig. 4(*a*) and (*b*)]. The feedstock is usually a medium molecular weight aromatic oil that must be heated to 200–250°C to have sufficient fluidity for processing. Yields are high (30 %–60 %), air pollution is virtually nil, and it offers superior process control capability. Blacks ranging in prime particle size from 100 nm down to about 10 nm, with variations in structure level (degree of aggregation of prime particles), can be produced by varying furnace conditions, feedstock properties, residence time in the hot zone, and quench distances (how far downstream the cooling sprays are introduced into the furnace).

Oil Furnace Carbon Blacks: These pigment blacks essentially satisfy all requirements of industrial blacks and account for 95 % of all the carbon black produced today.

Thermal Cracking or Thermal Decomposition: This category of carbon black processes uses thermal cracking or thermal decomposition of a gaseous hydrocarbon in the absence of flame. This includes thermal blacks and acetylene blacks, which are not used in the coatings industry.

MECHANISMS OF INTERACTION WITH LIGHT [4]

Since coatings vehicles are usually transparent polymer-containing solutions, the function of a pigment in rendering

the coating opaque and imparting a desired color is to intercept and modify incident visible light.[3] Carbon black accomplishes this by means of two mechanisms: light absorption and light scattering.

1. Light Absorption—By nature of its quasigraphitic microstructure, carbon black strongly absorbs visible light across the spectrum. In dispersed media, because of its relatively fine particle size and high surface area, it is an extremely efficient light absorber and thus appears black. To achieve opacity, it is necessary to have a sufficient number of carbon black aggregates distributed throughout the polymeric matrix to intercept virtually all of the incident light (Fig. 5). This condition is often referred to as the opacity loading level and translates to about 2 %–3 % carbon black by weight in most vehicle systems. Loadings of carbon black above the opacity loading level will not further enhance the depth of color (blackness).
2. Light Scattering [5]—Another factor that contributes to carbon black's appearance is its relatively weak light-scattering ability. When dispersed in a vehicle, individual aggregates of carbon black are much too fine to be efficient scatterers [6]. Nevertheless, light scattering plays a significant part in the details of carbon black optical performance.

[3] Strictly speaking, the term "visible light" is redundant, since by definition, light is the "visible radiation" that occurs between 400 and 750 nm. However, in common usage, the term visible light is often used.

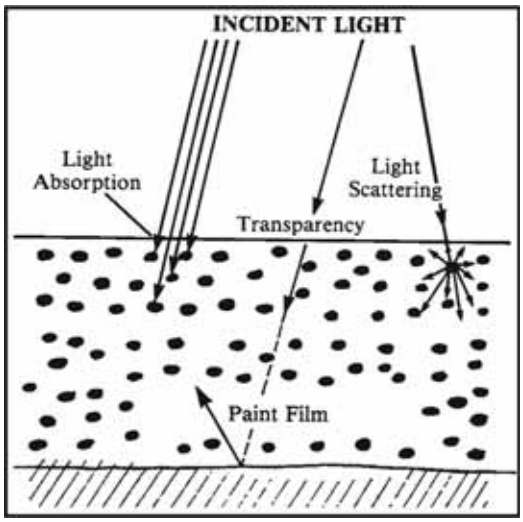

Fig. 5—Optical function of carbon black. This diagram is an oversimplification of how carbon black functions in that primary aggregates are depicted as spherical and of roughly the same size. In reality, the aggregates are irregular in shape and occur as a distribution of sizes, which complicates the optical functioning considerably. However, the fundamental processes as shown still represent the theoretical basis for more complete treatments of the subject.

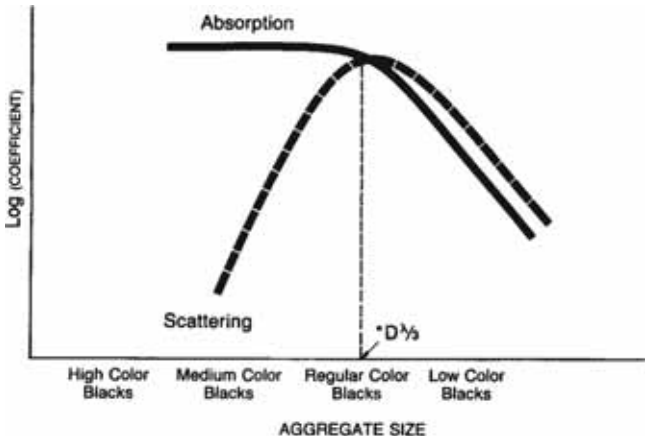

Fig. 6—Carbon black optics. *Dλ/3 is an aggregate size equal to one-third the wavelength of the incident light.

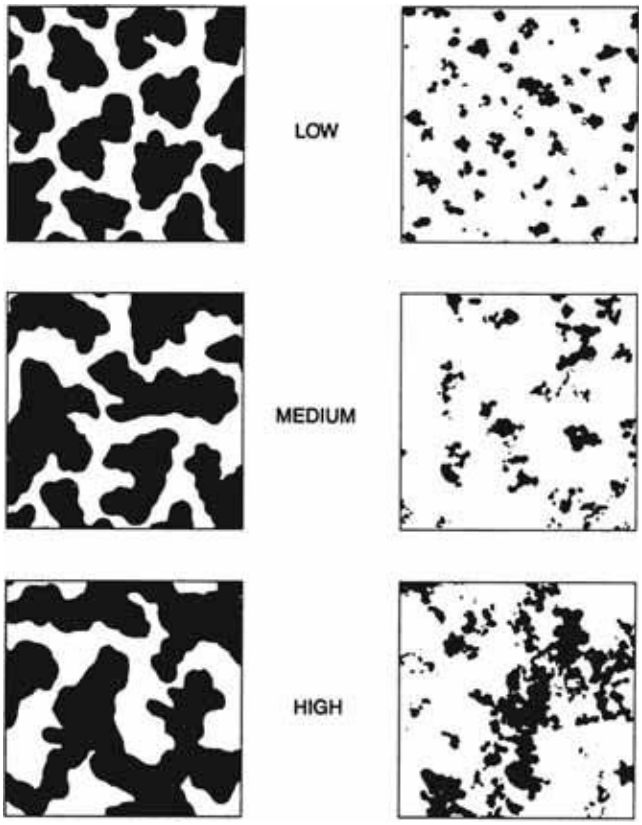

Fig. 7—Structure comparison.

Carbon Black Parameters Affecting the Optical Function

GENERAL PRINCIPLES

When dispersed in a transparent vehicle, the primary aggregates of carbon black are the optically functional units. Thus, the optical function is affected by variations in the two key carbon black parameters that determine aggregate size: prime particle size and structure.

As primary aggregates decrease in size, the specific surface area increases and incident light must penetrate more carbon, which results in increasing light absorption. Both absorption and scattering efficiencies (per unit weight of carbon black) increase with decreasing aggregate size (Fig. 6) down to a size equal to about one third the wavelength of the incident light, *D* (about 180 nm for "white light"). Further decreases in aggregate size show a leveling off of absorption efficiency and a decrease in scattering efficiency. As size decreases, electrical conductivity, ultraviolet radiation protection, tint, and blackness all increase but dispersibility decreases.

The size of the prime particles determines the size of the primary aggregate at a fixed level of aggregation. The level of aggregation is known in the carbon black industry as "structure." It is a parameter that not only indicates the average number of prime particles composing a primary aggregate, but also the degree of anisometry, branching, and chaining or shape irregularity (Fig. 7). The higher the degree of structure the greater the void space within and around a primary aggregate. In fact, the extent to which a carbon black absorbs oil or dibutylphthalate (DBP), which fills the void spaces, is a common industry measure of its structure. As structure is increased, blackness and tint are reduced, but electrical conductivity, viscosity, and dispersibility are improved.

JETNESS

The industry term for degree of "blackness" is "jetness," which increases with decreasing aggregate size for two reasons: (1) increasing light absorption efficiency and (2) decreasing light-scattering efficiency. As primary aggregates become smaller, incident light must penetrate more carbon, resulting in more light absorption per unit weight of black. Also, despite the individual variations of absorption and scattering efficiencies per unit weight, as shown in Fig. 6, the ratio [4] of absorption efficiency to scattering efficiency, *A/S,* essentially increases continuously with decreasing aggregate size. Thus both mechanisms, absorption and scattering, are synergistic with respect to jetness, and the degree of jetness is controlled by the *A/S* ratio. The smaller the aggregate, the higher the *A/S* ratio and the jettier the black.

Structure can also be a measure of aggregate size for a given prime particle since it reflects the number of prime particles composing a primary aggregate. In this sense it is also an indicator of scattering efficiency. Low-structure blacks have smaller primary aggregates, exhibit less scattering, and have higher *A/S* ratios. High-structure blacks have larger primary aggregates, exhibit more scattering, and have lower *A/S* ratios. Given two carbon blacks of comparable prime particle size, the black of lower structure (smaller, more compact primary aggregates) will show the higher jetness because of a higher *A/S* ratio.

TINTING STRENGTH

Carbon black's primary tinting application is to make gray colors by blending with a white pigment. Addition of a fixed amount of a number of different carbon blacks to a titanium dioxide, TiO_2, dispersion, for example, will result in various depths of gray color. The darkest gray will represent the carbon black highest in tinting strength. Since even a dark gray surface reflects a great amount of light relative to a black surface, the increment of light scattered by the carbon black is insignificant. For this reason, the controlling mechanism in tinting strength is light absorption [7]. Finer primary aggregate size, which favors increased absorption, will enhance tinting strength (Fig. 8). As the primary aggregate size is determined both by prime particle size and structure, higher tinting strength is favored by fine particle size, lower structure blacks. However, as shown in Fig. 6, at an aggregate size equal to one-third the wavelength of incident light, the absorption efficiency, and consequently tinting strength, levels off and becomes independent of further decreases in size. This phenomenon can be seen in Fig. 8 as well.

OPACITY

The extent to which a coating will cover or "hide" a substrate is a function of the nature of the pigment and its loading level. As mentioned earlier, the opacity loading level of carbon black in a coating system is usually 3 % or less by weight for normal paint film thicknesses (around 1.0 mil). With much thinner films, higher loadings would be required to achieve opacity. In other words, there must be a sufficient number of primary aggregates dispersed throughout the film to prevent any significant amount of incident light from passing through the film.

Carbon black creates opacity through the two mechanisms cited earlier, absorption and scattering of visible light. In fact, opacity of carbon black can be considered as being directly proportional to the sum of the absorption coefficient and the scattering coefficient, $(A + S)$. This means simply that light that is either absorbed or scattered is not transmitted through the film. From this relationship, it is also possible to predict that optimum opacity, as a fixed loading, would be rendered by blacks having an aggregate size close to one-third the wavelength of incident light (in short, blacks in the regular to medium color categories for white light of 180 nm, as per Fig. 6).

One convenient way to express the opacity of films is to use the parameter called optical density. This is a function of the percent of incident light transmitted as follows:

$$\text{optical density} = -\log_{10} T_\lambda$$

where:

T_λ = transmitted light/incident light and
λ = wavelength of incident light

An optical density of 1.0 would indicate a transmission of 1 % (0.01), 2.0 would indicate a transmission of 0.1 % (0.001), etc. Since T_λ will vary somewhat with wavelength, it is necessary to use the subscript notation to denote the wavelength of the incident light. Further, there is a logarithmic relationship with film thickness, F (expressed as weight of coating per unit area, g/m^2), for a fixed carbon black loading, i.e.,

$$\text{optical density} = -\ln(F)$$

UNDERTONE

In the carbon black industry, blacks are visually characterized as having a blue or brown undertone or some gradation in between when dispersed in a coating system. In a black coating, it is called mass tone and in a gray it is called tint tone. The phenomenon of undertone results from the fact that both scattering and absorption efficiencies of carbon black vary with wavelength [8]. Preferential absorption of blue light tends to make the unabsorbed light reaching the observer favor the red end of the spectrum (browner tone). The degree of preferential absorption/scattering of the blue end of the spectrum increases with decreasing aggregate size. Thus, in a gray finish, where the absorption mechanism is in control, the finer the aggregates the browner the tint tone. In mass tone, we have the more complex situation wherein both preferential scattering and preferential absorption, each with a separate wavelength dependency, contribute to undertone.

GLOSS

The term gloss is generally taken to mean the specular reflectance of a surface measured at some specific angle (for example, 60°—ASTM D523, Standard Test Method for Specular Gloss). As with any pigment added to a transparent vehicle, the gloss of the dried film will be influenced by the loading and the properties of the carbon black. Starting with an unpigmented coating having optimal gloss in the

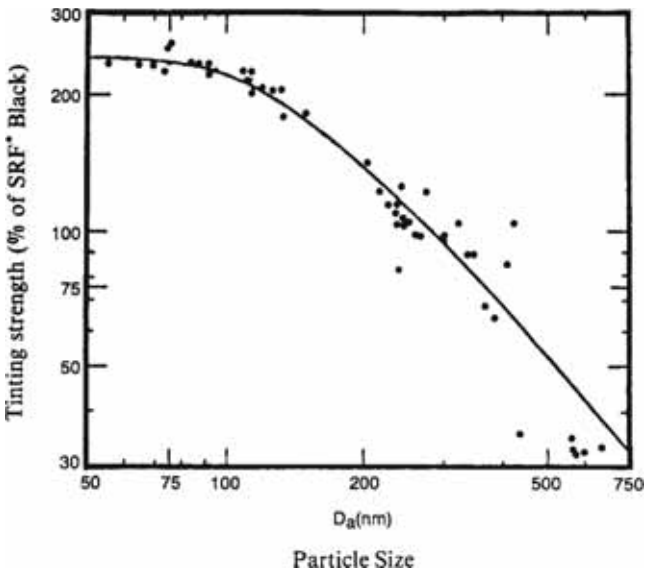

Fig. 8—Tinting strength of a range of carbon blacks.

dried film and adding a given carbon black incrementally (assuming excellent dispersions), a point will be reached where gloss begins to deteriorate until eventually the finish becomes flat. Since it is the polymers in the dry film that create the smooth surface for reflection, the addition of particulate substances, such as pigments or fillers in significant concentrations, can only interfere with the "smoothness" of the surface.

The properties of carbon black that affect the gloss of a coating are aggregate size, structure, and surface chemistry. Other factors being constant, the finer the aggregate size, the less the effect on surface texture. The finer aggregate blacks tend to result in coatings with higher gloss when properly dispersed. Higher structure, which means more void space and therefore higher oil absorption, tends to work against gloss. This is because more vehicle is "tied up" for a given loading of black in comparing a higher structure with a low structure black. Once again we must emphasize the importance of quality of dispersion. Since higher structure blacks are somewhat easier to disperse, the effect of structure can only be properly observed in cases where optimal dispersion has been achieved. Higher-structured carbon blacks results in improved electrical conductivity.

Surface chemistry generally refers to the amount of volatile content or chemisorbed oxygen complexes on the surface, that is, hydroxylic, carboxylic, quinonic, or lactonic groups. Carbon blacks often are chemically oxidized after formation, a process termed "after treatment," to increase volatile content. While this is usually done to improve rheological properties (for example, flow and viscosity), it normally creates improved gloss as well. The volatile content acts as a built-in dispersing agent and serves to reduce the amount of vehicle needed to completely wet the surface of the black.

The Effect of Dispersion Quality

GENERAL PRINCIPLES

The influence of the key carbon black parameters on dispersibility must first be defined [9]. As the primary aggregates of carbon black become finer, dispersion becomes more difficult for two reasons: (1) more energy is required to "wet" the higher surface areas and (2) to overcome the greater attractive forces between aggregates because more particles per unit weight of carbon black means smaller interaggregate distances.

Structure plays a key role as well. Low-structure blacks allow closer "packing" (higher density), which results in smaller interaggregate distances and stronger attractive forces and more difficulty in dispersion. Higher structure means more void space (lower density), which reduces interaggregate attractive forces and provides greater accessibility to vehicle penetration or greater ease of dispersion. While lower-structure blacks are more difficult to disperse ultimately, they contain less occluded air (lower density) to be displaced so that they incorporate or "wet-out" more readily than high-structure blacks.

Surface chemistry can be a factor in dispersion both as volatile content or simply as adsorbed moisture. Higher volatile content, acting as a built-in dispersing agent, tends to favor easier dispersion. Adsorbed moisture, present in all carbon blacks in proportion to surface area and ambient conditions in limited amounts, has proven to be beneficial to dispersion in liquid systems.

Density, bulk density, and physical form of carbon black also influence dispersibility. Carbon black as produced is extremely "fluffy" and must be substantially densified (removal of occluded air by agitation), usually to over 10 lb/ft^3 for handling purposes. When the densification is done by rotary agitation in drums, either wet or dry, the result is spherical pellets, which offer ease of handling and reduced dusting. Densification packs agglomerates more closely, increasing interaggregate attraction and making dispersion a more difficult process. Pelletization adds the dimension of pellet hardness, which must be overcome prior to actual dispersion. However, pelleted blacks "wet-out" very quickly and therefore are suitable for use in certain types of equipment (Table 3).

Optimal dispersion of carbon black can be defined as that condition in which all agglomerates are broken down into their constituent primary aggregates; each aggregate is separated from the others, and the surface of each is completely covered by the polymeric species. Primary aggregates are the characteristic units of carbon black and are not broken down under normal dispersion conditions. The steps involved in the dispersion process are as follows.

1. *Incorporation* (*Wetting*)—This step involves the displacement of occluded air and covering the surface of agglomerates with the vehicle being used, yielding a workable dispersion mix. Sometimes this is referred to in the coatings industry as premixing.
2. *Pellet Breakdown*—When pelleted black is used, step 1, incorporation, is easier since initial mixing causes little, if any, pellet fracture. Thus, at the worst, larger pellet fragments need to be "wetted" by vehicle. Pellet breakdown must then be accomplished by the application of additional energy (for example, longer mixing) after step 1.
3. *Deagglomeration*—This is the principal step in achieving optimal dispersion and the one that consumes most of the applied energy. Interaggregate attractive forces must be overcome to break down agglomerates into their constituent primary aggregates.
4. *Stabilization*—To stabilize the deagglomerated aggregates at this stage of the process, each of the aggregates must adsorb sufficient vehicle to completely deactivate its surface.

This process can often be facilitated by the use of dispersing agents.

To function efficiently in an optical sense, carbon black must be optimally dispersed. The primary aggregates, which characterize carbon black, must be separated from

TABLE 3—Preferred form of carbon black for various processes

	Preferred Form	
Equipment	Fluffy (Powdered)	Pellets (Beads)
Two-roll mill	. . .	X
Three-roll mill	X	. . .
Steel ball mill	. . .	X
Attritor	X	. . .
Disk disperser	X	. . .
Sand/shot mill	X	X

TABLE 4—Suggested vehicle solids to carbon black ratios for mill base compositions

Type	Nitrogen surface area, m^2/g	Suggested ratio, vehicle solids/carbon black
High color	230–560	3.5/1.0 to 4.5/1.0
Medium color	200–220	2.5/1.0 to 3.0/1.0
Regular color	45–140	1.5/1.0 to 2.0/1.0
Low color	25–40	1.0/1.0

one another and distributed fairly uniformly throughout the vehicle matrix to be most efficient at intercepting incident light. Choosing a grade with high surface area for high color applications, for example, must be combined with designing an effective dispersion system to ensure full color development. Mill base formulations, grade selection, physical form of carbon black (fluffy or pellets), and premixing as needed all play a part in ensuring quality dispersion. Perhaps the most important factors in mill base formulation are (1) providing sufficient vehicle solids to accommodate the carbon black surface (Table 4) and (2) adjusting viscosity to a level suitable for the chosen dispersion equipment.

DISPERSION MECHANISMS

Available liquid system dispersion equipment utilizes either or both of the two main dispersion mechanisms: (1) shearing force and (2) collision of agglomerates with each other and with dispersion media particles. These mechanisms describe the manner in which energy is applied to carbon black agglomerates during the dispersion process. For example, disk dispersers and three-roll mills use shearing force while ball mills, sand mills, and attritors rely on collisions.

DISPERSION QUALITY TESTING

It is possible to stabilize carbon black dispersions at various levels of deagglomeration. The term "macrodispersion" is applied to very moderate levels of deagglomeration at which only the larger agglomerates are fractured. "Microdispersion," on the other hand, refers to levels of deagglomeration approaching the ideal of single primary aggregates.

The most accurate way to measure dispersion quality is microscopically. Using 100-power optical micrographs, it is possible to set up a classification system. However, this is costly and time consuming as well as somewhat impractical for production control. More commonly used in the coating industry is the grind gage (Hegman gage, paint club gage, etc.). These devices do not measure microdispersion. Since it is microdispersion that largely determines color performance, it is possible to have two identical mill bases, both "off-scale" on a grind gage, one of which is significantly poorer in dispersion quality. The better dispersed system would be blacker (jettier) and glossier. This leads to the most practical indirect method, that is, using color and/or gloss development, properties that are extremely sensitive to small variations in degree of microdispersion.

Selecting a Grade of Carbon Black for Coloring BLACK COATINGS

For coloring purposes, a grade of carbon black should be selected that is as low as possible in surface area, but consistent with end use color specifications. This enables the formulator to take advantage of the greater ease of dispersion and lower cost associated with the lower surface area. The desired structure level should be high enough to give acceptable dispersibility, but not so high as to adversely affect gloss or rheology. In some cases, the use of after-treated grades will give an edge in dispersion and gloss as well as protect the working rheology at higher loadings. Normally, at opacity level loadings, rheology is only a problem when more concentrated mill bases are used.

Implicit in the selection of a grade of carbon black is the choice of the fluffy (also termed "powdered") or pelleted (also termed "beaded") form. The choice is usually made on the basis of dispersion equipment available or on ease of incorporation or both. Listings of preferred forms for best results with each of the major pieces of equipment are useful (Table 3) to formulators. Regarding ease of incorporation, if, for example, a steel ball mill, which is a very effective disperser, is to be used, the edge in dispersion provided by the fluffy form is not really needed, so it is wise to consider the pelleted form, which will "wet in" quickly and which creates less dust during handling.

Candidate grades must be dispersed in the specific formulation in which they are intended to be used. Keeping in mind the sensitivity of color and gloss development to dispersion quality, it is useful to evaluate jetness and gloss both at the end of the prescribed grind cycle and again after an extended cycle. This technique not only identifies which of the candidates will provide the color and gloss levels needed, but also indicates whether or not full color value from a given grade will be achieved under the prescribed dispersion conditions. The factors of carbon black cost and dispersibility must be weighed against desired color and gloss levels in making a final decision. Some commonly used oil furnace grades for the coatings industry are listed in Table 5.

Black Tinted Coatings

While selecting a black for tinting purposes involves the principles mentioned earlier under *General Natures of Carbon Black* on mass tone color, some key points need emphasis. The selection depends upon required tinting strength (see Table 5), tint tone, and relative ease of dispersion.

Tint tone (see under the topic Carbon Black Parameters Affecting the Optical Function the section on *Undertone*) refers to the color undertone in tinting. If very blue undertone is needed, grades such as LCF 2 and LCF 3 are suggested. Sometimes it is necessary to sacrifice some tinting strength by going to grades with larger aggregate size to maximize blue tint tone (for example, going from LCF I to LCF 2). High-tint-strength blacks tend to give browner undertone, which is desirable in some applications.

Finally, where dispersion stability (that is, flocculation resistance) is critical, after-treated blacks can be helpful. Medium-flow furnace black, for example, exhibits excellent stability and high tinting strength and is often used for tinting in relatively poor wetting vehicles.

Measuring Appearance Properties of Carbon Black Coatings

A black coating pigmented with carbon black at the opacity level (less than 3 % by weight) will probably reflect only about 1 % of the incident light. This presents some unique

TABLE 5—Oil furnace black color grades for coatings. Note: The data are typical of commercial I grades representative of the indicated categories [11]

[a]Based on Nigrometer scale values, so lower numbers mean higher jetness.

problems in trying to make absolute instrumental measurements since the sensitivity of available instruments is simply not adequate. For this reason, it has been traditional in the carbon black industry and even among end users to depend upon visual judgments of appearance properties in many cases. While no one challenges the incredible sensitivity and versatility of the human eye, it has the drawback of not being able to quantify its observations. Nevertheless, using special techniques, it is possible to obtain quantitative measurements on all appearance properties as outlined below.

JETNESS

Jetness or blackness is a function of surface area, i.e., a parameter that is inversely proportional to aggregate size (Fig. 9). Traditionally, the industry assigned nigrometer "scale" values, which are a direct function of the amount of light reflected by dispersed samples (coatings, plastics, etc.).

Smaller "scale" values indicated jettier carbon blacks. However, the modern approach is to measure the spectral reflectance of a black dispersion, which is made possible by the enhanced sensitivity of current instrumentation. The spectral reflectance curves can then be converted to Hunter L, a, b; or CIE coordinates [10] to quantitatively measure jetness and mass tone as well.

UNDERTONE

The mass tone is measured as described above in the section concerned with jetness. This is an important tool because visual ratings of jetness are usually influenced by the undertone variations among blacks being rated. Tint tone, on the other hand, can normally be measured directly

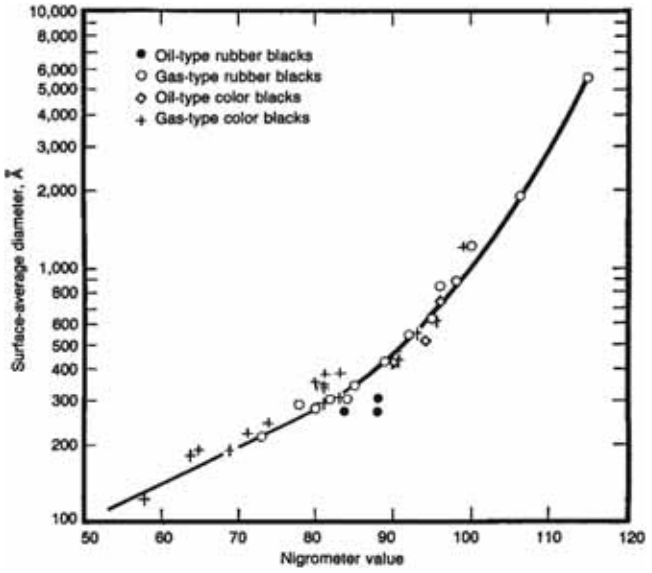

Fig. 9—Nigrometer values versus particle size for a range of carbon blacks.

via absolute reflectance (versus a white standard) using a spectrophotometer or a colorimeter. However, common practice is to measure against a gray standard (ASTM D3265, Test Method for Carbon Black-Tint Strength).

TINTING STRENGTH

As illustrated in Fig. 8, tinting strength increases with decreasing particle size. The differential measurement technique, described above, is used to assign tinting strength values. The procedure, ASTM Test D387, Test Method for Color and Strength of Color Pigments with a Mechanical Muller, involves dispersing carbon black together with a white pigment in wetting oil or other suitable vehicle. The reflectance of this dispersion versus a standard gray tile or gray vitreous enamel is then a measure of its tinting strength. While it was customary in the carbon black industry for many years to report tinting strength as a percent of a reference black (for example, IRB No. 4), some suppliers are now using an independent tinting strength index, allowing strength comparisons only within their own product lines.

GLOSS

Clearly, the property of gloss and the manner in which it is measured is not unique for carbon black coatings. Whether the pigmentation is black or any other color, the test (for example, for 60° gloss) is the same.

TESTING

A number of ASTM documents dealing with standard test methods and/or specifications have been mentioned in the above text and in certain tables. Table 6 is a supplemental list of such ASTM documents that may be of interest to readers or people working in the area of black pigments. The list does not contain all existing ASTM documents related to carbon black—more than 200 such documents exist.

SUMMARY

Individual key carbon black parameters have been viewed from the standpoint of their influence on the optical

function blacks. It is important to emphasize, however, that these parameters do not operate independently. The effect on optical functioning, and therefore on pigmentary properties, is a combined effect. When varied, each parameter influences the other parameters, which are also varying. Thus the situation is dynamic and complex.

Dispersion quality and its importance in realizing the full optical potential of a given grade has also been addressed. Therefore, in the grade selection process, the physical form of carbon black as well as key parameters must be considered in relation to the chosen dispersion technique.

Colored Organic Pigments*

Paul Merchak[1]

DEFINITION OF A PIGMENT

BEFORE ENTERING INTO ANY DISCUSSION RELATING to pigments, it is first necessary to clearly define what is understood to be an organic pigment as opposed to a dyestuff. In many earlier texts on color and articles concerning the use of color, the terms "pigment" and "dyestuff" are used almost interchangeably and often incorrectly.

A definition of a pigment has been proposed by the Color Pigments Manufacturers Association (CPMA)[2] in response to a request from the Toxic Substance Interagency Testing Committee. This definition was developed specifically to enable differentiation between a dyestuff and a pigment with the intention of forever ending the confusion surrounding these two terms. As such, it is worthwhile reproducing this definition in its entirety:

> "Pigments are colored, black, white, or fluorescent particulate organic and inorganic solids which usually are insoluble in, and essentially physically and chemically unaffected by, the vehicle or substrate in which they are incorporated. They alter appearance by selective absorption and/or by scattering of light.
>
> Pigments are usually dispersed in vehicles or substrates for application, as for instance in inks, paints, plastics, or other polymeric materials. Pigments retain a crystal or particulate structure throughout the coloration process. As a result of the physical and chemical characteristics of pigments, pigments and dyes differ in their application; when a dye is applied, it penetrates the substrate in a soluble form, after which it may or may not become insoluble. When a pigment is used to color or opacify a substrate, the finely divided insoluble solid remains throughout the coloration process."

Additionally, the older terms "lake" and "toner" may be encountered when dealing with pigments. American terminology, applied to pigments, defines a toner as an organic pigment that is free of inorganic extender pigments or carriers; as such, the pigment is unadulterated and exhibits maximum tinting capacity for the pigment type. A lake, conversely, is an organic colorant that has been combined with an inorganic substrate or extender such as barium sulfate (Blanc Fixe) or alumina. In European terminology, toners are considered to be water-soluble acid or basic dyestuffs that are converted into insoluble pigmentary forms by appropriate precipitation with an inorganic compound. As such, Barium Lithol red (C. I. Pigment Red 49:1) and the phosphotungsto molybdic acid (PTMA)-based Rhodamine (C.I. Pigment Violet 1) are considered toners. In the coatings industry, the term "toner" may be used to refer to a secondary color that is added to alter the primary hue of the paint. The term "lake" now has an accepted definition as that used in America.

A most confusing European term, the use of which should be discouraged, is "pigment dyestuff." This term is meant to refer to insoluble organic pigments devoid of salt-forming groups, for example, Benzimidalone Orange (C. I. Pigment Orange 36).

INTERNATIONAL NOMENCLATURE—THE COLOUR INDEX (C. I.) SYSTEM

In any publication discussing either organic or inorganic pigments, it is highly likely that the author will make use of the coding system as published as a joint undertaking by the Bradford Society of Dryers and Colourists in the United Kingdom and the Association of Textile Chemists and Colorists in the United States.

This system is known as the "Colour Index," [1] and, as such, is a recognized trademark, hence the retention of the "u" in "colour" whenever reference is made to a "Colour Index" name or number.

The Colour Index (C. I.) identifies each pigment by giving the compound a unique "Colour Index Name" and a "Colour Index Number." This description is proving to be most valuable to persons within the coatings industry responsible for assembling data on the composition of a coatings formulation for documents such as Material Safety Data Sheets, shipping information, product composition, or hazard data sheets. As such, the identification of a pigment by mention of its C. I. name and number unequivocally identifies the chemical composition of the pigment in a manner acceptable to meet government bodies. For example, DNA Orange has the Colour Index name of Pigment Orange 5 (PO 5) and the Colour Index Number of 12075.

The Colour Index Name for a pigment is abbreviated as:
PB—Pigment Blue
PBk—Pigment Black
PBr—Pigment Brown
PG—Pigment Green
PM—Pigment Metal
PO—Pigment Orange

PW—Pigment White
PY—Pigment Yellow

CLASSIFICATION OF PIGMENTS BY CHEMISTRY

Pigments in paints and coatings may be broadly divided into opaque or hiding whites and colored toners. All the opaque whites are inorganic compounds and, as such, fall outside the contents of this chapter. For the sake of clarity, it should be noted that such compounds include the following:

Lithopone (co-precipitate of barium sulfate and zinc sulfide)
Zinc oxide
Antimony oxide
Titanium white (mixture of titanium dioxide and blanc fixe)
Titanium dioxide (rutile form)

The colored pigments as covered in this section are all organic in nature and, as such, contain a characteristic grouping or arrangement of atoms known as a "chromophore," which imparts color to the molecule. In addition, the molecule is likely to feature a number of modifying groups called "auxochromes" that alter the primary hue of the pigment in a more subtle way—such as shifting a red to a more yellow shade or a blue to a more red shade while still maintaining the primary hue of red or blue rather than pushing the hue over to an orange or a violet. The entire colored molecule may be referred to as the "chromogen."

Perhaps the most important of the chromophores is the azo chromophores (—N═N—). The naphthol reds, monoarylide and diarylide yellows, benzimidazolone yellows and oranges, pyrazolone reds and oranges, and azo condensation pigments are all examples of organic pigments that feature the azo chromophore. Of equal importance is the phthalocyanine structure based on the compound tetrabenzotetra-azaporphin. Halogenation of this compound results in a major shift in hue from a blue to a green. Pigments are also derived from heterocyclic structures as perylene, diketopyrrolopyrrole, quinacridone, and carbazole dioxazine violet. Finally, there are pigments that result from the vat dyestuffs and miscellaneous metal complexes.

CLASSIFICAITON OF PIGMENTS BY COLOR

Reds

METALLIZED AZO REDS

Many reds used in the coatings industry contain the azo chromophore (—N═N—) and, as such, are termed "azo reds." A further subdivision is possible into acid, monoazo metallized pigments such as Strontium Red 2B (PR 48:3), Manganese Red 2B (PR 48:4), and non-metallized azo reds such as Toluidine Red (PR 3), and the very popular naphthol reds (PR 170; PR 188).

Typically, each of the metallized types contains an an ionic grouping such as sulfonic (–SO_3H) or carboxylic acid (–COOH), which will ionize and react with a metal cation such as calcium, manganese, strontium, or barium to form an insoluble metallized azo pigment. Conversely, non-metallized azo reds do not contain an anionic group in their structure and, therefore, cannot complex with a metal cation.

All azo reds contain one or more azo groups and are all produced via a similar reaction sequence involving diazotization and coupling. Diazotization involves the reaction of a primary aromatic amine with nitrous acid to yield a "diazonium salt," which is immediately "coupled" to the other half of the molecule, called the coupler, to yield the colored pigment. It is usual practice to produce the nitrous acid "in-situ" from the addition of hydrochloric or sulfuric acid to sodium nitrite. This serves to explain the presence of inorganic salts such as sodium chloride or sodium sulfate in the unwashed pigment, salts that have to be removed by washing at the filtration state prior to discharging the pigment from the filter. It is at the coupling stage that the colored, insoluble pigment is formed. Careful control of the reaction rate by control of *p*H, temperature, concentration, addition rates, agitation, etc., are critical at this stage to produce the desired particle size pigments. Once the insoluble pigment is produced, the particle size, crystallinity, or morphology may be altered either by a thermal treatment of the pigment slurry or after isolating the pigment by subjecting it to a solvent or thermal treatment. Fig. 1 illustrates the structure of a series of metallized azo reds that are of considerable commercial importance and that find some, albeit limited, use within the coatings industry. Each of these structures feature a molecule based on the coupling of a naphthalene ring structure to a

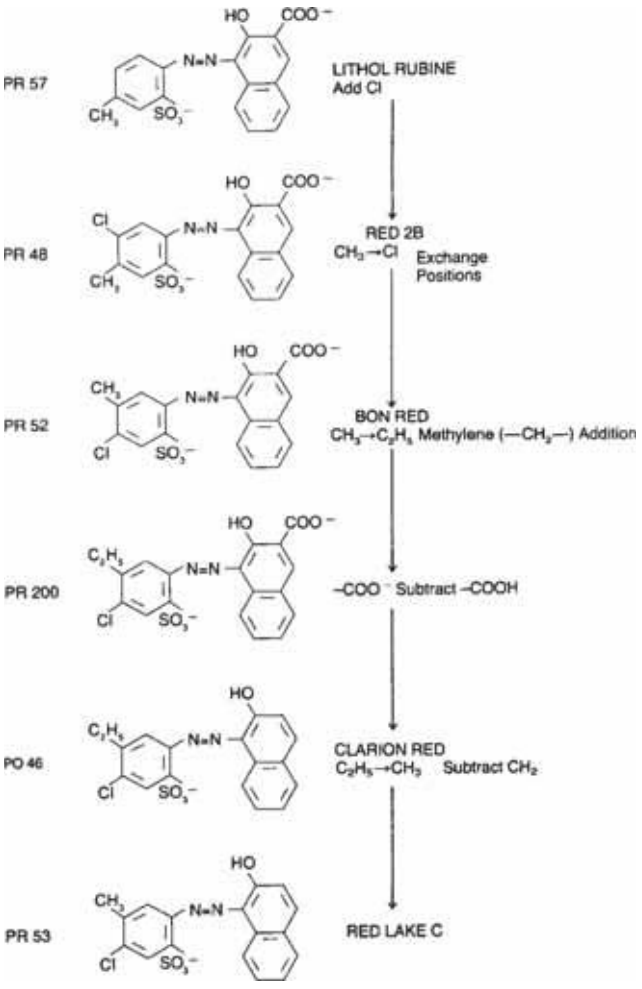

Fig. 1—Structure of metallized azo reds.

benzenoid structure. A brief description of the more common metallized azo reds is as follows:

Lithol Reds—Barium Lithol PR 40:1, C. I. Number 15630:1; Calcium Lithol PR 49:2, C. I. Number 15630:2

This pigment was discovered in 1899 and its major use is in the printing ink industry and finds only limited application within the coatings industry at masstone levels, that is, at a level where the tinting strength of the pigment is not diluted with a white-tint base. Examples of the use of this pigment are for such reds as those used on tool boxes, fire extinguishers, gas cylinders, oil filters, and the less expensive lawn mowers where the fastness properties of the pigment are acceptable.

The pigments are bright reds with high tint strength and good dispersion characteristics; the barium salt is lighter and more yellow in shade than the calcium salt, which may best be described as a medium red. Neither pigment can be recommended for outdoor exposure applications, since their exterior durability is inadequate for such situations. Additionally, they cannot be used in situations that require pigments to withstand an environment that is highly acidic or highly alkaline since Lithol Reds under such conditions give weaker, yellower shade products, resulting from an exchange of the alkaline earth salt by neutralization of the pigment acid functional groups or exchange with the added base agent.

Permanent Red 2B—Barium Red 2B, PR 48:1, C. I. Number 15865:1; Calcium Red 2B, PR 48:2, C. I. Number 15865:2; Strontium Red 2B, PR 48:3, C. I. Number 15865:3; Manganese Red 2B, PR 48:4, C. I. Number 15865:4.

Discovered in the 1920s, the Red 2B pigments are azo reds prepared by coupling diazotized 1-amino-3-chloro-4-methyl benzene sulfonic acid (2B acid) with 3-hydroxy-2-naphtholic acid (BONA).

A major end use of the barium and calcium pigments is in baked industrial enamels, where outdoor fastness properties are not a prerequisite of the application. Their use in alkaline systems is again severely restricted due to the tendency of these metal salts to exchange ions in highly alkaline environments. The barium salt is characterized by a clean, yellow hue as compared to the bluer calcium salt. The barium salt has a poorer light fastness and weaker tinting strength, but a slightly better bake stability as compared to the calcium salt.

The Manganese Red 2B has sufficiently improved light fastness to allow its use in implement finishes and aerosol spray cans for touchup paints. This salt is bluer, dirtier, and less intense as compared to the calcium salt. Extension of the manganese pigment with any pigment such as titanium dioxide or Molybdate Orange (PR 104) to an amount greater than 15 % is not recommended since the durability of the pigment will be adversely affected.

The term "light fastness" used throughout this chapter refers to the pigment's stability to withstand exposure to light, both direct and indirect, natural or artificial, without suffering any visible change in appearance. The most damaging component of light appears to lie in the ultraviolet region of the electromagnetic spectrum and, as such, a rapid evaluation of a pigment's likely reaction to long-term exposure of such radiation can be assessed using exposure equipment that maximizes exposure to ultraviolet radiation. Many high-performance pigment's are exposed under application conditions in specially maintained areas of Florida to more fully evaluate their "fastness," that is, their behavior on outdoor exposure involving intense sunlight, high humidity, and changing weather conditions.

Lithol Rubine Red—Calcium Lithol Rubine, PR 57:1, C. I. Number 15850:1.

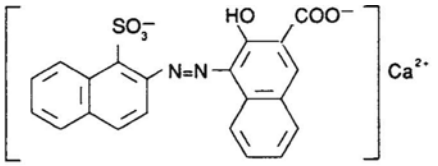
This pigment is made by coupling 3- BONA with diazotized-2-amino-5-methyl benzene sulfonic acid (4B acid). This blue-shade red was discovered in 1903 and has found widespread use in the printing ink industry ever since the process "magenta" of the four-color printing process, for offset, gravure and flexographic printing.

A clean blue-shade red with high tint strength, its major application in the coatings industry is for interior applications calling for an inexpensive red with both good solvent and heat resistance. Again, this pigment must be used at near masstone levels to maximize its fastness properties.

BON Reds—Calcium BON Red, PR 52:1, C. I. Number 15860:1; Manganese BON Red, PR 52:2, C. I. Number 15860:2.

These reds are manufactured by coupling diazotized 1-amino-4-chloro-3-methyl benzene sulfonic acid onto BONA. The pigments were first commercialized in 1910. They are characterized by outstanding cleanness, brightness, and color purity. The manganese salt offers a very blue-shade red with improved light fastness as compared to the calcium salt. As such, the manganese salt is suitable for outdoor applications and, as with the Manganese Red 2, can be used in blends with Molybdate Orange (PR 104) to give bright, economical reds.

BON Maroon—PR 63:1, C. I. Number 15880:1



Illustrated in Fig. 2, BON Maroon was first synthesized in 1906 by Ernest Gulbransson of Farbwerken Meister, Lucius, and Bruning. The manganese salt is the only one that finds commercial significance rather than the calcium or barium variations. Its light fastness is such that the pigment can be used at masstone levels for implementation and bicycle finishes. Over 50 years ago, when specifications were not as demanding as today, BON Maroon actually found application in automotive finishes.

NON-METALLIZED AZO REDS

As implied by their classification, the non-metallized azo reds do not contain a precipitating metal cation and, as such, offer increased stability as they do not suffer from neutralization or ion exchange problems in highly acidic or alkaline environments, as compared to the metallized azo red previously discussed.

Toluidine Red—PR 3, C. I. Number 12120.

This pigment, described in Fig. 3, was first synthesized in 1905 and is chemically the reaction product from coupling the diazonium salt of 2-nitro-4-toluidine (MNPT) onto 2-naphthol (beta naphthol). Various shades of Toluidine Red are commercially available and these are described

2-naphthylamine-1-sulfonic acid ⟶ 3-hydroxy-2-naphthoic acid (BON)

Fig. 2—Structure of BON Maroon, PR 63:1.

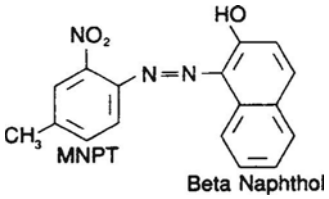


Fig. 3—Structure of Toluidine Red PR 3.

as "very light," "light," "medium," "dark," and "very dark." These are also graded as offering "haze resistance" and being "easy dispersing."

Almost the entire worldwide production of Toluidine Red is consumed by the coatings industry. The pigment provides a bright, economical red of acceptable light fastness when used in full shade coupled with a high degree of color intensity and good hiding power. However, the pigment is not fast to white over-striping since it will blend through, turning white into pink, and it shows a marked tendency to bleed in high Kauri-Butanol solvents.

Toluidine Red is used almost exclusively at masstone levels, that is, in full shade without the addition of opaque extenders such as titanium dioxide or zinc oxide. Usage extends to such applications as farm implements, lawn and garden equipment, and bulletin paints where a bright, economical red of moderate light fastness is required to fill the user specification. Because of the pigment's poor durability in tinted shades, a reduced or extended pigment with an opaque white is rarely used at reduced levels.

Para Reds—Para Red, PR 1, C. I. Number 12070; Chlorinated Para Red, PR 4, C. I. Number 12085; Parachlor Red, PR 6, C. I. Number 12090.

Each of these three pigments, which are shown in Fig. 4, is based on the coupling of a primary amine to betanaphthol. The position of the –chloro or –nitro auxochromes on the molecule controls the shade of the pigment. In fact, Chlorinated Para Red differs from Parachlor Red only in the position of the –nitro and –chloro groups on the benzene ring. As such, these pigments are isomers.

Use of these pigments in the coatings industry has declined rapidly due to the ever-increasing and exacting demands placed on colored finishes by the industry. All of these pigments will bleed in solvents typically used in the coatings industry and, as such, cannot be used in any finish that requires over-striping.

As a class of insoluble azo reds, they are characterized by intense shades of red through scarlet. Their good alkali resistance, light fastness, and durability when considered as a function of their cost recommends them for use in latex paints and outdoor signs. At temperatures above 270°F (121°C), the pigments will sublime. Light fastness of tints is significantly inferior to that of the pigments at full shade.

Naphthol Reds—Naphthol Reds are chemically defined as monoazos of 2-hydroxynaphtholic acid N-arylamides without anionic, salt-forming groups. Their individual properties are dependent on the specific composition of the pigment, in addition to the conditioning steps used in their manufacture. As a class, they are pigments that exhibit good tinctorial properties combined with moderate fastness to heat, light, and solvents. The Naphthol Reds are extremely acid-, alkali-, and soap-resistant pigments. Such

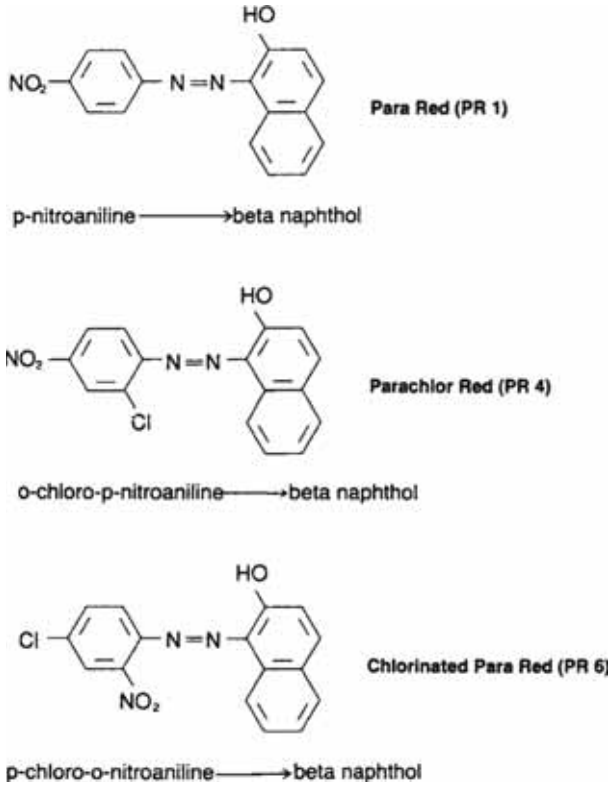

Fig. 4—Structure of para reds.

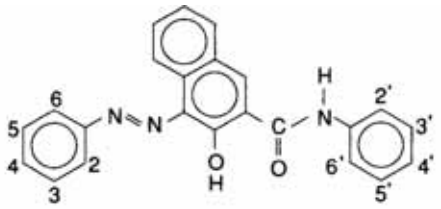
properties lead to their use in masonry paints and latex emulsions that are formulated under alkaline conditions.

Naphthol Reds may be described as "medium performance" reds since they exhibit properties that fall somewhere between Toluidine Red and Quinacridones with a cost that corresponds accordingly. Fig. 5 illustrates the generic structure of the naphthol molecules and gives the chemistry of several of the types described below. Those Naphthol Reds of commercial significance that should be briefly covered are:



Pigment Red 22, C. I. Number 12315—a light yellow shade Naphthol used in air-drying alkyds and aqueous systems that can be satisfied with this pigment's marginal light fastness.

Pigment Red 112, C. I. Number 12370—a Naphthol Red that possess a very clean, yellow hue and that finds uses in both industrial and architectural coatings. The tendency of the pigment to bloom at high concentrations and its poor over-striping fastness has limited its more widespread use. In Europe, this pigment finds a major outlet in store tinting systems. Light fastness at both tint and full shade is rated good.

Pigment Orange 38, C. I. Number 12367—is a very yellow shade, bright red pigment with good solvent fastness. It can be used in baking enamels at high concentrations without showing any tendency to bloom.

Pigment Red 5, C. I. Number 12490—has only marginal fastness to heat and solvents. Nevertheless, it finds application in implement coatings. The opaque grade of this pigment can be combined with iron oxide to give an economical red with high hiding.

Pigment Red 146, C. I. Number 12485—is a very blue-shade red that finds its major use in interior architectural

Colour Index Name	Colour Index Number	Substituents 2	4	5	2′	4′	5′

PR 112	12370	Cl	Cl	Cl	CH_3	H	H

Fig. 5—Generic structure and key to the naphthol reds.

applications. Its poor exterior durability makes the pigment unsuitable for outdoor finishes.

Pigment Red 170, C. I. Number 12475—is a medium-performance, moderately priced red. It is available as both a transparent and an opaque grade. Manufacturing techniques are used to produce the pigment in two crystal phases, each exhibiting a unique hue. The opaque grade finds use in farm tractor and implement finishes. Its use with iron oxides allows a practical approach to formulating reds with acceptable light fastness, hiding, and economics. It is a fair statement that this pigment finds use in just about every paint and coatings application method practiced in the United States, from water-based through powder-coating products. Blends with quinacridones are used in automotive refinish paints where durability requirements are not as exacting as those for the original factory-applied finishes. In a color sense, the pigment is almost identical to the diketopyrrolopyrrole pigment PR 254.

Pigment Red 187, C. I. Number 12486—is a transparent pigment with excellent heat fastness, moderate durability, and good bleed resistance. Its uses extend to bicycle, coil, and powder coatings.

Pigment Red 188, C. I. Number 12467—is a yellow, clean-shade red with acceptable durability at all depths of shade. It is fast to over-striping at temperatures below 160°C and therefore finds use in higher-quality industrial finishes. A Naphthol Red with a shade that is almost an orange, PR 188 is used in the in-store tinting systems that are popular at hardware-type outlets throughout the United States.

High-Performance Reds

These types of pigments may be briefly defined as products that will meet the exacting demands of the automotive industry with respect, particularly to the outdoor exposure requirements demanded by controlled exposure in Florida and Arizona for as little as two, and as long as, five years.

The high-performance reds considered fall into five basic classes:

Quinacridone red and violet
Vat dyestuff-based reds as the perylenes
Benzimidazolone reds
Disazocondensation reds
Diketopyrrolopyrrole

QUINACRIDONE REDS

These pigments are heterocyclic in nature since their structure comprises a fused ring in which the ring atoms are dissimilar and being a combination of carbon and nitrogen rather than only carbon as has been the case with the previous pigments discussed. The addition of differing auxochromic groups such as methyl (—CH_3) and chlorine (—Cl) gives Pigment Red 122 and Pigment Red 202, respectively, both described as magentas.

The theory behind the superior durability of pigments with the quinacridone structure is that considerable hydrogen bonding occurs between molecules through the carbonyl (═C═O) and imino (═N—H) ring atoms (see Fig. 6).

As a group of pigments, the quinacridones find their primary uses in automotive, industrial, and exterior coatings. A minor use is in the preparation of quality furniture stains and finishes. The pigments combine excellent tinctorial properties with outstanding durability, solvent resistance, light fastness, heat fastness, and chemical resistance. Table 1 lists those shades currently commercially available. Possibly the only potential drawback exhibited by the quinacridones is their poor rheology in high solids, solvent-based coating formulations used for original equip-

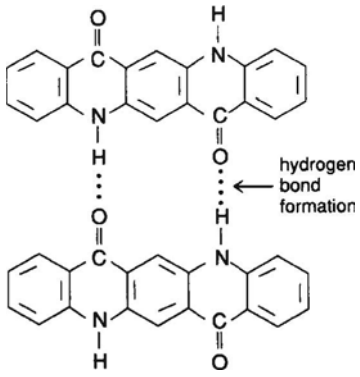

Fig. 6—Translinear quinacridone showing proposed hydrogen bonding mechanism.

TABLE 1—Classifications of quinacridone pigments

Colour Index Name	Hue	Comments
PO 49	Gold	Quinacridone quinone
PR 122	Magenta	2,9-dimethyl
PR 192	Red-yellow	Mono methyl
PR 202	Magenta	2,9-dichloro
PR 206	Maroon	Solid solution
PR 207	Scarlet	4,11-dichloro
PR 209	Red-yellow	3,10-dichloro
PV 19	Violet-blue	Beta crystal
PV 19	Red-yellow	Gamma crystal
PV 42	Maroon	Solid solution

ment manufacturer (OEM) automotive applications. When the formulator is working with such high pigments bases, it is often impossible for levels as high as 20 % pigment to be achieved with many quinacridones available in today's marketplace due to poor flow and thixotropic properties that can be a feature of these pigments. Poor rheology, resulting in a heavy-bodied paint, is often the limiting factor in achieving a highly concentrated mill base when quinacridones are used as a major component of red formulations. As pressures increase to reduce the volatile organic content that is part of a solvent-based paint, the need for pigments that can be dispersed at high levels with minimal effect on the flow properties of the mill base will only increase proportionately. Fortunately, this class of pigments does not appear to give similar flow problems when formulated into a water-based OEM coating. Thus, they continue to be used as aqueous systems are developed as an alternative to high solids, solvent-based coatings. The rheology problem, however, is replaced with the situation color stylists face when trying to create an exact match in an aqueous system for a style that was made using solvent- based paint. A point worthy of note is that 2,9-dichloroquinacridone magenta (PR 202) is inherently considerably better in rheology than is the 2,9-dimethylquinacridone magenta (PR 122). Ironically, as more water-based formulations are developed, the Pigment Red 202, so vital in high-solids solvent systems, is being replaced by Pigment Red 122 since rheology is not an issue, and the Red 122 offers a better hue than does the Red 202 in the water-based systems.

VAT REDS

Vat Red pigments based on anthraquinone include such structures as Anthraquinone Red (PR 177), Perinone Red (PR 194), Brominated Pyranthrone Red (PR 216), and Pyranthrone Red (PR 226) as described in Fig. 7. The term "vat pigments" originates from the fact that this class of pigments is related to the vat dyestuffs used originally in the dying of cotton. Only their high cost limits the more widespread use of the pigments throughout the coatings industry.

Anthraquinone Red, PR 177, C. I. Number 65300. This is a medium-shade red with excellent all-around fastness

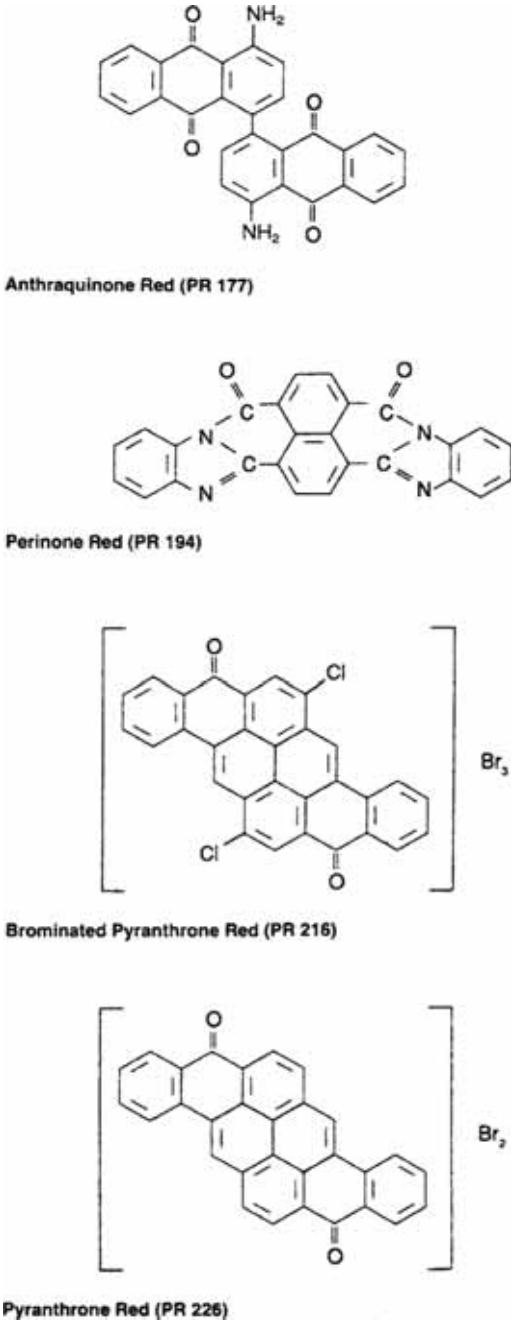

Fig. 7—Structure of typical vat reds.

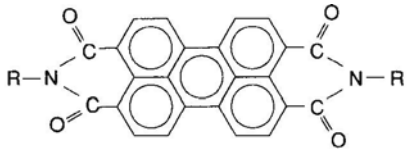
properties. Again, it finds major use in the automotive industry for the production of clean, bright red coatings.

Brominated Pyranthrone Red, PR226, C. I. Number 59710. This pigment is a yellow shade red that can be classed as an automotive-grade pigment because of its excellent fastness properties. Neither light nor dark shades will suffer on prolonged exposure to Florida atmospheres. Transparency is generally not adequate for this pigment to be used in metallic or mica finishes.



Perylene Reds

These pigments provide pure, transparent shades and novel styling effects when used in metallic aluminum and mica finishes. The perylenes offer improved flow characteristics when used in high-solids formulations. Perylenes may

also be described as vat pigments and in fact are the only class of such pigments that were developed specifically for the pigment marketplace rather than as dyestuffs. These pigments are generally not clean enough for use as a self-shade, accordingly they most often find use in blends with such compounds as the quinacridones to produce clean, transparent finishes. Almost all of the perylenes have a structure as shown by the generic formula given as Fig. 8, that is, they are based on *N*, *N*′-substituted perylene-3, 4,9.10-tetracarboxylic di-imide. An exception of note is Pigment Red 234, Fig. 9, which is derived from the perylene tetra carboxylic dianhydride.

Benzimidazolone-Based Reds

This subdivision of reds includes such pigments as Pigment Reds 171, 175, 176, 185, and 208. Benzimidazolone-based reds are azo reds that contain the Benzimidazolone structure as part of their makeup. These reds all possess the generic structure based on a central naphthol molecule as illustrated in Fig. 10. Such structures exhibit a significantly high molecular weight that greatly influences durability and fastness properties of the pigment.

PR 208	$COOC_4H_9$	H

Fig. 10—Structure of the benzimidazolone reds.

Benzimidazolone reds are primarily used in the coloring of plastics because of their outstanding heat stability, although some uses are found within the coatings marketplace. They have excellent fastness to light at all depths of shade, good weather resistance, and excellent fastness to over-spraying at elevated temperatures. They all find use in coil coatings, power coatings, camouflage paints, automotive refinish, and farm implements where less-expensive, less-stable pigments would be inadequate.

Pigment Red 175 is a highly transparent red with good light fastness that finds application in the automotive base-coat/clear-coat systems since it is not sufficiently durable for top-coat systems without a clear coat to provide additional protection to the pigment. Pigment Red 171 is also a transparent pigment, but it has a maroon shade that finds use in industrial systems. Pigment Reds 176, 185, and 208 find considerable use in quality printing ink applications but currently no use in the paint and coatings industry.

Disazo Condensation Reds

These types of pigments have been commercially available in Europe since 1957 and in the United States since 1960. Their outstanding fastness properties have resulted in their use in high-quality industrial finishes. Fig. 11 illustrates three typical structures of the disazo condensation reds. The figure merely serves to show the size and variation of the structures of pigments within this class.

Pigment Red 242, C. I. Number 20067, Fig. 12, is a bright yellow shade disazo condensation pigment with excellent fastness properties that is finding increased use in high-quality industrial finishes and as a lead replacement pigment for those high-qualtiy coatings that now must be formulated lead free.

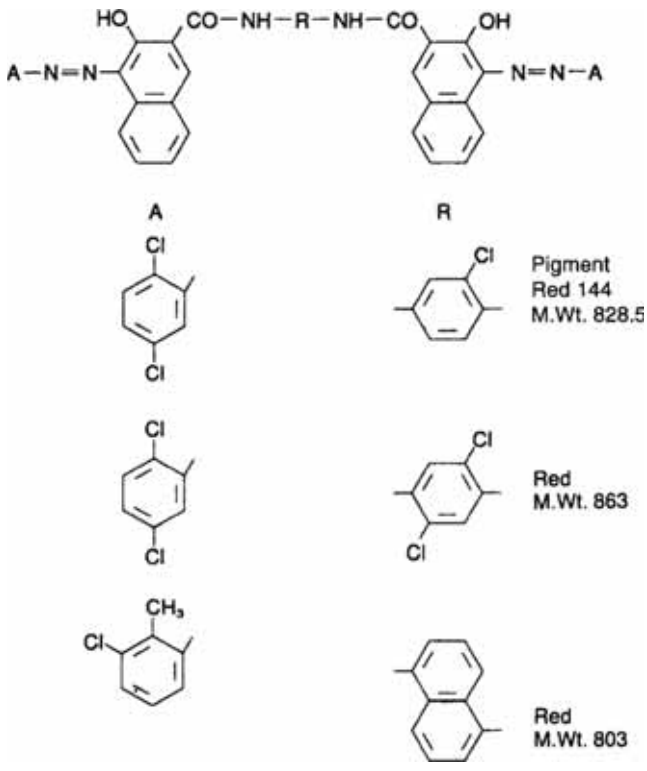

Fig. 11—Structure of the disazo condensation reds.

Pigment Red 214, C. I. Number 200660, Fig. 13, is another example of a disazo condensation red with properties similar to those of Pigment Red 242.

THIOINDIGOLD REDS

The thioindigold serves as a nucleus for a wide range of red to violet pigments including such pigments as Pigment Reds 86, 87, 88, 181, and 198 (see Fig. 14). These pigments are all noted for their brightness of shade and generally good fastness properties, resulting in their use in the coatings industry. Many of these pigments have been discontinued. Pigment Red 88, at one time widely used in automotive finishes, has been withdrawn from the marketplace for environmental reasons. Formulators wishing to find a match for the shade of PR 88 should attempt a match by blending quinacridone violet (PV 19) with perylene violet (PV 29) beginning with a ratio approaching 8 parts of the quinacridone to 1 part of the perylene as a starting point.

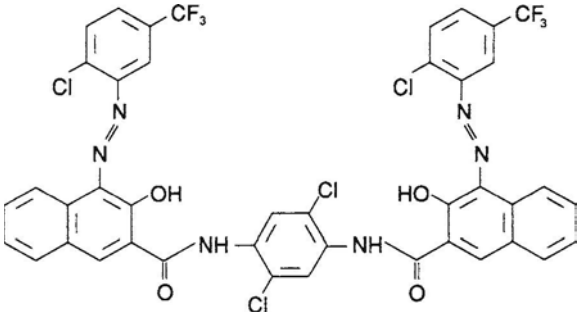

Fig. 12—Structure of Pigment Red 242.

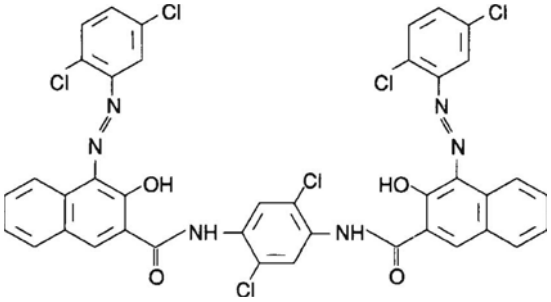

Fig. 13—Structure of Pigment Red 214.

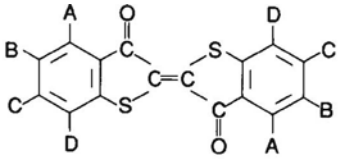

DIKETOPYRROLOPYRROLE REDS

An essential feature common to these pigments, which have been synthesized in hues from scarlet to a very blue shade red, is the two fused five-membered ketopyrrole rings. Reds based upon this structure are currently finding widespread use in both automotive and industrial systems to provide brilliant, saturated red shades of outstanding durability, and are used alongside quinacridones and perylenes. Grades and chemistries in the marketplace are outlined in Table 2. By control of the particle size, diketopyrrolopyrrole pigments may be produced as transparent or opaque grades. Yet again, the excellent fastness properties provided by a pigment of such low molecular weight is explained by the significant intermolecular hydrogen bonding shown to exist throughout the crystal lattice [3]. These pigments also find use in plastics and high-performing printing ink applications.

NOVEL HIGH-PERFORMANCE REDS

In recent years, several novel organic reds have been commercialized and targeted exclusively to meet the requirements of the coatings marketplace.

Pigment Red 257, C. I. Number 562700, Fig. 15, is a nickel complex with a red-violet masstone and a magenta undertone that exhibits fastness properties similar to that of quinacridone. Pigment Red 257 is particularly useful in the formulation of high-quality industrial and automotive coatings. The pigment also exhibits excellent rheological properties in highly pigmented systems.

TABLE 2—Listing of current "diketopyrrolopyrrole" based pigments including oranges and reds

Colour Index Name	Colour Index Number	Composition	Comments
PR 254	56110	1-chloro-pyrrolopyrrole	Used in powder and automotive coatings
PR 255	561050	Un-substituted pyrrolopyrrole	Used in industrial and automotive coatings
PR 264	561300	Dibenzyl-pyrrolopyrrole	Very blue shade, automotive and powder
PR 270	N/A	Not declared	Transparent red
PR 272	561150	Methyl-pyrrolopyrrole	Bright red for fibers and plastics end uses
PO 71	561200	Benzyl cyanide- pyrrolopyrrole	Transparent orange for metallic finishes and textile printing
PO 73	561170	Trimethylphenyl-pyrrolopyrrole	Opaque, bright orange for decorative and industrial finishes

Pigment Reds 251 and 252 are both based on the pyrazoloquinazolone structure as described in Fig. 16. These pigments are monoazo compounds derived from pyrazolo(5,1-b)quinazolones as the coupling compound and substituted anilines or polycyclic amines as the diazo component. Each pigment exhibits excellent brightness of hue at full shades, good gloss retention, and high scattering power combined with good light and weather fastness. As such, they are finding increased use in industrial and automotive coatings.

Blues

COPPER PHTHALOCYANINE BLUE

The most important and most widely used blue throughout all applications of the coatings consuming industry is copper phthalocyanine blue, Pigment Blue 15, C. I. Number 74160, Fig. 18.

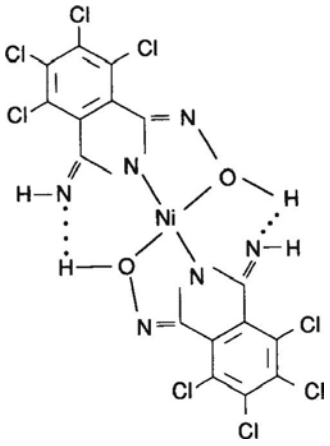

Fig. 15—Structure of Pigment Red 257.

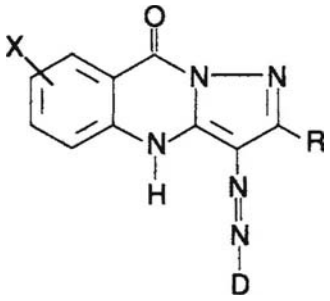

Fig. 16—Generic structure of pyrazoloquinazolone (basis of Pigment Red 251 and 252).

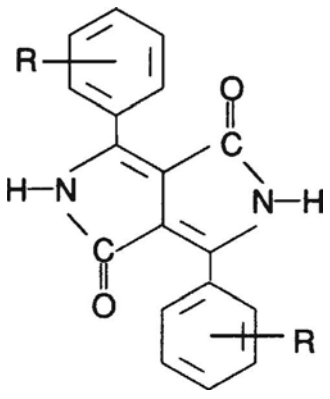

Fig. 17—Generic structure of pyrrolo-pyrrole.

First described in 1928 by chemists working for the Scottish Dye Works, this pigment has steadily increased in importance to become a product with worldwide significance. The only metal derivative of significant commercial use is that of copper, derivatives of other metals having been shown by research to have less desirable shade or fastness characteristics. Metal-free phthalocyanine, Pigment Blue 16, C. I. Number 74100, once found an outlet as a green shade blue. However, this pigment's inferior heat stability and poorer chemical resistance, coupled with the significant higher price than that of the copper-containing pigment, has resulted in a rapid decline in its consumption for all but very special applications. The newer aluminum phthalocyanine, Pigment Blue 79, C. I. Number 741300, has found use in aqueous ink applications where the presence of copper is a problem.

Copper phthalocyanine is predominantly available in two crystal forms, the alpha and the beta forms. The alpha crystal is described as Pigment Blue 15, 15:1, and 15:2. It is a clean, bright red shade of blue. The beta crystal is described as Pigment Blue 15:3 and 15:4, and is a clean green or peacock shade. The beta form is the most stable crystal form and readily resists re-crystallization. The alpha form, conversely, is the least stable form, which readily converts to the more stable, green shade, beta crystal. As such, the crystal requires special proprietary treatments to produce a red shade product that is stable to both crystallization and flocculation.

Copper phthalocyanine gives excellent performance in most coatings applications, but there is considerable variation between the surface treatments employed to stabilize the alpha crystal types. The coatings formulator should bear this in mind when choosing a grade for a specific application. Use of any of the unstabilized grades in strong solvents or in systems that experience heat during dispersion or application will result in a shift in shade to the greener side and a loss of strength as re-crystallization takes place within the unstabilized crystal.

Pigment Blue 15, C. I. Number 74160, is a red shade, alpha crystal. It is the least stable of the family and as such is referred to as "crystallizing red shade blue."

Pigment Blue 15:1 is a modified alpha crystal also having a red shade, but with modification to stabilize the structure against phase transformation to the beta crystal. In some instances, the molecule is chlorinated to the extent of one molecule of chlorine per molecule of copper phthalocyanine to give "monochlor" blue (C. I. Number 74250).

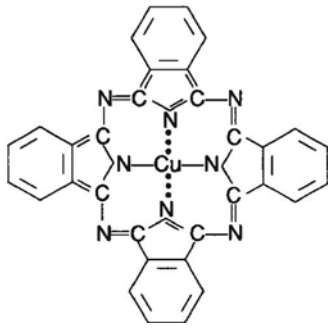

Fig. 18—Copper phthalocyanine, PB 15.

Pigment Blue 15:2, described as "non-crystallizing non-flocculating" red shade blue, is an alpha crystal that is stabilized against both flocculation and crystallization by using additive technology. Such additives are introduced during the manufacturing or blending operation, and are essentially derivatives of copper phthalocyanine that confer stability by a steric hindrance mechanism.

Pigment Blue 15:3 represents the most stable crystal, green shade, beta copper phthalocyanine.

Pigment Blue 15:4 is a descriptive of a beta blue that has been modified with phthalocyanine-based derivatives that are designed to be system specific to confer flocculation resistance to the pigment after the dispersion process.

Other specialized, more expensive crystal modifications also exist such as Pigment Blue 15:6, a very red shade, epsilon crystal.

Copper phthalocyanine is a pigment that offers brightness, cleanness, strength, and economy with all-around excellent fastness properties. The only drawback to this pigment is its tendency to change to a coarse, crystalline nonpigmentary form when used in strong solvent systems. If the crystal has not been adequately stabilized, it has a tendency to flocculate from white pigments such as titanium dioxide when used to tine such paint and lacquer systems. Another negative is the fact that copper phthalocyanine blues exhibit the phenomenon of bronzing when applied at masstone levels, deep tints, and in metallic systems.

Miscellaneous Blues and Violets

Indanthrone Blue—Pigment Blue 60, C. I. Number 69800. Belonging to the class of pigments described as "vat pigments," Indanthrone Blue is a very red shade, nonbronzing flocculation-resistant pigment with outstanding fastness properties. Two crystal modifications are available on the market, the more common α-modification and the more recently introduced even redder shade δ-modification. This pigment is used in paint systems requiring high durability of an intense red shade blue as a shading pigment at low levels where the expense of using the pigment is justified.

Carbazole Violet—Pigment Violet 23, C. I. Number 51319. A pentacyclic structure, intense violet shade pigment that possesses excellent fastness properties. It has found use in virtually all applications including paint, plastics, and inks, though use in the automotive industry has diminished as a result of increasing demands for durability. The pigment typically has a very high surface area and provides high tinctorial strength.

Yellows

MONOARYLIDE YELLOWS

These are azo pigments whose manufacture is based on the diazotization and coupling sequence as mentioned when dealing with azo reds. The structures of the major monoarylide yellows are illustrated in Fig. 19.

Hansa Yellow G, Pigment Yellow 1, C. I. Number 11680. This is a bright yellow pigment that is made by coupling diazotized 2-nitro-4-methyl aniline onto acetoacetanilide. It has a major use in trade sales, emulsion, and masonry paints. Its major disadvantages are its poor bleed resistance in most popular solvents, poor light fastness in tint shades, and very inferior bake resistance due to its tendency to sublime.

Hansa Yellow 10G, Pigment Yellow 3, C. I. Number 11710. This pigment is a very green shade yellow that is made by coupling the diazo of 4-chloro-3-nitro aniline onto 2-chloro acetoacetanilide. Greener in shade than Pigment Yellow 1, this pigment is used in the same types of applications and suffers from the same deficiencies as Pigment Yellow 1 with the exception that Pigment Yellow 3 is suitable for use in exterior applications at high tint levels.

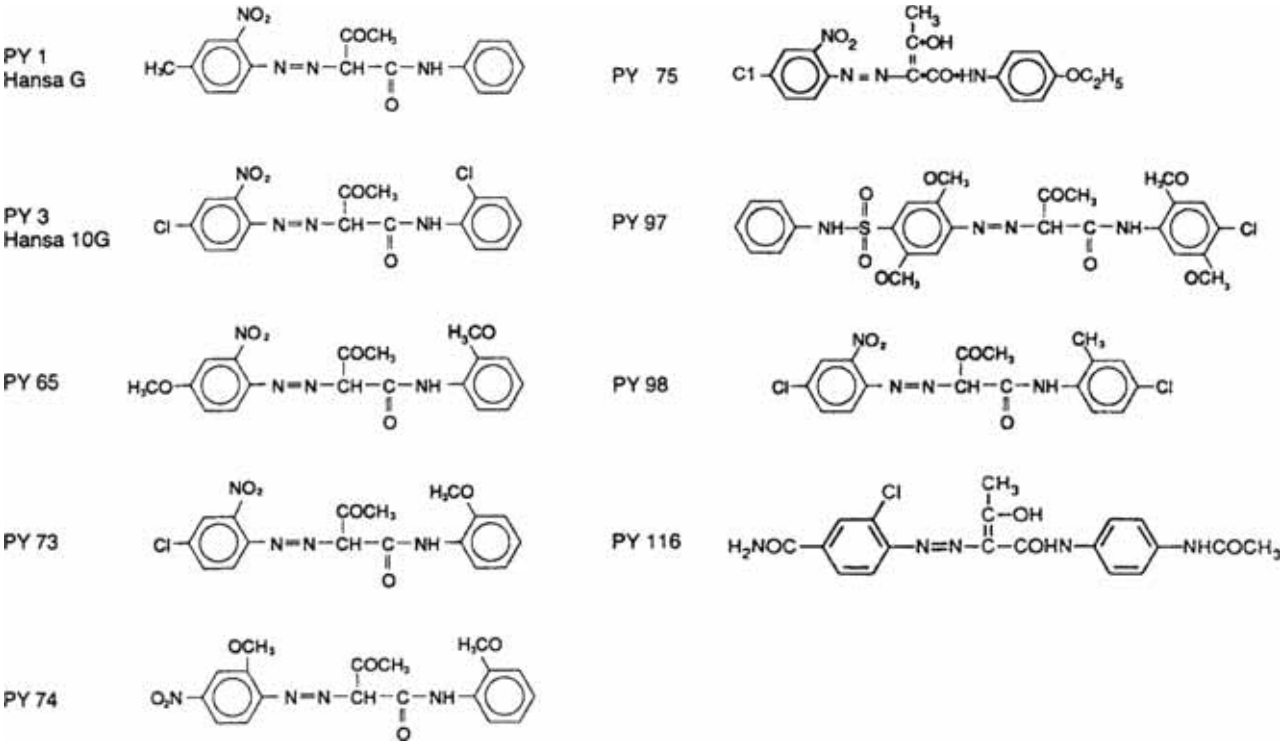

Fig. 19—Structures of the major monoarylide yellows.

Pigment Yellow 65, C. I. Number 11740. This is a monoarylide pigment produced by coupling diazo 2-nitro-methoxy aniline with 2-acetacetanlaidine. It has a redder shade than the two yellows previously discussed. Pigment Yellow 65 is used in trade sales, latex, masonry paints, and road traffic marking paints that are specified as being lead free. The bleed resistance and baking stability are little improved over PY 1 and PY 3.

Pigment Yellow 73, C. I. Number 11738. This pigment is prepared by coupling diazo 3-chloro-2-nitro aniline onto 2-acetoacetanisidine. It has a shade close to that of Pigment Yellow 1 that finds use in a similar application. Not considered durable enough for exterior application, Pigment Yellow 73 nevertheless plays an important role in interior inter-mix systems due to its stability against re-crystallization in the presence of glycols and wetting agents used in latex systems.

Pigment Yellow 74, C. I. Number 11741. This is the produce obtained from the coupling of diazo 4-nitro-2-anisidine onto 2-acetoacetanisidide, which offers the user a pigment suitable for outdoor applications that is considerable stronger and somewhat greener than Pigment Yellow 1. Major outlets, as with all the monoarylide yellows, are in latex trade sales and masonry paints. Additionally, an opacified grade is available that is optimized for its exterior durability, although of lower tint strength than the normal transparent grade.

Pigment Yellow 73 and the opaque grades of Pigment Yellow 74 show the least tendency to crystallize in organic solvent systems.

Pigment Yellow 75, C. I. Number 11770. This is a pigment produced by the coupling of 4-chloro-2-nitroaniline onto acetoacetophenetidide. It is a red shade yellow that has found use in traffic paint.

Pigment Yellow 97, C. I. Number 11767. This yellow is derived from the coupling of diazo 4-amino-2,5-dimethoxy-benzene sulphoanilide to 4-chloro-2,5-dimethoxy acetoacetanilide. It surpasses the Hansa yellows in solvent bleed and light fastness, especially in reduced shades. This yellow is finding use in high-quality decorating paints.

Pigment Yellow 98, C. I. Number 11727. Similar in shade to Pigment Yellow 3, but considerably stronger and more heat stable, this pigment has only met with limited commercial success in trade sales, masonry, and decorative paints. Manufacture is accomplished by coupling diazo 4-chloro-2-nitro aniline onto 4-chloro-2-methyl acetoaceta-nilide.

Pigment Yellow 116, C. I. Number 11790. This is a product from the coupling of diazo 2-chloro-5-carbamoyl aniline onto 4-acetylamino acetoacetanilide. It is similar in shade to light chrome yellow (PY 34) and has improved

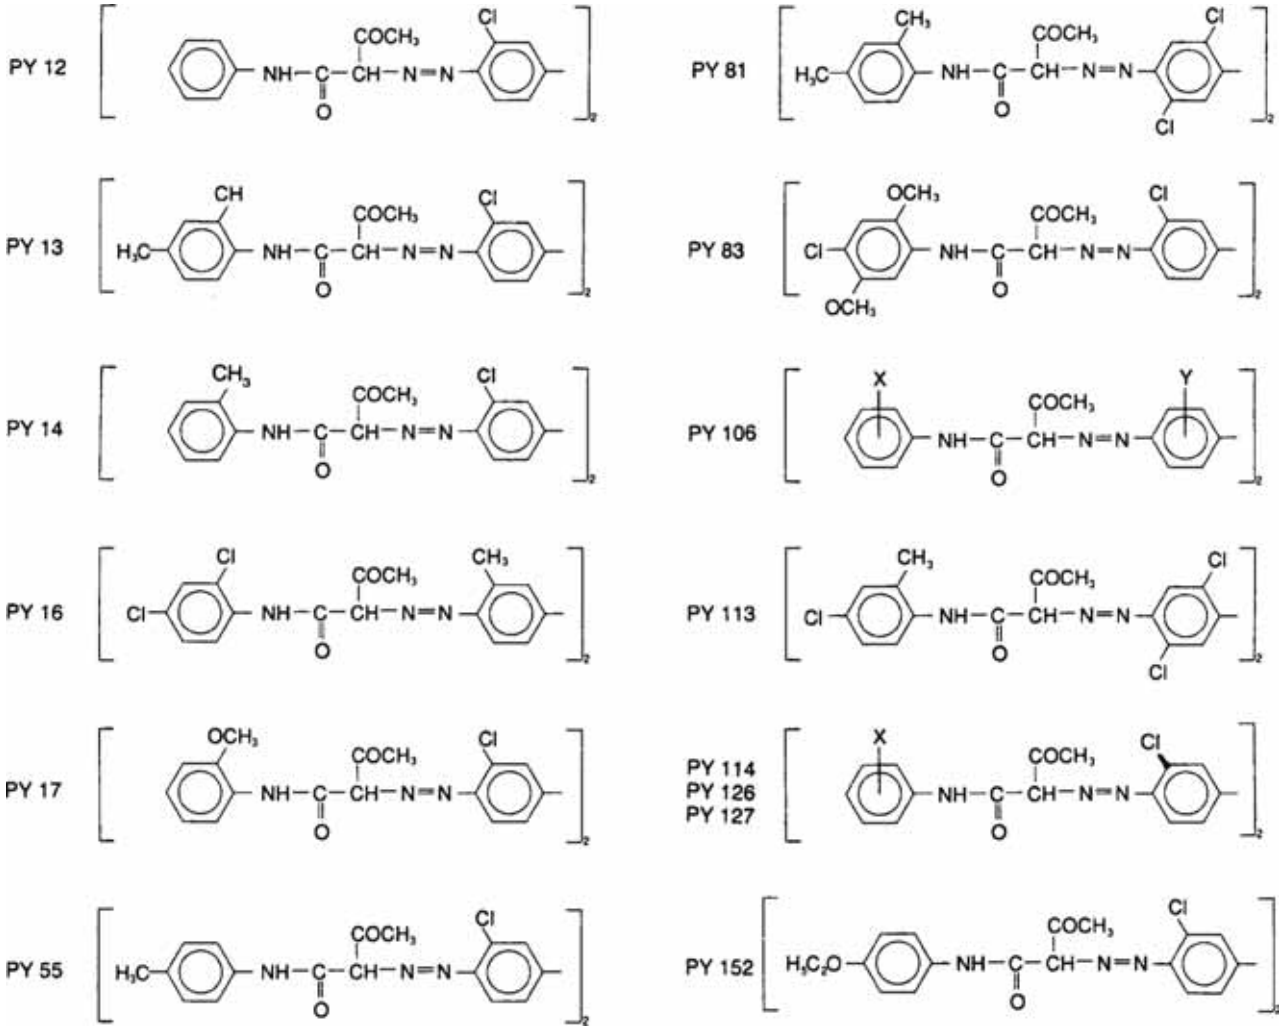

Fig. 20—Structures of the major diarylide yellows.

light, heat, and solvent fastness as compared to the other monoarylide yellows. As may be expected from its shade, this pigment's major use is in lead-free coatings.

METALLIZED AZO YELLOWS

Pigment Yellow 62, C. I. Number 13940, Calcium Salt. Pigment Yellow 62 is rather unique in that it is a metallized azo yellow that finds use in coloration of rubber, low density polyethylene, poly(vinyl chloride), and polypropylene fibers. This pigment is a calcium-based azo yellow produced from the diazotization and coupling of 4-amino-3-nitro benzene sulfonic acid onto acetoaceto-toluidide followed by conversion of the sodium salt to that of calcium. The pigment is a green shade yellow with good economy and moderate fastness properties to light, acids, and alkali. The maximum heat stability is rated at 475°F, measured at 0.1 % pigment with 1.9 % TiO_2 and a 5-min. dwell time. It is for this reason that Pigment Yellow 62 may have application in certain powder coating applications where economics are key.

DIARYLIDE YELLOWS

The structures of this commercially important range of organic yellows are shown in Fig. 20. This figure clearly shows the similarity between each of these pigments, which are principally a backbone structure centered on 3,3′-dichlorobenzidine with modifications to the shade and properties by variation of the coupling component used in the pigment's manufacture. Table 3 contains a summary of the properties of the major diarylide yellow pigments of commercial significance.

Each of the diarylide yellows offer low cost, reasonable heat stability, and moderate chemical resistance. The major worldwide market for this class of yellows is the printing ink industry. These yellows are approximately twice as strong as the monoarylide yellows dealt with above. Furthermore, they offer improved bleed resistance and heat fastness. Nevertheless, none of the diarylide yellows have durability properties that would allow for their use in exterior situations and, as such, should never be considered for outdoor applications. Minor applications exist in the area of toy enamels and pencil coatings, especially if a lead-free formulation is specified.

A range of opacified diarylide yellows is available. They undergo an after treatment that reduced their surface area and, consequently, opacity was increased. These specific types also exhibit improved fastness properties when compared against their non-opacified, transparent counterparts.

BENZIMIDAZOLONE YELLOWS

These yellows are illustrated in Fig. 21. They take their name from the fact that each features the 5-acetoacetylaminobenzimidazolone molecule as the coupler component. These pigments have exceptional fastness to heat, light, and over-striping. These properties are directly attributed to the benzimidazolone group within the pigment's structure. They were first described in 1964 and offered to the marketplace in 1969. They were initially used for the coloring of plastics, but the pigments are finding increased use in the coatings industry where their excellent fastness properties are demanded. Table 4 gives a summary of the properties of this class of pigments.

HETEROCYCLIC YELLOWS

All these yellow pigments contain a heterocyclic molecule within their structure as illustrated by the examples presented

TABLE 3—Properties of the major diarylide yellows

Colour Index Name	Common Name	Properties
PY 12	AAA Yellow	Poor lightfastness and bleed resistance. Major use is in printing inks.
PY 13	MX Yellow	Redder shade than PY 12, improved heat stability and solvent fastness. Major use is in printing inks.
PY 14	OT Yellow	Green shade, some use in interior finishes, poor tint light fastness.
PY 16	Yellow NCG	Bright green shade, with good heat and solvent fastness. Used in full shade for coatings.
PY 17	OA Yellow	Green shade. Some use in interior finishes. Poor light fastness.
PY 55	PT Yellow	Red shade. Some use in interior finishes, poor light fastness. Isomer of PY 14.
PY 81	Yellow H10G	Bright green shade. Same shade but much stronger than PY 3.
PY 83	Yellow HR	Very red shade. Improved transparency, heat stability, and light fastness over PY 12. Some interior finish use.
PY 106	Yellow GGR	Green shade. Poor tint light fastness. Major use in packaging inks.
PY 113	Yellow Hi0GL	Very green shade. More transparent than PY 12 and offering better heat and solvent fastness. Some interior use.
PY 114	Yellow G3R	Red shade. Improved solvent and light fastness over PY 12. Major use in oil-based inks.
PY 126	Yellow DGR	Similar shade to PY 12 but offering improved heat and solvent fastness. Major use is in printing inks.
PY 127	Yellow GRL	Bright red shade. Poor light fastness. Major use is in offset inks.
PY 152	Yellow YR	Very red, opaque pigment. Poor light fastness. Some use in interior finishes as a lead-chrome replacement.

in Fig. 22. Even with their molecular complexity, these new high-performance yellows continue to be used to satisfy the exacting demands of the coating industry. Pigments such as Isoindoline Yellow (PY 139) and Quinophthalone Yellow (PY 138) are typical examples of such complex, novel chromophores introduced in 1979 and 1974, respectively.

All of these pigments find application in high-quality coatings where the end-use can justify the price of these high-performing products. Table 5 summarizes the properties of the heterocyclic yellows available that find some use within the coatings industry.

Oranges

Table 6 lists those orange pigments that have significance in today's marketplace.

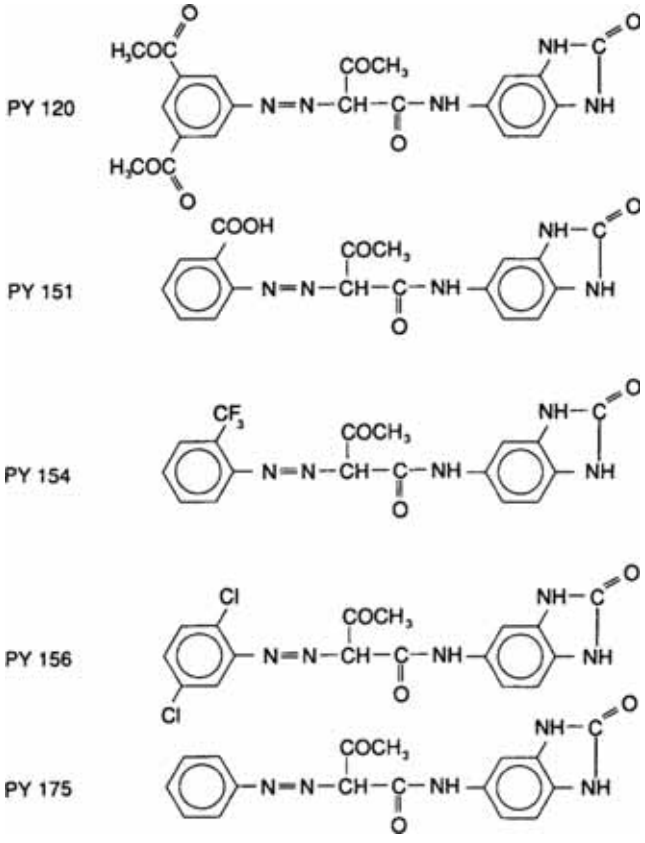

Fig. 21—Structures of the benzimidazolone yellows.

AZO-BASED ORANGES

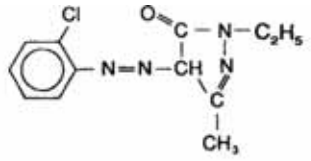
These oranges show considerable variation in structure as can be seen from Fig. 23. All, however, have the azo chromophore (—N═N—) featured within the molecule. The benz-imidazolone oranges all feature the azo chromophore in addition to all being produced using 5-acetoacetylaminobenzimidazolone as the coupling agent.

Orthonitroaniline Orange, Pigment Orange 2, C. I. Number 12060. This pigment is prepared by the chemical diazotization and coupling technique used for all azo pigments. It is the product of coupling diazo orthonitro aniline onto beta-naphthol. Its major outlet is in printing inks, and its use is not recommended in coatings due to the pigment's poor resistance to solvents and inferior light fastness.

Dinitroaniline Orange, Pigment Orange 5, C. I. Number 12075. Coupling diazo dinitroaniline onto beta-naphthol produces Pigment Orange 5. This pigment has good light fastness in full tone and moderate solvent fastness under this condition. As such, Pigment Orange 5 finds outlets in latex paints and air-dry architectural and industrial finishes. Its poor baking stability rules out its use in high temperature baking enamels.

Pyrazolone Orange, Pigment Orange 13, C. I. Number 21110, is synthesized by coupling tetrazotized 3,3′-dichlorobenzidine onto 3-methyl-1-phenyl-pyrazol-5-one. The pigment is a bright, clean yellow shade product that may be used for interior coatings, particularly as a replacement for lead-based orange pigments such as Molybdate Orange.

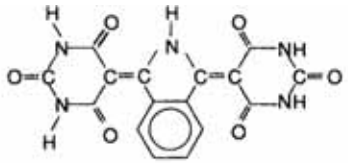
Dianisidine Orange, Pigment Orange 16, C. I. Number 21160, is a diarylide orange produced by coupling tetrazotized 3,3′-dimethoxybenzidine onto acetoacetanilide. It finds usage in baking enamels and interior coatings at full shade.



Tolyl Orange, Pigment Orange 34, C. I. Number 21115. This is a diarylide pigment manufactured by coupling tetrazo 3,3′-dichlorobenzidine onto 3-methyl-1-(4′methylphenyl (-pyrazol-5-one). This orange is a bright, reddish shade offering moderate light fastness and good alkali resistance, but poor solvent fastness. As such, the pigment is used in interior coating applications, particularly where a lead-free formulation is specified.

Pigment Orange 46, C. I. Number 15602. A metallized azo pigment manufactured by coupling diazotized 2-amino-5-chloro-4-ethyl benzene sulfuric acid onto beta-naphthol followed by reacting this product with barium to yield the barium salt of the pigment. The pigment is not recommended for coatings due to its poor light fastness,

TABLE 4—Properties of benzimidazolone yellows



Colour Index Name	Common Name	Properties
PY 120	Yellow H2G	Medium shade, good solvent fastness, excellent light fastness, used in industrial finishes.
PY 151	Yellow H4G	Greener shade with good solvent fastness, excellent light fastness. Industrial and refinish applications.
PY 154	Yellow H3G	Green shade, but redder than PY 151. Good solvent fastness, excellent light fastness. Industrial and automotive refinish.
PY 156	Yellow HLR	Redder shade, transparent, good exterior durability in full shade and tint. All exterior coatings and refinish areas.
PY 175	Yellow H6G	Very green shade. Good solvent fastness, excellent light fastness. Used in all exterior coatings and refinish areas.

TABLE 5—Properties of the heterocyclic yellows	
Colour Index Name	**Properties**
PY 60	Arylide Yellow. Very red shade. Moderate light and solvent fastness. Good acid and alkali fastness Trade sales, latex, and masonry paints.
PY 101	Methine Yellow, bright yellow. Highly transparent and exceptionally brilliant. Industrial finishes and specialty coatings. Moderate bleed and alkali resistance.
PY 109	Tetrachloroindolinone. Green shade with excellent brightness, strength, and durability. Automotive finishes.
PY 117	Greenish yellow copper complex of an azomethine. Excellent chemical, light and heat fastness. Specialty finishes.
PY 139	Azomethine Yellow, very green shade. Excellent chemical, light, and heat fastness. Industrial and specialty coatings.
PY 138	Green shade quinophthalone. Clean hue and excellent overall fastness properties. High-quality industrial and automotive areas.
PY 139	Red shade Isoindoline. Similar in masstone to medium chrome (PY 34). Excellent light and solvent fastness. Industrial and automotive coatings.
PY 150	Pyrimidine Yellow. Very green shade. Good heat and light fastness. Industrial coatings.
PY 153	Red shade nickel dioxine. Excellent fastness properties except poor acid resistance. Specialty coatings and baking enamels.
PY 155	Azo Condensation Yellow. Green shade, excellent fastness properties in full shade. Industrial and specialty coatings.
PY 173	Isoindolone Yellow. Very green shade with excellent fastness properties. Industrial and specialty finishes.
PY 182	Triazinyl Yellow. Medium shade with excellent fastness properties at masstone levels. Industrial finishes.

PO 67	12915	Pyrazoloquinazolone

inferior alkali resistance, and inadequate solvent fastness. It finds its major outlet in the printing ink marketplace.

Benzimidazolone Oranges, Pigment Orange 36, C. I. Number 11780. This product is formed from the coupling of diazo 4-cloro-2-nitroaniline to 5-acetoacetylamino-benzimidazoloe. It is a bright red shade orange with high tint strength. In its opacified form, this pigment offers excellent fastness to both heat and solvents and a hue similar to Molybdate Orange (PR 104). As such, the pigment is used in automotive and high-quality industrial finishes that must be lead free and that were formerly made using the lead-based pigment Molybdate Orange.

Pigment Orange 60, C. I. Number 11782. This is a transparent, yellow shade orange that also exhibits excellent heat and solvent fastness with an exterior durability that allows the pigment to be used in automotive and high-performance industrial finishes. It is made by coupling acetoacetylamino-benzimidazolone to 4-nitro-analine.

Pigment Orange 62, C. I. Number 11775. This is a relatively new member of the benzimidazolone oranges. It is a yellow shade pigment that shares the light fastness properties of PO 36 and PO 60, but has inferior solvent fastness and exhibits a slight bleed in alkaline systems. Currently, the pigment is being used in oil-based inks and artists' colors. Its use in the coatings industry is being explored.

MISCELLANEOUS ORANGES

Fig. 24 illustrates the structures of those oranges that fall into a "miscellaneous" category as far as such structures have been declared. Table 7 summarizes the properties of

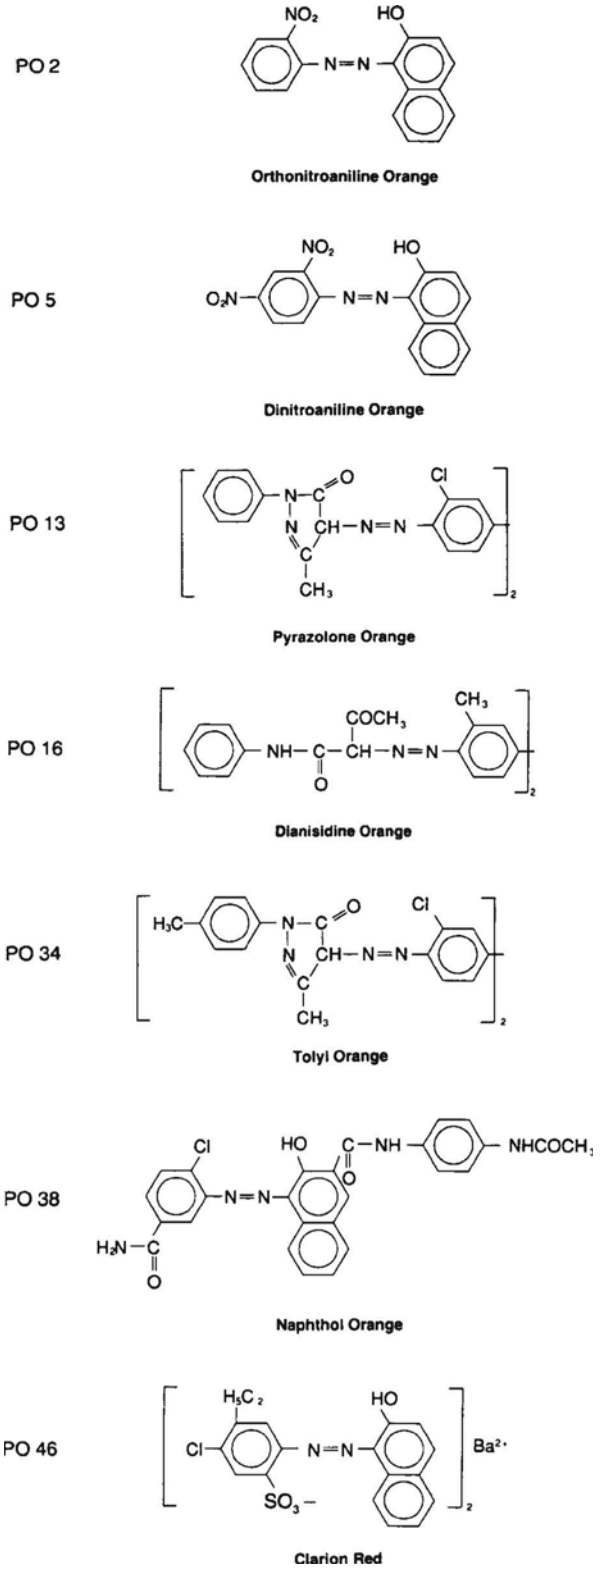

Fig. 23—Structures of azo-based oranges.

this series of pigments, each of which is finding increased usage within the coatings industry.

Greens

COPPER PHTHALOCYANINE GREEN

When a self-shade green is required, rather than a green produced by mixing blue and yellow, copper phthalocyanine is the green of choice. This pigment is based on halogenated crude copper phthalocyanine involving either chlorine or a mixture of chlorine and bromine. The chlorinated product is Pigment Green 7, whereas the mixed chlorine/bromine product is Pigment Green 36.

Pigment Green 7 is a blue shade green made by introducing 13–15 chlorine atoms into the copper phthalocyanine molecule, whereas Pigment Green 36 is a yellow shade green based on a structure that involves progressive replacement of chlorine in the phthalocyanine structure with bromine. Fig. 25 illustrates the proposed structures of the phthalocyanine greens. The most highly brominated product, Pigment Green 36, sometimes is referred to as "green 6Y" or "green 8G." It has an extreme yellow shade and contains 12–13 chlorine atoms.

Both greens exhibit outstanding fastness properties to solvents, heat, light, and outdoor exposure. They can be used equally effectively in both masstone and tints down to the very pale depth of shades. Metallic automotive paints may feature phthalocyanine green at all shade depths.

MISCELLANEOUS GREENS

Table 8 contains a brief summary of the properties of other commercially available organic green pigments that may find some use in the coatings industry. It should be noted, however, that green blends such as Brunswick Green (PF 15) and Mineral or Phthalo Chrome Green (PG 13), once widely used in industrial coatings, are now being replaced by the more economic organic green—phthalocyanine green.

Pigment Greens 1, 2, and 4 are triphenyl-methane-based dyes complexed with PTMA to allow their use as pigments. Their fastness properties are inadequate for most applications.

Pigment Green 8, C. I. Number 10006, is the bisulfide complex of 1-nitroso-2-naphthol reacted with ferrous sulfate and then with sodium hydroxide. It is one of the oldest chelate-based pigments that maintain some minor commercial significance as a colorant for cement. Exhibiting excellent alkali stability, this pigment suffers from poor acid fastness.

Testing of Pigments for Use in Coatings

Many tests can be applied to a pigment to assess its suitability in a coating formulation. However, it is of paramount importance that the formulator is satisfied that the tests have a clear relationship to the end use of the coating. It is pointless to evaluate a pigment's interior performance only to then use the pigment in an exterior application. For a pigment to be merely the shade and opacity as required by the customer is not an adequate safeguard that the pigment will perform as expected once the product is employed in its intended end use. In today's marketplace, more than at any other time in the past, with quality relationships being of such commercial significance, it is vital that the user and supplier have a full understanding of what is expected of any coating formulation that is in commercial production. The coatings business is under constant change and review, and it is in this atmosphere of change that care must be taken to ensure "fitness for use" of any colored organic pigment is fully explored.

Many types of tests will be run on a pigment that are not specific to an application but which are a property of

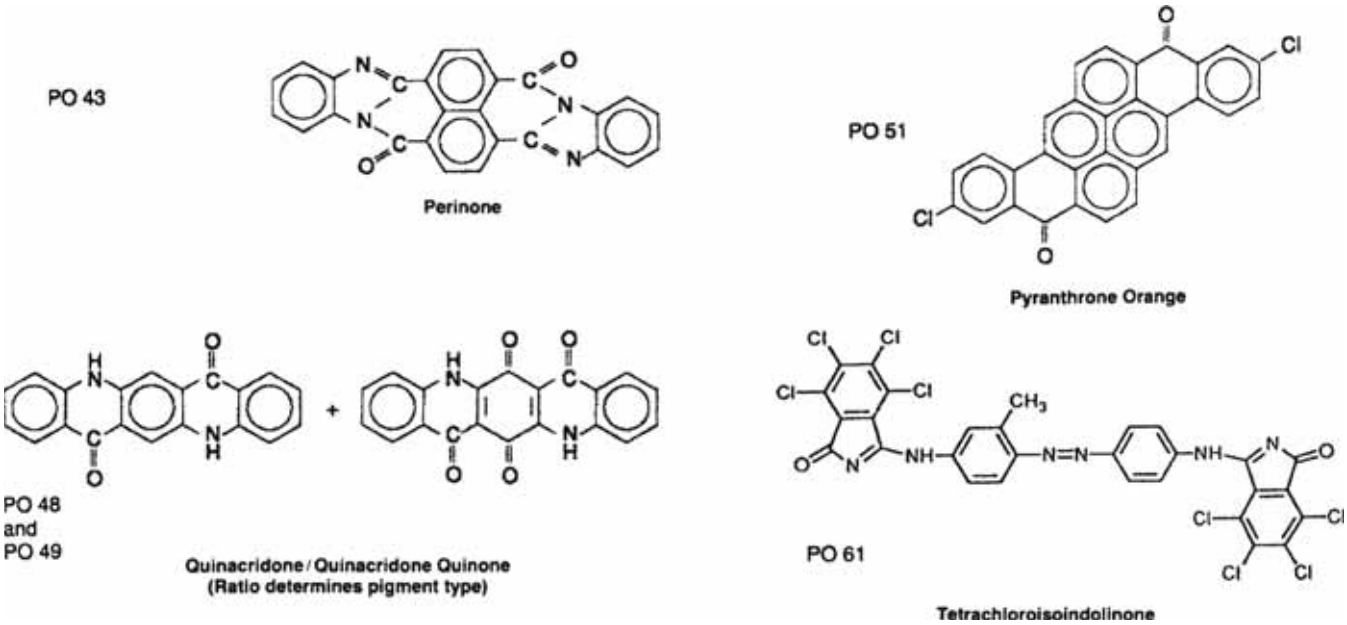

Fig. 24—Structures of the miscellaneous oranges.

TABLE 7—Properties of the miscellaneous orange pigments

Colour Index Name	Properties
PO 43	Perinone. Red shade. Strong clean vat pigment with excellent fastness properties. Used in metallized finishes and high-grade paints. Shows slight solvent bleed.
PO 48	Quinacridone gold. Yellow shade. Excellent light fastness. Lacks rightness in masstone. Used in metallics.
PO 49	Quinacridone deep gold. Red shade. Dull masstone. Excellent durability. Used in metallics.
PO 51	Pyranthrone orange. Medium shade. Excellent solvent, light, and heat fastness. Dull in tint. Exhibits slight solvent bleed. Used in air-dry and baked enamels.
PO 52	Pyranthrone orange. Red shade. Vat pigment with excellent solvent, light and heat fastness. Dull in tins. Slight solvent bleed. Used in air-dry and baked enamels.
PO 61	Tetrachloroisoindolinone orange. Medium shade. Exhibits some solvent bleed. Used in metallic automotive finishes.
PO 64	Bright red shade. Excellent solvent and light fastness. Used in industrial coatings.
PO 67	Yellow shade. Excellent brilliance in full shade. Good gloss retention. Very good weather and light fastness in full shade. Used in industrial and automotive coatings.

the pigment in question and which need to be known in spite of the end use application.

COLOR AND TINT STRENGTH [3]

The most obvious property of a pigment is its hue, that is, its color as being distinctly red, orange, yellow, green, blue, violet, etc., and the finer detail that distinguishes a green shade blue from a red shade blue. The other properties may be taken as those that are significant when the pigment is used in full tone and those of significance when the pigment is used in reduced shades after diluting the full shade with an opaque white, such as titanium dioxide (PW 7).

Evaluation of any pigment must include a test of full color or masstone that requires inspection of the pigment, undiluted with white, but fully dispersed in a medium that has relevance to the coating's formulation. Inspection of this full color shows the hue, intensity, transparency, cleanness, and jetness of the pigment. Comparison of these factors by making side-by-side evaluations with a standard or specification full color will illustrate just how close the pigment being used comes to the standard. The full color can then be tinted with a white base such as one made from titanium dioxide to enable the pigment's tinting strength to be assessed against a previously approved standard or control. Such a tint is known as a bleached, tinted, or reduced drawdown or display.

OIL ABSORPTION [4]

A broad definition of oil absorption is the amount of oil or vehicle that produces a uniform, cohesive paste when thoroughly incorporated with the test pigment. For standard purposes, it is the amount of refined linseed oil, by either weight or volume, necessary to produce a cohesive paste from 100 g of dry pigment. Since the transition point of going from a partially wetted powder to a cohesive paste is not a clearly defined measure, this test will always be

subject to differences between laboratories and technicians as to when the test's end point is reached. The figure for oil consumption is used by many coating formulators to give an indication of the effect different pigments will have on the flow properties of the system and to calculate the pigment loading limits.

BLEED TEST [5]

This test gives an indication of the extent to which the pigment will dissolve, however minutely, in the solvents the pigment is likely to be exposed to during its use. Additionally, an over-stripe test can be incorporated where the coating containing the pigment under test is over-striped with a white paint and allowed to dry. The extent of the discoloration of the white is an indication of the pigment's over-stripe bleed.

An attempt can be made to quantify this bleed by use of the "Grey Scale for Assessing Change in Color" (B.S. 2662) where the bleed is rated from 5, representing no visible bleed, to 1, corresponding to considerable bleed.

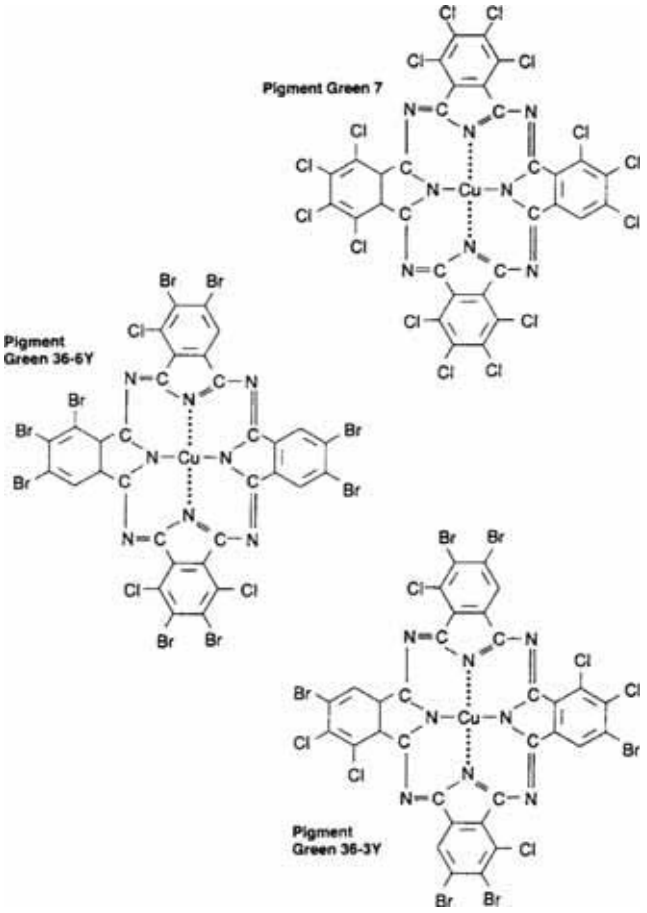

Fig. 25—Proposed structures for phthalocyanine greens (PG 7 and PG 36).

FASTNESS TESTS

The term "fastness" is used in this context to relate to how susceptible or durable a pigment is to the parameter under test. As such, the pigment's fastness to light, heat, solvent, etc., can be measured and rated using a "Fastness Scale." These scales rate a pigment from 1 (poor fastness) to 5, the highest number (excellent fastness), in all cases except light fastness, which is subdivided into 1 through 8, 1 being total failure while the highest number, 8, carries an outstanding rating corresponding to "no visible change" over the period of exposure.

Among those properties important to the formulator are fastness to solvents, where bleeding is observed by allowing a quantity of the dry pigment to stand for 24 h in contact with a solvent and observing any discoloration of the solvent that occurs; fastness to heat, where the effect of stoving temperatures on the pigment formulated into a finished coating is observed; fastness to acidic or alkaline environments; and fastness to light, where several tint levels of a formulation are exposed in such artificial sources as the Xenon or carbon arc fade-ometer [6]. To assess a pigment's behavior in accelerated exposure, the "Blue Wool Scale" is used to calibrate the measuring equipment (B.S. 1006).

EXPOSURE TESTING

It is now generally accepted within the coatings industry on a worldwide basis that the true test of a high-performance pigment is through prolonged outdoor exposure at specifically chosen sites throughout the United States and the world. To this end, many commercial establishments exist that provide a controlled service to expose sprayed panels of pigmented coatings angled in a predetermined manner toward the sun for periods extending as long as five years with assessments at predetermined intervals during this five-year period. Typically, many duplicate coated panels

TABLE 8—Properties of the miscellaneous commercial green pigments

Colour Index Name	Chemical Name	Properties
PG 1	Brilliant Green (Tri-phenylmethane PTMA)	Brilliant blue shade. Poor alkali, soap resistance, solvent bleed and light fastness. May be used in interior finishes.
PG 2	Permanent Green (Tri-phenylmethane PTMA)	Blend of Pigment Green 1 and Pigment Yellow 18. Bright yellow shade. Poor fastness properties overall.
PG 4	Malachite Green (Tri-phenylmethane PTMA)	Bright, blue shade. Poor fastness properties overall.
PG 8	Pigment Green B (Nitroso)	Yellow shade. Dull hue. Poor fastness properties. May be used in interior emulsions.
PG 10	Green Gold (Nickel azo complex)	Yellow shade. Loses metal in strong acid or alkali. Good light fastness. Moderate solvent fastness. Used in automotive and exterior paints.

will be exposed per test with a panel being returned to the formulator every six months, such that a measure of the system's weatherability as a function of time is maintained on record for each pigment and each system used in the outdoor situation.

SPECIFIC GRAVITY [7]

Defined as the mass of a given volume of a substance as compared to the mass of an equal volume of water at a previously specified temperature, the specific gravity of a pigment is used to obtain a bulk density or "bulking volume" of the pigment. This is a subjective test that cannot be easily compared between technicians and between laboratories.

Inorganic Colored Pigments

Peter A. Lewis[1]

CLASSIFICATION OF INORGANIC PIGMENTS BY CHEMISTRY

BROADLY SPEAKING, COLORED INORGANIC PIGments all fall into one of four groups: lead chromates, metal oxides, sulfides, or sulfoselenides with a few miscellaneous pigments that do not fit into one of these classes such as cobalt blue, ultramarine blue, iron blue, and bismuth vanadate yellow. This chapter describes the chemistry, manufacture, and properties of each of these classes of inorganic pigments. Inorganic whites such as zinc oxide, titanium dioxide, lithopone, and zinc sulfide, while pigmentary in nature and most definitely a part of the coatings industry, fall outside of the scope of this chapter and are discussed elsewhere in this manual.

By chemistry, inorganic pigments can be subdivided as shown in Table 1. In addition to the inorganic pigments listed in Table 1, there also exist a series of pigments classed as mixed metal oxides (MMOs); for example, zinc iron chromite brown (PBr 33), cobalt chromite green (PG 26), cobalt titanate green (PG 50), and cobalt aluminate blue (PB 28 and PB 36). Currently, these mixtures are also referred to as complex inorganic colored pigments (CICP). Often CICP and MMO terminology are used interchangeably, but CICP indicates the pigment is colored. These types of inorganic pigments are sometimes also called ceramic colors because of their widespread use in the ceramics industry. Since they are covered in the next chapter of this book, no additional consideration will be given to these colors in this chapter. Before going further into this chapter, the reader is directed to Chapter 21 for an explanation of the "Colour Index" and the description of pigments, both inorganic and organic, that has become part of a global understanding with respect to pigment nomenclature.

Transparent iron oxide pigments are finding increasing importance for automotive [1] and wood [2] coatings as well as other coating end use areas. These nano-size (average size less than 0.1 μm) [3] pigments are available in various colors, such as yellow, red, green, blue, black, and brown. They provide color with transparency, durability, ultraviolet radiation protection, heat resistance, and improved transparency that accentuates particular coating effects. These interesting pigments are solid materials that achieve their transparency through their extremely small size and shape. They will be mentioned in some, but not in all, of the color classifications given below.

CLASSIFICATION OF PIGMENTS BY COLOR

Most often, when searching for a color to fulfill a particular specification, the coatings formulator is likely to begin the search on the basis of color rather than chemistry. Accordingly, the remainder of this section will concentrate on the classification of inorganic pigments based on their color rather than their chemistry.

Reds

IRON OXIDE REDS

Pigment Red 101, C. I. Number 77491: Fe_2O_3: Available as both natural and synthetic products, these pigments also carry such historic names as haematite (hematite), mars red, ferrite red, rouge, turkey red, bauxite red, chinese red, and Persian Gulf oxide. Transparent red iron oxide pigments are also available. Synthetic iron oxide makes up the largest volume of manufactured iron oxides and is produced by one of five major syntheses:

1. By calcining iron sulfates.

$$12FeSO_4 \cdot H_2O + 3O_2 \rightarrow 2Fe_2O_3 + Fe(SO_4)_3 + 12H_2O$$

2. From synthetic black oxide by calcining the material in a controlled atmosphere containing oxygen.

$$4FeO \cdot Fe_2O_3 + O_2 \rightarrow 6Fe_2O_3$$

3. Precipitated red oxide can be prepared in an aqueous medium by growing seed nuclei in the presence of a ferrous salt and scrap steel, the lightness/darkness of the resulting pigment being determined by the crystal size distribution of the precipitate.
4. By calcining synthetic yellow iron oxide to give the dehydrated product, Fe_2O_3.
5. Reaction of iron pentacarbonyl oxidized in oxygen and water to produce very pure compounds that are mainly used in semi-transparent applications.

Techniques used to prepare transparent iron oxides can be found in the literature [3]. The wide range of red iron oxide shades available, in addition to their acid and alkali resistance and their economy, accounts for the large volume of these pigments used in today's coatings marketplace.

MOLYBDATE ORANGE

Pigment Red 104, C. I. Number 77605: This pigment is a very yellow shade of red that has the common name

[1] *Director, Communications & Regulatory Affairs, Sun Chemical Corporation, Colors Group, Cincinnati, OH 45232. NOTE: The author passed away after submitting his chapter for the manual. The reviewers' comments have been incorporated into the text by the editor.*

TABLE 1—Summary of colored inorganic pigments

Lead Chromates	
Pigment Yellow 34 $PbCrO_4 \cdot xPbSO_4$	Primrose, medium and dark chrome yellow
Pigment Red 104 $PbCrO_4 \cdot xPbSO_4 \cdot yPbMoO4$	Molybdate orange
Pigment Orange 21 $PbO \cdot xPbCrO_4$	Light and dark chrome orange
Pigment Green 15 $PbCrO_4 \cdot xPbSO_4 \cdot yFeNH_4Fe(CN)_6$	Chrome green (mixture of lead chrome and iron blue)
Metal Oxides	
Pigment Yellow 42 Pigment Yellow 43 $Fe_2O_3 \cdot xH_2O$	Yellow iron oxide—synthetic Yellow iron oxide—natural
Pigment Red 101 Pigment Red 102 Fe_2O_3	Red iron oxide—synthetic Red iron oxide—natural
Pigment Brown 6 Pigment Brown 7 Fe_2O_3	Brown iron oxide—synthetic Brown iron oxide—natural
Pigment Green 17 Cr_2O_3	Chromium oxide green
Pigment Green 18 $Cr_2O_3 \cdot 2H_2O$	Chromium oxide green, hydrated
Sulfides and Sulfoselenides	
Pigment Yellow 35 $CdS \cdot xZnS \cdot yBaSO_4$	Lithopone, cadmium yellow
Pigment Yellow 37 CdS	Cadmium Yellow
Pigment Orange 20 $CdS \cdot xCdSe \cdot yBaSO_4$	Cadmium lithopone orange
Pigment Red 108 $CdS \cdot xCdSe$	Cadmium red
Miscellaneous Types	
Pigment Blue 27 $Fe(NH_4)_2Fe(CN)_6 \cdot xH_2O$	Iron or Milori blue
Pigment Blue 28 $CoAl_2O_4$	Cobalt blue
Pigment Blue 29 $Na_{6-8}Al_6Si_6O_{24}S_{2-4}$	Ultramarine blue
Pigment Violet 16 $MnNH_4P_2O_7$	Manganese violet
Pigment Yellow 184 $4BiVO_4 \cdot 3Bi_2MoO_6$	Bismuth vanadate/molybdate yellow

of molybdate orange, a pigment based on oxides of lead, chromium, and molybdenum with the empirical formula of $PbCrO_4 \cdot xPbMoO_4 \cdot yPbSO_4$, a solid solution of lead chromate, lead molybdate, and lead sulfate.

Molybdate orange is produced by the addition of a solution of sodium chromate, sodium molybdate, and sodium sulfate under carefully controlled conditions into a solution of lead nitrate at a temperature between zero and 40°C to precipitate the mixed crystal. Control of particle size, particle-size distribution, and crystalline shape combine to determine the actual hue of the pigment, from a red shade of yellow to a red shade of orange with specialty hues such as "chili red."

An opaque pigment with high solvent fastness, moderate heat fastness, and good economy, molybdate orange finds its major outlet in the coatings industry, particularly industrial finishes. On the negative side, the pigment has poor alkali and acid resistance; nontreated grades also tend to darken markedly on prolonged exposure to the environment. Additionally, the pigment is based on lead, which has been under an "environmental cloud" for some years. As a result, molybdate orange has been replaced in most paint and coating applications by more expensive, but less toxic, organic pigments such as benzimidazolone orange (PO 36) in architectural, industrial maintenance, and almost all original equipment manufacturer (OEM) paints made in the United States.

CADMIUM RED

Pigment Red 108, C. I. Number 77202 and 77196, $CdS \cdot xCdSe$: Cadmium sulfoselenide red, Pigment Red 108, is a solid solution of cadmium sulfide and cadmium sulfoselenide produced by calcining co-precipitated cadmium sulfides and sulfoselenides. The pigment's hue is determined by the amount of cadmium sulfoselenide incorporated into the solid solution and, to a lesser extent, the temperature of processing. Pigment Red 108:1 (C. I. Number 77202:1), cadmium red lithopone, is a co-precipitate with barium sulfate having the empirical formula:

$$CdS \cdot xCdSe \cdot yBaSO_4$$

Cadmium red features excellent stability to heat, alkali, solvents, and light when used at high tint and masstone levels. The pigment offers the formulator a clean bright red with high chroma. Use of the pigment in an extended formulation with an opaque white as a light tint is not recommended since the durability will suffer at weak tint levels.

MERCURY CADMIUM RED

Pigment Red 113, C. I. Number 77201, $CdS \cdot xHgS$: Mercadium red is yet another calcined co-precipitate. It is mercuric sulfide co-precipitated with cadmium sulfide to give a pigment with the empirical formula CdS-xHgS, offering good hiding properties and good solvent resistance with excellent brightness. The pigment's inferior heat and acid resistance when compared to Pigment Red 108 has limited its use in coatings applications.

Violets

Pigment Violet 15, C. I. Number 77007, $Na5HAl_4Si_6S_4O_{24} \cdot H_2O$ and Pigment Violet 16, C. I. Number 77742, $Mn(NH_4)P_2O_7$: Technically these are blue-shade reds, and the two most important inorganic violet pigments are Pigment Violet 15, ultramarine violet, prepared by the oxidation of ultramarine blue, Pigment Blue 29, and Pigment Violet 16, manganese violet, prepared when manganese dioxide and diammonium phosphate are slurried together at high temperature in phosphoric acid.

Ultramarine violet has good heat and light fastness and a brilliant red shade. The pigment will react with metals to form sulfides, and it finds use in cosmetic applications, specialty acrylic poster paint and artists' colors.

Manganese violet does not possess the same brightness of hue as Pigment Violet 15 and has only moderate opacity and poor alkali resistance. On the plus side, the pigment has improved light fastness and superior resistance to solvents and over-stripe bleed. Major uses are in the plastics and cosmetics industry with some minor uses in artists' colors.

Blues

IRON BLUE

Pigment Blue 27, C. I. Number 77510, $Fe_4[Fe(CN)_6]_3{\cdot}xH_2O$: Also known as Chinese blue, Prussian blue and Milori blue, this pigment is manufactured by reacting ferrous sulfate and sodium ferrocyanide in the presence of ammonium sulfite to yield a leucoferricyanide, Berlin white, which is then isolated and dissolved in sulfuric acid and oxidized with sodium chlorate to yield iron blue.

$$Na_4Fe(CN)_6 + FeSO_4 + (NH_4)SO_4 \rightarrow Fe(NH_4)Fe(CN)_6 + 2Na_2SO_4$$

Berlin white

$$6Fe(NH_4)_2Fe(CN)_6 + 3H_2SO_4 + NaClO_3 \rightarrow 6FeNH_4Fe(CN)_6 + NaCl + 3(NH_4)_2SO_4 + 3H_2O$$

Differing grades of iron blue that offer varying depth of hue, strength, oil absorption, and dispersion characteristics exist. Chinese blue, for example, offers a greener undertone, whereas bronze blue features a surface "bronziness" effect that varies with a dependence on the viewing angle and film thickness.

Iron blue offers good resistance to weak acids but markedly poor resistance to even mild alkali; furthermore, the pigment has a tendency to "bleach out" on storage, losing almost all its color when incorporated into a paint formulation that contains oxidizable vehicles such as linseed oil. The pigment has only acceptable light fastness properties when used at masstone levels; extension of the paint with a white, such as titanium dioxide, gives a weak blue tint that will rapidly fade on exposure to the environment.

ULTRAMARINE BLUE

Pigment Blue 29, C. I. Number 77007, is a polysulfide of sodium alumino silicate of unknown constitution. Going by such varied common names as laundry blue, dolly blue, and lapis lazuli, this pigment, which is made by the controlled grinding of a mixture of calcined kaolin, soda ash, sulfur, coal, and sodium sulfate, is Pigment Blue 29. Empirically the product is $Na_6Al_6Si_6O_{24}S_4$, and its major use is as a component of laundry powders and detergent soaps. Metals such as potassium, lithium, or silver may also be incorporated into the structure. Less than 5 % of the production is used in the coatings industry for interior emulsion paints that require high alkali resistance and moderate light fastness.

Yellows

STRONTIUM YELLOW

Pigment Yellow 32, C. I. Number 77839, $SrCrO_4$: Strontium chromate is prepared by precipitating a suitably soluble chromate with an appropriate strontium salt. Finding a primary use in corrosion-inhibiting coatings, this pigment has poor tint strength, low opacity, and unsatisfactory alkali and acid resistance, which limits its more widespread use in the coatings industry. Little of this pigment is now manufactured in the United States.

CHROME YELLOW

Pigment Yellow 34, C. I. Number 77600 and 77603, $PbCrO_4{\cdot}xPbSO_4$: A co-precipitate of lead sulfate and lead chromate, Pigment Yellow 34 has the empirical formula $PbCrO_4x$-$PbSO_4$. Various types exist that differ in the ratio of the lead sulfate to lead chromate and as such are described as medium chrome, primrose, and lemon chrome yellows. Typically primrose chrome will contain 23 %–30 % lead sulfate in the solid solution of the co-precipitate, whereas a medium chrome will contain 0 %–6 % lead sulfate. During manufacture, proprietary techniques are employed such that the orthorhombic crystal form is produced almost exclusively in preference to the unstable monoclinic form.

Many different grades of this type of pigment are available and they offer such improvements in properties as better chemical resistance, decreased tendency to darken on exposure, improved weathering, and as a silica-encapsulated product to minimize solubility of the lead contained within the pigment.

Primrose chrome exhibits a very green shade and offers good light fastness, high opacity, and low rheology coupled with economy of use. The coatings industry, closely followed by the ink and plastics industry, is the largest consumer of primrose chrome. Medium chrome is used widely in road-marking paints in the United States where the law requires a yellow marking line as opposed to white. Grades that have been pre-darkened by the use of antimony during the precipitation stage offer much increased stability to weathering since these grades will not darken further on exposure to sulfur in the atmosphere. Due to the concerns regarding the toxicity of lead-based pigments and their persistence in the environment, there has been a very significant move to replace such pigments with organic equivalents that do not contain lead [4]. The use of lead-based pigments, both yellows and white, in architectural and decorative paints was discontinued in the United States over 25 years ago.

ZINC CHROMATE

Pigment Yellow 36, C. I. Number 77955, $4ZnO{\cdot}K_2O{\cdot}4CrO_3{\cdot}3H_2O$: Also called zinc yellow, this pigment is identified as Pigment Yellow 36, as opposed to the lithopone version incorporating barium sulfate, which is Pigment Yellow 36:1 (C. I. No. 77956). It is a bright, green shade of yellow made by the precipitation of hydrated zinc potassium chromate from the reaction of sodium bichromate with zinc oxide and potassium chloride. Used primarily in corrosion-inhibiting coatings, its poor tinctorial strength and poor resistance to acid and alkali severely limits this pigment's use elsewhere.

CADMIUM ZINC YELLOW

Pigment Yellow 35, C. I. Number 77205, $CdS{\cdot}xZnS$: Yet another solid solution, cadmium zinc yellow is prepared from a cadmium salt co-precipitated with zinc sulfide. Calcination of this product gives pure cadmium zinc sulfide. The hue of the pigment is readily altered by varying the

ratio of the two components of this solid solution. Levels of zinc sulfide of 14 % to 21 % yield a green or primrose shade, while 1 % to 7 % results in a redder shade that achieves a golden hue. Incorporation of barium sulfate during manufacture produces a lithopone version, Pigment Yellow 35:1.

Cadmium zinc yellows offer bright, clean, opaque pigments with excellent resistance to heat, light, and strong solvents. Their poor fastness to mineral acids and marked tendency to fade when used at low tint levels limits their use within the coatings industry.

CADMIUM SULFIDE YELLOW

Pigment Yellow 37, C. I. Number 77199, CdS: Also known as cadmium lemon yellow, this pigment is obtained by the calcination of calcium sulfide. This color can be produced with hues ranging from a green shade to a very red shade by simply varying the calcination conditions. Offering excellent stability to heat, light, acids, and alkali, this pigment's only major drawback is its tendency to fade in the presence of moisture. A lithopone version exists, $CdS{\cdot}xBaSO_4$. (C. I. No. 77199.1), which is a "primrose yellow" shade.

IRON OXIDE YELLOWS

Pigment Yellow 42, C. I. Number 77492, $FeO(OH) \cdot nH_2O$: As with most of the commercially available iron oxides, this pigment can also be obtained as the natural grade, Pigment Yellow 43, also known as Mars yellow, or the synthetic variant, Pigment Yellow 42, originally obtained from the mineral goethite (hydrated iron oxide). Both opaque and transparent grades are marketed.

The natural yellow oxides, $FeO{\cdot}xH_2O$, will also contain clay and various other minor minerals. Available under several names, often related to the country of origin or the pigment's history, the natural yellow oxide is also called Indian ochre, ocher, sienna, and limonite.

The synthetic oxide is produced by direct precipitation using ammonium hydroxide and ferrous sulfate, via the Penniman-Zoph process from scrap steel and a ferrous salt to grow seed particles, or by the aniline process where nitrobenzene is reacted with metallic iron to produce iron oxide and aniline. The synthetic product has the empirical formula $Fe_2O_3{\cdot}xH_2O$, irrespective of the manufacturing process.

Iron oxide yellows are economical pigments with excellent light fastness, weatherability, opacity, and flow properties. On the downside, they are dull in masstone and exhibit only fair tinctorial strength and moderate baking stability at best. It is their value in use that has resulted in their widespread acceptance throughout the coatings industry.

BISMUTH VANADATE/MOLYBDATE YELLOW

Pigment Yellow 184, C. I. Number 771740, $4BiVO_4{\cdot}3Bi_2MoO_6$: The most modern of the inorganic pigments discussed in this section, Pigment Yellow 184, was introduced into the marketplace in 1985. It is also know as bismuth vanadate yellow and is manufactured by dissolving bismuth nitrate, sodium vanadate, and sodium molybdate in nitric acid followed by precipitation of a complex mixture of the metals. The precipitate is calcined to give a poly crystalline product, $4BiVO_4{\cdot}3Bi_2MoO_6$. The product is a green shade of yellow.

The pigment is used principally for brilliant solid shades in both automotive and industrial coatings. It is recommended for use in alkyd and acrylic paints, water-based paints, nitrocellulose lacquers, and baking enamels. The pigment has excellent weather fastness coupled with good hiding power and gloss retention (light fastness). Thermal stability is also good. The pigment has found use in replacing lead-based pigments in such traditional colors as "school bus yellow" as well as chrome and cadmium pigments. Earlier grades suffered from the unusual phenomenon where the color under shadows would darken only to lighten again once the shadow was removed. This photochromic effect has been investigated [5] and CIE chromaticity diagrams were developed for changes of bismuth vanadate pigments under the influence of sunlight or incandescent light. More stable grades of the pigment have been introduced and these do not suffer this drawback.

Oranges

CHROME ORANGE

Pigment Orange 21, C. I. Number 77601, $x\text{PbCrO}_4{\cdot}y\text{PbO}$: A basic lead chromate also known as chrome orange, this color is formed under alkaline conditions to give a product of empirical formula $x\text{PbCrO}_4{\cdot}y$ PbO, shades varying from a yellow to red shade dependant on the alkalinity maintained during the reaction sequence [6].

As with all lead-containing pigments, the product will darken on exposure to the atmosphere with the rate of darkening dependant on the sulfur content of the air. The pigment offers low cost, moderate light fastness, and finds use in the protective coatings marketplace with some use as a shading pigment for road traffic paints. Grades encapsulated within an amorphous silica structure that offer a product that is environmentally safer due to the occlusion of the lead within the silica shell [7].

CADMIUM ORANGE

Pigment Orange 20, C. I. Number 77202, $CdS{\cdot}x\text{CdSe}$: Cadmium orange, cadmium sulfoselenide orange, is a solid solution produced by calcining cadmium selenide with cadmium sulfide at approximately 1000°C (1800°F). A change in the ratio of the solid solution components gives pigments that vary from bright yellow (PY 35) to bright red (PR 108). Barium sulfate added or produced during the processing will form the lithopone grade, Pigment Orange 20:1.

This pigment is used in industrial coatings, for color-coding applications, in ceramics and where chemical and heat resistance are principal end use requirements.

CADMIUM MERCURY ORANGE

Pigment Orange 23, C. I. Number 77201, $CdS{\cdot}x\text{HgS}$: This pigment is a solid solution of mercury sulfide in cadmium sulfide. Various hues can be obtained by controlling the formation of the mixed crystal manufactured by precipitating the sulfides of cadmium and mercury from a solution of their soluble salts. The final stage is calcination in an inert atmosphere to give an extremely heat-stable pigment with excellent chemical and weather resistance as well as solvent fastness. Little of this pigment is manufactured in the United States, and its use in paint and coatings is minimal due to environmental concerns [8].

Greens

CHROME GREEN

Pigment Green 15, C. I. Number 77520, 77601, 77603: This pigment, also known as Brunswick green, is merely a mix-

ture of a green shade chrome yellow (PY 34) and iron blue (PB 27). As such, Pigment Green 15 offers a range of hues with a light yellow shade to a deep dark shade, providing good hiding, high tint strength, and moderate chemical resistance at an economical price. It can be used for bake enamels where the bake temperature does not exceed 148°C (300°F), but is restricted to exterior and industrial coatings applications as opposed to decorative finishes because of its lead content.

CHROMIUM OXIDE GREEN

Pigment Green 17, C. I. Number 77288, Cr_2O_3: Chrome oxide green is a pure, calcined chromium oxide, Cr_2O_3, manufactured by reduction of sodium bichromate with carbon or sulfur:

$$Na_2Cr_2O_7 + 2C \rightarrow CO + Na_2CO_3 + Cr_2O_3$$

This pigment has a unique use in camouflage paints because of its ability to reflect infrared light. Otherwise, the product finds a use where its price can be justified by the resultant excellent light and chemical resistance properties the pigment features. Minor applications also exist in the cosmetics industry and as a colorant for cement.

HYDRATED CHROMIUM OXIDE GREEN

Pigment Green 18, C. I. Number 77289, $Cr_2O(OH)_4$: Also known as Viridian green or Guignets green, Pigment Green 18 is a hydrated chromic oxide of formula $Cr_2O_3 \cdot 2H_2O$ from the hydrolysis of the product produced by calcining sodium bichromate with boric acid. The pigment is an intense, bright, blue shade of green with outstanding fastness properties in both masstone and deep tints.

Browns

NATURAL IRON OXIDES

A natural product obtained from either iron oxide mines operating principally to supply ore as feedstock for blast furnaces with a small off-take directed to the pigment industry or pigment mines, which operate solely to supply pigment grade ore. Typically the mined ore is slurried in an aqueous suspension and washed through a series of stages to remove sand and clay after which the slurry passes into a separator tank, then through a Dorr bowl rake where the iron oxide ore is separated and dried as a thin layer on a rotary drum drier. The dried natural ore is pulverized and classified to produce pigmentary iron oxide. Pigment Brown 7 is an iron oxide brown that is available in shades ranging from light red to deep purple brown. Empirically the product is Fe_2O_3. Metallic brown is produced from calcined hematite (PR 102) and burnt sienna from calcined limonite (PY 43).

Pigment Brown 7:x is a ferrosoferric oxide derived from ores containing 25 % manganese dioxide with a distinct composition as $Fe_2O_3 \cdot x$MnO with varying proportions of clay. Classical names include such as raw umber, burnt umber, raw sienna, burnt sienna, and Turkish umber.

SYNTHETIC BROWN OXIDES

Pigment Brown 6, C. I. Number 77491, 77492, 77499: Also known as brown magnetite iron oxide, Pigment Brown 6 is produced by controlled oxidation of Pigment Black 11. Chemically the product may be represented as $Fe_2O_3 \cdot x$FeO$\cdot y H_2O$.

Pigment Brown 11 (C. I. No.77495) is magnesium ferrite from the calcination of a blend of ferric and magnesium oxides, $MgO \cdot Fe_2O_3$.

The volume of all types of brown oxides used in coatings is generally low, since most browns are achieved by mixing yellow, red, and black pigments. As a class, these pigments have good chemical resistance and high tint strength and as such find some use in wood stains and furniture finishes. Minor applications also exist in the field of colorants for cosmetics and for the coloration of cement.

Ceramic Pigments

Richard A. Eppler[1]

CERAMIC PIGMENTS ARE COMPLEX MIXTURES of oxygen-containing materials that have been calcined at high temperatures to form specific crystalline phases [1]. In most cases, oxide raw materials are carefully mixed and then calcined in either batch kilns or continuous calciners [2]. After calcination, they are ground to the necessary fineness in mills. Micronizers and/or jet mills are used to break agglomerates. The final production step involves careful control of the color tone.

Because these pigments are formed at high temperatures, they generally offer superb thermal stability and are relatively inert. This results in excellent weathering and light fastness properties. Most of these pigments have superior acid and alkali resistance. They are nonmigrating and nonbleeding in nature and do not interact with polymer systems [3].

The principal disadvantage of ceramic pigments is their low tinting strength. In addition, some are relatively high in cost. This is particularly true with cobalt-containing pigments. Some of these pigments are difficult to disperse. However, the recent development of easily dispersed ceramic pigments should eliminate this problem. A final concern is the inherent hardness of these pigments. Their hardness can lead to processing system damage through abrasion. When using ceramic pigments, processing system components designed for use with abrasive materials should be considered.

The major use of ceramic pigments is for applications such as vinyl siding, automotive paints, coil coating, and high-temperature systems where the product is thermally cured and then placed in an outdoor setting.

CERAMIC PIGMENTS USED IN ORGANIC PAINTS

The major criterion used in selecting ceramic pigments for organic paints is hardness. The pigments listed in Table 1 and discussed below are those that can be used in paint processing equipment without causing excessive wear. Property attributes of the pigments are given in Table 2. All are compatible with most polymer systems, with manganese-doped rutile especially useful when it is necessary to avoid iron.

Nickel-doped rutile, which is often called sun yellow, is produced from a mixture of various amounts of titanium (IV) oxide, nickel (II) oxide, and antimony (V) oxide by high-temperature calcination [1]. The result is formation of a crystalline matrix of rutile that has the basic chemical formula $(Ti,Ni,Sb)O_2$. The pigment is used for coloring high-performance industrial coatings, wire coatings, vinyl sidings, automotive and other exterior paints, as well as for roofing, granules, porcelain enamels, and ceramic bodies.

Chrome-doped rutile is prepared from a mixture of varying amounts of titanium (IV) oxide, chrome (III) oxide, and antimony (V) oxide by high-temperature calcination [1]. The resultant crystalline rutile matrix has the basic chemical formula $(Ti,Cr,Sb)O_2$. The orange-yellow pigment is used for coloring the same systems as nickel-doped rutile.

Manganese-doped rutile is prepared from a mixture of various amounts of titanium (IV) oxide, manganese (II) oxide, and antimony (V) oxide by high-temperature calcination [1]. The resulting crystalline rutile matrix has the basic chemical formula $(Ti,Mn,Sb)O_2$. The brown pigment is used for coloring the same systems as nickel-doped rutile.

Spinel brown pigments are an example of the 2-4 inverse spinels [4]. The basic pigment is prepared by a high-temperature calcination of titanium (IV) oxide and iron (II) oxide [1]. The resulting crystalline matrix of spinel is brown in color and has the basic chemical formula Fe_2TiO_4. The spinel phase permits extensive substitution, within defined limits, with other compounds to provide a variety of shades of brown. Modifiers used for substitution include Al_2O_3, CoO, Cr_2O_3, Fe_2O_3, MnO, and ZnO. The pigments are used for coloring high-performance industrial coatings, wire coatings, vinyl sidings, and automotive and other high-quality exterior paints.

Titanate green and blue-green pigments are also produced by high-temperature calcination of mixtures of titanium (IV) oxide, cobalt (II) oxide, nickel (II) oxide, and zinc (II) oxide to form a crystalline matrix of inverse spinel [1]. The pigments have the basic chemical formula $(Co, Ni, Zn)_2TiO_4$. The pigments are used for coloring the same systems as the spinel brown pigments.

Cobalt blue pigments are crystalline spinels formed by high-temperature calcination of cobalt (II) oxide and aluminum (III) oxide in varying amounts [1]. The basic cobalt blue pigment (CAS 68186-86-7) has the chemical structure $CoAl_2O_4$. The lighter-colored cobalt blue is prepared by addition of zinc (II) oxide to the ingredients used for the basic pigment. The chemical structure of the resultant material (CAS 68186-87-8) is $(Co,Zn)Al_2O_4$. Blue-green shades are produced by introduction of chromium (III) oxide, partially replacing aluminum (III) oxide in the basic cobalt blue system. It has the chemical formula $Co(Al, Cr)_2O_4$. In addition to being used to color the same systems as the rutiles, the cobalt blues are used in ceramic glazes.

Cobalt phosphate violet is prepared by high-temperature calcination of cobalt (II) oxide and phosphorus (V) oxide

TABLE 1—Recommended ceramic pigments for use in organic paints

Ceramic Pigment	Pigment Powder Color	Color Index/Name	CAS Number
Nickel-doped rutile	Yellow	77788/Pigment Yellow 53	71077-18-4
Chrome-doped rutile	Orange-yellow or maple	77310/Pigment Brown 24	68186-90-3
Manganese-doped rutile	Brown	77899/Pigment Yellow 164	68412-38-4
Spinel brown	Brown	77543/Pigment Black 12	68187-02-0
Titanate greens and bluegreens	Green	77377/Pigment Green 50	68186-85-6
Cobalt blue	Blue (basic)	77346/Pigment Blue 28	68186-86-7
Cobalt-zinc blue	Blue (lighter than basic)	77347/Pigment Blue 72	68186-87-8
Cobalt chromite blue	Blue-green	77343/Pigment Blue 36	68187-11-1
Cobalt phosphate violet	Purple	77360/Pigment Violet 14134	13455-36-2
Manganophosphate violet	Purple	. . .	10101-66-3
Ceramic black	Jet black	77428/Pigment Black 28	68186-91-4
Ceramic black	Jet black	66502/Pigment Black 27	68186-97-0

to form a crystalline phosphate [1]. It has the formula $Co_3(PO_4)2$. It is used for coloring the same systems as the spinels and in printing inks. Manganophosphate violet is produced by a precipitation process from ammonium salts of manganese (III) and phosphorus (V) [3]. This pigment has the chemical formula $NH_4MnP_2O_4$. It is used for inks and other applications where heat stability is of less importance.

One ceramic black is a jet black powder produced by calcination of mixtures of copper (II) oxide and chromium (III) oxide to form a crystalline spinel [1]. The basic jet black has the formula $CuCr_2O_4$. A marginally stronger black is produced by a high-temperature calcination of cobalt (II) oxide, iron (III) oxide, and chromium (III) oxide in varying amounts, also to form a spinel. The product has the chemical formula (Co, Fe)(Fe, $Cr)_2O_4$. The ceramic blacks are used in the same systems as the above-described rutiles.

Like most pigments, ceramic pigments are manufactured to have a suitable particle size for incorporation into the coating, but when a paint manufacturer receives them in bags of dry material, the particles generally have agglomerated or have absorbed moisture [5]. They are stuck together in groups by this layer of water or absorbed air. Hence, in the dispersing process, these layers must be destroyed and the primary particles dispersed in the paint.

There are a number of wetting and dispersing agents that can be added to a paint [5]. Discussion of this topic will

TABLE 2—Properties of recommended ceramic pigments (see Table 1 for color and pigment reference numbers)

Ceramic Pigment	Heat Stability	Weathering Properties	Light Fastness	Acid/Alkali Resistance	Hydrolytically Stable	Nonmigrating/ Bleed
Nickel-doped rutile	High	Excellent	Excellent	Excellent	Yes	Yes
Chrome-doped rutile	High	*Excellent	Excellent	Excellent	Yes	Yes
Manganese-doped rutile	High	Excellent	Excellent	Excellent	Yes	Yes
Spinel brown	High	Excellent	Excellent	Good	Yes	Yes

Ceramic jet black	High	Excellent	Excellent	Excellent	Yes	Yes
Ceramic Jet black-stronger	High	Excellent	Excellent	Excellent	Yes	Yes

[a]Manganophosphate violet has good acid resistance, but poor alkali resistance.

be found elsewhere in this manual. However, one important additional factor should be noted. Most ceramic pigment manufacturers today offer a line of easily dispersed pigments. These products are formulated with a proprietary dispersant. Adding the dispersant to the pigment itself promotes optimum contact between the dispersant and the pigment.

TESTING OF CERAMIC PIGMENTS

Ceramic pigments are usually tested for two important properties: particle size and tinting strength. Hardness is essentially a property of the pigment crystal produced and is insensitive to production details. Hence, handbook values for the crystal are usually adequate for most purposes.

There are three aspects of particle size to be considered: (1) the particle-size distribution, (2) the concentration of coarse particles, and (3) the particle shape as it affects the formulation of the paint. The measurement and reporting of particle-size distribution of pigments in paints is contained in ASTM Practice for Reporting Particle Size Characteristics of Pigments (D1366) [6]. The practice covers measurements by microscopic techniques, sedimentation methods, turbidimetric methods, absorption, and permeability methods.

The recent laser dispersion and electric sensing zone techniques are not yet dealt with in this standard. The procedures described in ASTM Test Method for Particle Size Distribution of Alumina or Quartz by Electric Sensing Zone Techniques (C690) and ASTM Test Method for Determining Particle Size Distribution of Alumina or Quartz by Laser Light Scattering (C1070) should be applicable to ceramic pigments [7].

Determination of the concentration of coarse particles that may cause defects in a coating is covered by ASTM Test Methods for Coarse Particles in Pigments (Dl85) [6].

The amount of pigment that may be added to a paint formulation is a strong function of the shape of the pigment particles. Higher loadings are possible for pseudo-spherical particles than is possible with plate-like particles. This property of a pigment is measured by determining the oil absorption characteristics of the pigment as described in ASTM Test Method for Oil Absorption of Pigments by Spatula Rub-out (D281) [8].

Tinting strength is the other important characteristic that needs to be evaluated. The determination of the color of a pigment requires that it be dispersed into a medium similar to that in which it is to be used. It is never acceptable to imply application color from the color of a dry pigment. The techniques for dispersing a pigment in a suitable vehicle and then measuring the color in both masstone and letdown are detailed in ASTM Test Method for Color and Strength of Color Pigments with a Mechanical Muller (D387) [8].

Extender Pigments

Richard A. Eppler[1]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CONTENTS of the 14th edition were drawn upon. The author acknowledges the author of the 14th edition, Henry P. Ralston. The current edition will review and update the topics addressed by the previous author, introduce new technology that has been developed, and include up-to-date references.

INTRODUCTION

Coating formulators use extender pigments to reduce the raw material cost of a coating formulation and to improve coating performance. Extender pigments are relatively inexpensive compared to titanium dioxide or color pigments and are easily incorporated into a coating. Most are white or near-white inorganic minerals, beneficiated to varying degrees, with a coarser particle size and lower oil absorption (binder demand) than primary pigments.

Extender pigments include inexpensive fillers, such as coarse calcium carbonate, which are used to reduce cost by filling coating volume with minimal impact on performance. Very fine particle size silicates, particularly certain kaolins and ultrafine talcs, can enhance coating performance and provide very favorable economics by effectively separating the individual pigment particles, optimizing the opacifying effect.

The industrial mineral extenders—wollastonite, talc, mica, kaolin, feldspar, and nepheline syenite—are used as functional fillers, chosen for specific features that improve coating performance, such as better durability, coating stability, rheology, and dry film properties. These effects of the silicates on coatings are a consequence of (a) the mineral's structure, which influences the particle shape, (b) the volume fraction of the mineral in the coating film, which is affected by the particle shape and size, and (c) the mineral's compatibility with the binder matrix, which depends on the particle physical and surface chemical properties.

Some of these properties are derived from the unique platy particle shape of talc, kaolin, or mica, or the acicular particle shape of wollastonite. Platy extenders tend to enhance the mechanical properties of the film by lateral reinforcement. They also minimize internal stress by allowing better stress dissipation along the plane of the pigment. When oriented parallel to the substrate, they reduce the porosity of the film, sealing it. Acicular particles reinforce the film, by preventing cracking and increasing tensile strength.

While extender pigments can vary in form and use, the added value delivered to the coatings formulator remains [1–3].

CALCIUM CARBONATE

Description

Calcium carbonate, also known as calcite, whiting, or limestone, has the chemical formula $CaCO_3$. It is produced by dry or wet grinding of marble or calcite ores, or by precipitation via carbonization of slaked lime. Product from ground limestone is dependent upon both the initial crude mineral and the subsequent degree of processing or beneficiation. The ore is crushed and milled; the dry ground product is air classified to different particle-size fractions. Wet ground product is milled as a slurry, undergoes flotation to remove impurities, and is then filtered and dried. The proximity of the supplier to the customer is a major consideration, as transportation is a significant portion of the cost of the material.

Precipitated calcium carbonate is produced by heating natural limestone to form calcium oxide, which is then slaked in water and reacted with carbon dioxide to form a low-solids slurry. The precipitate is vacuum filtered, dried, and ground. Both particle shape and size of precipitated grades can be carefully controlled by altering reaction conditions to yield effective extender pigments.

Calcium carbonate is used primarily as an inexpensive filler material. However, fine-particle-size precipitated grades and fine-ground limestones may have some value as an extender pigment to lower titania or color pigment concentration [1,4,5].

Physical Properties

Calcium carbonate products are differentiated by physical properties, such as particle size, brightness, residue, and, for precipitated grades, oil absorption. Fine-particle-size products have an average particle size of from less than 1 to about 4 μm with coarse-particle-size grades ranging up to about 15 μm. Most calcium carbonates are high in brightness, ranging from 90 to 98, with a *p*H of 9–10. Ground carbonates have low oil absorption, which correlates with low resin demand in coatings. The finer grades may be modestly higher.

Coatings Performance

Calcium carbonate is widely used in water-based trade sales architectural coatings since it is less expensive than titanium dioxide, a primary pigment in paints and coatings, and significantly lowers raw material cost. Fine-particle-size calcium carbonate functions as an extender by spacing titanium dioxide and maintaining or improving optical properties of the dry coating film at lower titanium dioxide levels. Higher-oil-absorption (binder demand) precipitated grades may contribute to opacity.

[1] *President/Owner, Eppler Associates, 400 Cedar Lane, Cheshire, CT 06410.*

Copyright © 2012 by ASTM International

Finer-particle-size grades tend to develop high gloss and high brightness, which can have a positive effect on the color of the coating.

Coarser grades of calcium carbonate are primarily used as fillers to reduce cost but also contribute to flatting and enhance low sheen control. Some grades may cause frosting and chalking in exterior applications.

KAOLIN

Description

Kaolin, also known as china clay, is an aluminum silicate with the chemical formula $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$, which is commercially available in both hydrous and calcined (anhydrous) forms. Domestic deposits occur primarily along the fall line in South Carolina and Georgia. It has a platy particle shape with finer particles present as individual platelets and coarse particles present as stacks of platelets or booklets.

The hydrous form is produced by air flotation or water washing. Air-floated grades are crushed and ground to a specific particle size and air-classified. This process is very dependent on the initial ore deposit.

Water washing involves processing the mineral in an aqueous slurry and separating particles of different size, which can then be recombined to yield products with controlled particle-size distribution. These products can also be further beneficiated by bleaching, ozonation, high-intensity magnetic separation, or chemical flotation to remove impurities and improve color. Some grades are subjected to a delaminating process that physically separates coarse platelets from one another.

Water washing offers a more carefully controlled product available in either slurry or dried form. Predispersed spray-dried beads offer ease of handling and are suitable for water-based coating systems. Pulverized acid grades are recommended for solvent-based coatings.

Calcined (anhydrous) forms are produced by subjecting water washed and bleached kaolin to thermal treatment. Low temperature calcination (650–700°C) removes structural hydroxyl, forming amorphous metakaolin. Specific gravity is decreased, while hardness and porosity are increased. When added to a coating, they promote trapping of air pockets, improving the opacity of the coating, probably by lowering the refractive index of the matrix. Fully calcined clays (1000–1150°C) are transformed into mullite, with increased hardness and specific gravity.

Physical Properties

Kaolins are also differentiated by properties such as particle size, brightness, residue, and oil absorption. Because of kaolin's effect upon the optical properties of coatings, they are offered in more varieties than are other functional fillers. Hydrous kaolins have an average particle size ranging from an extremely fine 0.2 up to 5 μm depending on the product. Dry brightness ranges from 85 % to 90 %, and most water-washed grades are very low in residue. Acid grades have a *p*H of 4–5, while predispersed grades are 6–7. Kaolins are chemically inert. Water-washed grades are lower in impurities such as soluble salts than are air-float grades.

Calcined grades range from below 1 to 2.5 μm in average particle size and are usually higher in brightness and hardness than hydrous grades. These grades have a more irregular particle shape and higher oil absorption than the hydrous grades.

Coatings Performance

Fine particle-size hydrous kaolins are commonly used in latex and alkyd trade sales paint. Finer particle size improves opacity and allows for cost reduction by extending/reducing the amount of titanium dioxide. Finer particle-size products also develop higher gloss and are particularly useful in enamels and semigloss formulations. Chemically modified hydrous kaolins are effective in high-solids and water-reducible industrial coatings.

Delaminated grades also develop good opacity, and the platy particle shape improves barrier resistance and film integrity. Delaminated grades or coarser hydrous grades are more suitable for interior wall paints and exterior trade sales formulations and exhibit more controlled chalking and better overall durability. Air-floated grades are not used significantly in coatings because the higher water-soluble salt content can cause viscosity instability.

Calcined kaolins are widely used in interior latex and alkyd trade sales flats to develop dry hiding and reduce cost at lower titanium dioxide levels. Dry hiding is due to the higher oil absorption (binder demand) of the calcined grades, resulting in more air/pigment and air/binder interfaces in the dry paint film. These grades develop good flatting, and the harder calcined particles also improve scrub resistance in interior latex coatings [1,6,7].

TALC

Description

Talc (also known as soapstone) is a hydrated magnesium aluminum silicate with the chemical formula $3MgO \cdot 4SiO_2 \cdot H_2O$. Deposits are found domestically in New York, Vermont, Montana, Texas, and California. Talc varies widely in purity depending on its source and may also contain dolomite, limestone, and silica, among others. Western talcs are highly platy, while eastern talcs have an acicular particle shape, and often contain substantial quantity of tremolite and other serpentine minerals. Both dry and wet grinding techniques are used in its beneficiation. Ore flotation processes are used to produce high-quality products. Dry processing includes use of jaw crushers, Raymond mills, and cyclones. Advanced milling technologies eliminate oversized particles.

Physical Properties

Key properties for talc include composition, color, particle size, water solubility, and oil absorption. Some grades are available with an average particle size of 1–3 μm, but most are around 5–15 μm. It is unique in its softness (Moh hardness 1–2) and lubricity. Brightness ranges from 70 to 85 for inexpensive grades and 87 to 92 for premium grades. Oil absorption depends on particle shape and size but in general fits in between calcium carbonate and kaolin. Slurry pH is basic at 9–10. Talcs are hydrophobic and organophilic.

Coatings Performance

Talcs are used in many different types of coatings including interior and exterior trade sales paints, primers, traffic paints, and industrial coatings. Western platy talcs develop good flatting and provide good chemical and water resistance due to high-purity and low-soluble calcium. These are best for sanding primers because of softness and good sealing properties, while coarse grades help develop surface roughness ("tooth"). Platy talcs have good flow

properties and improve barrier resistance and durability in exterior trade sales paints and enamel hold-out in interior applications. Talcs also enhance durability of traffic paints. Eastern acicular talcs have better color and develop lower viscosity at high loadings due to lower oil absorption [1,5,8].

SILICA

Description

Silica is a general term describing products with the chemical formula SiO_2 of which both natural and synthetic types are available. Those most widely used in paint and coatings are crystalline, microcrystalline, diatomaceous, precipitated, and fumed. They differ in method of production, physical properties, and function.

Crystalline silica is produced by crushing, grinding, and classifying quartz. Microcrystalline differs from crystalline in that its deposits, found principally in Arkansas, have a higher concentration of fine particles. It is produced in a similar manner as crystalline, but the ore is finer in particle size. Both are decreasing in usage because of reported health and safety issues related to crystalline silica.

Diatomaceous silica, also known as diatomaceous earth or simply diatomite, consists of the skeletal remains of single-celled aquatic plants called diatoms. Domestic deposits are located in California, Nevada, and Washington. The ore is crushed, milled, dried, and air-classified. Calcined grades are processed in high-temperature rotary kilns to remove organics and separated into selected particle size ranges by air classification. These products have superior color and are preferred for coatings applications.

Synthetic silicas are produced by a number of differing chemical and thermal processes. Precipitated silica is produced by acidification of sodium silicate in water solution, to form aggregates of ultra-fine particles. Aggregate size and degree of structuring are controlled by reaction conditions. Fumed silica, produced via high temperature hydrolysis of silicon tetrachloride with hydrogen, also exists in aggregates of ultra-fine particles, and particle size and surface area are also dependent on reaction conditions. It is more expensive than precipitated silica to produce.

Physical Properties

The several silica products are the optimum solution for chemical resistance in service. Since processing of crystalline silica is essentially a size reduction operation, particle size and particle-size distribution are the primary means of differentiating products. Crystalline silicas range from 2 to 10 μm average particle size. They are low in oil absorption, providing inertness and durability. Microcrystalline grades are easier to disperse and are less abrasive than crystalline grades. Brightness is from 85 % to 90 % and *p*H from 6 to 7. Oil absorption is intermediate between calcium carbonate and hydrous kaolins. These extenders are translucent and do not contribute to hiding as do some calcium carbonates and kaolin. Crystalline silica (quartz) has been identified as a carcinogen, limiting its use in some applications.

Diatomaceous silica is a very high oil absorption material found in aggregates ranging in mean particle size of 2 to 20 μm. They often contain up to 30 % organic material. Calcined grades are more porous and have a brightness of 87 % to 90 %.

The synthetic silicas are differentiated by surface area and particle size. Surface area of precipitated types is about 60–300 m^2/g, while fumed silica ranges from 50 to 400 m^2/g. Ultimate particle size of the individual particles are less than 0.1 μm for both; however, precipitated grades may develop larger aggregates. Fumed silica has a *p*H of 3–4, and precipitated silica has a *p*H of 6–8. These grades are often made hydrophobic by reaction with organofunctional silanes to improve performance in coatings. They are essentially amorphous so they will not cause silicosis.

Coatings Performance

Crystalline silica is used in trade sales, industrial coatings, and primers. It is an inexpensive extender that contributes to low sheen control, burnish resistance, and durability with minimal impact on rheology in latex trade sales paints. It is also used in powder coatings where its low binder demand does not affect flow properties.

Diatomaceous silica is primarily used as an inexpensive flatting agent in latex trade sales paints because of its high binder demand. Precipitated silicas are used as flatting agents in solvent-based industrial coatings. Fumed grades, more expensive than precipitated because of high-energy requirements during production, are used as rheology modifiers and flatting agents in industrial coatings [1,3,5,9].

MICA

Description

Mica is a family of hydrous aluminum potassium silicates of which one, muscovite, has the chemical formula $K_2O \cdot 3Al_2O_3 \cdot 6SiO_2 \cdot 2H_2O$. Micas are best known for a very platy particle shape and high aspect ratio. These are coarser in particle size than most extenders. Higher-aspect-ratio micas are produced by frictional wet grinding. Dry processing in high-pressure air jets to both delaminate and reduce the particles results in lower-aspect-ratio mica.

Physical Properties

Most coating grades of mica have an average particle size of 5 to 50 μm. Residue of 325 mesh varies from less than 1 to as high as 50 %, depending on the particle size of the product. Brightness ranges from 65 % to 80 %, low compared to other extenders, while *p*H is 7–8. Oil absorption is higher than other hydrous minerals and is closer to coarse-calcined kaolins.

Coatings Performance

Mica is best known for its very platy particle shape, which forms layers parallel to the paint film. Mica reinforcement increases durability and resistance to moisture penetration, corrosion, checking, heat, and chemicals. It helps prevent cracking in exterior architectural coatings and traffic paint. It prevents cracking and sagging in textured coatings. Mica provides good barrier resistance in primers and roof coatings. Its platy particle shape, however, limits loading levels due to rheology constraints [10].

WOLLASTONITE

Description

Wollastonite is a calcium metasilicate with the chemical formula $CaO \cdot SiO_2$ of which the primary domestic source is New York. It has an acicular particle shape, is white in

color, and is alkaline in pH. It is beneficiated by wet processing and/or high-intensity magnetic separation. Powder grades are milled in inpact mills to a low aspect ratio (3:1 to 5:1) and top particle sizes 325 mesh to 10 μm. High aspect ratio (HAR) grades are carefully attrition milled to yield aspect ratios of 12:1 to 20:1. Needle lengths range from 200 to 20 μm micrometers.

Both powder and HAR grades of wollastonite are available with organosilane treatments for compatibility with organic coatings. They are blended wet, and then dried.

Properties

Typical coating grades range from 2 to 10 μm in mean particle size. More important is the aspect ratio, as discussed in the last paragraph. Brightness ranges from 80 % to 95 %, and *p*H is 9–10. Wollastonite exhibits moderate hardness for scrub resistance, and moderate oil absorption relative to its non-spherical shape. Its acicular particle shape provides some reinforcement in coatings; and the high *p*H is effective in buffering latex systems. Surface-modified grades improve performance in industrial coatings by reducing resin demand and improving bonding between the mineral and resin.

Coatings Performance

In addition to their use for corrosion control, high whiteness powder grades of wollastonite are used in architectural, industrial, and marine coatings to ensure film integrity in service. HAR wollastonite grades are used in asphalt coatings, coal tar coatings, texture coatings, and block fillers for mechanical strength and durability. Wollastonite is used in epoxy powder coatings due to its low binder demand and water resistance. Adhesion, chip resistance, and thermal stability are benefits of using wollastonite. Coarser acicular grades are used in primers for a micro-textured surface [11].

FELDSPAR AND NEPHELINE SYENITE

Description

Feldspars are the most widespread mineral group, comprising about 60 % of the Earth's crust. They are commonly differentiated according to the dominant alkali, although most contain both soda and potash. Commercial feldspars are produced by flotation and magnetic separation followed by milling. Air classification is used for the finest grades.

Nepheline syenite is a rock composed of sodium and potassium feldspars and nepheline. It can form only in a geologic environment deficient in silica. In Canada, typical nepheline syenite is approximately 25 % nepheline, 55 % sodium feldspar, and 20 % potash feldspar, yielding a nominal chemical formula $K_2O{\cdot}3Na_2O{\cdot}4.5Al_2O_3{\cdot}20SiO_2$. It is produced by crushing, dry magnetic separation, and milling.

Properties

Milled feldspars and nepheline syenite crystalize as angular nodular particles, leading to low surface area, easy dispersion, and low vehicle demand. High loadings are possible. The particles interlock to improve the durability of the coating film, conferring crack resistance, high hardness, abrasion, and scrub resistance. They have high brightness (95 %–98 %) and are relatively coarse in particle size (2 to 16 μm).

Coatings Performance

The low binder demand of these materials make them particularly effective in exterior trade sales and architectural coatings. Their very low tint strength make them useful for deep-tone and pastel colors with minimum colorant. They provide good tint retention and prevent checking and cracking in exterior paints and also develop good scrub resistance in interior latex paints. They are the closest replacement for crystalline silica when toxicity concerns are raised.

Nepheline syenite is often favored over feldspar because it is silica-free. However, in acidic environments, such as acid rain, the durability of coatings using feldspar is superior [12].

BARIUM SULFATE

Description

Barium sulfate ($BaSO_4$) is available as barytes, its naturally occurring form, or as blanc fixe, a synthetic precipitate. Barytes has a nodular particle shape with deposits found predominantly in Nevada, Georgia, Missouri, Montana, Tennessee, Illinois, and Washington. The ore is beneficiated by flotation techniques and then wet ground to obtain the required particle size and bleached to improve color. Some higher quality ores are dry ground and air classified. Blanc fixe is a very white, fine-particle-size extender not as widely used in paints and coatings as barytes. It is precipitated to a specific particle size from solutions of barium salts and sodium sulfate. Blanc fixe is also used to make lithopone (extended) grades of pigments. Multistage washing and filtration removes soluble impurities, and the products are then dried and ground.

Physical Properties

Barytes is best known for its high density and very low oil absorption relative to other extenders. Particle size ranges from about 1 to more than 10 μm depending on the grade. Brightness also varies from below 70 % to greater than 90 % depending on the source and degree of beneficiation. Slurry *p*H runs from 4 to 10. Blanc fixe is a more uniform product with a 1–2 μm average particle size and high brightness (95 %–98 %).

Coatings Performance

Barytes is used in industrial and automotive primers and undercoats. Its low oil absorption allows for high loadings with less impact on rheology compared to higher binder demand extenders. It helps develop a smooth surface with minimal impact on the gloss of subsequent coats. Because extenders are sold by weight, high density can be a disadvantage in trade sales coatings where more weight is needed to fill a given volume. Higher density relative to other pigments can increase settling and cause stability problems. Blanc fixe has been used to develop dry hiding as a partial replacement for titanium dioxide in trade sales and industrial coatings [13].

OTHER

Sodium Aluminosilicates

Synthetic sodium aluminosilicates are produced by reacting aluminum sulfate with sodium silicate to produce a structured extender. These have high brightness (92 %–98 %) and relatively coarse particle size of 5–6 μm. Sodium

aluminosilicates are used as partial replacements for titanium dioxide in latex trade sales paints similar to calcined kaolin but at higher cost; some of the highly structured grades are used as flatting agents in latex paint [14].

Calcium Borosilicate

Synthetic calcium borosilicate is produced by melting complex mixtures of alkaline earth silicates and borates, followed by fritting and milling to produce a structured extender with particle size 1–10 μm microns and oil absorption 25–45 [15].

Alumina Trihydrate

Alumina trihydrate (ATH) has the chemical structure $Al(OH)_3$ and is produced from bauxite ore as an intermediate in aluminum production. It is most commonly used as a flame retardant and smoke suppressant in thermoplastic and thermoset polymer applications. ATH has a brightness ranging from 85 % to 98 % depending on the grade. Some very fine particle size grades, less than 1 μm, may be effective in spacing titanium dioxide in trade sales paints [14].

COMPARISON OF DIFFERENT EXTENDER PIGMENTS

Physical Properties

Physical properties of the pigment extenders described above are compared in Table 1. Calcium carbonates are available in different particle size grades and are very white in color and high in brightness. Low oil absorption enables high loading levels with minimal influence on rheology.

TABLE 2—Comparative properties of extender pigments in coatings

TABLE 3—ASTM standards for extender pigments

Standard	Title
Specifications	
D602	Specification for Barium Sulfate Pigments
D603[a]	Specification for Aluminum Silicate Pigments (Hydrous)
D604[a]	Specification for Diatomaceous Pigment
D605	Specification for Magnesium Silicate Pigment (Talc)
D607	Specification for Wet Ground Mica Pigments
D1199	Specification for Calcium Carbonate Pigments (Anhydrous)
D3619[a]	Specification for Aluminum Silicate Pigments (Anhydrous)
D4288	Specification for Calcium Borosilicate Pigments
Analytical	
D34	Guide for Chemical Analysis of White Pigments
D715	Test Methods for Analysis of Barium Sulfate Pigment
D716	Test Methods for Evaluating Mica Pigment
D717	Test Methods for Analysis of Magnesium Silicate Pigment
D718	Test Methods for Analysis of Aluminum Silicate Pigment
D719[a]	Test Methods for Analysis of Diatomaceous Silica Pigment
D4487	Test Methods for Analysis of Calcium Borosilicate
D5381	Guide for X-ray Fluorescence (XRF) Spectroscopy of Pigments and Extenders
Physical Properties	
D153	Test Methods for Specific Gravity of Pigments
D185	Test Methods for Coarse Particles in Pigments, Pastes, and Paints
D281	Test Method for Oil Absorption of Pigments by Spatula Rub-out
D1208	Test Methods for Common Properties of Certain Pigments
D1210	Test Method for Fineness of Dispersion of Pigment-Vehicle Systems by Hegman-Type Gauge
D1366	Practice for Reporting Particle Size Characteristics of Pigments
D1483	Test Method for Oil Absorption of Pigments by Gardner-Coleman Method
D2448	Test Method for Water-soluble Salts in Pigments by Measuring the Specific Resistance of the Leachate of the Pigment
D3360[a]	Test Method for Particle Size Distribution by Hydrometer of the Common White Extender Pigments
D4139	Guide for Determining Volatile and Non-Volatile Content of Pigments
D5380	Test Method for Identification of Crystalline Pigments and Extenders in Paint by X-ray Diffraction
E70	Test Methods for pH of Aqueous Solutions with the Glass Electrode

[a] These ASTM Standards have been withdrawn; however, the designations and titles have been included for historical purposes.

High *p*H makes these products appropriate for latex paints. Surface-treated grades are available for solvent-based systems. Precipitated forms are higher in brightness, finer in particle size, and have higher oil absorption approaching that of calcined kaolins.

Hydrous kaolins are the finest particle size naturally occurring extenders. Neutral predispersed grades are available for latex systems, and acid grades are available for solvent-based systems. These products have very low residue, which improves gloss development. The calcined grades have slightly better color and higher oil absorption contributes to opacity.

Talcs are available in a wide variety of grades depending on the source. These are more similar to calcium carbonate in particle size, although brightness is somewhat deficient. Platy particle shape is a key parameter, improving durability.

Crystalline silica has lower binder demand than kaolin or talc. It improves coating stability and durability. There is concern about its toxicity. Coarser grades are effective flatting agents.

The high oil absorption of diatomaceous earth makes it an effective flatting agent. Precipitated and fumed silica, as more carefully controlled reaction products, are more appropriate for industrial coatings applications where high oil absorption is acceptable.

Mica is much coarser in particle size than most extenders. Its platy particle shape improves durability. It also has lower brightness and high residue, which limit the levels at which it may be used.

Wollastonite has a unique acicular particle shape, which provides superior stability and durability, with less increase in oil absorption than platy talc or mica.

Feldspar, nepheline syenite, and barytes are coarser-particle-size products. Feldspar and nepheline syenite find use as replacements for crystalline silica when there are toxicity concerns.

Comparative Performance in Coatings

Performance characteristics of the extenders previously discussed are compared in Table 2. Coarse calcium carbonate filler does not provide significant improvement in coatings performance and is primarily used to reduce

cost. Fine-particle-size hydrous kaolin helps develop hiding power and gloss. These extenders develop good film properties, help maintain stability, and aid in coating application. Calcined kaolin also contributes to opacity development and is fairly good in maintaining film properties, rheology, and application properties. Talc and mica are platy materials that improve durability and develop good film properties but may have a deleterious effect on rheology, particularly at higher loadings. Crystalline silica is an adequate filler, which improves durability, but it is toxic. Amorphous silicas improve durability without the toxic problem, but are limited in possible loading by very high oil absorption. Wollastonite is an acicular material that improves durability and film properties without the adverse effect on oil absorption of platy materials. Feldspar and nepheline syenite are fillers of low oil absorption, which improves durability. They act very similar to crystalline silica and can be used as replacements for it.

PERTINENT ASTM TEST STANDARDS

ASTM standards useful in evaluating extender pigments are shown in Table 3. Standard specifications are useful for categorizing extenders by mineral type and provide some general test guidelines. Analytical standards are useful for chemical analysis of extenders for identification purposes.

Standards for measurement of physical properties are very useful in categorizing extenders and for predicting suitability for a particular coatings application. Particle size, oil absorption, fineness of dispersion, *p*H, and water-soluble salt content are important parameters in determining the suitability of an extender for a particular coatings application. Actual product specifications should always be mutually agreed upon by supplier and user.

Metallic Pigments

Russell L. Ferguson[1]

PREFACE

THIS CHAPTER IS BASED ON THE CONTENTS OF THE 14th edition. Careful consideration has been given to the addition of new information, test methods, and technology, thus providing the most up-to-date information available on metallic pigments.

Metallic pigments, including aluminum zinc, gold, bronze, nickel, and stainless steel, provide the paint and coatings industry with a variety of aesthetic and functional properties. These pigments, either in flake or powder form, contribute to the metallic effects associated with automotive topcoats; general industrial finishes; silver, gold, and copper finishes; metallic ink systems; and many of the high-performance primers for coatings systems. In addition to providing metallic and polychromatic effects, they provide functional anticorrosive benefits.

HISTORY AND MANUFACTURING METHODS

The origin of metallic coatings can be traced back to early civilizations, who utilized thin gold sheets to overlay wood, bone, or other materials. As the artisans molded these foil sheets, the thin edges would break off into flakes. It was soon discovered that by mixing these flakes in a resinous polymeric material, a similar effect could be achieved. This process was later continued, and by shredding the foil into flakes, artisans were able to produce gold and later silver and bronze metallic effects on ornamental objects. In the middle of the 19th century, a mechanical stamping process, along with newly developed smelting processes, made gold and silver substitutes more readily available. Aluminum, gold, bronze, and later stainless steel and nickel became readily accepted substitutes.

Today, with *only a few exceptions,* most metallic pigments utilize the hall wet-ball milling method [1]. This process carries out the particle-size reduction in the presence of a suitable lubricant and solvent, offering a safer production method. Eliminating the explosive hazards associated with mechanical stamping processes has allowed the production of finer metallic flakes that finds widespread use today. Stamping and dry-ball milling are still utilized in the manufacture of gold bronze flakes.

The post-milling manufacture processes for metallic flakes generally include a screening operation to remove undesirable particles, along with tight controls on aesthetic properties. Color adjustments, along with polishing and blending operations, are utilized in the final stages of the manufacturing process. The metallic flake pigments are available as a dry flake or in a wide range of solvents, including aliphatic and aromatic solvents, alcohols, plasticizers, water, and coalescing solvents.

Zinc powders have a similar but divergent history. Not being sought after for aesthetic properties, they were first used in the mid-1800s for anticorrosive functionality and were referred to as "blue powder." Zinc-gray coatings were used extensively for industrial and marine environments by the early 1900s. However, it was not until the late 1930s and 1940s that the industry gained a firm foothold. The manufacture of zinc dust is carried out by melting and vaporizing zinc metal followed by a controlled condensation of the vapor in an inert atmosphere. The product is collected, screened, classified, and packaged [2].

In addtion to zinc powders, there is one additional type of metallic pigment not manufactured by the Hall wet ball milling method. Physical vapor deposition (PVD) is a method used to produce aluminum pigments with very unique characteristics. High purity aluminum metal is vapor deposited, in a vacuum chamber, onto a flexible web that is surface treated with a release coating. The metal is deposited in a very thin layer and subsequently removed by solubilizing the release coating in a solvent bath. The metal is then collected, sized, and concentrated for sale.

PROPERTIES

Metallic pigments share similar properties; however, each is distinct enough to be considered separately.

Aluminum

Aluminum flakes should be differentiated based on their manufacturing method, i.e., milled using the Hall process and PVD using a vapor deposition process. All aluminum pigments, however, are manufactured from aluminum metal with a purity ranging from 99.3 % to 99.97 %, depending on the grade being manufactured. Although amphoteric in nature, the pigment exhibits a high degree of chemical resistance. Aluminum pigments owe their aesthetic and functional properties to the geometry of the particle, particle-size, and particle distribution. The pigment is a flake-like particle (lamellar) and has either a round or irregular perimeter. Once formulated into a coating, they orient parallel to the substrate and film surface. This orientation provides for exceptional barrier properties in the appropriate coating system. Metallic or polychromatic coatings containing aluminum flake pigments, either by themselves or in combination with transparent colors, offer a two-tone quality often sought after. The two-tone, or flop, feature is an important characteristic in many automotive top coats.

There are two general types of *milled* aluminum pigments: leafing and nonleafing. Leafing grades are manufactured using a saturated fatty acid as the lubricant (typically stearic acid); which allows the flakes to float at, or near, the surface of a paint film. This continuous layer of flakes provides a solid silver color, unable to be tinted with other pigments. The nonleafing grades utilize an unsaturated fatty acid as the lubricant (typically oleic acid), which allows the flakes to orient throughout the paint film. Nonleafing pigmented coatings can be tinted with organic pigments to offer a polychromatic appearance.

Milled aluminum flakes range in size from 0.1 to 2.0 *μm* in thickness and 0.5 to 200 μ*m* in diameter. Generally, aluminum flakes are supplied in a paste form with a typical composition of 64 % aluminum metal, 1 % lubricant, and 35 % hydrocarbon solvent [3].

PVD-generated flakes have dramatically different physical properties than milled flakes. The flakes have very regular, well-defined perimeters, exceptionally smooth surfaces, and are very thin. The thickness of these flakes is measured in angstroms with a typical mean thickness of 300 Å.

Gold Bronze

Gold bronze pigments are neither gold nor bronze, but are typically manufactured from a composition of copper and zinc alloy. By altering the copper-zinc ratios, four standard gold bronze colors can be produced. The standard alloy subdivisions are: (1) copper—100 % copper, 0 % zinc; (2) pale gold—90 % copper, 10 % zinc; (3) rich pale gold—85 % copper, 15 % zinc; and (4) rich gold—70 % copper, 30 % zinc. Further oxidative treatments can be utilized to produce special colored bronzes, varying from brown-golds to oranges and reds. Additionally, blending of any of the above-mentioned bronze powders will result in an almost unlimited pallet of gold-bronze colors.

Gold-bronze pigments are flake-like particles (lamellar) with an irregular perimeter. In a coating or ink application, they orient parallel to the substrate and film surface [4].

Zinc Pigment

Zinc dust is the only metallic pigment that is not found in a lamellar form. Produced through the condensation of zinc vapor in an inert atmosphere, the zinc dust is a spherical particle averaging about 8 μm in diameter. Zinc dust is predominantly zinc metal (96 %–97 %), with some zinc oxide (3 %–4 %), and traces of lead, cadmium, iron, and other elements.

Stainless Steel Flake

Stainless steel is a composition of iron, chromium, nickel, manganese, and molybdenum. There are three groups of stainless steel alloys available: (1) martensitic, (2) ferritic, and (3) austenitic, differentiated according to alloy composition. Of the three groups, austenitic is the most corrosion resistant and typically used to manufacture stainless steel flake. Austenitic alloys owe their corrosion resistance to higher levels of nickel and molybdenum. Stainless steel pigment has a lamellar geometry and will orient itself parallel in a coating system. Stainless steel flake has a high degree of durability and will resist tarnishing, abrasion, and chemical attack. Additionally, stainless steel flake is able to maintain stability in water-based systems.

Nickel

Nickel pigments can be found in either powder or flake-like form. They are typically composed of nickel metal, with traces of carbon, oxygen, sulfur, and iron. Nickel flake powders are available dry, as a paste in mineral spirits, or as a paste in mineral oil. Nickel powders have good electrical conductivity [5].

METALLIC PIGMENT GRADE CLASSIFICATION

Aluminum Pigments

Aluminum pigments are more widely used than any other metallic pigment and can be divided into a number of different categories. The grade classification is, in general, determined by the intended use. Most of the following categories contain a wide range of grades from very coarse large flakes to very fine small flakes.

LEAFING GRADES (MILLED)

The standard grade category is composed of a series of grades from very coarse flakes (having water coverage from) to very fine flakes (having water coverage in the area of 35,000 cm^2/g). These grades are used, primarily, in trade sales and maintenance coatings. Their leafing values are traditionally 50 % minimum.

The ultra-leafing grades are characterized by very high leafing values (in the area of 90 + %) and exceptional brightness. Their uses include aerosol coatings and ink applications.

NONLEAFING GRADES (MILLED)

The standard grades are represented by a full range of products from very coarse, low-opacity to very fine, high-opacity grades. They are used in diverse applications from maintenance coatings to general industrial applications and automotive refinish.

The automotive grades are distinguished from standard grades by possessing improved aesthetics, including brighter, more sparkling appearances, with tighter control on particle-size distribution. Many subcategories exist under this heading, including specialized grades for base coat/clear coat systems, circulation resistance, etc.

Plasticized and polymer-modified grades are represented by a full range of products designed for end-use systems that cannot tolerate solvents (mineral spirits). The primary end use is plastic and ink applications.

The dedusted grade category comprises dry aluminum flakes held loosely together by Teflon bonds, resulting in a nondusting product. These grades are used in some general industrial coatings; however, the primary application is to act as a sensitizer for slurry explosives.

The surface-treated grades include aluminum flakes whose surface chemistry has been altered to allow for improved aluminum flake performance. These grades are used in powder coatings and some solvent-borne coatings where improvements in flake orientation and performance are desired.

The aqueous grade category consists of aluminum pigments treated with various chemical components to stabilize the flake for use in waterborne systems. Various levels of inhibition and performance are available.

PHYSICAL VAPOR DEPOSITED (PVD)

The grade differentiation is based on percent solids, and the solvent in which the metal is dispersed. The typical com-

position is 10 % metal flake, 90 % solvent, although metal concentrations as high as 20 % are available. The types of solvents used are almost limitless; however, ethyl acetate is most common. The particle size of these flakes can also be controlled; however, most grades fall within the 12–17 μm median particle size range. Although most of these products are used in solvent-borne coatings and ink systems, appropriate inhibition permits use in waterborne applications.

Gold Bronze Pigments

These pigments are primarily used for coating and ink applications. They can be divided into four categories, based on alloy composition:

1. *Copper*—coppery-red color (100 % copper).
2. *Pale gold*—reddish gold color (90 % copper, 10 % zinc).
3. *Rich pale gold*—gold color (85 % copper, 15 % zinc).
4. *Rich gold*—greenish gold color (70 % copper, 30 % zinc).

Zinc Pigment

The zinc pigment, dust and flake, is used in coatings, primarily for corrosion-resistant properties. The categories available are:

1. *Regular zinc dust*—7–8 μm particle-size diameter.
2. *Fine zinc dust*—5–6 μm particle-size diameter.
3. *Ultra-fine zinc dust*—3–4 μm particle-size diameter.
4. *Zinc flake*—Available in several grades, based on particle-size.

Stainless Steel Flakes

These flakes are used in specialized coatings that require good resistance to severe environmental conditions.

Nickel Powder and Flake

The powder and flake are used in coating and plastic systems to provide electrical conductivity and corrosion-resistance characteristics.

FORMULATION AND APPLICATION GUIDELINES

Formulation Considerations

Metallic flake pigments, by the nature of their geometry and composition, are malleable and therefore somewhat fragile. The dispersion of these flakes into a coating system is critical in maintaining optimum aesthetic and functional performance. The preferred dispersion process involves the addition of vehicle or solvent to the metallic pigments, with slow-speed mixing, to gently separate the flakes. Once a thick, uniform slurry of metallic flakes, solvent, and vehicle is achieved, the formulator can continue to let down to final product composition. Severe dispersion techniques, such as Cowles high-speed mixers, sand mills, etc., will destroy the flake integrity, resulting in loss of aesthetic and perhaps functional properties. Zinc pigment, which is not a flake, can be dispersed using conventional paint dispersion techniques.

Appropriate selection of vehicle, solvents, and additives must also be considered when formulating with metallic pigments. The leafing properties of aluminum and bronze flakes can be detrimentally affected by such properties as acid value of the resin; polar solvents, or solvents with low-surface tension; moisture in the system; and additives, including driers that are good wetting agents. Since most *milled* metallic pigments contain mineral spirits, coating system compatibility must be considered.

The current trend toward waterborne coatings also poses problems in formulation. Dispersion of metallic pigments is assisted by the correct selection of an appropriate coalescing solvent. However, even good dispersion will not guarantee good coating performance. Metallic waterborne coatings have the potential for hydrogen gas generation. This potential has been addressed by many manufacturers through various inhibiting processes. While many inhibited grades are available on the market today, performance may vary in different aqueous systems. In addition to the potential for hydrogen gas generation, tarnishing and printability have been addressed by manufacturers of gold bronze flakes. Stainless steel flakes, because of the very nature of their composition, can be used in waterborne coating formulations without the possibility of gas generation.

The use of waterborne coatings is generally targeted toward resolution of environmental issues, most notably VOC reduction. There are other solutions to the VOC issue such as the use of powder coating sytems. Specialized grades of aluminum pigments have been developed to meet the needs of these 100 % solids systems. These grades have been surface-treated to allow for improved flake orientation, along with modified electrical conductivity. Applied electrostatically, the surface-treated aluminum flake will perform in a similar fashion to the powder coating resin.

PVD flakes, because of their high volatile contents, generally pose issues relating to their use in low VOC type systems. However, appropriate solvent carriers help limit this concern. PVD flakes, because of their exceptionally high aspect ratio (diameter:thickness), along with their very high opacity or coverage, require special attention when formulating. Typical inks and coating systems have very high pigment-to-binder ratios (from 2:1 up to as high as 8:1), thus very little resin is employed to assist in flake orientation. At the same time, the loading levels of the pigment are held at low levels because of the exceptional hiding or opacity.

The application of metallic pigmented coatings and inks will depend on the system being used. Traditional ink application methods will apply to both leafing and nonleafing metallic pigments. In the case of coating systems, leafing metallic pigments can be applied by brush, roller, or spray application. *PVD and milled* nonleafing grades, however, must be applied using appropriate spray application techniques. Improper application techniques can lead to poor flake orientation, which will result in reduced aesthetic and functional properties.

Market Applications

Metallic pigments are widely used in the coating, ink, plastic, and explosive markets. In the coating industry, metallic pigments offer both functional and aesthetic properties. Those pigments that are lamellar (aluminum, gold, bronze, stainless steel, and nickel) are opaque and orient parallel to substrate and coating film surface. Thus, they provide a barrier to ultraviolet and infrared light, along with moisture and oxygen penetration. Zinc pigment, while not a flake, possesses superior corrosion protective properties for steel or iron substrates. Because zinc is higher in the electromotive series, it acts as the anode of a corrosion cell. The iron or steel substrate is protected by the zinc because of the formation of insoluble compounds with lower oxidation states.

The aesthetic benefits of metallic pigments are widely known in the coatings industry. In the area of trade sales

and maintenance coatings, aluminum pigments provide very bright silvery finishes typically found in many roof coatings, aerosol applications, and bridges. In general industrial and automotive coatings, various polychromatic and metallescent appearances are produced utilizing nonleafing grades. *The PVD aluminum flakes can also generate a second surface image that is mirror like. These pigments are useful in applications that require high specular reflectance.*

In the ink and plastic industries, the primary benefits derived are from aesthetic properties. Gold bronze flakes, along with aluminum flakes, provide attractive polychromatic finishes.

The explosives industry utilizes aluminum flake pigment as a sensitizer in slurry explosives.

Economics of Use

The extensive market for metallic pigments has mandated their use in a wide range of systems for many years. Their properties, both functional and aesthetic, along with the traditional economic values associated with their properties, have established them as an important raw material in the coating, ink, and plastic markets. The economics of these pigments are dependent on a number of factors, including cost of the raw material, degree of sophistication of the pigment, and the end product for which it is intended.

TESTING

ASTM Test Methods

ASTM covers various specifications and test procedures for metallic pigments. Included are:

- D962—Specification for Aluminum Powder and Paste Pigments for Paint.
- D480—Test Method for Sampling and Testing of Flaked Aluminum Powders and Pastes (includes tests for volatile analysis; coarse particles; leafing properties; brushing, smoothness, lustre properties; and easily extracted fatty materials).
- D95—Test Method for Water in Petroleum Products and Bituminous Materials by Distillation.
- D185—Test Methods for Coarse Particles in Pigments.
- D235—Specifications for Mineral Spirits (Petroleum Spirits) (Hydrocarbon Dry-cleaning Solvent).
- D267—Specifications for Gold Bronze Powder.
- D520—Specification for Zinc Dust Pigment.
- D521—Test Methods for Chemical Analysis of Zinc Dust (Metallic Zinc Powder).
- D4017—Test Method for Water in Paints and Paint Materials by Karl Fischer Method.

Other Test Methods and Specifications

ASTM test methods cover many of the properties of metallic pigments; however, there are additional test methods and non-ASTM tests that further serve to characterize these pigments. Included are:

- *Federal Specification: TT-P-320D Pigment, Aluminum Powder and Paste for Paint*
- *DIN 55923: Pigments; Aluminum Pigments and Aluminum Pigment Pastes for Paints; Technical Delivery Specification*
- *ISO 1247: Aluminum Pigments*
- *BS 388: Specification for Aluminum Pigments*
- *GOST5494: Aluminum Pigments*

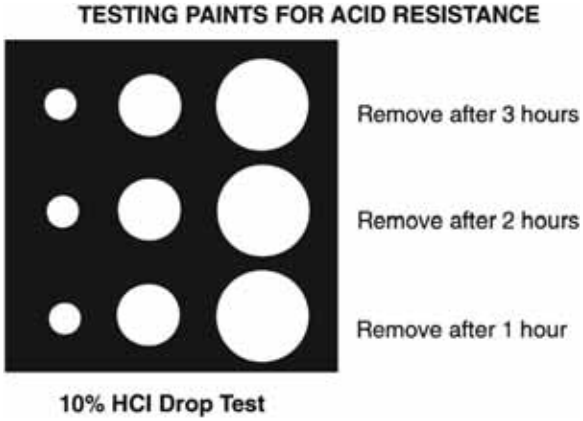

Fig. 1—Testing paints for acid resistance.

ACID SPOT TEST

This test is designed to determine the acid resistance of aluminum pigments in coating systems. A metallic pigmented coating is tested by placing drops of a 10 % solution of hydrochloric acid on the panel. Three rows of three drops are placed on the panel and each row is removed after 1 h intervals (Fig. 1). If the aluminum pigment is acid resistant, no spotting will be apparent after the first or second hour, with only slight spotting after 3 h. A nonacid-resistant aluminum will show definite spotting from the acid solution after the first hour.

PARTICLE-SIZE ANALYSIS

One of the key elements in any metallic pigment is the particle-size distribution. Instruments are available on the market today to characterize, or fingerprint, metallic pigments. Unfortunately, most of these instruments are incapable of characterizing lamellar-shaped pigments; however, their increased sophistication has allowed for a very close approximation. In addition to providing a distribution of the particles in a pigment, also provided are surface area, average particle size, and percentages at various levels.

WATER COVERAGE

This test can be used to determine the particle-size thickness and surface area of leafing and nonleafing metallic flake pigments. This test has been fully described by Edwards and Ray [6]. A dry metallic pigment is dusted onto a surface of clean distilled water, which is contained in a shallow rectangular pan. The accurately weighed flake metallic pigment is dusted onto the surface of the water and separated until it is one flake thick. The coverage of metallic flake on the water can then be measured, and total surface area can be calculated based on the weight of the metallic flake pigment used. The thickness of the metallic flake pigment can also be calculated using simple density and volume calculations.

DEGRADATION TEST

This test is designed to determine the level of flake deterioration in a coating system when subjected to severe stress. Automotive coating systems are often circulated through pumps, regulators, and long piping and tank systems to keep all the components of the coating in suspension. Circulation may have detrimental effects on the metallic flake integrity, causing bending, curling, and even breakage of the metallic flake. The loss in aesthetic properties due to

flake deformation results in a darkening of the coating, along with a change in the flop characteristic. This test is designed to evaluate the capability of the metallic flake to resist deformation under these stress conditions.

A metallic pigmented coating is placed into a water-jacketed Waring blender. Using a standard cutting blade, the blender is operated at high speeds for 5-15 min. The metallic coating is a sprayed pre- and post-blender operation, and visual and instrumental comparisons are made. The degree of flake deformation can be translated into numerical data based on the brightness of the metallic coating (face and flop).

GASSING TEST

Aluminum and other metallic pigments, by their very nature, will react with water to generate hydrogen gas. Today, due to VOC regulations, more and more coating and ink systems are moving toward waterborne technologies. Metallic pigment manufacturers have developed technologies to inhibit the aluminum flake pigments, and this test is designed to determine the gas generation potential and stability characteristics of metallic flake pigmented aqueous coating systems. Approximately 200 mL/s of a metallic pigmented coating is charged into an Erlenmeyer flask. Attached to the flask is a glass condenser with Tygon tubing coming out of the top and extending into an inverted buret filled with water. The Erlenmeyer flask is suspended in a hot oil bath, which accelerates the potential for hydrogen gas evolution. This test is operated for seven days (168 h) at a temperature of 52°C. The acceleration of the environmental conditions will allow for hydrogen gas generation, which will pass out of the Erlenmeyer flask, through the Tygon tubing, and into the inverted buret. The water in the inverted buret is displaced by the hydrogen gas and generation can be easily read through this displacement (Fig. 2). The specifications for gas generation should be designed around the metallic flake pigment and coating system tested. The specification for gas generation should not exceed the volume of the buret (typically 100 mL/s).

ELECTRICAL RESISTIVITY/CONDUCTIVITY

In waterborne coating systems, it is often useful to know the conductivity or resistivity of the components of the system. In order to measure metallic pigments, it is necessary to disperse the metallic pigment in an isopropyl alcohol/de-ionized water mixture. This mixture should be agitated using an air mixer for at least 5 min, after which the metallic pigment should be filtered out. The resultant filtrate can be tested for resistivity/conductivity using a conductivity meter (i.e., Jenway Conductivity Meter, Model 4010).

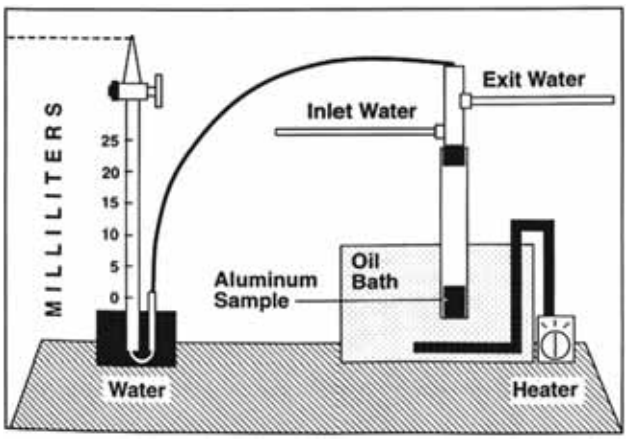

Fig. 2—Gas evolution test for metallic coatings.

pH MEASUREMENT

In waterborne coatings and ink systems, it is often necessary to know the *p*H of the components of the system. The *p*H of metallic pigments can be evaluated by adding the metallic pigment to a mixture of isopropyl alcohol/de-ionized water. The slurry should be mixed using an air mixer for at least 5 min. The metallic pigment should then be filtered out, and the *p*H of the resultant filtrate can then be evaluated.

AESTHETIC PROPERTIES

Metallic pigments are used for the aesthetic properties they lend to coating systems. Every metallic pigment grade offers its own unique appearance due to the properties of the individual pigment. Visual and quantitative data can be generated to provide numerical data describing aesthetic differences. It should be noted, however, that the appearance of a metallic film is significantly impacted by various application methods. Coating application plays a definitive role in flake orientation, which is critical to optimized metallic appearance. Many papers have been written describing the mechanism and challenges of flake orientation in paint films [7–10]

- The *face-color,* or *head-on-brightness,* attribute generally refers to the amount of reflected light from a metallic pigmented coating when viewed at approximately 20° to 25° off of specular [11].
- The *flop, flip/flop,* or *metallic travel angle* refers to the amount of reflected light when viewing a metallic pigmented coating at an angle that is 70° to 110° off of specular. Metallic travel is often referred to as the degree in change of brightness going from the face angle to the flop angle [12].
- *Seed level* refers to the degree of protrusion of the metallic flake through a coating film surface.
- *DOI (distinctness of image),* closely related to gloss, refers to the reflection of an image from a metallic pigmented coating back to the observer. The clearer, or more distinct, the reflected image, the higher the DOI value. Typically, the finer the pigment, the higher the level of DOI [13].
- *Patina* is the packing appearance of the metallic flakes in coating systems. A good patina is often described as having a smooth velvety appearance, lacking individual flake identity in the coating. If an observer sees only a continuous metallic film without breaks, protrusion, or individual flake identity, the metallic coating is considered to have a good patina. Many coating systems and pigment parameters affect the patina of a coating system. Typically, higher solids coatings, poor application methods, coarse pigments, and poor flake orientation contribute to poorer patina properties.
- The *color* attributes from the face and flop angles can be numerically measured. There are a number of instruments available today that are capable of measuring reflected light at different angles. All of them are goniospectrophotometers and are capable of measuring

reflected light on metallic pigmented coatings at angles from 10° off specular to 110° off specular. Measurement techniques are described in ASTM E2194, Standard Practice for Multiangle Color Measurement of Metallic Flake Pigmented Materials.

PHYSICAL PROPERTIES

- *The aspect ratio of metallic flakes, which is a ratio of flake thickness to median flake diameter, can be calculated using data generated by the water coverage test, and particle size analysis. A mathematical calculation can be made from the water coverage test to generate reliable information on flake thickness, which can then be compared to the median particle size, thus generating the aspect ratio.*
- *Another physical property relating to flake brightness is surface smoothness of the metal flake. Using Atomic Force Microscopy, relative differences in flake smoothness can be measured. This advanced technology offers analytical information, which, when combined with other physical information, can describe the aesthetic property of the flake.*

Effect Pigments

Paul J. Nowak[1]

EFFECT PIGMENTS ARE "TYPICALLY" DEFINED as flake or platy structures that impart a directional light reflectance, scattering, absorption, or optically variable appearance to the substrate in or on which they are applied. It will be shown that effect pigments are no longer limited in composition to inorganic materials and in fact can have alternative geometries. The mechanisms, however, by which all effect materials manipulate light, and thus color, still revolve around three basic optical principles, "reflection," "interference," and "diffraction." It should be noted that while metallic flake pigments can also be considered effect materials, the article will focus on structures that manipulate light primarily through selective interference, and more recently diffraction, rather than "specular" reflection only. It should be emphasized, however, that reflection is still an integral parameter in the most recent technologies developed.

WHY EFFECT PIGMENTS?

What is the driving force that has led to the development of so many different types and complexities of effect materials? The answer to this question may be more closely related to our human condition versus commercial reasoning. For centuries, man has made colors symbolic of the events and materials found in nature. While solid colors have regional differences in terms of significance [1], a few colors and effects could arguably be considered universal. For example, the sparkle and luster of precious metals have always denoted value. Pearls and other precious stones denote wealth, and silk gives the impression in our mind's eye of a specific tactile feel and thus a sense of luxury. The natural forms of such materials have been pursued throughout history requiring men oftentimes to go beyond the boundaries of the known, risking their lives to acquire such materials. So is it the rarity of a substance that triggers the desire or is it a psychological drive that may be simply stated as perception? After all, color and effect are merely our individual interpretation of a small part of the vast electromagnetic spectrum that encompasses and connects all things. Color is not a tangible object. It is a vast and complex interactive biological process whose preference is not static but rather dynamic. So it is more likely that the development of effect materials is a result of our ability to relate, on a deep emotional level, to the symbolic representations that our culture and society has effected. They are tools used to appeal to our changing moods and emotions caused by our own physiological and psychological makeup at the moment, to create preferences and associations that we then link to the color-emotion response itself.

From a commercial standpoint, with the prominence of branding, color and effect are often the living embodiment of a brand's values and personality [2]. They are identifying factors that connect with the consumer, are recognizable, stand out from the competition, and trigger, on a subliminal level, the buying decision [1]. Color and design play a pivotal role in ensuring that the consumers' perception of the brand is mirrored in the package or product. Consumers make a brand purchase just as much as they make a product purchase. The study of the importance of color and effect on us as human beings is still largely not well understood.

HISTORY

Many excellent reviews on effect pigments have been written [3–5]. In contemporary terms, the most common effect pigments are referred to as pearlescent (nacreous) or iridescent pigments. Pearlescent pigments are high-refractive-index materials that are coated onto thin transparent flakes that usually are mica, but many other substrates have been investigated as, for example, silica flakes [6]. Various flake materials will be discussed in the ensuing text. The flakes reflect incident light but allow a portion of the light to be transmitted. Basically, they are an attempt to create the natural luster effect seen in pearls or seashells [7]. These types of materials hold by far the lion's share of this specialized, rapidly growing and changing market, and they were described in detail in the previous edition of this manual [8]. Pearlescent pigments, interference pigments, and special-effect pigments are all names used for effect pigments.

The origin of effect pigments has been customarily attributed to the French rosary maker Jaquin, who isolated the silvery substance (guanine/hypoxanthine) found inside fish scales around the 15th century [9]. The widespread commercial use of such material really had its start in the early 20th century where it was used to simulate mother of pearl by incorporation into early forms of plastic, cosmetics, and even applied to automobiles [10]. Due to the obvious difficulties of isolating large quantities of guanine, synthetic mono-crystalline alternatives were developed in the 1930s and included compounds such as mercurous chloride, lead hydrogen phosphate, lead hydrogen arsenate, and basic lead carbonate. Due to the obvious toxicity concerns, these materials have been replaced by bismuth oxychloride [11], which is still commercially produced.

Despite many efforts to create natural pearl essence synthetically, a method to create the necessary platelike structure has never been found even though the internal crystal structure has been duplicated. This inability to

[1] *Marketing Manager, Wacker Chemical Corporation, 3301 Sutton Rd., Adrian, MI 49221, www.wacker.com.*

Copyright © 2012 by ASTM International

synthesize a true pearl essence led to the multi-layer "inorganic synthetics." Most notably was the work by Linton of E.I. DuPont and others that was carried out in the early 1960s. These efforts involved coating titanium dioxide, iron oxide, or combinations thereof onto mica platelets via a hydrothermal process [12]. In this instance, the failure of the obvious synthetic approach to produce natural pearl essence was responsible for the ultimately greater success of creating a new type of color unknown in previously existing pigments. It is this initial work by Linton that is credited as the foundation on which most, if not all, successive technologies have been based.

In the 40-plus years that have followed, numerous variations of the Linton method have been duplicated and improved upon. Additionally, postprocessing of standard oxide-coated mica-based pigments has provided a means to create new color variants. A couple of examples, which are historically important as well as commercially important, are the DynaColors® [13] introduced to the market by the Mearl/Engelhard Corporation of Iselin, NJ,[2] in 1988.

In this instance, standard high-performance organic pigments have been coated onto variants of oxide-coated micas to create interference colors at the specular angle and a dramatic highly saturated color at the diffuse or flop angle. There were few limitations with respect to the color combinations that could be created. With such technology, it is possible to create colors with very specific and dramatic color shifts. Outside of the cosmetics industry, these materials were the first attempt at creating what we now consider true optically variable color effects.

Alternatively, the Infinity Colors® [14] developed through a joint project between Shiseido of Japan and Merck GmbH/EMD Industries of Hawthorne, NY[3], and was introduced to the general industrial market in 1991. In this instance, the TiO_2 coated onto mica was subjected to a solid-state redox reaction using a rotary kiln in the presence of nitrogen, Fig. 1. The reduction of the TiO_2 allowed for the creation of a dark color base, which not only greatly improved opacity, but also when subsequent layers of TiO_2 or other oxides were deposited in varying thicknesses on this surface, unique, highly chromatic, optically variable colors were produced. By using such methods and variations of them, literally hundreds of colors based on metal oxide combinations coated onto mica have been produced, leading to an estimated global market of $600 million dollars per year.

Since the early 1960s, the implementation of computer-controlled manufacturing, improvements in particle size classification methods (primarily the ability to selectively remove large or fine particles), the availability of higher purity precursors, and more advanced mica beneficiation methods have pushed the envelope for this class of effect materials. The result of these advancements has been not only an improvement in the overall batch-to-batch consistency, but also a tremendous improvement in the purity and number of colors available. Some of the more recent product lines introduced to the market using these

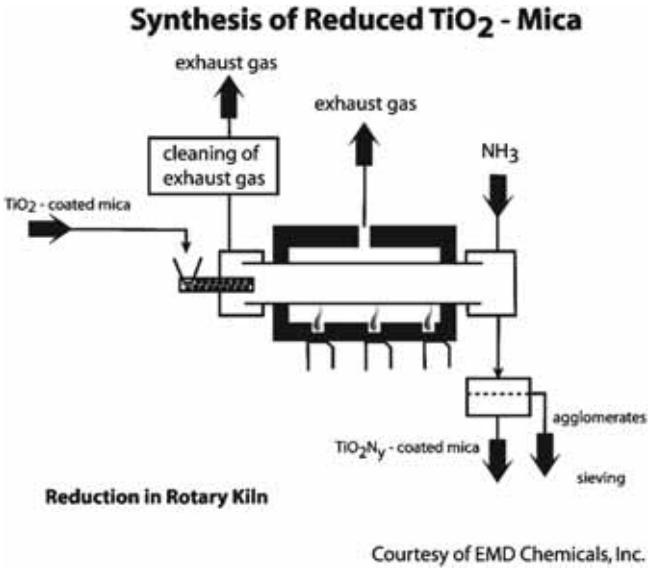

Fig. 1—Synthesis of reduced TiO_2-mica.

developments are the Ultra Colors® developed by Merck GmbH and the Lumina Colors® developed by the Engelhard Corporation in the mid- to late 1990s.

More recently, several new classes of materials have been developed that build off of the advancements in manufacturing and the development of alternative substrates to mica. Such advancements allow for the application of more complex optical principles, such as those used in the field of interferometry on a commercial scale. These newer materials are more precisely able to separate closely spaced spectral wavelength bands and impart goniochromaticity (change in color with viewing angle) through either interference or diffraction of the visible wavelengths of light.

REFLECTIVITY AND THIN FILM INTERFERENCE

To understand the recent developments in effect pigment technology, it is necessary to understand some basic laws of optics as well as a few more complex principles. For purposes of studying effect pigments, light is considered as a wave that follows Maxwell's theory [15].

Based on this wave nature of light, it is known that the speed of light in a vacuum is a constant. However, when light passes through matter its speed is altered and its direction is changed. The measure of these changes is called the index of refraction, **n**. Table 1 lists the index of refraction for several materials that are utilized in both traditional and non-traditional effect materials.

When light passes from a substance of low index of refraction to a substance of higher index of refraction, the speed of light is decreased and if the light enters at an angle, the refracted ray is bent toward the normal. If, however, light enters a substance from a medium of high index of refraction to a medium of low index of refraction, the opposite is true and the light is bent away from the normal. In Fig. 2, Snell's law is used to calculate the angle **e**" between the perpendicular (normal) and the light ray entering the medium:

$$\mathbf{n}_1 \sin \mathbf{e} = \mathbf{n}_2 \sin \mathbf{e}'' \quad (1)$$

The factors $\mathbf{n}_1$ and $\mathbf{n}_2$ are the refractive indices of the involved optical media. They can be considered as a relative measure of the optical density.

TABLE 1—Refractive index for materials used in effect materials

Medium	Refractive index, n
Vacuum, air	1.0
Water	1.33
Alumina	1.35
MgF_2	1.38
Plastics, paint	1.4–1.7
Mica	1.5–1.6
SiO_2	1.50
Synthetic mica	1.55
Guanine, hypoxanthine	1.85
Basic lead carbonate	2.09
Bismuth oxychloride	2.15
Fe_2O_3	2.4
TiO_2 (anatase)	2.5
TiO_2 (rutile)	2.7

Another important factor to consider in studying effect materials is the reflection of light. We generally speak of two kinds of reflection. One is specular and the other is diffuse. Specular reflection occurs when the angle of incidence equals the angle of reflection (**e** = **e**' of Fig. 2). It is dependent on the absorption coefficient (**k**) of the material. For example, metals have an extremely low absorption coefficient and for practical purposes reflect all of the light impinging on their surface. To get optimum specular reflection such as that with a mirror, the surface has to be extremely smooth. If the surfaces are not smooth, light is not reflected in a specular manner but is diffused resulting in a lower luminous flux being generated (θ_r), see Fig. 3.

Effect pigments follow the laws of reflection of smooth surfaces, and there have been a large number of developments in the past ten years that have resulted in the ability to create smoother surfaces. However, in many constructions of effect pigments the platelets besides being smooth are also transparent. This means that only a portion of the light is reflected. That portion that is not reflected is transmitted through the platelet to the next layer, where it can be further reflected, creating what we visually perceive as depth, Fig. 4.

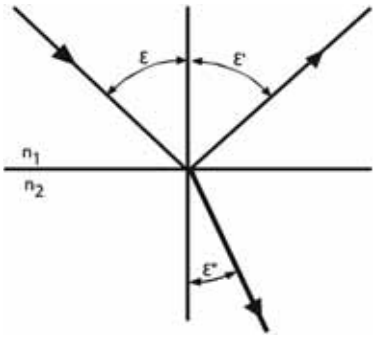

Fig. 2—Effect of increasing refractive index on light.

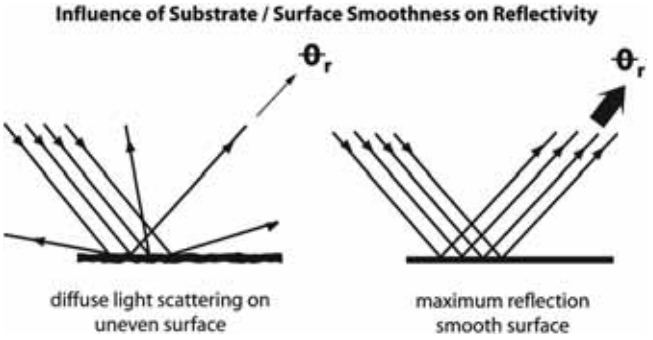

Fig. 3—Influence on substrate/surface smoothness on reflectivity.

The reflection and transmission of the light from the phase boundaries of multiple thin film structures is the basis for interference, thus the generation of color, and follows the superposition principle based on Maxwell's equations [16]. If as in Fig. 3, a parallel plane layer with the refractive index $\mathbf{n}_2$ lies in a medium with a different optical density, then $\mathbf{n}_1 = \mathbf{n}_3$. As mentioned, a light ray **L** reflected upon an interface to an optically denser medium (g_1) will be shifted in phase length by half a wavelength or 180°. At interfaces to substances with a lower refractive index, no phase shift occurs. The phase shift λ/2 for the former case is pictured in the shape of a sine wave, Fig. 5.

Both partial rays $\mathbf{L}_1$ and $\mathbf{L}_2$ can interact with each other. Interference effects can occur. The rays have an optical path difference resulting from the phase shift λ/2 of $\mathbf{L}_2$ and the geometrical and temporal detour of $\mathbf{L}_1$, Fig. 3. The detour of the $\mathbf{L}_1$ partial ray (at vertical incidence) is $2\mathbf{dn}_2$. The product $\mathbf{dn}_2$ is known as the "optical thickness" in the case where the pigment platelet thickness plays a roll [17].

During sinusoidal oscillation, the optical thickness can result in a wave crest of one partial ray meeting the wave trough of the other, Fig. 6. This situation in which the light intensity is weakened (destructive interference) occurs when in Eq (2) the following conditions are met (m = 1,2,3. . .); λ =wavelength of partial rays: m is an integer that allows the equation to describe reflections of successive orders.

$$\lambda_{\min} = \frac{2\mathbf{dn}_2}{m-1} \qquad (2)$$

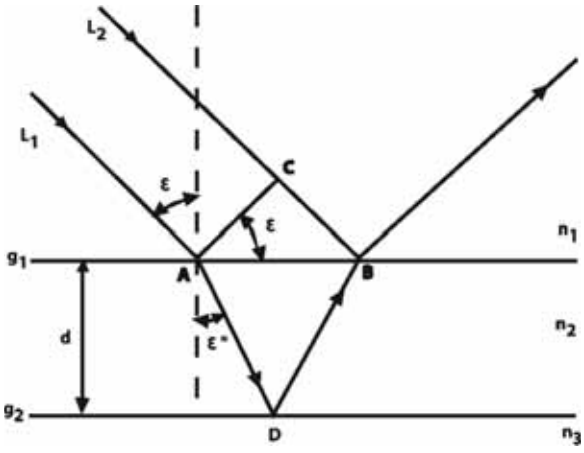

Fig. 4—Diagram to determine the phase relationship between interfering light rays.

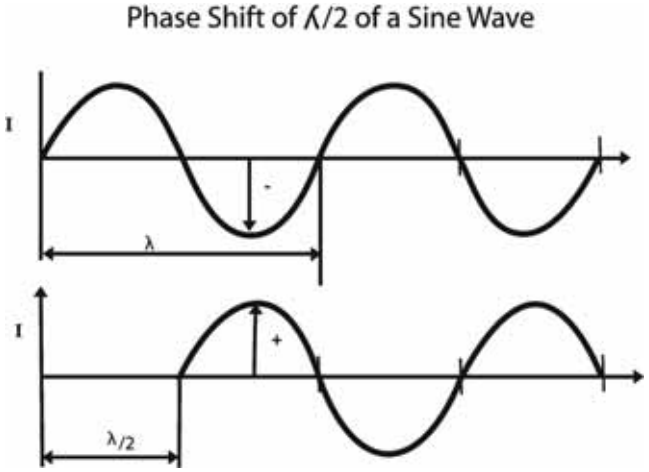

Fig. 5—Phase shift of λ/2 of a sine wave.

All colors in the achromatic spectrum whose wavelengths correspond to the equation will be cancelled out. If, however, a wave crest meets a wave crest, the intensity of light is amplified (constructive interference) and Eq (3) is valid (m = 0,1,2,3. . .):

$$\lambda_{max} = \frac{4\mathbf{n}_2\mathbf{d}}{2m-1} \tag{3}$$

All colors whose wavelengths correspond to this equation will be amplified. The relative intensity of the reflection maximum can be calculated using a simplified Fresnel equation [18]. Since Eqs (2) and (3) are only valid for one wavelength or its multitudes, a part of the visible spectrum will weaken or be deleted while another part will be reflected optimally. This is called selective reflection [19] and can be calculated by using Eq (4)

$$\mathbf{r}(0^0)_{max} = \left[\mathbf{n}_2^2 - \mathbf{n}_1^2/\mathbf{n}_2^2 + \mathbf{n}_1^2\right]^2 \tag{4}$$

The color of the reflection maximum depends upon the layer thickness of the material in which the light enters at the interface g_1, Fig. 3. The maximum shifts to larger wavelengths with increasing layer thickness. The numerator indicates that the greater the difference in refractive indices, the greater the reflectance. The effect of the difference is magnified by the exponents.

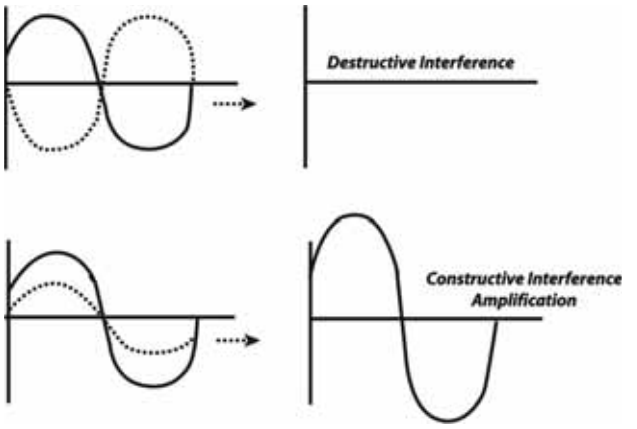

Fig. 6—Interaction of light rays with various phase lengths.

With increasing layer thickness a minimum is added to the reflection maximum in the visible range and clear color impressions on the order of the colors of the rainbow result. For example, if we increase the optical path length to 100 nm, the reflection maximum lies in the bluish-white range, and if the product $\mathbf{n}_2\mathbf{d}$, Fig. 3, is further increased to 140 nm, a reflection maximum of yellow-white results. By increasing the optical thickness further, reflection colors are produced that change continuously from white, yellow, red, violet, blue, and green, each reflection color accompanied by its complementary transmission color. This pattern of color is repeated with the colors of the second and higher orders. The color series of higher orders follow in the same manner by increasing optical path length. As the layer thicknesses increase, maxima and minima follow each other more quickly and become more difficult to resolve. The colors in the various higher orders are extremely desirable as they typically differ in shade, brilliance, and level of saturation [20], Fig. 7.

In interference, the reflection and transmission colors vary with angle of incidence. The reflection maximum and minimum shift to lower wavelengths as the angle of incidence increases. The color shift is governed by the expressions

$$\lambda_{max} = (4\mathbf{d}/2m-1)(\mathbf{n}_1^2 - \sin^2\mathbf{i}) \tag{5}$$

and

$$\lambda_{min} = (2\mathbf{d}/m-1)(\mathbf{n}_1^2 - \sin^2\mathbf{i}) \tag{6}$$

in which **i** is the angle of incidence at the initial phase boundary. Equations (5) and (6) reduce to Eqs (2) and (3) for perpendicular incidence where **i** = 0°. The radical in Eqs (5) and (6) change more rapidly with i for smaller values of $\mathbf{n}_1$. Thus a lower refractive index produces a greater color shift.

From the discussion above, it can be seen that through the manipulation of the variables within the optical equations it should be possible to maximize the levels of reflection at the phase boundaries by using semi-transparent metal layers. When light falls on a metal, we would expect that it should be totally absorbed. It is exactly because of this extremely strong absorption of metals that absorption does not have an opportunity to occur! To understand this apparent paradox, we need to examine the process of reflection.

In dealing with an insulating material, such as most inorganic and organic substances, the percent reflectivity **R** for a beam of light falling on the material at normal incidence, or on leaving the material, is given by the equation:

$$\mathbf{R} = 100(\mathbf{n}-1)^2/(\mathbf{n}+1)^2 \tag{7}$$

where **n** is the refractive index. A typical dielectric medium with **n** = 1.5 gives **R** = 4 %; thus most of the light is transmitted into the medium and only very little is reflected. When light falls onto a metal, it is so intensely absorbed that it can penetrate to a depth of only a few hundred atoms, typically less than a single wavelength. Since the metal is a conductor of electricity, this absorbed light, which after all is an electromagnetic wave, will induce alternating electrical currents on the metal surface. These currents immediately remit the light out of the metal, thus providing an extremely strong reflection.

Mathematically, in Maxwell's equations we need to replace the refractive index n by the complex refractive index

$$\mathbf{N} = \mathbf{n} + \mathbf{ik} \tag{8}$$

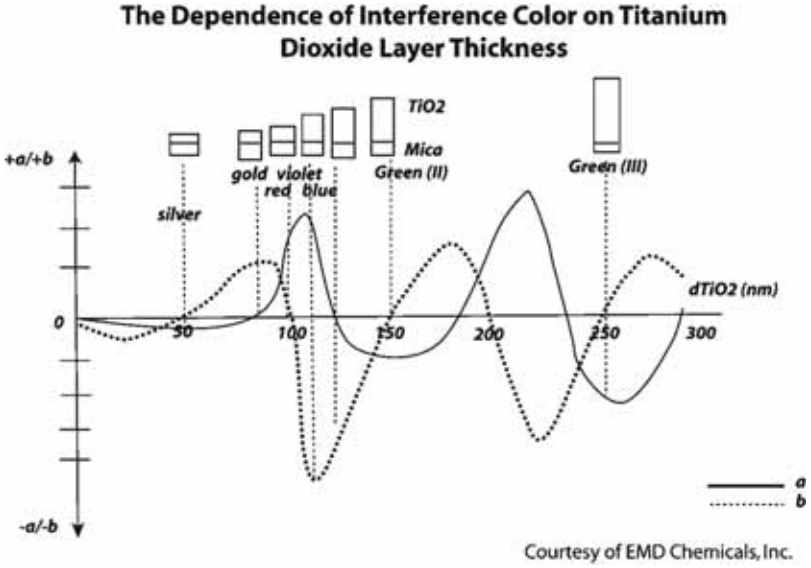

Fig. 7—The dependence of interference color on oxide layer thickness.

where **i** is the imaginary square root of negative one and **k** is the attenuation index, coefficient of absorption, or extinction coefficient. Equation (7) now becomes

$$\mathbf{R} = \left[100(\mathbf{n}-1)^2 + \mathbf{k}^2\right] / \left[(\mathbf{n}+1)^2 + \mathbf{k}^2\right] \qquad (9)$$

The percent reflectivity for silver, as an example, and sodium D light, the values **n** = 0.18 and **k** = 3.6 give a reflectivity of 95 %. The metallic luster thus turns out to be no more than a high reflectivity. To show its high reflectivity the surface of a metal alloy or semiconductor must, of course, be very smooth.

Multiple reflections between parallel surfaces of semitransparent metals are used in the Fabry–Pérot filter used in the study of interferometery [21]. Through modification of the geometric thickness or path length, the transmitted beams can be made to constructively and destructively interfere. With the usual air-dielectric interface, a reflectivity of 4 % is generated, the intensity of these reflected beams falls rapidly, and the resulting interference pattern

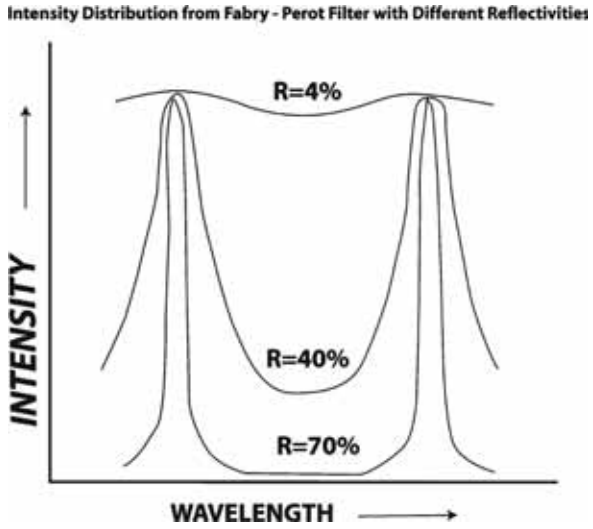

Fig. 8—Intensity distribution from Fabry-Pérot filter with different reflectivities.

is shown in the top curve of Fig. 8. If the reflecting surfaces are metallized, the multiple reflections become more effective and there is a drastic change in the transmission pattern as shown in the second and third spectral curves of Fig. 8. Therefore, using such a construction, it is possible to resolve very closely spaced colors and significantly improve the levels of saturation, especially at the higher orders of interference. In addition, the spectral bands are separated as well as magnified, resulting in extremely sharp color changes at various angles of viewing, which is essentially a change in the angle of incidence. Only until recently has it been possible to construct such a material on a commercial scale mainly due to the developments in manufacturing. It is this ability to magnify and resolve color using such a system that the Chromaflair® pigments produced by Flex Products, a JDS Uniphase Company,[4] are based. They provide not only very highly saturated interference colors but also have a very sharp angle-dependent multiple-color effect. Such materials are without a doubt the most intricate and highly sophisticated effect pigments on the market today (see Fig. 9).

Advances have been made recently with the more traditional interference effect materials as well. While they are not as precisely constructed as the Fabry–Pérot filters, they do share many of the same attributes, namely, the ability to produce optically variable colors with strong angle dependence and reasonably high saturation.

In these cases, multiple thin films of varying thickness of high refractive index such as the traditional metal oxides (optical stacks) are coated onto substrates or layers of low refractive index. By varying the thickness of the dielectric and the metal oxides, they also can produce relatively narrow transmission bands through constructive and destructive interference. One example is the structure of Fig. 10, using only dielectric (nonmetallic) layers as the substrate. Here, each layer contributes to the development of color. The TiO_2 layer being a higher refractive index material does not separate the light ray as far from the normal as the SiO_2 layer. Thus

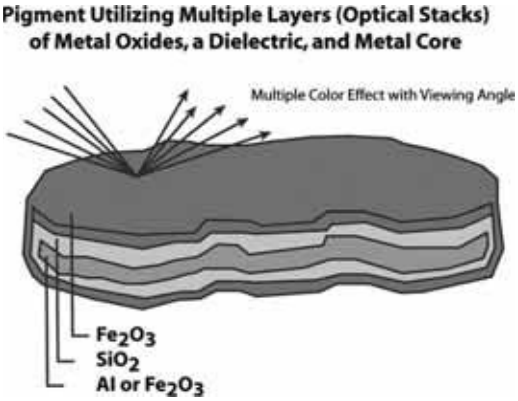

Fig. 9—Thin film interference pigment flake cross section (Fabry-Pérot filter type).

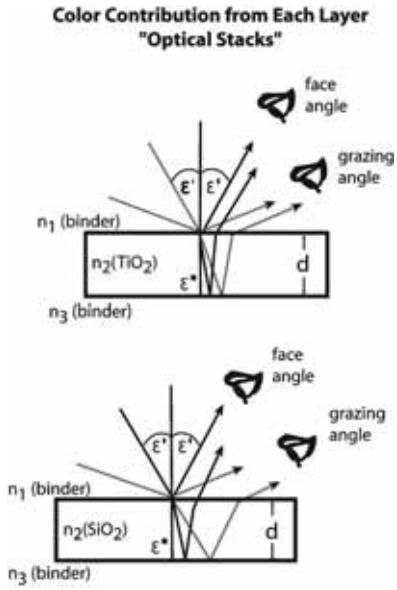

Fig. 10—Color contribution from each layer of an optical stack.

by varying the thickness of each layer, each can be tailored to a specific thickness to reflect selectively, specific wavelengths of light as previously discussed. Since there is very little absorption in such a construction, essentially all of the light not transmitted is reflected. Materials used for such dielectric interference filters include MgF_2, borosilicate glass, alumina, or SiO_2. The latter two materials are marketed under the trade name of Xirallic® and Colorstream™, respectively. They are manufactured by EMD Chemicals of Hawthorne, NY.

Another variation is to use a standard metallic flake as a core and then coat the metal with a dielectric material followed by a semi-transparent metal oxide. The optical principles of color generation in this case are more similar to the Fabry–Pérot filters. Here, the effect of the metal core is to enhance the amount of light available for constructive and destructive interference. BASF GmbH of Ludwigshafen, Germany,[5] is currently marketing such materials[4] under the trade name of Variacrom®.

Using these principles, the extent of extinction and enhancement of particular wavelengths is efficiently

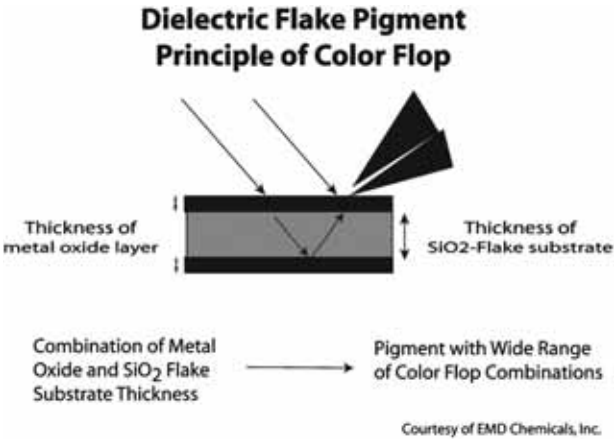

Fig. 11—Dielectric substrate pigments principle of color flop.

increased although less so than with the Fabry–Pérot filter types. Through the manipulation of the composition of materials and thicknesses of those materials "optical stacks," there has been created a totally new series of effect pigments that exhibit highly saturated interference colors, a high degree of reflectivity, with the potential for high color dependence on viewing angle (color flop), Fig. 11.

DIFFRACTION

An alternate method of separating light into its various components is by diffraction [22]. Diffraction is the bending of light waves around an object. The term diffraction is used to describe the behavior of light when it departs from rectilinear propagation. This happens when the edge of an object produces an interrupted wave front and the light then bends around the edge: The resulting color-producing phenomena involve interference. While diffraction necessarily involves interference, the reverse is not true [23].

Just as increasing the number of reflections in the Fabry–Pérot etalon increases the sharpness of the interference colors, so the same happens with a diffraction grating. The diffraction grating can be defined as an optical component made by a periodic assembly of reflecting or transmitting obstacles (grooves) separated by a distance comparable to the wavelength of light applied. Various shapes, such as triangular symmetrical, triangular blazed, square-wave with different top plateau sizes, and sinusoidal gratings can be produced. Additionally a variety of groove frequencies, blazed angles, and depth profiles can be produced. For a given grating frequency, the depth, shape, and orientation of the grooves determine the relative intensity of the various interference orders through the process as previously discussed, mainly constructive and destructive interference.

When light is incident on a grating, it is diffracted into discrete wavelengths. The incident beam is separated forming the zero order diffraction or specular reflection, that is a mirror effect color of the incident light. First order diffractions (negative first order and first order) surround the zero order. Eventually other higher orders surround the first orders depending on the groove frequency of the grating, Fig. 12.

The ability of a grating to diffract light is described by the grating equation:

$$m\lambda = \mathbf{d}(\sin\alpha + \sin\beta), \tag{10}$$

[5] BASFAG Ludwigschafen, Germany, www.basf.com.

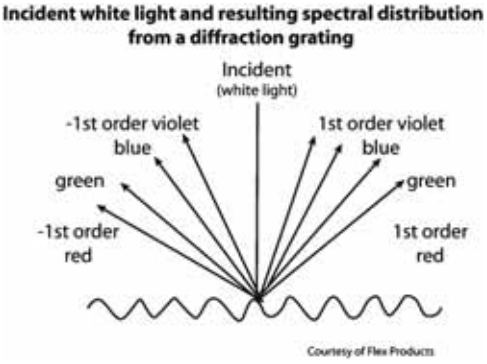

Fig. 12—Incident white light and resulting spectral distribution from a diffraction grating.

where α and β are the angles between incident light and normal, and the diffracted beam and the normal to the grating, respectively. The integer m is called the diffraction order. For $m = 0$, $\beta = -\alpha$ for all λ, where the wavelengths are not separated, this is the specular reflection or zero order.

The higher the groove frequency, the greater the angular separation between orders. The size of the grating will improve definition of the various orders (resolving power) as adjacent spectral lines are clearly separated. Finally, for a given grating frequency, the orientation of the grooves, the depth and shape, determine the relative intensity of the various orders.

In nature, color by diffraction is relatively rare. However, one of the most outstanding natural diffraction gratings is the gemstone opal, showing on a white or black background, flashes of varied colors can be observed. This was at one time thought to involve thin film interference, but electron microscope photographs taken of an opal reveal its secret, demonstrating a regular three-dimensional array of equal-size spheres, Fig. 13. The actual composition of the spheres is amorphous silica (SiO_2), containing a small amount of water. These spheres are cemented together with more amorphous silica containing a different amount of water so that a small refractive index difference exists between the spheres and the cement [24].

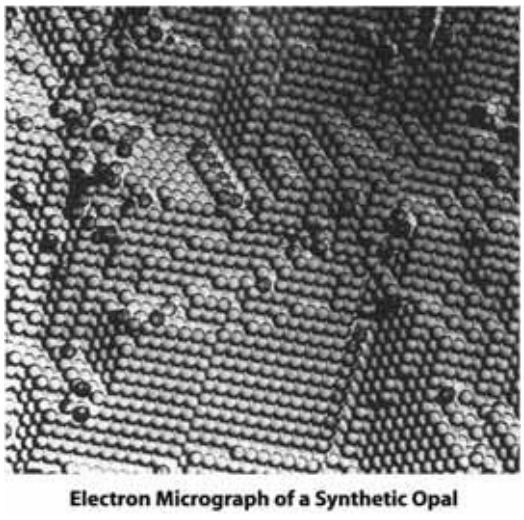

Fig. 13—Electron micrograph of a synthetic opal.

The theory of a three-dimensional diffraction grating consisting of stacks of identical layers is well known from the field of x-ray crystallography, Fig. 14, where Bragg's law applies, Eq (11). Reinforcement of diffracted waves occurs when the angle of incidence for diffraction from a layer equals the angle of reflection, and when the path difference between the reflections from adjacent layers with a spacing **d** is a whole number of wavelength. The condition for reinforcement becomes

$$\mathbf{n}\lambda = 2\mathbf{nd}(\sin\theta) \tag{11}$$

In natural opals, the uniformly packed spheres providing diffraction occur in patches ranging from less than a millimeter to more than a centimeter across. Within each patch the color will vary with the angle of viewing, with the longest wavelength appearing at normal incidence with $\mathbf{I} = 0$ as in

$$\mathbf{n}\lambda = 2\mathbf{d}(\mathbf{n}^2 - \sin^2\mathbf{I})^{1/2} \tag{12}$$

Films of certain types of liquid crystals, organic compounds with a structure intermediate between that of a crystal and that of a liquid, can show a left-handed or right-handed twisted structure resulting in layer gratings with a repeat distance in the range of visible light. Such substances are called cholesteric or chiral liquid crystals (not superimposable on their mirror images). When a beam of white light falls on a film of such a substance, a narrow wavelength region will be reflected by diffraction according to Bragg's law. This is expressed in the form of Eq (13), where **n** is the refractive index, **p** is the pitch distance in nm, and θ = angle of viewing.

$$\lambda_{ref} = \mathbf{np}\cos\theta \tag{13}$$

An interesting and unique phenomenon occurs with such substances. The light will be circularly polarized with the sense of the polarization related to the handedness of the twist of the structure. Both the opposite polarization and all other wavelengths are transmitted through the film. The diffracted light resembles that from an ordinary diffraction grating except for the polarization. It should be noted that the diffracted color does not depend on the total film or layer thickness as it does with interference pigments, but rather on the layer "repeat" distance within the film. Similar to a typical diffraction grating the colors vary

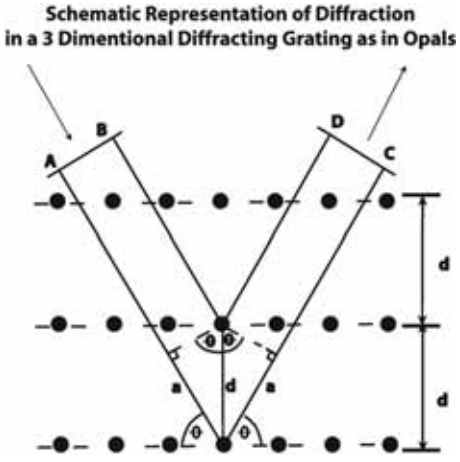

Fig. 14—Schematic representation of diffraction in a three-dimensional diffraction grating as in opals.

with viewing angle [25]. One difference, however, is that in diffuse light the interference phenomenon is still visible.

Closely related to the diffraction effect in opals is the ability of small particles to selectively scatter light [26]. This scattering of light will depend on whether the wavelength of the light is large or small compared to the diameter of the particle. In practice, two different theories are used to describe the scattering or diffraction of light from a particle [27]. They can be distinguished by a dimensionless size parameter, (**a**).

$$(\mathbf{a}) = 2\pi\mathbf{r}/\lambda \qquad (14)$$

For very small values of (**a**), the Rayleigh theory of light is valid. For larger values of (**a**), the Mie theory [28] of light scattering is necessary. For very large values of (**a**), diffraction, reflection, and refraction can be used to explain scattering. In practice, Raleigh theory is normally only employed to describe the interactions between gas molecules and light. However, it can be used up to an (**a**) value of 0.5 without incurring great error. Raleigh's theory can be simply expressed by Eq(15),

$$\mathbf{Is/Io} = \text{constant}/\lambda^4, \qquad (15)$$

where **Is** is the intensity of scattered light and **Io** is the initial light intensity. In general, the shorter wavelengths are more efficiently scattered by very small particles. The end result is that it is possible to create optically variable color effects with such small particles. Good blue scattering can be observed from particles as large as 300 nm (still smaller than the 400 nm wavelength of violet light) down to particles just a few atoms or molecules in size, say 1 nm in diameter. The exact shade of blue depends in a very complex way on the size of the scattering particles, the distribution of sizes, their arrangement, and even their shapes.

When the size of the particle approaches and then becomes larger than the wavelength of light λ, the Mie theory is used to explain the scattering. The scattering is no longer predominantly blue, but sometimes shows different colors, mostly red and green bands, but only at certain angles. The Raleigh scattering effect is the basis for the nanoparticle size TiO_2 type of effect pigments that produce a soft opalescent highlight with a blue undertone [28].

In more recent times (within the past ten years), novel approaches to using the physical principles behind generating color through interference and diffraction have resulted in what are now considered "state of the art" effect pigment chemistries. These developments have primarily revolved around the development of novel substrates and methods of manufacture building on the foundation of the original layer substrate technology.

DEVELOPMENT OF NEW SUBSTRATES

Apart from naturally occurring muscovite mica, naturally occurring phlogopite, sericite, and biotite have all been used to create various pearlescent and iridescent pigments. Each of these common materials has their various advantages and disadvantages when it comes to physical properties [29]. However, of these, the most widely used type of mica is muscovite, chemically defined as $KAl_2(AlSi_3O_{10})(OH)_2$. More specifically is a grade of muscovite mica that originates from mineral deposits in India. It differs from domestic sources in that it has improved optical clarity due to a lower level of iron and manganese contaminates. The bulk color is typically a pale pink, rather than beige or yellow. The improvement in the initial quality of the substrate bulk color allows for the ability to create brighter, and whiter, white pearlescent pigments and more chromatic iridescent pigments. The mica is ground as an aqueous paste in a Muller or friction mill to delaminate it into very thin platelets with smooth surfaces. As the mill rollers go over the mica, it becomes thinner and smaller in particle-size, increasing the aspect ratio (lateral diameter to thickness). These mica flakes are then dried, sieved, and classified into the desired starting particle-size distribution.

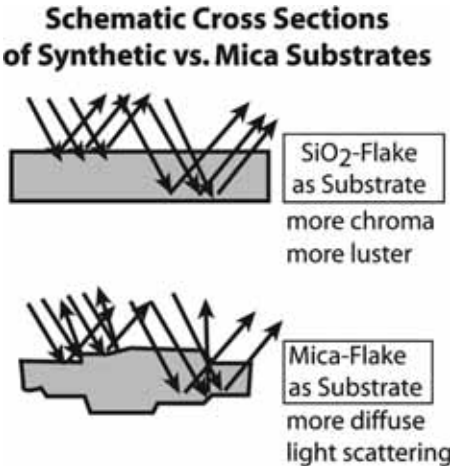

Fig. 15—Schematic cross section of synthetic versus mica substrates.

The optimum particle size distribution as measured by laser diffraction methods falls between 10–40 μm. This is the particle size at which maximum luster occurs. Smaller particles <5–10 μm act as light scatters due to insufficient coating or inefficient parallel orientation. Particles larger than 40 μm give a coarse effect and reduce opacity. It has been found that not only the particle size distribution but also the uniformity in thickness of each particle is important. The wet grinding process while fairly good with respect to delamination and creating smooth flat flakes is by no means optimum. There is some unavoidable uneven delamination of the mica layers resulting in a "stair step" type morphology on the surface. These "steps" scatter light similar to the platelet edges, which, in turn, reduces the direct light reflection from the coated pigment surface, Fig. 15. Furthermore, multiple domains of thicknesses reduce the intensity of the interference chroma and cause a desaturation of the reflected color. The fact that most mica in use today is a naturally occurring mineral, it inherently has variation in terms of purity, crystal structure, and surface smoothness. Therefore, nearly all of the newer substrate technologies that have been developed to date optimize the prerequisite properties of the substrate that are delineated in Table 2.

The importance of the initial substrate quality cannot be overstated. Of particular interest in this respect is the development of synthetic mica or fluoro-phlogopite, $KMg_3(AlSi_3O_{10})F_2$, by Topy Industries in conjunction with Nihon Koken Kogyo (NKK)[6] of Japan in 1992, and commercialized in

1995 under the trade name Ultamica® [30] and distributed in North America by Itochu Specialty Chemicals Inc. The synthetic mica contained significantly fewer impurities and provided a means to significantly optimize the level of luster and chromaticity of interference and reflected light. Synthetic mica still, however, had to be ground and classified, leading to irregular surfaces and uneven thickness although it was greatly improved, see Fig. 16.

In the late 1990s the Engelhard Corporation of Iselin, NJ², introduced a series of interference pigments based on a synthetic borosilicate glass [31]. The glass had many of the prerequisites of an ideal substrate (e.g., low refractive index, optical clarity, smooth surface, fairly uniform thickness, and a high aspect ratio) and was introduced to the market under the Firemist® trade name.

The latest generation of effect pigments based on the layer substrate principle has been the development of synthetic substrates based on calcium-aluminum-borosilicate, and SiO_2 flakes [32] by Merck KGaA. These synthetic substrates are manufactured in a way similar to the web coating device used for synthetic mica [33], see Fig. 17. The thickness can be controlled so precisely as to impart an interference color of its own. This, when combined with a layer of metal oxide similar to other more common pearlescent pigments, allows for the development of a series of optically variable pigments (OVPs) in which the color is viewing angle dependent. They generate their colors through the optical principles of simple interference filters. The materials have been commercialized under the trade name Colorstream®, by Merck/EMD Chemicals of Hawthorne, NY.

From the above discussion with respect to the prerequisites of a substrate, these materials have a low refractive index (1.5, 1.3), respectively, an absolutely flat surface, optical clarity due to lack of impurities, and a thickness that can be very well controlled, allowing for a higher and more uniform aspect ratio. Due to the ability to artificially control the thickness during the manufacturing process, delamination of the flake is no longer required. Therefore, the issues with a step type surface and variations in thickness are eliminated. The resulting pigments can be made with soft, gradually changing color effects as well as monochromatically and dichromatically combined interference effects.

Another new substrate developed by Merck/EMD, which has recently become commercially important, is based on crystalline alumina flakes ($A1_2O_3$) [34]. This substrate is created through a crystal growth method similar to the early mono-crystalline materials such as bismuth oxychloride, in which two solutions of metal salts are added to an acidic medium at roughly the same time, leading to platelets with extremely flat surfaces, a sharp particle size distribution, high aspect ratio, excellent optical clarity, and good crystalline properties. These crystals also require no milling. The deposition of metal oxides onto this type of surface results in pearlescent and interference pigments with a significantly greater degree of luster, and interference colors of high color purity and saturation for its particle size than has previously been known. They are currently supplied under the trade name Xirallic®. These newly developed pigments are arguably the most commercially

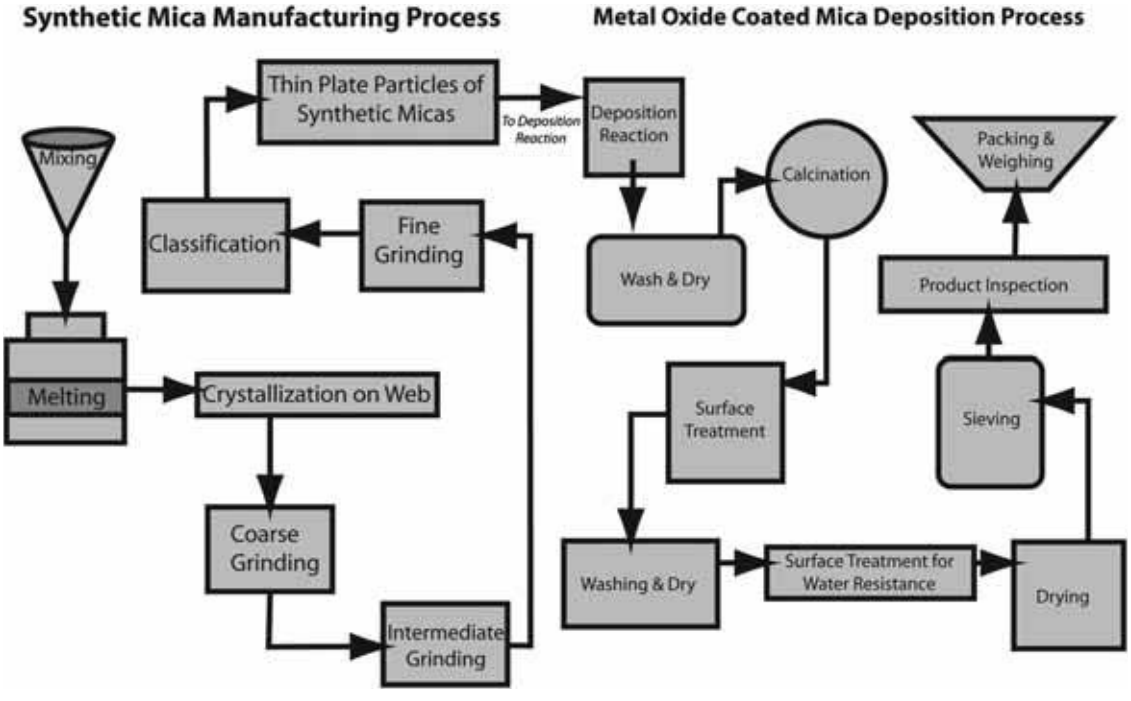

Fig. 16—Synthetic mica manufacturing process and metal oxidecoated mica deposition process.

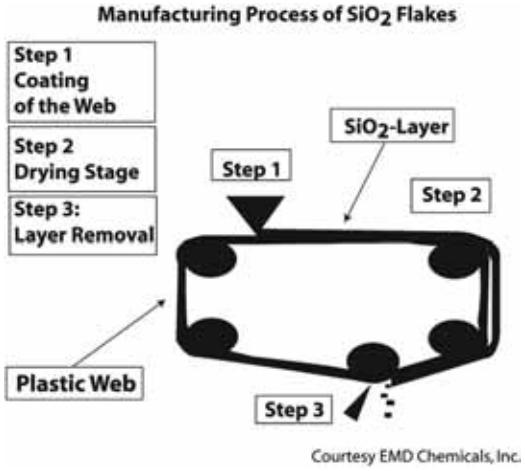

Fig. 17—Manufacturing process of SiO_2 flakes.

important effect pigments to be introduced to the market since the original metal oxide coated mica-based pigments.

DEVELOPMENTS IN MANUFACTURING

The standard hydrothermal process of depositing metal oxides on the surface of a substrate has drawbacks (see Fig. 18). While the improvement in surface smoothness of substrates allows for a smoother oxide coating, the crystallite growth is, from an optical standpoint, fairly rough, and the aqueous method cannot be used for all possible substrates or all metal oxide depositions. If we can gain anything from the evolution of effect materials to date, it is that where there have been limitations, there have been methods found to overcome those limitations. Two of the companies leading the way in this regard are Flex Products, a JDS Uniphase Company of Santa Rosa, CA, and BASF of Ludwigschafen, Germany.

The process by which these companies create lamellar pigments with optically variable interference effects is based on deposition of metal oxides on a platy substrate by either chemical or vacuum vapor deposition. The idea of creating effect pigments by vapor deposition was actually described in a patent by Greenstein in 1955 [35] but it was not until the process was actually developed for other applications by the Polaroid Corporation in 1979 [36] that it was actually proven to be feasible.

The two methods, while similar in theory, differ quite substantially in the means by which the deposition and the resulting pigments are constructed. In the BASF system

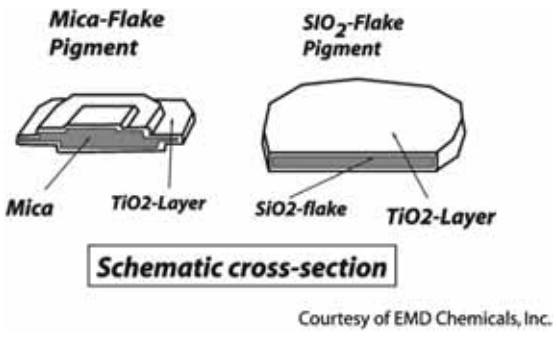

Fig. 18—Schematic cross section of mica versus synthetic flake.

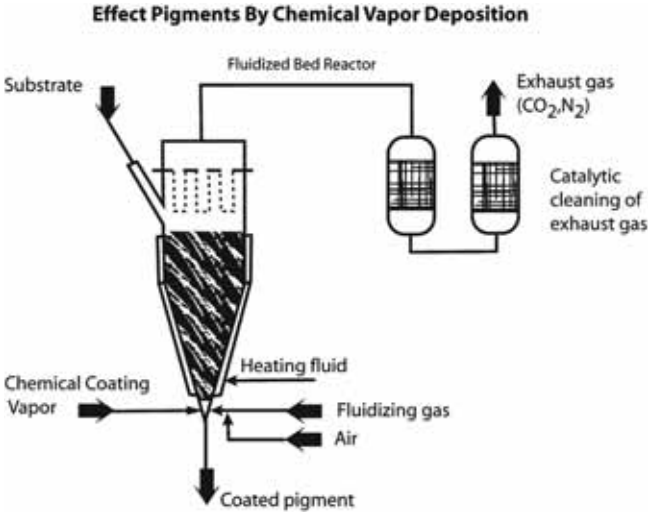

Fig. 19—Effect pigments by CVD.

first described in 1981 by Ostertag [37] (Fig. 19), a substrate is introduced into a cylindrical reaction chamber with a conical bottom and fluidized by the introduction of nitrogen. The fluidization results in a complete separation of the substrate particles, so that all surfaces of the pigments are free. Once the fluidization is complete, the various chemicals are introduced in a vaporized form. If the reaction conditions are properly adjusted, the formed nano-crystalline oxide particles are packed close together on the surface of the substrate building a smooth and optically homogenic film. The coating time determines the thickness of the oxide layer. Once the appropriate thickness has been reached, the reactor is cooled and the particles sieved to remove any agglomerates. In principle, a variety of different substrates and coatings are possible using the chemical vacuum deposition process. It especially allows materials that cannot be handled in acidic aqueous media to be coated, i.e., aluminum or organic pigments. Due to this feature, completely new species of pigments can be manufactured. They are currently supplied to the marketplace under the trade names of Paliocrom® and Variacrom®, respectively.

The second method is based on vacuum vapor deposition, see Fig. 20, and it was first described by Optical Coatings Laboratories, Inc., [38] and commercialized by Flex Products. This class of effect pigments creates Color by

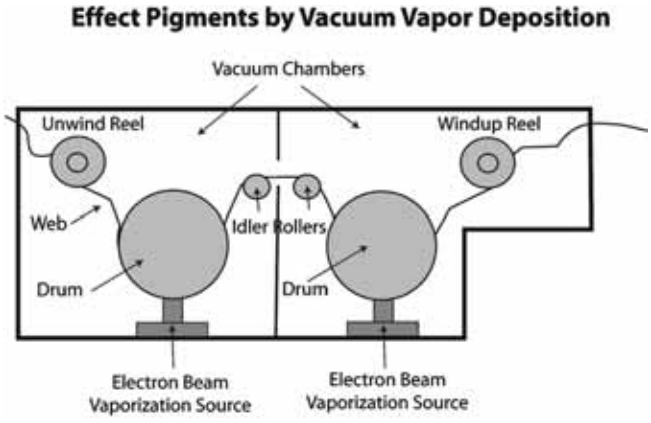

Fig. 20—Effect pigments by VVD.

Physics™. The optical principles on which they create the sharp, dramatic, optically variable interference colors are based on Fabry–Pérot type light filters [39] and thin film interference, which was previously discussed.

The pigment is comprised of three to five layers of precisely controlled thickness that are deposited on a polymeric film. Large rolls of the polymer film, either soluble or non-soluble, are passed through a vacuum chamber containing an electron beam that vaporizes the deposition material from a crucible. Running the film at a specific speed through the chamber controls the thickness of the various layers deposited. This method is, to date, the most precise in terms of controlling thickness of the various layers deposited. The film is then brought in contact with a chill roller and subsequently passed back and forth multiple times in order to build the various layers. These layers are comprised of an opaque reflective core (aluminum oxide) followed by a layer of MgF_2 which has a low refractive index, at quarter wave thickness, on top of which is deposited a thin glass-like layer (SiO_2), followed by a semi-transparent layer of absorber metal oxide. The pigments can be made in either a symmetrical or nonsymmetrical fashion. In addition, many color combinations can be constructed by varying the thickness of the various layers or composition of those layers. The thin film is stripped from the web by passing it through a solvent bath where the pigment particles are "released," and due to their specific gravity (2.0–4.0 gm/cm^3), fall to the bottom of the tank, where they are subsequently recovered, washed, and dried. The particle size is adjusted by dispersing the material in a solvent and ultrasonically agitating. Again the flakes are filtered, dried, and if an even smaller particle size is required they can be subjected to an air grind using an impact pulverizer without readily destroying the color characteristics of the flakes. The result is a pigment with high reflectivity, opacity (due to the metallic core), and outstanding sharp color changes, in a very narrow particle size distribution and a thickness of 1 μm (see Fig. 21).

The color is computer controlled to provide a running color profile at a specific angle across the width and length of the web. An average can be ascertained for the roll that then makes it possible to modify the color at a later step in the event that the color is slightly off by essentially adding a lower or higher color. For example, if the average dominant wavelength of a roll is 495 nm and the desired wavelength is 490 nm, the desired wavelength can be obtained by adding some lower-wavelength material having an average value of 485 nm to achieve the 490 nm target. In addition, it is also possible to blend batches after final sizing to get an even more precise and consistent color match to standard [40].

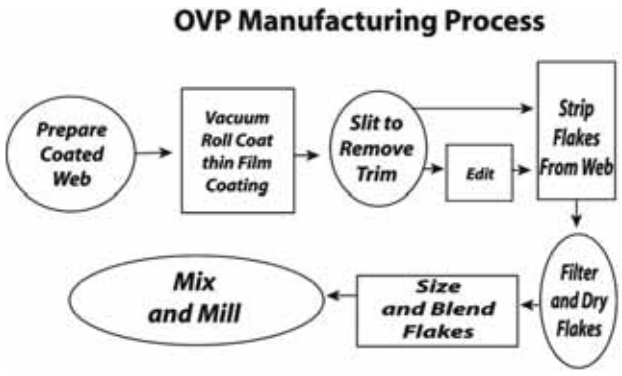

Fig. 21—OVP manufacturing process.

DIFFRACTION

Another exciting development in effect pigment technology arises from the development of color through diffraction rather than thin film interference. There are many demonstrations of diffractive optical effects in non-flake form, notably linear diffractive gratings on plastic or metal foils and holograms [41]. The major characteristic of colors by diffraction is that they are only visible in direct light and disappear when light is diffused. There is a strong color change with viewing angle and the color reflection is iridescent in nature (see Fig. 22).

Three companies have introduced variants of such technology to the marketplace. They are Flex Products of Santa Rosa, CA[4] [42], Spectratek Technologies, Inc., of Los Angeles, CA,[7] and Eckart GmbH[8] (Prismatic Metalure®). Of particular commercial interest are the developments by Flex Products, in which several limitations with respect to particle size, color development, and aspect ratio have been optimized or overcome.

The process by which these pigments are constructed utilizes the vacuum vapor deposition (VVD) process as mentioned above for the Chromaflair® line of colorants. The pigments are produced under tolerances similar to semiconductor chip technology. The particles are comprised of an embossed reflective core layer (usually aluminum) that provides the optical interference pattern of a diffraction grating. This reflective optical layer is then encapsulated by a dielectric layer (MgF_2) that provides the necessary rigidity and durability to the diffractive pigment flakes. The line frequency of the diffractive structure on the flakes is between 1400 and 2000 ln/mm such that light corresponding to the range of visible wavelengths in the first or higher order diffracted beams is substantially

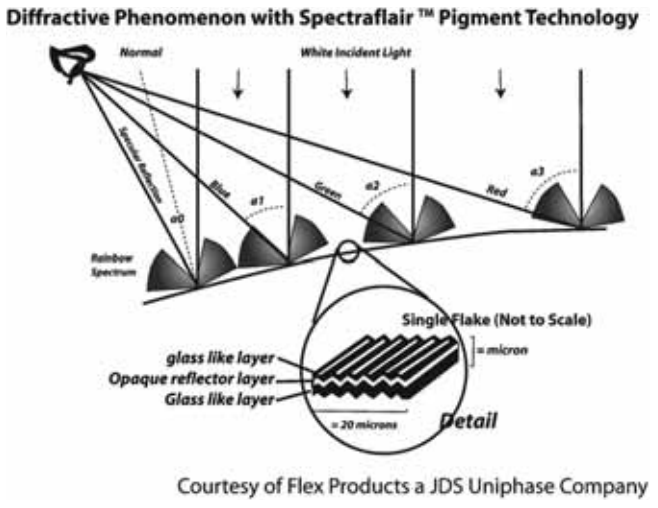

Fig. 22—Diffractive phenomenon with Spectraflair™ pigment technology.

angularly separated from the same range of wavelengths in higher order diffracted beams when illuminated at normal incidence up to about 60° from normal incidence. Additionally, the diffractive structure amplitude, which in a grating is the depth of the grooves (160 nm or greater), is such that the zero order diffracted beam is substantially suppressed in intensity so that the intensity of the higher order beams are enhanced over the desired range of wavelengths and/or angles of incidence. The diffractive structure is a linear sinusoidal grating that is constructed by depositing thin films (two to three atoms in thickness) on a structured surface substrate having a releasable intermediate coating layer such that the appropriately sized flakes defoliate from the substrate, replicating its shape. The "recovery" process of the flakes is then similar to the Fabry–Pérot OVPs discussed previously. The result is a very smooth, optically variable diffractive pigment with an average particle size of 25 μm and an overall thickness of 1–1.4 μm, resulting in an aspect ratio of approximately 25:1. The effect achieved with direct illumination is that of the rainbow and in diffuse light gives a liquid metal look. They are currently sold under the trade name of Spectraflair® and manufactured by Flex Products, a JDS Uniphase Company in Santa Rosa, CA.

UNSUPPORTED (NON-SUBSTRATE) EFFECT MATERIALS

It has been shown that many developments in the substrate layer principle have occurred since 1963 and have led to several "state of the art" effect pigments being commercialized. Another area of relatively recent commercial interest is the development of effect pigments that provide color by interference, diffraction, absorption, or a combination thereof, without the use of a supporting material. Several efforts in this regard have been concurrently developed over the last several years along with the advances in novel substrates and manufacturing. It has long been known that various mono-crystalline platy materials could be used as effect materials (e.g., bismuth oxychloride). Some relatively recent developments of particular commercial interest are synthetic platy micaceous iron oxide (BASF Corporation GmbH), platy graphite (Ciba-Geigy of Hawthorne, NY[9]), platy TiO_2 (EMD Industries, Hawthorne, NY, and Engelhard, Iselin, NJ), and nano-particle size TiO_2 (Dainichiseika Color and Chemicals America, Inc., Clifton, NJ[10]).

An area of special interest is the development of effect materials based on purely organic components rather than inorganic materials. Iridescent film technology developed and commercialized by the Engelhard Corporation uses thin film interference principles to manipulate light through the use of alternating layers of polymers differing in their respective refractive indices. The material is manufactured using a co-extrusion process whereby a specialized dye at the extruder head is used to create the 172-plus alternating polymer layers into a film that is then stretched, slit, and chopped using cryogenic techniques to create a flake that can be and is used as an effect material. Such polymers or more commonly called "glitters" have been commercialized for some time and have been developed in a variety of colors. To date, it has not been made robust or thin enough in its flake form for most industrial and high-performance decorative applications. They are, however, prevalent in the hobby, craft, graphic arts, and cosmetics industries.

Liquid crystal polymeric effect pigments (LCPs) have been introduced to create yet another class of unique effect materials. Through developments in the late 1990s by Wacker-Chemie GmbH [43], these materials are quickly becoming commercially important as a means to provide optically variable color effects with a high degree of metallic luster, through the use of a cholesteric or "twisted nematic" helical structure. They are in the chemical class of modified polyacrylates. They are manufactured, Fig. 23, by applying a solution comprised of nematic liquid crystal monomers, or oligomers, a chiral additive that acts as the template for the helical superstructure, and an appropriate cross-linking agent to form a polymer web. A sheer stress is applied to the resulting film to control the thickness and also orient the molecules into offset layers of parallel rows, each row having a slightly different molecular orientation. It is then exposed to ultraviolet radiation to complete cross-linking and to fix optical properties. Subsequently the cured film is mechanically removed from the web and subjected to an air impact pulverizer, wherein it is made to a specific particle size distribution, air classified, and packaged.

The color is controlled by spectrophotometrically monitoring various points across the web during the manufacturing process, and the process parameters are adjusted automatically as required to provide a uniform, consistent color. If required, additional blending of the flakes can be done to further adjust color to standard.

The resulting cigar-shaped polymer platelets are approximately 3–5 μm in thickness and can have a longitudinal diameter of between 40 and 200 μm and a specific gravity of 1.3 g/cm^3. Light falling upon the cholesteric nematic liquid crystal helix is split into two parts. Most of the light is transmitted but a small amount of light is reflected. The wavelength of the reflected light corresponds to the "pitch" (the distance between two layers of the same molecular orientation) of the cholesteric helix, Fig. 24. This determines the wavelength of light being reflected. If one thinks of the molecule as a spring and by either increasing or decreasing the ratio of the chiral additive to liquid crystal, it is possible to arbitrarily tune the wavelength of reflection by compressing or expanding the length of the spring. The wavelength of reflected light changes continuously with the

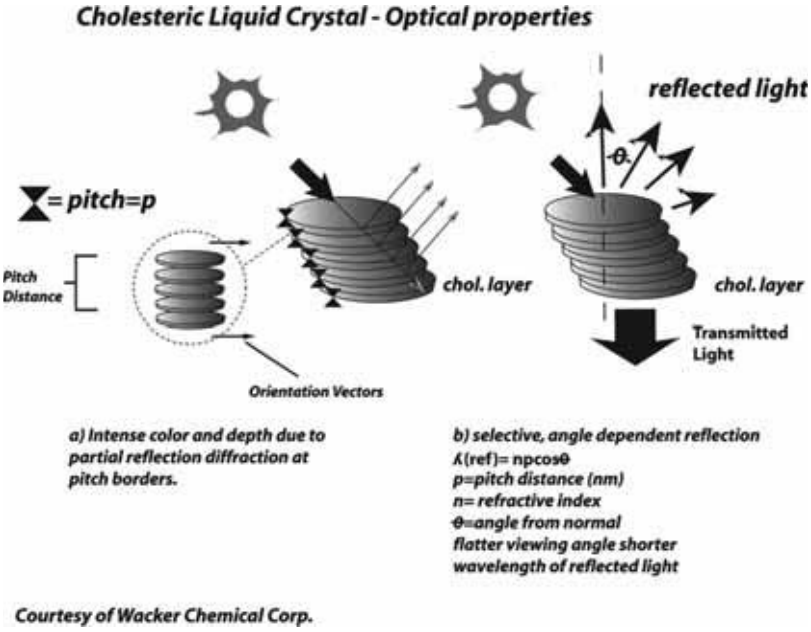

Fig. 24—Cholesteric liquid crystal-optical properties.

viewing angle due to the reflective diffraction of light by the edges of the rigid molecules comprising the helix. The color transition effect is significantly softer and less sharp than corresponding multi-layer inorganic materials based on Fabry–Pérot interference filters, or diffraction gratings, as discussed previously. Due to the sharp spectral reflection bands, however, the mixing of various colors results in each particle retaining its own individual color characteristics since there is little overlap of the spectral bands and thus little destructive interference. Such polymer flakes are also not as dependent upon orientation, as there are no edges to scatter the light, resulting in superior levels of chroma at the diffuse angle. In addition, such chiral molecules can reflect and transmit circularly polarized light based on the handedness of the helix. This property also allows color and effect to be seen in diffuse light. They are supplied to the marketplace by Wacker-Chemie GmbH of Munich, Germany, under the trade name of HELICONE® HC, which describes the helical-conical molecular structure.

FUNCTIONALITY

The ability of flake type materials to impart barrier properties to coatings is well established [44,45]. Over the course of the past 15 years numerous examples of functional effect pigments based on the layer substrate principle have been developed. In automotive and coil coatings, for example, patented surface treatments have been applied to improve humidity resistance for such high-performance applications [46–48]. They have also been modified to provide better adhesion, improved dispersion [49], and even handling characteristics during the coating and plastics master batch-manufacturing process (e.g., pre-wetted). Treatments have also been applied to enhance the performance of the matrix in which they are used. In cosmetics, for example, where smoothness and feel when applied to the skin are important, effect pigments have been developed that not only improve these properties but also improve press and payoff of the powders in which they are formulated. In sunscreens, where ultraviolet radiation protection is paramount, effect pigments have been developed to enhance ultraviolet-radiation-screening capabilities [50–52] while providing a soft lustrous glow to the skin and thus an enhancing cosmetic effect.

Traditionally, for use in powder coatings, effect materials needed to undergo a proprietary postproduction step called "bonding," whereby the pigment was essentially encapsulated in the powder resin. This process improved the transfer efficiency, facilitated the use of overspray as reclaim, and improved flake orientation. Surface treatment technologies have now been developed that can help eliminate the need for this extra step in the process [53]. Such materials are marketed under the trade names of Af flair® PC DB by EMD Chemical and Cyclo™ by the Engelhard Corporation.

In agricultural applications such as seed coatings, effect materials have provided not only an easy means of identification, but also a way to prevent premature germination and retain moisture during storage through decreases in diffusion. By incorporation into plastic horticultural film, it is possible to modify, through transmission and reflection, certain wavelengths of the electromagnetic spectrum which are beneficial to plants while blocking others enhancing the speed, and quality of growth [54].

The laser marking of plastics has become a rapidly expanding process used by end-product manufacturers due to its speed, permanence, and quality versus standard printing methods. Metal oxide-coated effect pigments have been found to enhance and broaden the types of polymers that can be used in this regard [55]. They provide a means to improve the contrast within the surface of the plastic by acting as a heat sink and allow the oxide on the surface of the pigment to be partially reduced to the black sub-oxides of titanium and can both amplify as well as enhance the dark coloring.

An area of significant commercial importance, especially with the newer generations of effect materials, is security. This functional application can be described to have differing levels of importance. For example, credit

cards and high-end luxury packaging may have a number of effect materials combined in specific ratios to create a brand color that is difficult to copy. The needs for brand identification, and protection, is a rapidly expanding area in which effect pigments are being used either in or on the products they are protecting. It has been known for some time that standard interference colors when printed onto documents cannot be photocopied due to the angle dependence of the color. Many of the newer technologies such as Chromaflair®, Spectraflair®, Variochrom®, Helicone®, and Color Stream®, which travel in multiple quadrants of color space, have been used in this respect for higher levels of security such as printing on currency, stock certificates, bearer bonds, and the like.

To a lesser extent in commercial importance are effect pigments that have been developed that provide conductivity for coating of plastics, magnetic, and anti-static properties.

TESTING

In the development and manufacture of effect pigments, investigators use several standard-testing procedures. These tests are both standard and in-house in nature, and most will not be listed herein. However, some ASTM tests that are of interest are tabulated in Table 3.

FUTURE

The future developments in effect pigment technology will undoubtedly be influenced by several factors. If history is any indication, the ability to create more varied and precise multi-layer films on a substrate in a cost-effective manner are expected to push the limits of physics as well as optics. Improvements in the ability to handle and create small particles of various compositions (nanoparticle technology), developments in geometries apart from platelets (spheres, prisms, rods, etc.), improvements and alternatives to hydrothermal, chemical vapor deposition (CVD), and VVD manufacturing technologies (e.g., sputtering [54] and biotechnology), and the development of alternative raw materials, or combinations of materials (hybrids) [56–58], can also be expected to play a role. Electrochemical, electromechanical, thermal, and laser-induced color may also be possible.

Changes currently under way, however, in areas such as application and processing technology are expected to have a more immediate impact on developments where in-mold coatings, pre-colored films, ultraviolet radiation-cured coatings, expanded use of powder, advances in printing type technologies, and the trend toward thinner decorative films will create the need for more advances in performance and functionality. In the cosmetics and pharmaceutical industries, where the need to deliver "active" ingredients is important, it may be feasible to see effect pigments playing a dual role in terms of not only providing color but also carrying and then delivering actives when applied to the skin.

The result of offshore manufactures entering the market will drive current producers to design and incorporate additional functionality into effect materials to add value. Whether it is to improve the performance of the pigments themselves, or the properties of the matrix in which they are used, the necessity to add value above and beyond color can be expected to become more important in order to defend against emerging competition.

Developments in color preference by young consumers influenced by the "age of electronics" or changing demographics, like the number of aging citizens and a more diverse ethnic population, will drive changes in color preferences and will require development of novel color shades and color combinations. A true red, or red to black combination, blue to orange, a true black pearl, brushed nickel, or gun-metal effect are just a few examples. Optically variable color effects are expected be more widespread as the general public becomes more comfortable with such dramatic effects.

In areas of brand identification, protection, and security, it is plausible to see effect pigments containing microscopic tags or possibly company logos, which could be applied to a particle through the use of lasers. It may even be possible to create radio frequency identification tags directly into multilayer effect materials.

While it is expected that many of the new technologies will be even more complex, there is some evidence to suggest that environmental considerations could create a trend toward utilizing materials from existing waste streams as effect pigments [59,60]. For example, the use of recycled

mirrored or colored glass (spheres, chips), metals, and rubber may become either an alternative or supplement to more conventional effect materials. Bead-Brite Research[11] and Rubber-Tech Research of Boca Raton, FL, have supplied such material to the markets.

SUMMARY

The past 40 years have witnessed an era of phenomenal growth and development in the area of effect pigment technology. Due to the advances and the complexity of such materials, it becomes important for both the designer and formulator alike to be aware of why these materials do what they do, allowing each to fully capitalize on their optical and appearance properties. The most significant constructions of commercial importance are graphically illustrated in Fig. 25. These developments have been fueled primarily by the advances in the methods of manufacture, the methods of application, the creation of new substrates, the availability of higher purity precursors, and utilization of alternative raw materials outside of the realm of the inorganic. Such advancements, applied to the original layer substrate principles and first described by Linton in the early 1960s, have led to the creation of totally new species of effect materials. They have expanded from simple thin film interference filters, to optical stacks of the Fabry–Pérot filter type, and even diffraction. The latest developments comprised of more optically precise constructions have subsequently created more dynamic and varied optical effects. Another very important factor that cannot be overlooked is society's voracious appetite for the new and different, which relates on the deepest level to the human condition of emotion.

It is expected that as further advancements are made, effect materials will play an even more prominent role in providing functionality to the products on or in which they are used. While effect materials may become even more complex in both their constructions and optical properties, the desire to use materials from current waste streams may also lead to further developments in this highly dynamic and emotional area of special effect pigment technology.

Measurement of Gonioapparent Colors

Allan B. J. Rodrigues[1]

TECHNICAL TERMS

THESE TERMS ARE SPECIFIC TO GONIOAPPARENT phenomena. The definitions below are from ASTM Standard E284 [1]. They are italicized when they first appear in this chapter.

annular, *adj* – descriptor for directional illuminating (or viewing) geometry in which the illuminator provides radiation (or the receiver possesses responsivity) that is distributed continuously and uniformly throughout the 360° of azimuth of the measurement. (See also *circumferential.)*

anormal, *adj* – of angles, measured with reference to the normal to the surface. (2008)

anormal angle, *n* – the angle subtended at a point on the specimen by a given ray and the normal. (2009)

Discussion – Use the inward normal with transmitted rays; use the outward normal for other rays. In uniplanar instruments, the "point" is the point of incidence and the anormal angle is understood to have a sign. The anormal angle of an illumination axis is positive or zero. The anormal angle of a detection axis is negative if the illumination and detection axes are on opposite sides of the line of the normal and positive or zero otherwise.

aspecular, *adj* – away from the specular direction.

aspecular angle, *n* – the angle subtended at the point of incidence by a given ray and the specular direction.

Discussion – In instruments, the "given ray" is understood to be a detection direction. In uniplanar instruments, the aspecular angle is to be understood to have a sign: negative when the specular direction lies properly between the detection direction and the illuminator axis and positive otherwise.

circumferential, *adj* – descriptor for directional illuminating (or viewing) geometry in which the illuminator provides radiation (or the receiver possesses responsivity) in many beams (or directions), normally distributed at uniform intervals and uniformly throughout the 360° of azimuth of the measurement. (See also *annular.*)

color angle, *n – in measurement of gonioapparent phenomena,* half the angle between the illumination and detection axes of the measurement geometry.

Discussion – The color of an interference pigment is determined by the angle of incidence of the light relative to the normal of the interference pigment flake. Flakes in a coating have an angular distribution, and the interference effect will be exhibited in a given measurement geometry only by the flakes that are oriented so that they behave as specular reflectors. Since the refractive index of the specimen is often unknown, color angle is defined here as if the flakes were in air. Color angle provides a relative indication of the angle between the flake normal and the illuminator axis.

color tolerance, *n* – the permissible color difference between sample and specified color.

far-aspecular, *adj* – pertaining to the appearance of a material when viewed from a direction far from the specular angle, typically 70° or more. (2006a). Note: The *adjective* **flop,** formerly used, is now deprecated.

far-aspecular angle, *n* – the aspecular angle when a material is viewed from a direction.

flake angle, *n – in gonioapparent coatings,* the angle subtended at a point on a pigment flake by the pigment flake normal and the specimen normal line through that point.

Discussion – A flake angle is understood to be the smaller of the two supplementary angles defined by the pigment flake normal and the specimen normal line.

flop, *n* – a difference of appearance of a material viewed over two widely different aspecular angles.

gonioapparent, *adj* – pertaining to change in appearance with change in illuminating or viewing angle.

gonioappearance, *n* – the phenomenon in which the appearance of a specimen changes with change in illumination or viewing angle.

Discussion – Examples of gonioappearance are specimens of coatings containing flake pigments.

goniochromatic match, *n* – match between a pair of specimens that holds under all sets of angular illuminating-viewing conditions.

Discussion – The specimens may or may not exhibit goniochromatism and may or may not exhibit metamerism.

goniochromatism, *n* – change in any or all attributes of color of a specimen on change in angular illuminating-viewing conditions but without change in light source or observer.

Discussion – Changes associated with first-surface specular reflection are not understood to lead to goniochromatism.

goniospectrophotometer, *n* – a spectrophotometer having the capability of measuring with a variety of illuminating and viewing angles using bidirectional geometry; also known as multi-angle spectrophotometer.

metallic, *adj* – pertaining to the appearance of a gonioapparent material containing metal flakes.

mid-aspecular, *adj* – pertaining to viewing a specimen between the near-aspecular and far-aspecular angles at an

[1] *Sr. Research Fellow, DuPont Performance Coatings, 950 Stephenson Highway, Troy, MI 48083.*

Copyright © 2012 by ASTM International

aspecular angle close to 45°. (2006a). Note: The term **face,** formerly used, is now deprecated.

mid-aspecular angle, *n* – the aspecular angle where a specimen is viewed between the near-aspecular and far-aspecular angles, typically at the mid-aspecular angle.

Discussion – This term also applies when the illuminating and viewing angles are interchanged.

near-aspecular, *adj* – pertaining to the appearance of a material when viewed from a direction close to the specular angle, typically within 25°. Note: The *adjective* **near-specular,** formerly used, is now deprecated.

near-aspecular angle, *n* – the aspecular angle when a material is viewed close to the specular direction, typically within 25°.

pearlescent, *adj* – exhibiting various colors depending on the angles of illumination and viewing, as observed in mother-of-pearl.

side-tone, *n* – appearance at the far-aspecular angle.

side-tone scattering, *n* – scattering of light in a material resulting in a milky appearance only when the specimen is viewed at the far-aspecular angle.

solid color, *n* – not containing flake or gonioapparent pigments.

sparkle, *n* – the visual contrast between the appearance of highlights on the particles of a gonioapparent pigment and their immediate surround.

specular, *adj* – pertaining to flux reflected from the surface of an object, without diffusion, at the specular angle.

specular angle, *n* – the angle of reflection equal and opposite to the angle of incidence.

Discussion – In gonioapparent phenomena, this definition assumes an illuminator subtending a small angle.

venetian-blind effect, *n – in surface coatings,* uniform change in an appearance attribute such as lightness as a directionally illuminated specimen is rotated in its own plane.

Discussion – The venetian-blind effect is thought to result from preferential orientation of flakes within a specimen, as may occur in the process of spraying paint on a vertical surface in the earth's gravitational field.

WHAT IS GONIOAPPARENT COLOR?

The painted ping-pong balls shown in Fig. 1 illustrate the phenomenon of gonioapparent color. They are illuminated by a single directional light and viewed against a dark background. The uppermost ball appears the largest. The entire ball is visible with about the same lightness across its surface except for a small *specular* highlight. The ball on the lower left appears smaller. Its lightness decreases as its surface is viewed away from the specular highlight, causing it to appear more rounded. The only clue to its true diameter comes from reflections off the other balls on its periphery. The ball to the right appears the smallest of all. Its lightness diminishes to near zero so rapidly that its outermost surface is not seen and it seems to have the smallest diameter of the three. These balls illustrate the phenomenon of *gonioappearance.* The ping-pong balls were all coated with glossy paints, the first with a gray paint containing a lot of white, light-scattering pigment. Paints used to coat the other two balls contained only transparent, nonscattering pigments and aluminum flakes. These flakes act like little mirrors within the coating, aligned roughly parallel to the coated surface. Most of the light illuminating the surface is reflected in the specular direction. Thus the lightness decreases as the viewing angle moves away from the specular direction, i.e., at larger *aspecular angles.* The coating on the third ball contained a coarser, shinier aluminum flake, resulting in a more rapid decrease in lightness, further accentuating the curvature of the ball. The third ball exhibits a greater *flop* than the second ball. Larger flakes with more polished surfaces are more effective in reflecting in the specular direction, resulting in a greater flop. Colors not containing flakes are generally referred to as solid colors; those containing flakes are gonioapparent colors.

A schematic of a paint film containing flake pigments is shown in Fig. 2. The flakes are distributed uniformly through the film, more or less oriented parallel to the substrate. Each flake acts like a mirror, reflecting incident light in a specular direction. If the flakes were perfect mirrors and perfectly oriented, all the light would be reflected in the specular direction. In practice, orientation is not perfect and the flake surface is not mirror smooth, so that there is dispersion of the reflected light. Additionally, some light scattering occurs off the edges of the flake. Fig. 3 shows photomicrographs of two different types of aluminum flakes. The flake on the left is shaped somewhat like cornflakes. The surface is a little rough and the edge of each flake is irregular, allowing for more light scattering. The flake on the right is often referred to as "silver dollar" flake. It is much more rounded with more polished surfaces. It allows for much better specular reflection, little edge scattering, and greater *sparkle.* The paint film itself generally contains some absorbing pigments to impart color. All pigments will also scatter light. Pigments of a larger particle size or a higher refractive index will scatter more light. Titanium dioxide is a good example of a high scattering

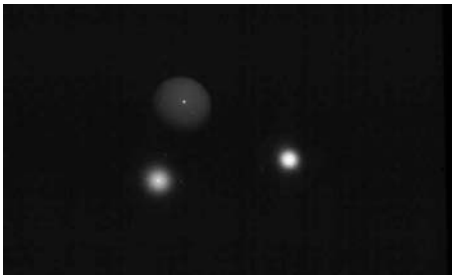

Fig. 1—Ping-pong balls coated with solid and metallic color paints.

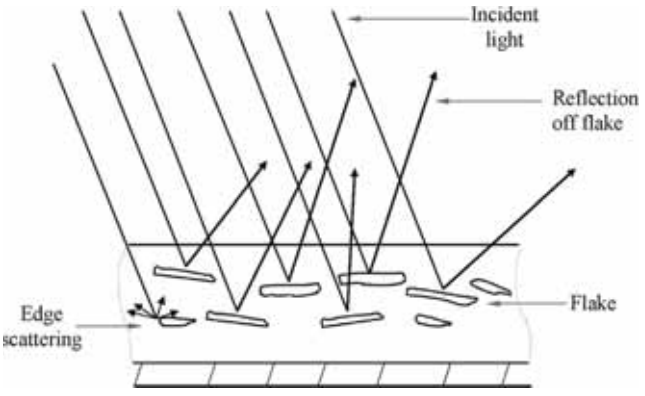

Fig. 2—Schematic of a flake-containing paint film.

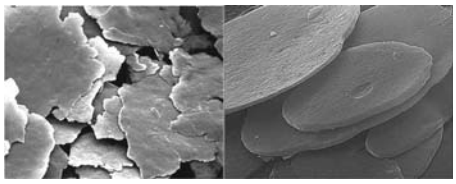

Fig. 3—Photomicrographs of two different types of aluminum flakes. Courtesy of Eckert America Corp.

pigment. The result of any light scattering within the paint film is that there is a decrease in light reflected back from the paint in the specular direction, and an increase in light reflected at larger aspecular directions, i.e., a decrease in flop. It also results in decreased sparkle.

Automotive stylists design car bodies, contouring them to make them more appealing to customers. Gonioapparent coatings accentuate these contours, just as they enhance the curvature of the ping-pong balls. Their sparkle further contributes to customer appeal. These enhancements to appearance account for their popularity with about 70 % of today's automotive colors being gonioapparent. Simple flakes, first introduced in a 1935 automotive paint, were made of aluminum. They have evolved over the years to include color-coated aluminum and flakes coated with thin metal-oxide layers exhibiting light interference effects. Coatings containing these flakes exhibit not only a lightness flop but also chroma and hue flop. This change in any or all attributes of color of a specimen on change in angular illuminating-viewing conditions but without change in light source or observer is called *goniochromatism*. It should be noted that goniochromatism, while prevalent in automotive finishes, is also observed in other finishes as well as products such as cosmetics. The discussion in this article is generally applicable to all such products. However, the experimental work was done with automotive paints. Some of the work described was done by a manufacturer of interference flakes, supplied to several coatings and noncoatings industries. The previous chapter of this book [2] provides an excellent review of goniochromatic pigments.

International standards for measuring color and appearance of finishes have been well established. ASTM has several Standard Practices for both visual (e.g., D1535, "Standard Practice for Specifying Color by the Munsell System," and D1729, "Standard Practice for Visual Appraisal of Colors and Color Differences of Diffusely-Illuminated Opaque Materials") and instrumental (e.g., E308, "Standard Practice for Computing the Colors of Objects by Using the CIE System," and E1164, "Standard Practice for Obtaining Spectrometric Data for Object-Color Evaluation") evaluation and specification of color as well as appearance (e.g., D523, "Standard Practice for Specular Gloss"). Yet none of these international standards addresses the gonioapparent characteristics of these finishes. ASTM subcommittee E12.12 was formed in 1989 to address standardization specific to gonioapparent color. It led to addition of a section in ASTM E284 [1] on specialized terminology on gonioapparent phenomena. Unlike solid colors, which can be measured diffusely or at one angle, measurement of gonioapparent color requires several angles of illumination and view. Practicality demands use of the minimum number of angles, sufficient to characterize the overall color.

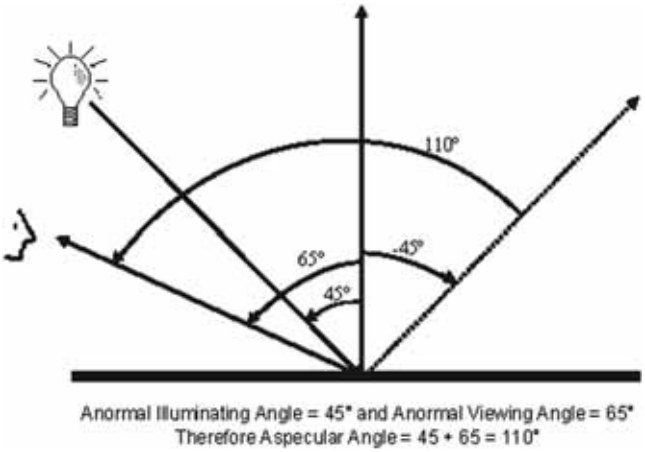

Fig. 4—Example of illuminating and sensing geometry.

CONVENTIONS FOR DESIGNATING MEASUREMENT GEOMETRY

Fig. 4 illustrates the traditional convention for designating measurement geometry. This convention has been to indicate the anormal angle, i.e., the angle away from the normal or perpendicular to the surface being measured. The illuminating beam is shown in Fig. 4 at 45° from the surface normal. Viewing angles on the same side of the normal are shown as positive, e.g., the viewing angle at 65° in the figure. Angles on the opposite side of normal are assigned a negative sign. Thus the specular reflection is at minus 45°.

Discussions in the early days of E12.12 led the subcommittee to recognize that gonioapparent colors were observed with attention to change in color as a specimen is viewed at increasing aspecular angles for a given direction of illumination. E12.12 introduced a modified convention, designating the illuminating angle with the anormal angle convention, while designating the viewing angle by its *aspecular* direction. ASTM E2175 [3], "Standard Practice for Specifying the Geometry of Multiangle Spectrophotometers," details this convention. Positive values of the aspecular angle are in the direction towards the illuminator axis. This aspecular convention is intuitive for those who have worked with gonioapparent colors. It is also an easy adaptation from the anormal convention because the aspecular angle is simply the sum of the anormal convention illuminating and viewing angles. Thus in Fig. 4, the 110° aspecular angle is the sum of the anormal illuminating angle (45°) and the anormal viewing angle (65°).

Longtime users of the anormal convention expressed discomfort with having to calculate the anormal viewing angle. Hence the convention finally agreed upon includes the illumination anormal angle, the viewing anormal angle and the aspecular angle. Under this convention, the 110° angle in Fig. 4 is expressed as 45°:65° (as 110°).

MEASUREMENT OF METALLIC COLOR AND COLOR DIFFERENCE

Gonioapparent colors may be viewed in three different modes. Object modulation utilizes a fixed angle of observation relative to the illuminating direction, and the specimen is rotated about an axis to change both viewing and illumination angles. This method is commonly used in viewing a panel coated with a metallic paint, where the light source

is usually fixed and the observer rotates the panel to view it at different aspecular angles. When viewing a car, it is generally stationary under sunlight, whose direction is fixed at any given time, while the observer moves around to view it from different angles. This is detector modulation. The third mode is source modulation, where the object and viewer are fixed, while the direction of illumination is varied. Alman [4] and Schmelzer [5] in independent studies reported that measured color of *metallic* specimens is independent of the method of changing aspecular angle. They showed that measured color is simply a function of aspecular angle itself. The objective then in measuring metallic color is to determine the minimum number of aspecular angles of measurement, optimizing these angles to best characterize color and color differences measured at all possible measurement angles. Three independent studies using different approaches arrived at very similar recommendations.

Venable [6] reasoned that light reflected from a metallic finish has a diffuse component (from multiple interactions with flake and other pigments) and a flake component (from a single reflection from a flake). The diffuse component dominates measurements far from the specular direction and can be characterized by a single measurement at an aspecular angle greater than 60°. The flake component is manifested at angles closer to specular and has an angular distribution dominated by the flake orientation, thus requiring two measurements to quantify. He recommended that one of these measurements be at an angle as close to specular as possible, while excluding first surface reflection (gloss). The other measurement angle for the flake component should be at a point where the flake component is still significant but its measurement is significantly different from that close to specular. He also suggests a model which, using measurements at 20°, 40°, and 70°, correlated well with goniocolorimetric data.

Saris et al. [7] correlated visual assessments of color differences with measurements at different geometries. They had 22 clusters of five metallic color panels, each providing ten color difference pairs, for a total of 220 observations by each of six observers. For uniformity of lighting conditions, observations were done in an "artificial window," simulating lighting at a natural window commonly used by color shaders in their laboratory. This "window" provided a color-corrected diffuse light about the size of a window behind the observer. The specimens to be viewed were placed on a table in front of the observer. This table could be tilted to provide three different viewing angles. Color differences were judged at these angles against a gray scale with six lightness difference pairs. An overall match rating was also recorded. Several instrumental measurements were taken, ranging from aspecular angles of 25°–115° and they also included a $d/8^{\circ}$ measurement. These were correlated to observations using a logistic regression model. Measurements at $d/8°$, 45°, and 95° correlated well with visual observations. Inclusion of the $d/8°$ measurement in the optimized combination is not surprising considering the "diffuse-directional" lighting used in the observations. Interestingly, statistically equivalent results were obtained with 25°, 45°, and 110° measurements.

Alman [4] measured lightness, hue and chroma of 36 metallic colors as a function of aspecular angle. The

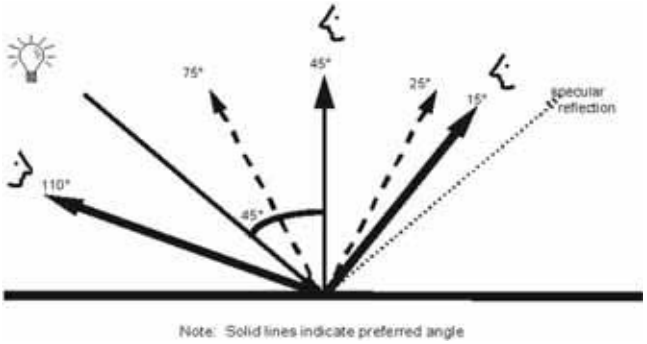

Fig. 5—Diagram of aspecular angles.

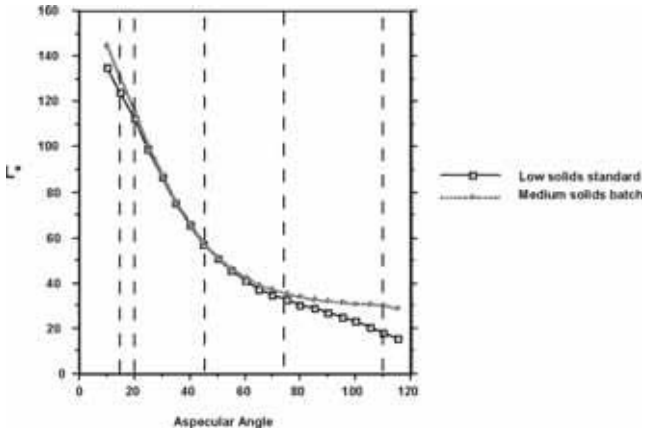
experiment was done in 1980. Metallics of those days exhibited a strong lightness flop, while chroma flop was small and hue flop almost nonexistent. Using polynomial modeling of lightness as a function of aspecular angle, he determined the residual error for each model. Large residual errors resulted from linear models, obviously unable to fit the curvature of the lightness response. Quadratic models with three appropriately chosen measurement angles dramatically reduced the average residual variance. Three angles of measurement requires attention to color data (e.g., L, a, b) at each of these angles, making colorimetric analysis a nine-dimensional problem. Further reduction in residual variance with four angles was insufficient to justify the increased complexity posed by twelve dimensions. Based on this work, he recommended measurement of metallics at aspecular angles of 15°, 45°, and 110°. Rodrigues [8] repeated this experiment with base coat/clear coat colors, including 18 metallics and 16 interference pearl colors used in automotive finishes of the late 1980s. The interference pearl colors exhibited strong lightness and chroma flop and some hue flop. These experiments confirmed 15°, 45°, and 110° as the optimum angles of measurement. ASTM E2194 [9], "Standard Practice for Multiangle Color Measurement of Metal Flake Pigmented Materials," standardized this geometry for measurement of metallic colors, as shown schematically in Fig. 5. The 15° angle is referred to as the *near-aspecular angle,* 45° as the *mid-aspecular angle*, and 110° as the *far-aspecular angle.*

Visual assessments of gonioapparent matches typically cover a wide range of aspecular angles, from very near specular (e.g., aspecular angle of 15°), all the way to far from specular (e.g., aspecular angle of 110°). Occasionally specimens are an acceptable match at angles between 25° and 75°, but visual and instrumental assessments find the match unacceptable outside this angular range. An example (Fig. 6) shows lightness as a function of aspecular angle for a standard (dark curve) and a batch (lighter curve) paint sprayed on aluminum panels. The curves are a reasonably good match at angles between 20° and 75° and were judged visually acceptable when judged at these angles. However, they deviate below 20° and above 75° and the panels were judged as an unacceptable overall match. Both paints contained the same absorbing and flake pigments. However, the standard was a low solids paint, while the batch was a medium solids paint. Higher solids allowed for less film shrinkage as the sprayed batch paint dried, resulting in poorer flake orientation. *Side-tone scattering* of light caused by poorer flake orientation was visually quite apparent



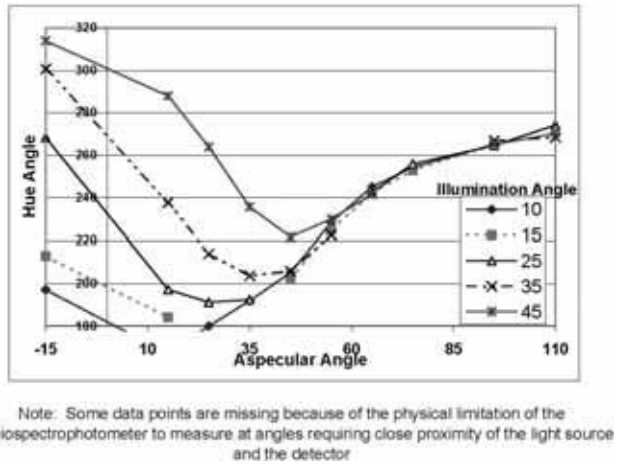


Fig. 6—L* gonio-curves on real metallic paints showing relative effectiveness of different geometries.

Note: Some data points are missing because of the physical limitation of the goniospectrophotometer to measure at angles requiring close proximity of the light source and the detector

Fig. 7—Hue shifts observed in strong interference colors.

with the batch being judged unacceptably lighter and bluer at the far-aspecular angle and slightly lighter at the near-aspecular angle.

Commercially available spectrophotometers often provide 25° and 75° aspecular measurements in addition to the angles standardized by E2194. The German standard DIN 6175-2 [10] recommends use of 25°, 45°, 75°, and 110°. E2194 allows for this variation in angles as shown in Table 1. Angles other than the preferred angles but within the acceptable range may be used for less critical color matches. For example, surface imperfections (e.g., orange peel) resulting from spray application of finishes can cause light to be reflected off the surface in a direction slightly away from the nominal specular direction. Measurement at 25° may be chosen as the near-aspecular angle when less sensitivity to application differences is desired. However, in critical color matching applications, batches should be resampled and re-sprayed to match surface texture of the standard specimen and adjusted to an acceptable color match at the standardized 15° near-aspecular angle.

E2194 also provides a ray-tracing procedure to determine the effective aspecular angle and sets tolerances for the percentage of rays that may deviate from the expected angle. The Society of Automotive Engineers standard J1545 [11], "Instrumental Color Difference Measurement for Exterior Finishes, Textiles, and Colored Trim," also recommends the angles standardized in E2194.

Fig. 5 shows a uniplanar geometry, i.e., the illumination axis, the viewing axes, and the normal to the specimen surface are all in the same plane. Some commercial instruments provide *annular* or *circumferential* measurement or illumination. Annular geometry provides measurement (or illumination) distributed continuously and uniformly throughout the 360° of azimuth of the measurement. Circumferential measurement (or illumination) is an approximation of annular, using a discrete number of sensors (or illumination beams) distributed at uniform intervals throughout the 360° of azimuth of the measurement. These measurements minimize directional effects such as surface irregularities or preferential flake orientation. For example, when paint is sprayed on a vertical surface, the Earth's gravity may cause the flake to tilt rather than remaining parallel to the surface as the paint dries. If two halves of such a painted panel are viewed side-by-side, both in the same orientation as when sprayed, they will appear as a good color match, regardless of aspecular viewing angle. However, if one half is rotated 180° in its own plane, the flakes in the two halves are now tilted in opposite directions and the two halves will no longer match. This is referred to as the *venetian-blind effect*. Annular or circumferential instruments will average out the directional effects of tilted flake and measure the two halves as being the same. They would be the appropriate instruments if the goal is to neglect these effects. However, often in the presence of the venetian-blind effect, these instruments will provide measurements that do not agree with visual assessments. If a measurement neglecting the rotational effect is desired, it can be achieved with a uniplanar geometry by averaging several measurements taken while rotating the panel orientation with respect to the instrument after each reading. Another drawback is that annular or circumferential geometry requires symmetry. Either the illumination or the viewing axis must be on the normal or else determination of the aspecular angle is ambiguous. This limits the maximum aspecular angle to something less than 90°, short of the 110° recommendation for critical color matching.

TABLE 1—ASTM E2194 angles for metallic color measurement

Aspecular Angle	Preferred angle for Critical Color Match	Acceptable Range
Near-aspecular	15°	15°–25°
Mid-aspecular angle	45°	45°
Far-aspecular angle	110°	70°–110°

MEASUREMENT OF COLORS CONTAINING INTERFERENCE FLAKES

A commercial automotive color, Mystichrome, containing Chromaflair®[2] interference flake was measured on a *goniospectrophotometer*. This measurement is shown in Fig. 7 with hue angle as a function of aspecular angle at several different illumination angles. Unlike metallics, where color

[2] Flex Products Inc., 1402 Mariner Way, Santa Rosa, CA 95407.

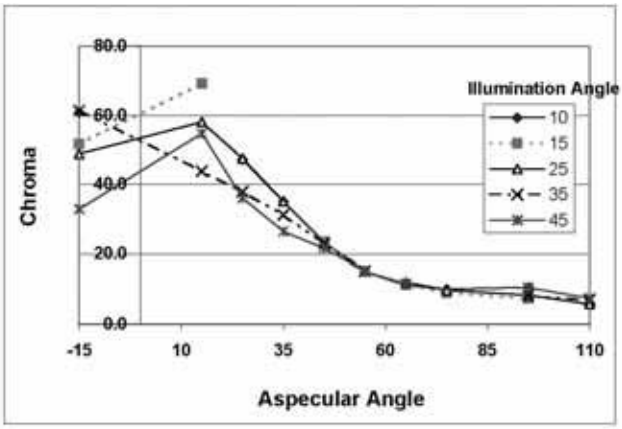

Fig. 8—Chroma shifts observed in strong interference colors.

is a function of only aspecular angle, hue of colors containing interference flakes is also a strong function of illumination angle. Hue is also dependent on whether viewing is in a positive or negative direction away from the specular. Thus the hue at aspecular angle minus 15° is very different from that at plus 15°. It is only at aspecular angles greater than about 55° that the hue shifts are seen to be independent of illumination angle. Fig. 8 shows that chroma of this color also has a strong dependency on angle of illumination and aspecular angle, with the curves beginning to overlap at an aspecular angle of about 45°. The degree of color shift and its dependence on illumination angle is obviously a function of the particular flake used, its content in the color and the types of other pigments in that color. The interference flake by itself would exhibit a stronger color shift. Fig. 9 shows hue shifts for a Chromaflair® interference flake in a clear paint containing no other pigments. It shifts from blue-green, through purple to green-yellow when viewed 10° off specular as illumination angle is changed. Thus manufacturers of these flakes must measure them at a wide variety of illumination angles, each at multiple viewing angles. ASTM E2539 [12], "Standard Practice for Multi-angle Color Measurement of Interference Pigments" covers the instrumental requirements and parameters needed to make instrumental measurements of thin film interference

TABLE 2—ASTM E2539 Specified Geometries for Measuring the Color Range due to Interference. Note: This table gives the minimum geometries for the quality control application. For other applications, additional geometries, such as 65°:50° (as 15°), may be desirable or needed

Illumination Angle	Detection Angle	Aspecular Angle	Designation
45°	–60°	–15°	45°:–60° (as –15°)
45°	–30°	+15°	45°:–30° (as 15°)
15°	–30°	–15°	15°:–30° (as –15°)
15°	0°	+15°	15°:0° (as 15°)

pigments. The Standard states that these "pigments are typically evaluated for color and appearance in a medium such as paint or ink." The geometries specified for measuring these pigments are shown in Tables 2 and 3.

The physics of light interference shows that the hue shift in interference pigments occurs only from flake oriented so as to act as specular reflectors of the illumination source to the detector. A term to address this is *color angle,* not used in E2539 but defined in E284. The discussion of this term in E284 states "flakes in a coating have an angular distribution, and the interference effect will be exhibited in a given measurement geometry only by the flakes that are oriented so that they behave as specular reflectors." Color angle is defined as half the angle between the illumination and detection axes of the measurement geometry. Fig. 10 is an *a*-b** plot of the measurements of Mystichrome. The curves show loci of constant aspecular angles with changing illumination angle. The slightly curved "spokes" emanating from a point close to the origin are loci of constant color angle. Each spoke is at approximately the same hue angle. This suggests that measurements at color angles could be useful in characterizing the hue shift of interference colors. Another potentially useful term in E284 is *flake*

TABLE 3—ASTM E2539 Specified Geometries for Measuring the Color due to Scattering or Orientation. (Note: The three angles designated with an asterisk (*) refer to preferred angles for critical measurements as specified in E2194.) (Note: Given a geometric configuration, the reverse geometry is considered equivalent, if all other components of the instrument design are equivalent.)

Illumination Angle	Detection Angle	Aspecular Angle	Designation
45°	–30°	15°	45°:–30° (as 15°)*
45°	–20°	25°	45°:–20° (as 25°)
45°	0°	45°	45°:0°(as45°)*
45°	30°	75°	45°:30° (as 75°)*
45°	65°	110°	45°:65° (as 110°)*

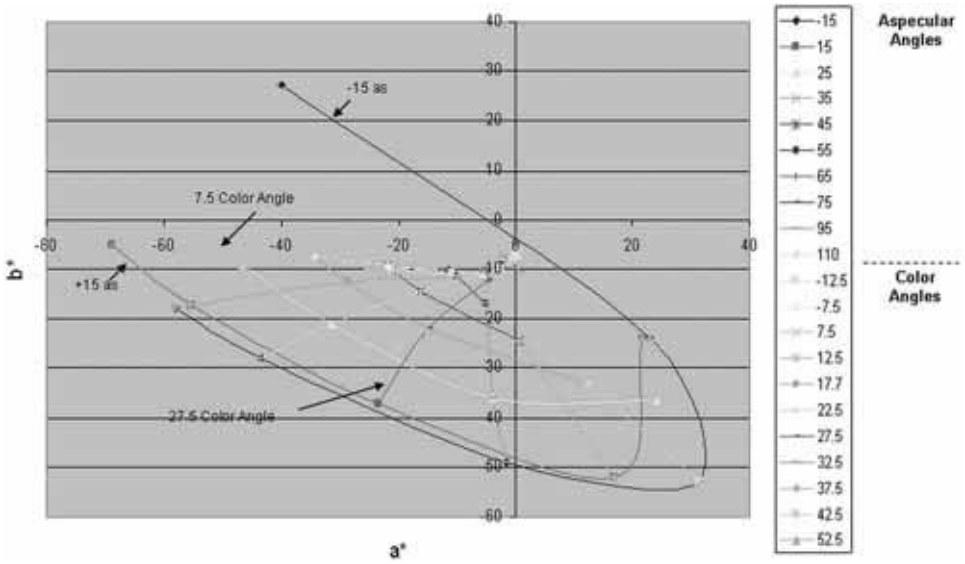

Fig. 10—Color loci for constant aspecular angles and for constant color angle in an automotive color with interference flake.

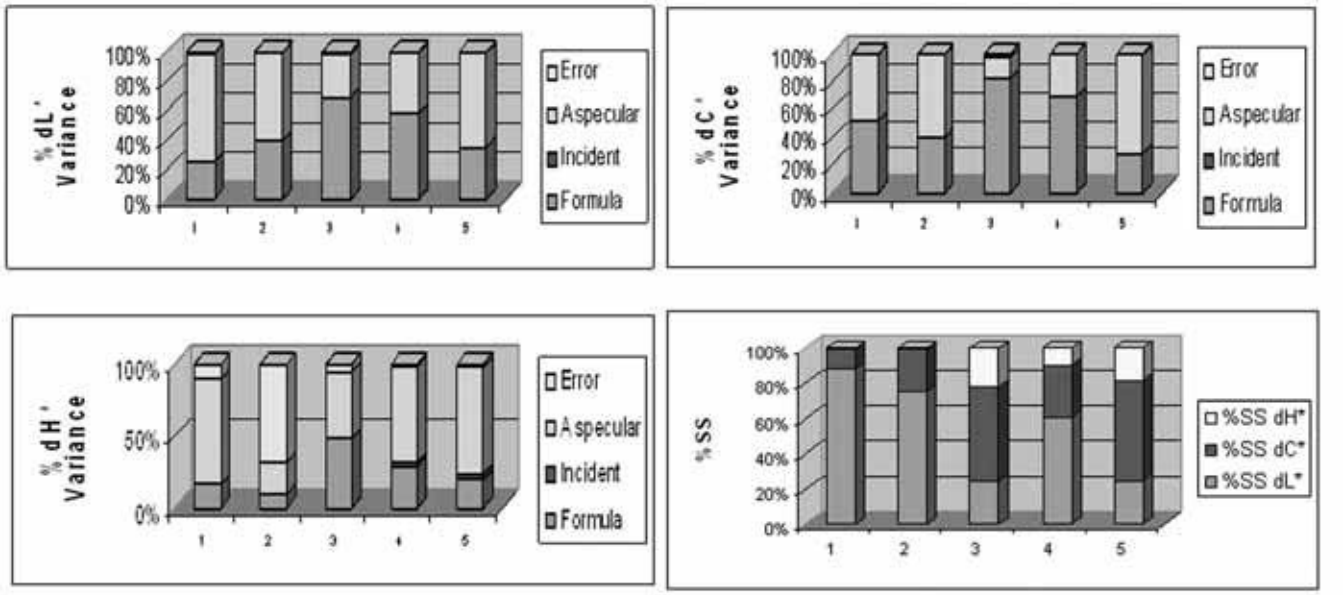
angle, defined as the angle subtended at a point on a pigment flake by the pigment flake normal and the specimen normal line through that point. Flake angle could be useful in characterizing the chroma shift of interference colors.

A task not yet addressed is to determine whether characterization of real colors containing interference flakes require the same set of angles as those in E2539. A subset may be sufficient for some products, e.g., automotive colors containing these flakes do not exhibit hue shifts as strong as the flakes themselves.

COLOR DIFFERENCE MEASUREMENT FOR QUALITY CONTROL OF COLORS CONTAINING INTERFERENCE FLAKE



Absolute color measurement is important when a manufacturer is matching a new color standard of unknown pigmentation. Spectral measurement must be used in order to identify the correct pigmentation and avoid a metameric match. The scope of Subcommittee E12.12 encompasses the goal to "study the color measurement of metallics and *pearlescents* looking at quality control aspects." Quality control requires measurement of color difference versus a standard rather than absolute color. After establishing the correct pigmentation, measurement of color difference from the standard is sufficient to adjust colorant ratios, shading the color to a visually acceptable match. Routine, repetitive manufacture of a color uses measurement of color difference from a standard color, generally of the same pigmentation as the batch being made. Interference flake manufacture would also entail measurement of color difference from a standard. E2539 addresses measurement geometry for that process. However, it has not been established that these same measurements are necessary for paints or other products containing interference flakes.

The sub-committee conducted a preliminary experiment to determine the importance of incident angle versus aspecular angle in color difference measurement of realistic automotive colors. Bronze and violet automotive colors were chosen and the interference pearl content increased to the limit of current color styling practice for real automotive colors. In each case a standard panel was weighed and sprayed. Additional panels were made by sequentially iterating each ingredient to provide color differences of 2 to 3 CIELAB units. Duplicate panels were sprayed to determine variation due to application. Measurements were made at aspecular angles of 15°, 25°, 45°, 75°, and 110°, each at incident angles of 15°, 30°, and 45°. Goniospectrophotometer limitations did not allow 25° and 110° aspecular measurements at all three angles of illumination. So the analysis included only the 15°, 45°, and 75° aspecular angles. Color differences (ΔL*, ΔC*, ΔH*) were calculated versus the standard. Analysis of Variance (ANOVA) analysis showed that the greatest variation is from the ingredients themselves (Table 4). This of course allows for ingredient adjustments to match the color. The incident angle variation is extremely small compared to the aspecular angle. In fact even under the controlled conditions of the experiment, application variation was more significant than the incident angle.

Steenhoek [13] extended this study to five automotive colors containing interference pigments with a reflective inner layer. These pigments show very strong interference effects. Analysis of Variance (ANOVA) analysis again showed that the greatest variation is from the ingredients themselves. Fig. 11 shows the variances in ΔL*, ΔC*, ΔH* for each of the five colors. A significance test ($p < 0.05$) showed that the only significant variables were the formula itself and the product of the formula and the aspecular readings.

TABLE 4—Summary of ANOVA results

These results suggest that currently used spectrophotometers with a fixed angle of illumination may be used for quality control of real automotive colors. They are, however, based on only two colors, not necessarily representative of all interference colors in automotive or other industries. Future automotive colors may include more dramatic interference effects. Further study is required to:

- Address more automotive interference colors, including those containing higher concentrations of strong interference effect flakes.
- Consider colors containing other pigments with gonioapparency resulting from diffraction effects, liquid crystals, etc.
- Optimize the choice of incident angles.
- Verify whether optimum aspecular angles are the same as currently standardized for metallic colors.
- Address any specific needs of industries other than automotive.

COLOR METRICS

To be useful, color measurements must be reduced to metrics correlating to color as seen by human observers. Color difference equations for solid colors have evolved since 1931 when the International Commission on Illumination (CIE) adopted the "Standard Observer." The CIE recommendation in 1976 of CIELAB and CIELCH, together referred to as CIE76, was a major milestone in relating these measurements to how we see color, but not uniform enough throughout color space to allow instrumental pass/fail judgements. CMC, CIE94, and CIEDE2000 [14] have been a series of improvements based on CIE76. They all start from ΔL^*, ΔC^*, ΔH^* from CIE76 dividing each by weighting functions S_L, S_C, S_H respectively to correct for the nonuniformity of CIELAB. All these equations were possible because of a large body of experimental data of observations on a variety of color differences on solid colors made from paints, textiles, and more recently video color displays. Very few observation data on gonioapparent colors have been published. Subcommittee E12.12 has been working with the Detroit Colour Council (DCC) J1545 Committee to create such data sets. Experience with gonioapparent colors dictates that a larger ΔL^* is visually acceptable in lighter gonioapparent colors. This relationship was recognized in the S_L function used in the CMC equations. The samples in the CMC study were threads wound on cards used for color judgments in the textile industry. Textiles have a texture that apparently makes human judgments more forgiving of lightness differences in lighter colors. CIE94 was based on glossy automotive solid colors and assigned S_L the value of unity, regardless of lightness. Colors containing flakes also have a visual texture. So they would be expected to have a similar tolerance for larger lightness differences in lighter colors.

Spectrophotometers measure reflectance factor, which is "the ratio of the flux reflected from the specimen to the flux reflected from the perfect reflecting diffusor under the same geometric and spectral conditions of measurement" [1]. Very light metallics can reflect more light in the near-specular direction than the perfect diffusor and hence their reflectance factor and L* may exceed 100 %. The S_L function used in the CMC equations is non-linear and should not be used at L* greater than 100, which would be extrapolating the function beyond its experimental conditions. DCC and E12.12 did visual assessments of lightness differences on a series of silver gray metallics over a wide lightness range. This established a linear relationship

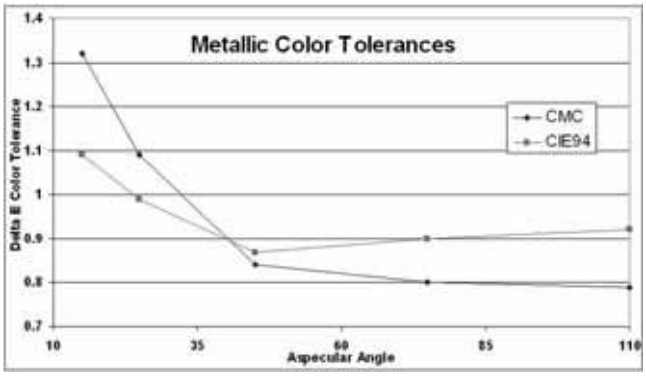

Fig. 12—Relative metallic color tolerances as a function of aspecular angle using CMC and CIE94 Equations.

between S_L and L* [15]. Modifying the CIE94 equations when used for metallic colors by dividing ΔL^* by this S_L function gave excellent agreement with the visual data. CIEDE2000 uses a V-shaped function for S_L, contrary to the findings of the DCC and E12.12 experiments. At this writing, CIEDE2000 has not been tested for gonioapparent colors.

These studies were extended to a few real automotive colors: beige, silver, gold, and teal metallics. Color difference pairs of these colors were shown to 20 observers in a Macbeth Skylight®[3] viewing booth at 15°, 25°, 45°, 75°, and 110° aspecular angles. They were asked whether they would accept the color match if seen on their own car. The frequency of acceptance as a function of color difference was analyzed to determine acceptability tolerances at each of these angles in both CMC and the modified CIE94 systems. Tolerances averaged over all colors are shown in Fig. 12. Both equations performed well. However, CIE94 gave more nearly equal tolerances at all aspecular angles. It should be noted that these are relative *color tolerances*. Actual commercial tolerances must be agreed upon between customer and supplier. However, these experiments suggest that these color difference equations could be used in setting those acceptability tolerances. Work continues to extend these studies to include larger numbers of current automotive colors including those containing interference flakes. It entails identification of a preferred experimental procedure for making simple pass/fail judgments by comparison to an anchor color difference pair. This will result in the creation of a database of observations on gonioapparent color differences allowing testing of existing color difference equations as well as development of improvements if necessary.

It should be noted that color difference is just one factor in determining acceptability of a color match. Even with solid colors, surface gloss or texture differences can cause a color difference pair measuring identically to be observed as an unacceptable match. It follows that in such cases, a pair judged as an acceptable match would very likely measure as having an appreciable color difference. Thus it is advisable to prepare color samples equal in appearance to the standard being matched before measuring or visually assessing color acceptability. Gonioapparent colors have additional appearance attributes, which must be accounted for. Both metallic and interference flakes differ in size, shape and surface texture. These can result in differences in sparkle and coarseness of visual texture. These appearance differences too can be a function of angle of illumination and view. All these factors must be considered in determining acceptability of a color match.

THE FUTURE OF STANDARDIZATION OF GONIOAPPARENT COLOR

Much progress has been made in measurement and determining color and color difference of gonioapparent colors. Standardizing organizations such as ASTM, DIN, CIE and SAE communicate with each other on this subject and membership sometimes overlaps. However, while standards have been clearly established for metallics, considerable research on interference colors is still underway. E2539 addressed measurement of interference pigments. The measurement of products containing these pigments has not been standardized. Different standardizing bodies do not always agree upon identical standards. The starting point must be agreement on terms and their definitions, followed by conventions (e.g., for designation of measurement geometry) and finally good experimental data to allow for data-based decisions in standardization. There must be openness to change. In the early days of instrumental color matching, diffuse measurements worked very well. Metallics required acceptance of the aspecular angle concept and optimized multiangle measurement. It is now accepted that absolute measurement of interference colors requires more than one illumination angle. Requirements for optimizing absolute color measurement may be more demanding than for color difference. The standardization process has to recognize and address the needs of different users of gonioapparent materials, the flake manufacturer, the coatings manufacturer, and the final user of the coating.

In addition to color measurement of gonioapparent colors, there is need for understanding and determining metrics for their special appearance characteristics such as flake sparkle and visual texture. Instruments aimed at such measurements have recently been available (BYK-mac[4] and X-Rite MA98[5]). Once these metrics are established, will color difference equations have to again be modified to account for them? For example, would the S_L factor be a function not only of L* but also sparkle and texture? Just as texture makes assessments of lightness differences more forgiving in lighter colors, would strong hue shifts in interference colors allow for larger tolerances of hue differences? There are many questions that must still be resolved. As one class of gonioapparent color is understood and its measurement standardized, a new class of gonioapparent flake is offered to the delight of color stylists and consumers. This is clearly a work in progress.

Protective Coatings and Inorganic Anti-Corrosion Pigments

Lucien Veleva[1]

INTRODUCTION

COATINGS ARE IMPORTANT WIDELY USED PRODUCTS that provide corrosion[2] protection of metals and other substrates. Paints that contain anti-corrosion pigments account for about 65 %–70 % of all areas protected by anti-corrosion coatings. Paint[3] provides a number of desirable attributes including relatively low cost, simplicity of application to simple and complex structures, aesthetic beauty, ease of repair and restoration, as well as metal corrosion protection that is markedly enhanced when anti-corrosion pigments are present.

Coatings may be classified in various ways such as by their end use, surface character, and so on. For example, an end-use classification might include coatings for transportation vehicles and associated hardware, such as boats, ships, piers, and other items subject to marine environments, such as reactors, drums, piping, buildings, etc., exposed to harsh industrial environments; pipeline coatings, architectural coatings; artists' paints that have aesthetic, aging, substrate nature needs; and many others. Each of these classes has different requirements. Marine coatings must be resistant to high humidity, chloride presence, and aqueous immersion; pipeline coatings must be resistant to crude oil, natural gas, water and aggressive aqueous solutions, and solvents; and so on [1–5]. Each end use will have its own particular requirements. Various chapters in this manual deal with coatings for a variety of end uses.

The three main components of an organic paint are pigment, binder, and volatile vehicle.[4] The pigment is an insoluble, finely ground material that provides color and opacity as well as corrosion resistance and water barrier properties when particular pigments are used. The binder is the polymeric, nonvolatile portion of a formulated coating. It is the important ingredient that forms a film[5] as paint dries, and it holds the pigment particles or other additives in a separated, suspended state within the paint film. Binders are either polymeric in nature or are capable of reacting and forming a thermoplastic or thermoset polymeric film under specified conditions. They are comprised of oils, epoxides, alkyds, polyesters, acrylics, vinyls, and the like. The volatile vehicle dissolves or disperses the binder, and it allows the coating to form in a thin, continuous film. In certain formulations, a curing agent[6] or hardener will be incorporated into the system. In the case of ultraviolet-radiation curable coatings, the curing agent will be a photoinitiator that effects rapid polymerization of combinations of monomeric and oligomeric species.

Completed coatings are comprised of one or more film layers with the number of layers and their individual thickness dependent on the particular end use involved and on specifications. For example, a three-layer coating system[7] might be composed of a primer that is directly applied to the substrate surface, a color coat or decorative layer, and a clear topcoat that protects the color coat and provides gloss. Appliances may have two coats, a primer and a colored topcoat. Automobile body coatings usually have four layers—an electrodeposited primer, a primer-surfacer, a color coat, and a topcoat. Powder coatings are often used as single-layer coatings. The most important layer in the coating system is the primer since it is primarily responsible for protection against metal corrosion. It must have excellent wetting and adhesion to the metal surface and to the next applied coating. Components of the primer, when used as an anti-corrosion paint, are various corrosion inhibitors[8] that are also known also as anti-corrosion pigments. Primer coatings are sometimes named after a pigment, for example, "zinc-rich primer (ZRP)," whose formability may be examined as described in ASTM D4146, Standard Test Method for Formability of Zinc-Rich Primer/Chromate Complex Coatings on Steel.

An organic coating system protects metal substrates against corrosion by means of one or more of several mechanisms:

- Decreasing the rates of anodic (oxidation) and/or cathodic (reduction) corrosion half-reactions that occur on the metal/paint interface.
- Introduction of high electrical resistance into the circuit of the metal/electrolyte corrosion cell[9] that is caused by the nonconductive organic film that is applied on the metal substrate.
- Acting as an effective physical barrier against the transport of aggressive species, such as water, which is the basis of the electrolyte/humidity conditions; oxygen, which is the oxidizing agent; and various corrosion ions (Cl^-, SO_4^{-2}, etc.) to the metal surface. In general, the anti-corrosion efficiency of an organic primer film is a function of four factors:
  - The nature of the metal substrate, that is, its susceptibility to oxidative corrosion.
  - The state of the metal/primer interface—for example, its electrical resistance and capacity, the nature of ions or molecules present in this region, etc.
  - The composition of the primer film and efficiency of the anti-corrosion pigments and any other inhibitors.
  - Corrosion aggressivity[10] of the environment and the characteristic nature to which the coated metal is exposed.

CERTAIN DEFECTS AND COATING APPLICATION

Although anti-corrosion pigments play an important role in protecting metals from corrosion, those applying the coating must make sure a number of considerations are met to ensure the coating properly functions. Blistering (Fig. 1) is probably the greatest cause of coating failure. It can be identified by small- to medium-sized bubbles or blisters that form under the paint film. These result in partial or complete detachment of the coating from the metal substrate. Blistering is caused by painting on a damp or wet surface, which causes trapped moisture to expand the paint film; painting in direct sunlight on a "hot" substrate, which dries the paint surface too quickly and traps solvent vapor in the film; painting during rain or in a very high humidity environment, including heavy dew; by painting over an insufficiently dried coating; or a low-quality paint that is porous.

When blistering occurs, the efficiency of anti-corrosion pigmented coatings is significantly diminished, and they cannot prevent metal corrosion; in fact, the process may well be accelerated. The corrosion products[11] formed in delaminated areas are usually voluminous in nature and exert pressure on the coating film. This pressure buildup will lead to cracking[12] or the appearance of micro-fissures and further loss of adhesion.

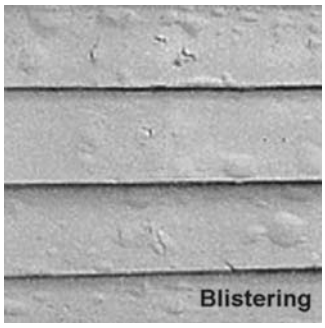

Fig. 1—Blistering of paint coating.

Blooming[13] and filiform corrosion[14] are failures that result in coating damage. These failures usually occur in coating areas that are defective or in areas that have low mechanical strength and physicochemical degradation (aging). Thus, from the corrosion protection standpoint, good substrate adhesion of the various layers is needed. Good adhesion will result in a surface with high ionic resistance that inhibits formation of local anodes and cathodes on the metal surface thus improving corrosion resistance. Since 1979, it has been suggested that the coatings having a critical resistance of less than $10^7\ \Omega\ cm^{-2}$ are not protective. Therefore, it is highly recommended that the electric resistance applied coatings, including any defective areas, be measured. This will provide important information for the analysis of degree of coating protection and failures. ASTM D5162, Standard Practice for Discontinuity Testing of Nonconductive Protective Coating on Metallic Substrates, is a practice for electrical detection of minute discontinuities. Some corrosion failures in paint coatings are shown in Fig. 2.

SURFACE PREPARATION

When the term "coating system" is used in a broad sense, surface preparation, pretreatments, dry film thickness, and manner of application are included. The protective efficiency and life of a coating system are markedly dependent on proper surface preparation, which may be costly but is a needed portion of the paint application process. It has been shown that over 80 % of all paint failures (peeling, efflorescence, etc.) can be attributed to poor or improper surface preparation (Fig. 3). Therefore, paint manufacturers often make comments such as "good paint deserves a good surface" or "the quickest way to achieve paint failure is inadequate surface pretreatment."

COATING CHARACTERIZATION METHODS

Investigation of the parameters that characterize coatings can be carried out according to specific methodologies established in international standards (ASTM, NACE, ISO,

[9] Corrosion cell/galvanic cell: The combination of different electrodes (anode and cathode), connected in series, in contact with an electrolyte (ionic conductor); see "Glossary of Corrosion-Related Terms," NACE International, 1998.

[10] Corrosion aggressivity/corrosiveness: The tendency of an environment to cause corrosion.

[11] Corrosion products: The substances formed as a result of the metal corrosion process. Usually they comprise a majority phase of various oxides and hydrated oxides (hydroxides) and sometimes a minority phase of carbonates, chlorides, sulfides, sulfates, or other.

[12] Cracking (of coating): Breaks in coatings that extend through to the substrate.

[13] Blooming/blushing: Whitening and loss of gloss of a coating, caused by moisture.

[14] Filiform corrosion: Corrosion that occurs under coating in the form of randomly distributed threadlike filaments.

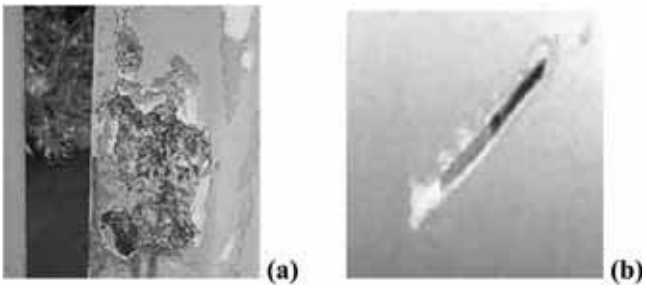

Fig. 2—Corrosion failures in protective paint coatings: (*a*) Area of corrosion of a substrate and appearance of red rust on steel. (*b*) Corrosion products ("rust") forming on steel, where the protective coating system has been damaged mechanically (scratch).

etc.). Several ASTM International documents are listed in the references section. These and other standards can be used to characterize, develop methods, and analyze coating failures. To select an appropriate anti-corrosive coating for an environment of interest, two tests are recommended—a natural weathering or field test under actual conditions and an accelerated laboratory test under selected, artificial conditions that is carried out in a test chamber. Accelerated laboratory tests provide rapid comparative results in a short time because they usually use higher values of some parameters (temperature, humidity, particular radiation, and aggressive environment) than those encountered in real or field conditions [6–8].

A new group has recently been investigating a method termed "accelerated test in natural conditions." Their efforts may result in an improved correlation between field testing and accelerated weathering. The "black box" test, in which the resistance of materials to solar radiation filtered through glass is evaluated, has been found to be a useful tool [9]. Procedures that deal with the black box test can be found in ASTM D4141, Standard Practice for Conducting Black Box and Solar Concentrating Exposures of Coatings; ASTM G24, Standard Practice for Conduction Exposures to Daylight Filtered Through Glass; and other standards.

INORGANIC ANTI-CORROSION PIGMENTS

Anti-corrosion pigments are coloring components of paint that can influence and control the corrosion of metal substrates by moderating the rate at which corrosion takes place. Because of this moderating effect, these pigments are also known as corrosion "inhibitors." These coating components are usually introduced into the primer layer.

A variety of metals such as aluminum, chromium, lead, iron, and zinc are known as effective anti-corrosive pigments, and they are introduced into the coating formulation as finely ground metal or powdered metal oxide. Oxides of lead, chromium, and iron (burnt sienna,[15] burnt umber,[16] and Tuscan red[17]) have been extensively used in the past. Currently, their usage is restricted because of toxicity considerations and their effect on the environment. However, it should be pointed out that the inhibiting protection provided by pigments such as red lead (also called *minium*, Pb_3O_4 or $2PbO \cdot PbO_2$), yellow zinc chromate ($ZnCrO_4$), and red zinc chromate ($ZnCrO_4 + Fe_2O_3$) is very satisfactory. Anti-corrosive primers based on such compounds have been used for a long time to satisfactorily protect metal structures exposed to a variety of hostile environments.

Zinc phosphate (ZP), barium metaborate, and strontium chromate pigments are also common ingredients in corrosion-inhibiting coatings. Thin wash-inhibiting primers are often formulated with chromate or phosphate pigments that are introduced in a synthetic polymeric binder such as a vinyl chloride copolymer. The variety of inorganic corrosion-inhibiting pigments includes also lead carbonate, strontium chromate, zinc oxide, and ZP.

Chromate-Based Compounds

Due to their excellent cost/efficiency ratio, chromates are one of the most used chemicals in corrosion protection systems for metallic surfaces. These anti-corrosive pigments are incorporated into paints in the form of solid, fine particulate materials that are dispersed throughout the paint film. They function as inhibitors, affording protection by an electrochemical mechanism. The chromate-containing, corrosion-inhibiting pigments include the sparingly soluble chromates of the alkaline earths, Ca, Sr, Ba, and Zn. They provide a source of active, inhibiting Cr^{6+} compounds that act as very powerful, effective corrosion inhibitors.

Chromate-based compounds are used in primers throughout industry as a component in corrosion protection systems for a range of metal substrates—even substrates exposed to aggressive environments of high chloride/chromate ratios. The oxo-anions of hexavalent chromium uniquely inhibit the corrosion of many metals and alloys, and they have been particularly useful for protecting the high-strength aluminum alloys against corrosion. Chromates are excellent inhibitors of oxygen reduction in near neutral and alkaline solutions. In these environments, they can stifle corrosion by suppressing the cathodic oxygen reduction that is the necessary partial reaction of the corrosion process.

The inhibition mechanism appears to involve reduction of Cr^{6+} to Cr^{3+} at a metal surface and formation of an irreversibly adsorbed Cr^{3+} hydroxide surface layer of near-monolayer thickness [10]. The results indicate that the adsorbed Cr^{3+} film formed by Cr^{6+} reduction is a powerful inhibitor of oxygen reduction on surfaces of aluminum and its alloys. This is due both to occupation of any active chemisorption sites and to inhibition of electron transfer. In the context of corrosion protection, Cr^{6+} acts as a "site-directed" irreversible inhibitor that migrates to active sites

[15] Sienna: Natural yellow-brown color pigment, the mineral limonite FeO (OH) · nH_2O, used in the production of oil paints. Along with ochre and umber, one of the first pigments used by humans for painting. Chemically, burnt sienna (a warm mid-brown iron oxide pigment) is formed by burning raw sienna.

[16] Umber: Natural brown clay pigment that contains iron and manganese oxides. The dark brown pigment burnt umber is made by heating umber, and it is used for oil and water color paint.

[17] Tuscan red: The mineral hematite (ferric oxide), it is the principle coloring agent in red ochres, such as Indian red, Terra Pozzuoli, Venetian red, etc. These pigments are basically hematite associated with varying proportions of mineral impurities such as clay, chalk, and silica.

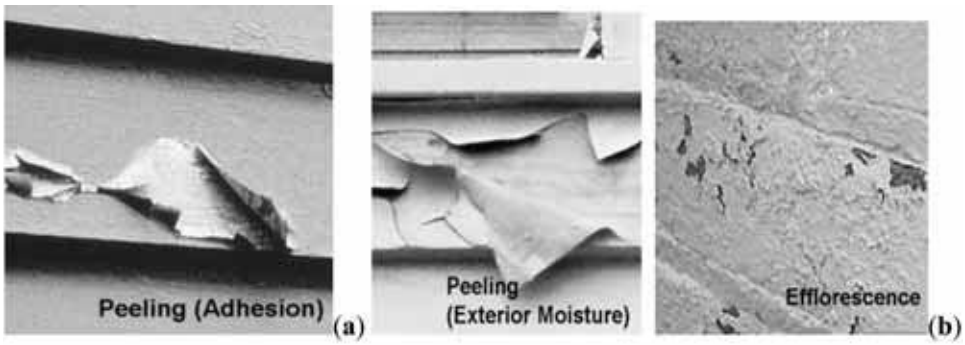

Fig. 3—Peeling (*a*) and efflorescence (*b*) failures in paint coatings.

for the oxygen reduction reaction. Here it is reduced to Cr^{3+} and forms a permanent inhibiting monolayer. The Cr^{3+} film formed is nonconductive and inhibits further Cr^{6+} reduction and outer-sphere redox processes. Evidence from older and more recent studies indicate that inhibition of aluminum corrosion is derived from both inhibition of oxygen reduction and inhibition of metal dissolution reactions mainly due to a delay in the onset of pitting. Inhibition of corrosion by chromates appears to be closely linked to their ability to irreversibly adsorb onto metal and oxide surfaces.

Chromates can also inhibit corrosion by slowly leaching from the protection system and migrating through moisture on the substrate surface where reaction with actively corroding sites takes place. This scheme results in passivation and suppression of pitting and crevice corrosion [11–13]. When present in even a very small concentration (as ~$10^{-4}M$), the dichromate ions (CrO_4^{2-}) effectively decrease the metastable pit nucleation rate and minimize pit growth rates that occur as a consequence of aggressive chloride ions attack. This has a large effect in the cathodic region and no effect in the anodic region. These observations suggest and confirm that chromate or its reduction product act as efficient cathodic inhibitors.

The distribution of $SrCrO_4$, $BaSO_4$, and TiO_2 in two chromate-inhibited primers has been characterized using electron microprobe analysis, Raman spectroscopy, x-ray diffraction, and position annihilation lifetime spectroscopy [14]. It was found that TiO_2 was evenly dispersed throughout the primer, while $BaSO_4$ and $SrCrO_4$ appeared as larger particles or platelets with sizes on the order of several microns. When immersed in solutions of *p*H 1, 3, 5, and 7, $SrCrO_4$, and possibly $SrCr_2O_7$, was observed to leach out of the primers after water uptake by the primer and dissolution of $SrCrO_4$ particles. The amount of chromate leached from the primers was greatest for *p*H 1, followed by *p*H 3, 5, and 7.

Kendig and Buchheit [15] have published a critical review that deals with the aqueous chemistry of chromium and the origins of chromium toxicity.

Zinc-Rich Paints

Anti-corrosive zinc-rich paints provide corrosion protection by two principal mechanisms:

a) Galvanic or sacrificial protection.[18] This is due to the fact that the standard electrode potential[19] of zinc (–0.76 V) is more negative than that of iron (–0.44 V), therefore in a zinc-iron (steel) coupling, zinc will take the role of sacrificial anode that corrodes (oxidizes) preferentially to iron. In this manner, zinc is protecting the steel (iron) surface from corrosion. Since this occurs, it indicates that very good electric contact between the zinc particles and metal substrate had been achieved and maintained. Due to the presence of coating defects (porosity), it is understood that the zinc-rich coating acts as a porous electrode.

b) Physical barrier protection. The physical barrier behavior of ZRPs is reinforced by the nature and quantity of zinc corrosion products. These products result in formation of a dielectric layer on the steel surface; moreover, these products are less voluminous than steel products, and, as a consequence, they do not exert a great deal of pressure on the organic coating.

Different ZRPs have been tested in industrial atmospheres. For example, when primers based on silicate and on epoxide (70 % and 79 % Zn powder, respectively) were investigated, the results indicated that the primers based on silicate provided better galvanic (sacrificial) protection than the epoxy primer. It is thought that in the coating the zinc particles are in electric contact with each other and also with the metal substrate (Fig. 4). With the zinc particles interconnected, sufficient galvanic (cathodic) protection is available to protect the metal substrate. However, while the zinc corrosion products are not as voluminous as with some primer systems, they produce a number of blisters in the paint coating [Fig. 4(*a*)]. Moreover, the migration paths for anti-corrosion agents through the organic coating could be achieved through the pore defects in the coating [Fig. 4(*b*)].

Zinc Oxide-Containing Systems

Powdered zinc oxide was introduced as an inhibitive, anti-corrosion pigment for primer formulations in the past few decades. Typically the pigment was used at 33–57 mass % of the primer composition. It contributed to successful anti-corrosion protection of metallic structures exposed to marine atmospheres, i.e., highly chloride-contaminated environments. Various organic compounds such as epoxy esters, galic acid (antioxidant) polyesters, polyurethanes, and the like are used as the binder for zinc oxide coatings. It should be noted that several physicochemical properties of zinc-rich paints (specific gravity, oil absorption, and other properties of a pigment inhibitor) may be affected due to the pigment volume concentration (PVC) considerations. More than 25 years of paint evaluation at the Kennedy

[18] Sacrificial protection: Reduction of corrosion of a metal in an electrolyte (humidity) by galvanically coupling it to a more anodic metal having more positive electrode potential.

[19] Electrode potential: The potential of an electrode in an electrolyte as measured against a reference electrode.

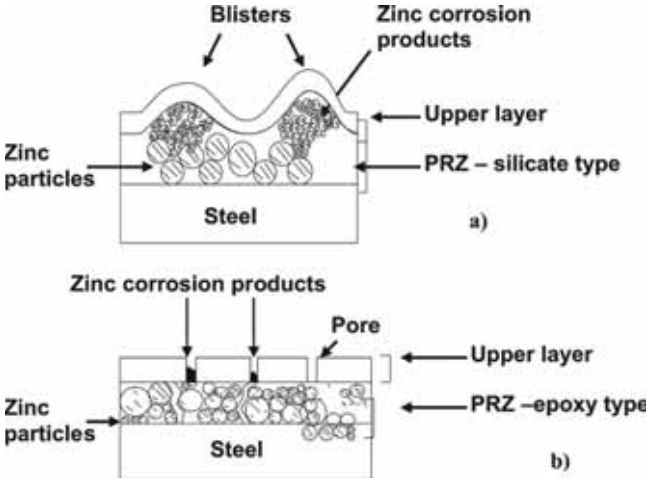

Fig. 4—Schematic representation of corrosion in steel protected by zinc-rich paint (ZRP): model of blister (*a*) and corrosive attack through the coating pore (*b*).

Space Center (marine-coastal test station) has identified the fact that zinc-rich paints are the best choice for corrosion protection of launching equipment and support equipment in service on land.

During production of zinc pigments, some zinc may get oxidized to ZnO when it comes in contact with oxygen and eventually all zinc dust will contain at least traces of ZnO as an impurity. The electrical properties of ZnO are interesting and complex. ZnO acts an inhibitor to chloride-induced corrosion, seals pores in primers, and improves the primer's barrier properties. Therefore, it has been interesting to include ZnO in a Zn-rich primer and to study its effect on corrosion-protection properties [16]. In the reported study, the effect of spherical ZnO on anti-corrosion properties was evaluated along with lamellar zinc. ZnO was added in various weight fractions to an epoxy-based primer at 60 % PVC. These coated panels were evaluated along with others for conductance, packing density, and morphology. Corrosion resistance was measured after a 3,000 h exposure in a salt spray. Open circuit potential (i.e., corrosion potential) was measured in a 3.5 wt % NaCl salt solution. When Zn and ZnO are mixed together, they quite likely formed *ap-n* junction at their interface. At a contact established between a metal and a semiconductor (known as a Schottky junction), electrons will flow from the material with the highest Fermi level to that with the lowest Fermi level, creating a positive charge in the semiconductor. This will allow electron transport in a controlled manner on the top surface of the coating, which provides better cathodic protection for the Zn-ZnO combinations rather than for Zn only. The packing density was better at 15 wt % ZnO, which implies that the compactness was enhancing junction formation. The best corrosion protection was obtained with 15 wt % of ZnO. Hence, Zn–ZnO *p-n* junction formation gives better corrosion resistance properties than either cathodic or barrier protection alone, and the combination would be the best choice for single-coat metal primer.

Electrochemical behavior of epoxy anti-corrosion paints based on zinc molybdenum phosphate and zinc oxide pigments has been studied. The main investigative tool used to describe the efficiency of epoxy-based anti-corrosion primers was electrochemical impedance spectroscopy (EIS) [17]. The film-forming material (binder) in these studies was a solvent-borne, bisphenol A epoxide polyamide, and several pigments were used with this binder. The main anti-corrosion pigment used was micronized ZnO (average particle diameter 1 mm) at loading levels of 10 % and 30 % by volume and with respect to the total pigment content. The complementary pigments used were ferric oxide (Fe_2O_3) and barium sulfate ($BaSO_4$). Twenty percent by volume of the resulting pigment mixture were replaced with zinc oxide. The ferric oxide was used because its colloidal particles are said to interact with metallic substrates and thereby increase coverage. Steel-coated samples were exposed to a 0.5*M* NaCl solution and during the test their corrosion potential was monitored every 24 h. The results indicated that addition of micronized ZnO to the base mixture had a positive reinforcement effect on the protective properties of the anti-corrosion primer. This was thought to be related to the isoelectric point of ZnO particles ($pH < 9$), which determines their positive surface charge and electrostatic attraction with the molybdate anion. In this case, the double-layer capacitor formed has a very high charge. Moreover, this strong attraction inhibits and saves ZnO particles from rapid dissolution by hydroxide. These results also indicate that there is an optimum concentration ratio of zinc molybdenum phosphate to zinc oxide that will ensure the good anti-corrosion properties.

Zinc Phosphate

ZP is the most commercially successful non-toxic inhibitive pigment used in paint formulations. Furthermore, the use of phosphates does not represent an excessive cost, and their application is even easier than other proposed alternatives for chromate pigments. This is the anti-corrosive pigment most frequently used in paints [18–21]. The massive use of nontoxic and environmentally acceptable ZPs developed an immense pressure for regulations that prohibited the use of red lead and chromated anti-corrosion pigments. Experimental results suggest that ZP and all phosphate-based pigments (zinc-aluminum polyphosphate, ZP modified with organic corrosion inhibitor, etc.) exhibit improved anti-corrosion efficiency when their concentration is increased [21].

The effect of ZP over the barrier properties of different paints has been studied using a variety of techniques. The investigations revealed that commercial ZP powder was a mixture of the dihydrate and tetrahydrate species, however, when it is blended with a polymeric binder, only the tetrahydrate form was detected. Incorporation of this pigment into a paint led to a definite improvement of the barrier properties. This was particularly apparent in the case of chlorinated rubber polymers. The finding suggests that the nature of binder-pigment interactions play an important role and should be given consideration in studies of barrier properties [22].

To improve the protective action of "environmentally acceptable" coatings, a second generation of materials aimed at combining, in a synergistic manner, the corrosion inhibition properties of phosphates and molybdates, called phosphomolybdate pigments, has been developed. Zinc molybdenum phosphate seems to be one good possibility, and it is claimed to have equal or superior anti-corrosion behavior when compared with chromate and ZP. From a corrosion point of view, when zinc molybdenum phosphate

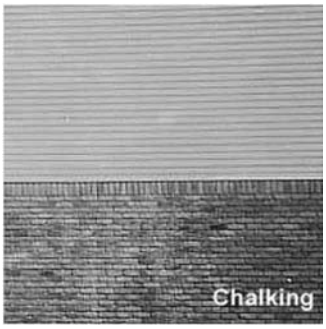

Fig. 5—Chalking of paint coating.

pigment is added to a water-borne paint and applied as a unique protective coating to a steel substrate, an interesting combination for study exists [23]. Paint with PVCs of 27 % and 10 % (v/v) of this pigment provided effective protection against weather conditions and improved properties such as chalking (Fig. 5), gloss, and yellowing. Similarly, the efficiency of zinc tripolyphosphonate (ZTPP) as an anti-corrosion pigment has been evaluated [24]. Solvent-borne paints containing $BaSO_4$, talc, and TiO_2 together with 30 % or 10 % v/v (by volume) of ZTPP, with respect to the total pigment content, have been formulated. Two polymers were chosen as film-forming materials: an alkyd and an epoxy-polyamide (1:1) mixture. The results demonstrated that ZTPP inhibited corrosion when incorporated into a paint film. It showed excellent performance when employed with the alkyl resin.

It should be pointed out that even though the literature reports indicate phosphate-based pigments to be "environmentally acceptable" and ZP is classified as "not hazardous" to human health under United States' regulations, according to other regulations of the United States and the European Union, ZP is considered "very toxic in an aquatic environment." Therefore, ZP-based pigments should not be qualified as "environmentally friendly" products. With this information in mind, the aim of a reported study [25] was to evaluate the anticorrosive performance of organic epoxy coatings pigmented with the following non-toxic pigments: ZP, zinc phosphomolybdate (ZPM), and zinc calcium phosphomolybdate (ZCPM). All of these coatings were compared with an epoxy coating pigmented with zinc chromate (ZC). The analysis was based on coated steel samples immersed in aqueous 0.01 mol/L sodium chloride solutions and in accelerated tests conducted in a salt-spray chamber. ZPM and ZCPM coatings performed best in the total immersion test, but in the salt spray test, the corrosion inhibitor performance of all three pigmented coatings was similar. This suggested that only in the less aggressive test is it possible to detect any difference between the coatings when investigating the non-toxic pigments.

Zinc Ferrites

The synthesis of zinc ferrites ($ZnFe_2O_4$) with different particle shapes for applications in anti-corrosion coatings provides a new way of protecting metals against corrosion [26]. One benefit obtained with these anti-corrosion pigments is the fact that they do not contain any environmentally harmful substances. They are synthesized through a high-temperature process that is conducted from about 600 up to 1,100°C from hematite (alfa-Fe_2O_3), goethite (alfa-FeO·OH), magnetite (Fe_3O_4), and specularite (Fe_2O_3) entering into a solid phase reaction with zinc oxide (ZnO). The formulated zinc ferrites particles have a rod-like, lamellar, and/or isometric shape. The zinc ferrites were used to prepare coatings with epoxy and with water-borne styrene-acrylate binders that were subjected to post-application tests for physical-mechanical and anti-corrosion properties. All of the synthesized pigments had good anti-corrosion efficiency in the binders studied. When compared with a commercially available anti-corrosion pigment, their protective power in coatings was demonstrably stronger.

Magnesium-Rich Primer

When two metals are exposed to a corrosive environment and placed in contact with each other, the more active metal will preferentially corrode and thereby provide sacrificial protection for the nobler or less active metal. This concept has been applied for many years by use of ZRPs for the protection of steel. Investigations using other compositions and metals, including manganese, have been made [27]. Zinc dust and magnesium-powder as pigments have been incorporated in epoxy-polyamide and butyl-titanate binders, with PVC that ranged from 20 to 74. These protective coatings were applied to mild steel substrates and immersed in an aqueous 3 wt % sodium chloride solution and the corrosion currents were measured to characterize corrosion performance. The results were found to be comparable indicating that magnesium-powder can be used an alternative to Zn-powder for metal-rich primers.

The electrochemical behavior of Mg-rich primer on aluminum alloys (specifically, AA2024 and AA7075) has been studied with EIS, open circuit potential, and potentiody-namic polarization [28,29]. Results showed that the magnesium-rich primer provides sacrificial protection for the aluminum substrate by means of a two-stage mechanism. In a first stage, corrosion of aluminum is prevented by cathodic polarization. Magnesium cathodically polarizes aluminum and shifts its potential below the pitting corrosion potential. The consequence of this polarization can be either the prevention of pit nucleation at the exposed aluminum areas or the inhibition of pit growth in the nucleated pits. During this stage, any defects on the surface will become cathodic whereas the magnesium particles are anodic. At the cathodic areas, reduction of hydrogen takes place and possibly dissolved oxygen increases the *p*H above the threshold for the precipitation of magnesium oxide. This precipitation leads to the formation of a porous layer that further inhibits corrosion by a barrier mechanism, which is considered to be the second or later stage of the protective mechanism. The typically high dissolution rate of magnesium is significantly decreased by its incorporation into the polymer matrix.

Iron Oxides

The iron oxides represent an important category of inorganic pigments in which iron is most often present in a trivalent form. Oxides, or rather hydroxide-oxides, can be used as pigments in paints [30]. Ferric oxide is usually introduced in the total pigment formula because its colloidal particles are said to interact with metallic substrates increasing its coverage. Yellow-goethite α-FeOOH with needle-shaped particles, red hematite alfa-Fe_2O_3 with granular particles, and specularite Fe_2O_3 with lamellar particles

so called iron mica, have been tested. The main features of the coatings containing these ferric pigments are the improvement of light stability and the resistance to weather conditions and ultraviolet radiation. The parallel-oriented lamellar particles of specularite moreover reinforce a paint film, improve its mechanical properties, and reduce internal tension.

Silicate-Based Pigments with Non-Isometric Particles

Talc, $Mg_3(OH)_2(Si_4O_{10})$, is a hydrated magnesium silicate that belongs to the group of silicates with a layered structure. It consists of electrically neutral layers without inserted cations, and this construction gives rise to qualities such as softness, smoothness, and lubrication. Its particles are disk-like, lamellar, or micro-fibrous. Talc is resistant to acids, has a low electric conductivity, and has high coating power. It positively influences the rheological properties of liquid paint and improves adhesion, strength, and anti-corrosion properties of the coating [29].

Wollastonite is a calcium meta-silicate, $CaSiO_3$ (structural formula: $Ca_3Si_3O_9$). It forms columnar needle-like or radial straw-like white crystals. It can be split into very fine fibers whose length to width ratio is 5:1 to 10:1 and can even exceed 20:1. Wollastonite is a chemically inert substance with low moisture content as well as suitable thermal and electrical properties. It belongs to a silicate family that has chain-like structures (SiO_4). Chain metasilicates $(SiO_3^{2-})_n$ are created by sharing of SiO_4 tetrahedron structures. The needle-shaped particles fit into each other well and reinforce the coating, improve ductility, have balancing effects, and facilitate creation of an even coating thickness.

The most effective pigment series comprises iron mica (silicate), muscovite mica [aluminum-potassium silicate, $(KF)_2(Al_2O_3)_3(SiO_2)_6(H_2O)$], and aluminum or glass flakes.

Graphite

Graphite is a key additive that provides a combination of color, conductivity, and ultraviolet radiation stability in coatings and other products. It is a high-purity, microscopic form of carbon produced by thermal cracking of a hydrocarbon raw material. The formation process consists of atomizing a heavy aromatic fraction of petroleum distillate in a preheated furnace followed by cooling and collecting the formed carbon black. The graphite lattice exists in the hexagonal structure of carbon. Graphite is found in a macrocrystalline (flaky), micro-crystalline, and even crypto-crystalline (amorphous) form. Particulate graphite (metalliferous) is rare. Unlike synthetic electrographite, natural graphite with a lamellar structure is often contaminated with various admixtures of forms.

The industrially important properties of graphite include excellent splitting capacity and plasticity, chemical and thermal resistance, and high thermal and electric conductivity. Graphite can be used in color coatings as a pigment with high chemical, ultraviolet radiation resistance and light stability. This pigment is also capable of arranging itself into barrier lamellar structures. Experimental results have shown that the best anti-corrosion efficiency is displayed by a pigment based on natural graphite due to the coating of particles with a polyaniline (PANI) layer [30]. The lamellar particles of graphite coated with the conductive form of PANI contributes to modification of conducting properties as well as to improved barrier and anti-corrosion efficiency.

Titanium Dioxide (TiO_2)

Titanium dioxide is an important white inorganic pigment that is used to provide hiding in paint. It is also called titanium white, Pigment White 6, or CI 77891. It is used as a pigment and a thickener that increases the viscosity and stability of the paint mixture and improves the suspension of added ingredients. Titanium dioxide has excellent chemical stability, heat resistance, and low electron conductivity, features that make it an excellent anti-corrosion pigment. Titanium dioxide is used in a finely suspended state and in a viscous medium to formulate paints. The medium may be a solution of a polymeric compound in an organic solvent or aqueous latex.

Titanium dioxide is a naturally formed mineral that is well known in its different structural forms as rutile (tetragonal), anatase (tetragonal), and brookite (orthorhombic). The most stable and common form is the mineral rutile. Titanium dioxide is considered as a mineral ultraviolet (UV) radiation blocker because of its high refractive index, its strong UV radiation absorbing capabilities, and its resistance to discoloration under UV radiation. In addition, it has strong photo-catalytic properties (Honda-Fujishima effect) and oxidative potential. Because of these facts, TiO_2 can directly oxidize oxygen or organic materials when, for example, it is added to anti-fouling paint. Incorporated into exterior paint for buildings, TiO_2 can substantially reduce airborne pollutants, such as volatile organic compounds (VOCs) and nitrogen oxides, because it becomes increasingly hydrophilic when exposed to UV radiation.

Titanium dioxide flocculation has a detrimental effect on opacity and other paint properties. It has been established that flocculation increases as a function of alkyd emulsion particle size. Mathematical modeling work has been used to compare theoretical light-scattering efficiency of alkyd emulsion paints with the measured scattering coefficients. An experimental proprietary flocculation-resistant grade of titanium dioxide has been incorporated into alkyd emulsion paints to demonstrate the beneficial effect on opacity that occurs when the level of flocculation in alkyd emulsion paints is reduced.

Titanates

An anti-corrosion pigment combination based on calcium titanate ($CaTiO_3$) with a perovskite[20] structure (Fig. 6) has been synthesized from titanium dioxide (TiO_2) and calcium carbonate ($CaCO_3$) in a high temperature reaction [31]. From an ecological standpoint, the application of a new anti-corrosion pigment for paints represents a highly positive trend. The synthesized pigment was used

[20] Perovskite structure: Any material with the same type of crystal structure as calcium titanium oxide ($CaTiO_3$), which is known as *the perovskite structure*. The general chemical formula for perovskite compounds is ABX_3, where A and B are two cations of very different sizes and X is an anion that bonds to both. The A atoms are larger than the B atoms. The ideal cubic-symmetry structure has the B cation in six-fold coordination, surrounded by an octahedron of anions, and the A cation in 12-fold cuboctahedral coordination (Fig. 6).

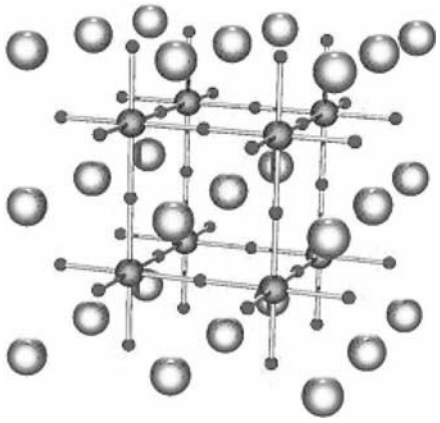

Fig. 6—Perovskite structure ABO_3. The red spheres are oxygen atoms, the deep blue are smaller (Ti^{4+}) metal cations (*B*-site) and the green/blue are the larger (Ca^{2+}) metal cations (*A*-site).

to prepare epoxy coatings with varying anti-corrosion pigment concentrations. The coatings were tested for physical-mechanical properties after exposure in corrosive atmospheres. The results were compared with the same titanium dioxide that served as a starting material for calcium titanate preparation. It was found that $CaTiO_3$ is a highly efficient anti-corrosion pigment for use in paints to protect base metals from corrosion.

Inorganic Oxoanionic Inhibitors

Inorganic oxoanionic compounds are considered as environmental safe materials. Common oxometallate anions are the molybdates (MoO_4^{2-}), phosphates (PO_4^{3-}), tungstates (WO_4^-, WO_3^{3-}), silicates (SiO_3^{2-}), vanadates (VO_3^-), and borates ($B_2O_4^{2-}$). With the exception, perhaps, of zinc, the most common inorganic cationic inhibitors are, for example, the rare earth cations, as La^{3+}, Nd^{3+}, Eu^{3+}, Y^{3+}, Ce^{3+}, Gd^{3+} [32]. However, it should be pointed out that these inhibitors have similar performance characteristics to those of chromate-based inhibitors, and they should provide corrosion inhibition over a wide *p*H range.

The use of rare earth salts of cerium and lanthanum [$Ce(NO_3)_3$ and $La(NO_3)_3$] and bis-sulphur silane (BTESPT) as chromate substitutes for galvanized steel conversion coatings has been proposed [33]. These compounds when applied by immersion and subsequent curing result in films that improve corrosion resistance and paint adherence. The two-step pretreatments result in good corrosion protection; however, the best performance was obtained with the lanthanum conversion coating. This was observed either on un-coated and coated substrates. The silane (BTESPT) by itself also shows some improved corrosion protection. The presence of the sulphur atoms on the silane molecule seems to play an important role in the deposition process. Thus, it can be suggested the presence of an internal layer rich in sulphur and zinc hydroxides/oxides together with the silane helps improve corrosion resistance.

Phospho-Molybdate Pigments

Phospho-molybdates are considered second-generation corrosion-inhibiting pigments that have been introduced in solvent- and water-based paints. Anti-corrosive pigments based on molybdate are recognized as effective corrosion inhibitors for coatings and these pigments are well established and have been commercially available for over 20 years. As environmental constraints continue to limit the use of many types of corrosion inhibitors and paints based on heavy metals, molybdate pigments are increasingly being specified for environmentally compliant paint systems.

Ongoing research has led to the development of "second generation" molybdate pigments, which are described as phospho-molybdate pigments. These compounds are believed to have exceptional corrosion-inhibiting activity. Recently completed testing, based on long-term outdoor exposure, indicates that they can provide better performance than traditional chromate-based corrosion inhibitors. In another development, phospho-molybdate pigments have been used to formulate a water-based acrylic coating system that was recently approved by the Florida Department of Transportation for bridge coatings.

Ion-Exchange Pigments

Ion-exchange pigments (IEPs) are a relatively new class of inhibitive pigments. They are one of the alternatives that could be adopted as non-toxic anti-corrosive pigments in paints. From a scientific viewpoint, they appear to be very attractive candidates. These compounds are inorganic oxides with a comparatively high surface area and that are loaded with ionic corrosion inhibitors by ion exchange with surface hydroxyl groups. As might be expected, the oxides are chosen for their acidic or basic properties to provide either cation or anion exchangers—thus, silica is used as a cation support and alumina for an anion support. The corrosion-protection behavior of these pigments is controlled by the rate of ion release by the exchanger. The ion-exchange release mechanism allows efficient use of a comparatively low loading of inhibitive pigments.

Calcium-exchanged silica, Al–Zn-decavanadate hydrotalcite (HT), and cerium (III) and calcium (II) cation exchanged bentonites have been incorporated as pigments in anti-corrosive paints. The other advantage of this approach is that it allows use of otherwise highly soluble inhibitors. With knowledge of process kinetics for ion release within the primer, it is possible to control the accessibility of inhibitors and therefore to control its diffusion onto the metal surface. The inhibition mechanism is related to the ion-exchange reaction. On exposure of paint films to an aggressive environment, water uptake occurs and exchange of calcium with hydrogen and ions and release of calcium ions takes place.

HTs, as anion exchange compounds, are layered clay materials and are used for a variety of industrial purposes. In general, they consist of a host structure with a fixed charge. Specifically, HTs are being synthesized with vanadates (HT/V), which have been shown to be excellent inhibitors of Al corrosion [34]. The ion exchange characteristic of HTs is used to release vanadates into an attacking electrolyte and stifle corrosion. In the case of HT/V, the host is a mixed Al–Zn hydroxide that is positively charged. The positive charge originates from the substitution of Al^{3+} on Zn^{2+} sites within the structure. Within the host, there are open channels or "galleries" that can accommodate anions and solvent molecules [35]. Cations may also be incorporated in the "gallery" provided that overall electro-neutrality is

maintained in the solid, but in the initial state, HT/V contains inhibiting anions in the gallery. On contact with an aggressive electrolyte containing chloride ions, an exchange reaction will occur in which the inhibitor anion is released and chloride is adsorbed into the HT gallery.

Experiments have shown that HT compounds dispersed as an additive in organic (epoxy) compounds led to potent corrosion inhibition of an underlying aluminum alloy substrate. Corrosion inhibition is derived from release of a decavanadate from crystalline Al–Zn hydroxide-based HT particles into electrolyte that has permeated the pore space of the coating. Decavanadate release is accompanied by uptake of chloride ion in an exchange reaction. The exchange of the large decavanadate anion for smaller chloride ion in the HT structure results in a predictable change in crystal structure, which can be detected by x-ray diffraction. The use of this additive also imparts the ability to detect environmental changes in the coating that are a prelude to substrate corrosion.

It was demonstrated that the anti-corrosion performance of paint pigmented with calcium-exchanged silica (Ca/Si) is at least equal to or better than that obtained with paints containing ZP [36] and closely approaching that of chromate while having better efficiency than iron oxide [37]. The results suggested a film-forming mechanism for calcium/silica coatings. Calcium, released from the silica surface, migrates to the paint-metal interface where a thin, inorganic layer is deposited. This layer is essentially impermeable to moisture/ions and hence prevents the corrosion reaction from proceeding. The anticorrosive effect of Ca/Si pigment can be described by considering two mechanisms: the exchange of calcium ions for cations (H^+, etc.) that are penetrating the coating from the environment, neutralizing the acid compounds and forming a protective layer consisting of calcium and iron silicate on the substrate [38]. Combinations with other active anticorrosive pigments (ZP/molybdate, for example) are generally possible and may be advantageous.

Novel corrosion-inhibitor pigments consisting of cerium (III) and calcium (II) cation-exchanged bentonites have been shown to provide effective cut-edge corrosion resistance in organic coated galvanized steel. The bentonite pigments were prepared from a naturally occurring bentonite with a cation-exchange capacity of 0.7 milliequivalents/g. Cation exchange was carried out by repeated washing with aqueous solutions of cerium (III) chloride and calcium (II) chloride to produce bentonites containing 31,500 ppm exchangeable cerium (III) and 13,500 ppm exchangeable calcium (II), respectively. The resulting bentonite pigments were dispersed in a polyester-based primer paint system to give a PVC of 19 %. For comparison, two similar primer systems were prepared containing a commercial calcium (II) exchanged silica pigment [Shieldex: 60,000 ppm calcium (II)] and a strontium chromate dispersion, both at a 19 % PVC. All primer systems have been applied to the zinc surface of galvanized 0.7 mm gauge sheet steel and over coated with an architectural polyester topcoat. The performance of the inhibitor pigments was compared by measuring the rate of corrosion-driven organic coating delamination from the cut edge of samples during 1,000 h of salt-spray testing. The calcium (II) bentonite pigment exhibited an anti-delamination performance similar to that of strontium chromate but superior to that of Shieldex. However, the cerium (III) bentonite pigment was superior in performance to both strontium chromate and Shieldex. Thus, the bentonite pigments represent promising, environmentally friendly, ion-exchange corrosion inhibitors that exhibit good anti-delamination performance in comparison with current commercial systems [39]. A schematic representation of the macro-structure of a bentonite clay is shown in Fig. 7.

Recent research, which focuses on the anti-corrosive protection of IEPs in alkyd coatings applied on low carbon steel specimens and formulated with anionic (vanadates-HT, HT/V 10 %) as well as cationic (calcium/silica, Ca/Si 5 %–15 %) ion-exchangeable pigments, has been reported [40]. The investigation compared the anti-corrosion efficiency of these IEPs with traditional ZC pigments. The results revealed that the anticorrosive behavior of $ZnCrO_4$ (10 %) stands out above that of the two IEPs considered in this study. The anti-corrosive performance of IEPs depends on the medium in contact with the coating. The anionic HT/V shows a tendency toward a better behavior in chloride environments (salt fog test, 0.5*M* NaCl solution) while the cat-ionic Ca/Si behaves well in non-chloride environments [humidity condensation and SO_2 (0.2 L)]. Good behavior was found for the Ca/Si pigment at the intermediate concentration of 10 %. The other two studied concentrations (5 % and 15%) afford the coatings that are highly deficient anticorrosive properties.

An electrochemical evaluation of the corrosion protection afforded by environmentally friendly coating systems that were applied on hot-dip galvanized steel samples has been reported [41]. The primers used polyphosphate (26 % P_2O_5) and anti-corrosive IEPs ($A1_2O_3$, CaO, SiO_2). Two types of coating systems were studied. The first series of metal samples was galvanized steel covered only with primer, and the second series were complete coating systems consisting of primer and topcoat. The results revealed that the pigments had a significant inhibitive effect, and they acted as cathodic inhibitors. The pigment action resulted in layer deposition on the metal surface and in reducing the corrosion rate. The barrier properties of the complete coatings (primer plus top coat) were not critical. On the contrary, the presence of low barrier properties and therefore a limited water uptake caused the pigment dissolution to induce the activation of the pigment inhibitive action.

The few studies conducted with IEPs are inconclusive about their anti-corrosive efficiency, and controversy surrounds their functioning mechanisms, interchange capacity, and anticorrosive performance.

Super Primers

The concept of a super primer is relatively new. When bis-silanes (SiH_4) are mixed with conventional primers or binders, they have been shown to impart excellent corrosion protection [42]. The concept of super primers, i.e., primers for metals with the conversion coating built in, has proven to be feasible. Such primers do not require a chromate (or other) conversion treatment of the metal and can be applied on any bare metal (Fig. 8). The VOCs content in the primer is kept low by using water-dispersed organic polymers. Because of the high concentration of organo-functional silanes contained in a super primer, its adhesion, both to the substrate and to primer overcoats,

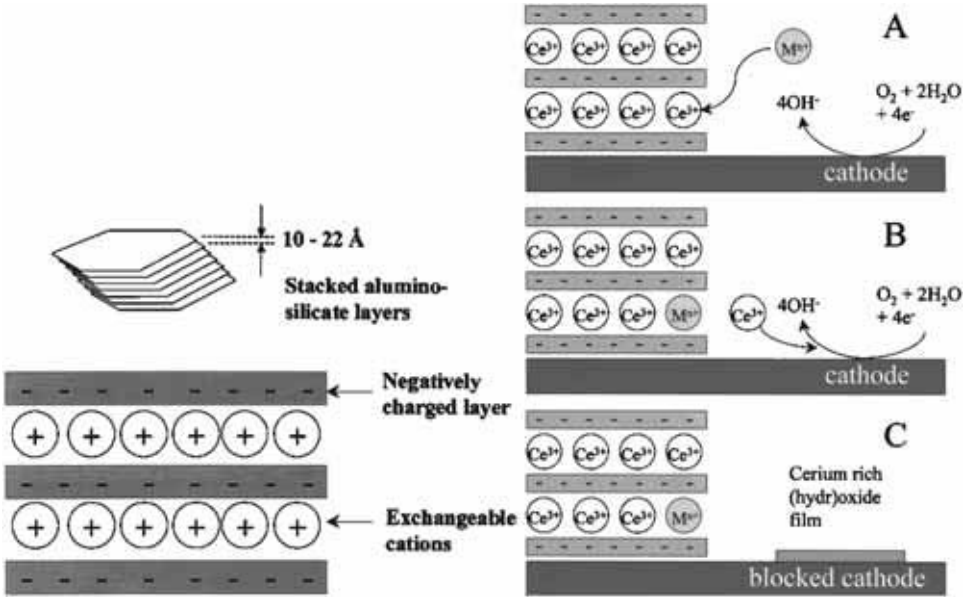

Fig. 7—(a) Schematic representation of the macro-structure of a bentonite clay. The negatively charged layers, with exchangeable compensating cations between them, are held together electrostatically. (*b*) Schematic illustration of the potential mode of operation of a cation exchanged bentonite inhibitor pigment on a corroding galvanized surface. (*c*) Schematic illustration of the negatively charged layers blocked by the numerous compensating cations between them [39].

is excellent. The corrosion resistance of the primer can be further improved by adding corrosion-inhibiting pigments such as micronized ZP into the formulation. A set of super primers has been developed, and they have been put through performance tests and characterized with a variety of methods. An attempt to explain the mechanism by which one of the coatings, the epoxy-acrylate-based primer, deposited onto aluminum, protects the metal from corrosion, is given (Fig. 9).

The corrosion-protection mechanism of the epoxy-acrylate coating, which is self-assembled into layers after it was deposited from a water-borne dispersion, is unique. The chemistry of the coating facilitates leaching of the ZP on demand when the coating is scribed and attacked by an electrolyte. The chemistry of the coating allows the ZP to act as chromate ions would act in a regular coating when the coating is exposed to salt water. The chromate ions are well known to leach out only on demand, as when a polymer coating is exposed to a corrosive environment. The extensive study of the epoxy-acrylate primer has demonstrated that ZP pigment particles can in fact function as active "on demand" corrosion inhibitors in this coating that has been formed from a water-borne polymer dispersion. In this particular coating the ZP is able to leach out only from the hydrophilic acrylate-silane-ZP layer, creating a reservoir of saturated ZP in the surrounding salt solution. At the same time, the hydrophobic epoxy layer protects the acrylate containing layer and thereby the rest of the coated metal.

Pigments for "Smart" Anti-Corrosion Coatings

Under certain conditions, the driving force of corrosion produces protective oxide films, a process typically referred to as metal passivity. In cases where passivity is difficult to achieve, for example, as with aluminum alloys in neutral sodium chloride solutions, it is conceivable that a "smart" coating can be micro- or nano-engineered to use the energy of the corrosion process to on demand generate a corrosion inhibitor for stopping or slowing corrosion at defects. Work at Rockwell Scientific Company provides evidence

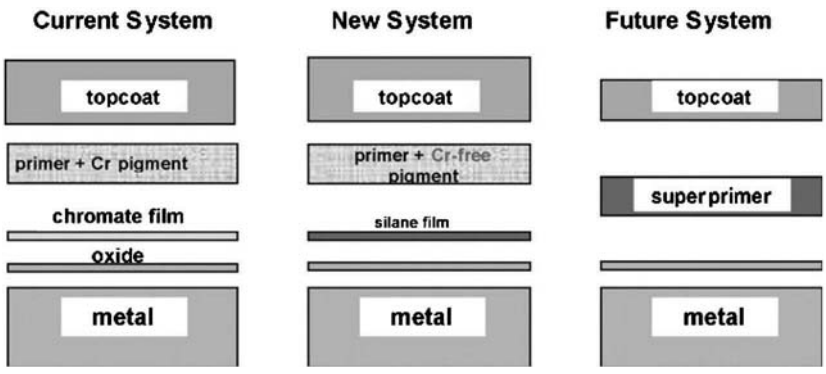

Fig. 8—Schematic of the superprimer coating system [42].

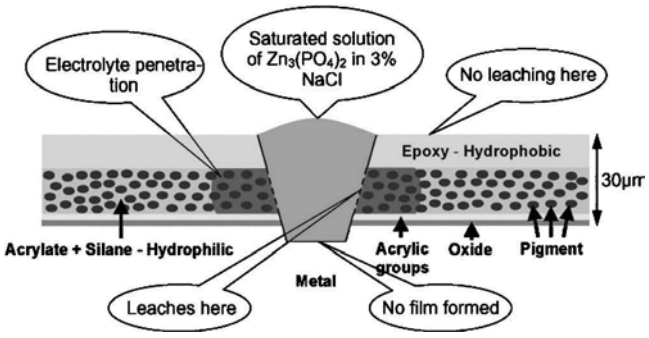

Fig. 9—Principle of the corrosion-inhibiting mechanism of the acrylate-epoxy-silane superprimer containing the ZP pigments, which protect the metal on-demand [42].

that anionic inhibitors for the oxygen reduction (cathodic) reaction, when used as dopants for conducting PANI films, inhibit corrosion of an aluminum (Al 2024-T3) substrate at a scribe [43]. In effect, the scribe polarizes the PANI, causing it to release the inhibitor.

PANI ranks high among electrically conducting polymers. Its high conductivity and chemical variability makes it suitable for a number of applications. In the course of polymerization, PANI has the ability to create thin conducting films with very good adhesion to various base materials [44]. To prove the retention of its inhibiting properties in a paint film, it was found advisable to apply this polymer in organic binders, where it would function as an organic corrosion inhibitor or an anti-corrosion pigment. Therefore, the main objective of a reported study was evaluation of the properties of organic coatings containing PANI and PANI in combination with other anti-corrosive pigments [45]. The adhesion, barrier, and anti-corrosion properties of the coatings containing PANI and selected chemically active pigments were studied as well as the combination of PANI with zinc dust. Epoxides of the bisphenol A type cured with a polyamine-based curing agent were used as a binder. To examine the synergic effect of PANI and anti-corrosion pigment in epoxy coatings, $Zn_3(PO_4)_2{\cdot}2H_2O$ with an acidic aqueous extract, $Ca_3(BO_3)_2$ with a basic aqueous extract, and $SrCrO_4$ with a neutral aqueous extract were tested. Comparison of the results of the corrosion tests revealed that the PANI plus $Zn_3(PO_4)_2{\cdot}2H_2O$ combination increased the anti-corrosion efficiency of organic coatings. Both these pigments utilize the acidic *p*H of the aqueous extract, and this may lead to very high anti-corrosion efficiency. The investigation of the total anti-corrosion efficiency of coatings with the PANI plus Zn-dust combination found that the PANI combination with a PVC of 5 % and Zn-dust [PVC/critical PVC (CPVC) = 0.65] achieves high anti-corrosion efficiency.

A new pigment for smart anticorrosive coatings, based on modified zeolite, has been proposed as a pigment for paints [46]. Alkyd paints were formulated by employing different anti-corrosion pigments: (1) 30 % by volume (v/v) of the modified zeolitic rock, (2) 10 % (v/v) of ZP, and (3) a mixture of 10 % (v/v) ZP plus 20 % (v/v) of the modified zeolitic rock. In every case, percentages were referred to the total pigment content. Titanium dioxide, zinc oxide, and barium sulfate were incorporated to complete the pigment formula. The PVC/CPVC ratio was 0.8. The performance of the resulting anticorrosive paints was assessed by accelerated tests in salt spray and humidity chambers and by electrochemical measurements of corrosion potential, ionic resistance, and polarization resistance. It was demonstrated that the modified zeolite is effective in protecting steel from corrosion when it is used in combination with ZP. There exists a synergism between the modified zeolite and ZP that allows the ZP content in anticorrosive paints to be reduced.

A group of mixed oxides with the structure of spinel and perovskite Zn–Al, Zn–Fe, and Ca–Ti inorganic pigments in combination with a conducting PANI phosphate layer were selected for the surface modification [30]. In many applications of paints, it is convenient to formulate a composite made up of inorganic particles (a pigment) with a suitable chemical composition that is coated with a functional layer of a conductive polymer. PANI has redox properties that can be used in protection against corrosion. When inorganic particles are suspended in the reaction medium used for the oxidation of aniline, they become coated with a thin (100 nm) layer of PANI. Such PANI modified particles have been tested in an attempt to find the potential synergetic effect and/or improvement of anti-corrosion properties. The study reports the anti-corrosion effects of various PANI-modified pigment particles in paints. Included in the study was another interesting group of functional pigments represented by iron oxides and silicates with various structures and diverse particle shapes. The last type of pigments included in the study was graphite of both natural and synthetic origin. Uncoated pigments and PANI powder have also been tested for comparison. Considering all the groups of pigments, the pigments coated with a PANI layer displayed the smallest corrosion loss. It is obvious that the extract of the pigments containing PANI contributes, with its optimum conductivity, to the passivation of the metal base. When testing paint films that contained mixed metal oxides, the pigments alone—that is, those without PANI coating—displayed improved corrosion resistance. The films based on iron oxides and silicate pigments exhibit similar results with regard to both PANI-coated pigments and pigments without coating. The excellent results of anti-corrosion efficiency were detected in the paint films that contained graphite-based pigments. The PANI coating of the synthetic graphite and especially of the natural form of graphite contributed to the marked enhancement of the total anti-corrosion efficiency of the paint film.

Needle-Shaped Anti-Corrosion Pigments

Use of synthesized, needle-shaped pigments in anti-corrosion paints for protecting metals is a new concept. The benefit of their use and method of synthesizing is that they do not contain heavy metals and are acceptable for the environment. The following pigments have been synthesized from oxides or carbonates at high temperatures: $ZnFe_2O_4$, $MgFe_2O_4$, $CaFe_2O_4$, $MgO{\cdot}2ZnO{\cdot}8Fe_2O_4$, and $CaO{\cdot}2ZnO{\cdot}8Fe_2O_4$ [47]. They were used to formulate epoxy coatings with a PVC of 10 % for the synthesized pigment and with the PVC/CPVC ratio of 0.3. The coatings were tested for physical-mechanical properties and in corrosion atmospheres. The test results revealed that all pigments had high anti-corrosion efficiency comparable with that of Zn–Al phospho-molybdate.

Spinel-Type[21] Pigments

Spinel pigments are oxides derived from the crystalline structure of the natural mineral "spinel," $MgAl_2O_4$. With these XY_2O_4-type oxides, the ionic charges can be balanced with three combinations of oxidation states: $X^{2+}B_2^{3+}$ (type I), $X^{4+}B_2^{2+}O_4$ (type II), and $X^{6+}B_2^{1+}O_4$ (type III). The structure of these oxides is determined by the grouping of voluminous oxygen-containing anions in a face-centered-cubic arrangement. Free cavities for the placement of cations are of two types: octahedric (coordination number 6) and tetrahedric (coordination number 4). In perovskite, the large ions, Ca^{2+} and O^{2-} and the smaller cation of Ti^{4+} located in one of the void spaces create a closely packed structure. Lamellar spinel-type pigments have been characterized as especially appropriate for high barrier efficiency coatings because they increase the diffusion path for water and oxygen. In addition, it has been shown that in addition to pigment particle shapes, their chemical compositions also plays a role.

Spinel pigments containing Zn(II), Ca(II), Mg(II), Sr(II), Fe(III), Al(III), and Ti(IV) cations have been synthesized as potential candidates for replacing toxic anti-corrosive pigments with pigments acceptable from the point of view of environmental protection [48]. Combining the cations in various oxide groups, the pigments were applied to alkyd, styrene-acrylate, epoxides, and chlorinated rubber binders. The binder containing acid groups gave aqueous extracts with better inhibitive properties than the non-reactive binders. The chemical composition of the synthesized pigments clearly shows that the compounds are ecologically harmless.

The spinel-type oxides are useful in heat-resistant organic coatings, and they are designed for applications where temperatures in a range of 200–500°C are encountered [49]. Several inorganic pigments (salts) are produced by Kremer Pigments Inc., as praseodym yellow $(Zr,Pr)SiO_4$, zirconium cerulean blue $(Zr,V)SO_4$, spinel black $(Fe,Mn)(Fe,Mn)_2O_4$, zinc-iron brown dark (metal oxide/hydroxide and 5 %–7 % of TiO_2), all of them are not classified as hazardous pigments. They are suitable for paints based on oil, acrylics, tempera, watercolor/gouache, lime/silicate binder, etc.

Metal Flake Pigments

Metal flake coating compositions are well known in the coating industry. In particular, metal flake coating compositions are widely used in automotive coatings to produce unique aesthetic effects and to provide anti-corrosion protection of metal substrates. Aluminum pigment, typically as an aluminum flake, is used in metallic decorative topcoats whereas *zinc* pigment-flake is used as anti-corrosive pigment—especially in primers. Both metal powder pigment flakes play the role of self-sacrifice anodes for rust prevention and corrosion inhibition, due to the more negative electrode potential relative to that of iron (steel). The flake-pigment is often used in the form of a pigment paste. The paste is processed and dispersed in a polymeric vehicle along with a conventional pigment to produce automotive paint coatings that have various appearance effects, such as silver metallic, gold metallic, blue metallic, and various other colored metallics.

Both aluminum and zinc pigments react in aqueous alkaline media (e.g., water-borne paints) with the evolution of hydrogen—a process known as "gassing" [50]

$$2Al + 6H_2O \Rightarrow 2Al(OH)_3 + 3H_2\uparrow$$

$$Zn + 2H_2O \Rightarrow Zn(OH)_2 + H_2\uparrow$$

The *p*H values of water-borne paints are about 8–9 and a severe problem exists with water-borne paint systems using aluminum or zinc pigments. This problem involves the hydrogen corrosion of these metals in aqueous alkaline paint media. The evolution of hydrogen during these corrosion reactions can lead to dangerous pressure buildups in containers. Therefore, inhibition against these corrosion reactions is necessary. Aluminum pigments can be stabilized with organic phosphorus compounds, but these have some disadvantages. Furthermore, aluminum and zinc pigments can be stabilized in water-borne paints by chromate (VI), which is, however, toxic. So, the investigation of alternative and especially non-toxic methods for the inhibition against these corrosion reactions has been necessary. Moreover, there is generally a great demand for environmentally friendly corrosion inhibitors (so called "green inhibitors").

It has been reported that the hydrogen corrosion of aluminum pigments can be inhibited by addition of the reducing saccharides fructose and mannose as well as with addition of the reducing ascorbic acid. Sucrose, a non-reducing sugar, did not inhibit this corrosion reaction [50]. With increasing additions of fructose or ascorbic acid, the hydrogen volumes evolved increased. This observation leads to the assumption that reaction products of aluminum and fructose or ascorbic are the actual corrosion inhibitors. The hydrogen corrosion of zinc pigment is inhibited only by ascorbic acid. So, the most efficient natural corrosion inhibitors for aluminum and zinc pigment is ascorbic acid. But corrosion inhibition of ascorbic acid on zinc pigment is much less effective when compared to aluminum.

It has also been reported that hydrogen evolution from aluminum and zinc pigments in aqueous media at a *p*H of 10 can be inhibited by several epoxy-ester polymers, which are suitable binders for anti-corrosive paints prepared with zinc pigments [51]. One particular epoxy-ester polymer was an excellent corrosion inhibitor both for aluminum and zinc pigments. These results indicate that the stabilization mechanisms of epoxy-ester polymers are similar with respect to the two different metal pigments. An increase of epoxy-ester addition results in decreasing hydrogen evolution, i.e., an increase of corrosion inhibition. Added paint binders such as saturated polyester or melamine do not significantly affect corrosion inhibition of aluminum and zinc pigments by the epoxy-ester. These results show that corrosion inhibition of aluminum and zinc pigments by epoxyesters works also in multi-component systems. The mobility of polymers dissolved in a liquid medium seems to be one general requirement for corrosion inhibition.

[21] Spinels are any of a class of minerals of general formula XY_2O_4 that crystallize in the cubic (isometric) crystal system, with the oxide anions arranged in a cubic close-packed lattice and the cations *X* and *Y* occupying some or all of the octahedral and tetrahedral sites in the lattice. *X* and *Y* can be divalent, trivalent, or quadrivalent cations, including magnesium, zinc, iron, manganese, aluminium, chromium, titanium, and silicon. Although the anion is normally oxide, structures are also known for the rest of the chalcogenides.

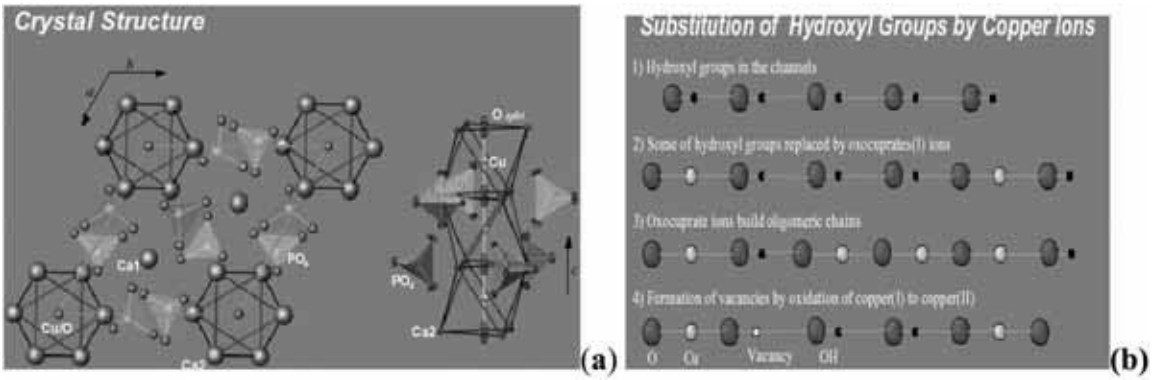

Fig. 10—Ceramic pigments: (*a*) Crystal structure; (*b*) substitution of hydroxyl groups by copper ions [54].

According to industrial company statistics, automotive color fashion dictates that in Europe 62 % and in North America 87 % of automotive paints be metallic in nature [52]. These values include metallic/pearl pigment combinations. The most important, high-demand aluminum flake products were those with a high resistance to gassing in water-based paints. As a consequence, the next step in the development of automotive paints with anti-corrosion behavior was development of encapsulated pigment technology. This technology involved production of encapsulated hydro-aluminum flakes as pigments that gave markedly improved protection properties. There were two types: chromium encapsulated with insoluble chromium III and acrylic encapsulated with a thermosetting acrylic polymer.

New, heavy metal free stabilization technology that guarantees gassing stability and optical properties comparable to chromate-passivated pigment types has been reported [53]. Silica encapsulation of aluminum flakes by means of a new sol/gel process provides aluminium pigments with long-term stability in water-based coatings. Excellent weather fastness and the best adhesion of the pigmented coating have been observed when examined after corrosion test exposure. In addition, no degradation under high shear stress could be observed.

Ceramic Pigments

Ceramic pigments are widely used and incorporated as fine particles in paints to impart color. Although many chemical compounds are effectively applied as pigments, there is still a need to find new compounds and mixtures that have bright colors and are relatively inexpensive, stable towards heat and light, non-toxic, and environmentally friendly. New types of ceramic pigments based on apatites[22] and containing linear copper (I, II) oxyanions in hexagonal channels through partial substitution of hydroxyl groups [Fig. 10(*a*) and Fig. 10(*b*)] have been reported [54]. In spite of the fact that only a small share of copper is in the divalent state, the compounds are brilliantly colored.

[22] Apatites: The most abundant and widespread of the phosphate minerals, formed in igneous/metamorphic rocks, crystallizing in hexagonal system. The apatite structure type includes no less than ten mineral species and has the general formula $X_5(YO_4)_3Z$, where X is usually Ca^{2+} or Pb^{2+}, Y is P^{5+} or As^{5+}, and Z is F–, Cl^-, or $(OH)^-$; for example, calcium phosphate $Ca_5(PO_4)_3$(F, OH, Cl).

TWO MECHANISMS FOR ANTI-CORROSION PROTECTION OF METAL

There are two mechanisms that are used to describe mechanisms for anti-corrosion behavior of different pigments/inhibitors used for metal substrate protection. These are *cathodic protection,* which involves the shifting of a metal potential to more negative values, and *metal passivation,* which involves the shifting of a metal potential to more positive values. Penetration of an aggressive electrolyte through the paint coating is accomplished through water or humidity absorption transport through the existing pores in the paint film or by the diffusion of oxygen and dissolved ions (contaminants) toward the paint/metal interface. These two processes determine the anti-corrosive paint efficiency. After the permeation of water, oxygen, and aggressive ions, a variety of corrosion reactions can occur at the metal/paint interface.

It is thought that the mechanism of coating detachment is cathodic in nature. It begins by casual formation of anodic and cathodic sites in the exposed area—a process that is necessary for initiation of the corrosion process. In an ordinary paint film, that is a film that does not have sacrificial anodes, the solid corrosion products that formed block the pores and other coating defects. In this way, the entrance of new oxygen for the iron oxidation to Fe^{2+} is limited. As a consequence, it is said that the entire coating is semi-permeable to oxygen and that the corrosion process is localized on the edges of pore defects. Because of this, the cathodic reaction that occurs on the edges of defects aids local *p*H increases from *p*H 10 to 14. The anodic reaction of metal dissolution, which occurs in the center of the coating defect, produces a local acid medium of *p*H 2 to 4. This process is depicted in Fig. 11. With these conditions existing, the high alkaline *p*H at the edges of defects diminishes the adhesion forces of the coating and causes the blister formation. Simultaneously, the lower acid *p*H in the center of the defects increases the rate of the anodic corrosion reaction.

THE CONCEPT OF PAINT MONITORING

Coatings, in a general sense, are used to increase the life or beautify of functional or decorative objects. In certain instances, both goals are important. Quite often labor costs are one of the most expensive considerations in applying and maintaining a coating. Therefore one desires and expects a long lifetime of protection and/or beauty from any applied coating. Today, prediction of the anti-corrosive

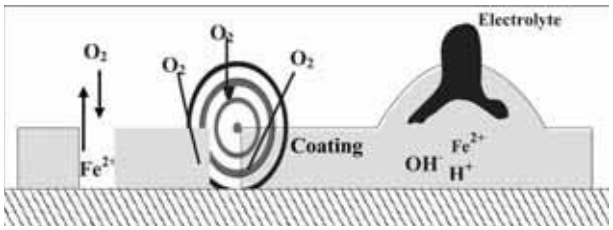

Fig. 11—Schematic representation of the three states for cathodic detachment of paint coating. The left part represents the first stage, when anodic and cathodic sites are separated in the exposed area; in the center—blocked defect, consequently transporting oxygen (O_2); and in the right—final situation.

properties of primers is one of the important lines of research in the field of organic coatings. Goals include improved protection and increased service lifetime for the coated substrates. The corrosion and degradation processes in organic/metal systems is complex. The main experimental routes used to examine different exposure processes are field testing and accelerated aging testing as in a salt fog spray cabinet. Such testing routines must be given serious planning because they are expensive to conduct. Salt spray (fog) is an accelerated test carried out with an aqueous 5 wt % sodium chloride solution, and it is one of the most widely used evaluation techniques. The practice is described in ASTM B117, Standard Practice for Operating Salt Spray (Fog) Apparatus, which provides a controlled corrosive environment for obtaining corrosion resistance of coated metals. Even though a useful tool, this practice is very subjective and does not give quantitative information about the corrosion process and its interpretation.

For this reason, various electrochemical techniques have been used to evaluate the corrosion protection performance of organic coating/metal systems: (a) anodic and cathodic polarization curves, (b) EIS, and (c) rapid testing that consists of a combination of cathodic polarization and EIS measurements (ac/dc/ac procedure). EIS has proven to be a useful technique for the study of anti-corrosive primer behavior, but to obtain good, meaningful results, long evaluation times of days, weeks, and even months are needed

The concept of inspection/monitoring is gaining importance for cost and environmental reasons. In addition to the traditional approaches of basic visual assessment and adhesion testing, new techniques for monitoring paint degradation and the resulting corrosion are emerging—these include the following:

- Thin film electrochemical sensors embedded under paint films.
- Electrochemical sensors applied to the outer surface of paint films.
- Microwave techniques.
- Thermography.
- Color and fluorescence changes (smart coatings).
- Fiber optic sensing.
- Chemical sensors for detecting surface contamination at the surface preparation stage.

SMART COATINGS

The use of "smart materials" for corrosion sensing purposes relies on a material undergoing a transformation through its interaction with a corrosive environment. It is such transformations that can potentially be used for indicating and detecting corrosion damage. Ideally the sensing function could be integrated with additional actuation and control functions designed to control corrosion damage.

Several initiatives have been launched on the front of using smart coatings as corrosion sensors, but presently the technologies reside mainly in the experimental laboratory domain. As such, they are "futuristic" in nature. Some smart coating principles including those relevant to corrosion sensing or that are potentially relevant include the following:

- Paint systems with color-changing compounds that respond to *p*H changes that result from the corrosion processes.
- Changes of coating compounds from non-fluorescent to fluorescent states when oxidation or complexation with metal cations takes place.
- Release of color dyes from incorporated dye-filled microcapsules when coating damage occurs.
- Use of pigments that absorb corrosive chemicals,
- Use of pigments that release corrosion-inhibiting chemicals on demand.
- Piezo-electric thin film applications.
- Fiber optics.

ENVIRONMENTALLY FRIENDLY PAINTS AND PIGMENTS-INHIBITORS

Due to the restriction limits on the use of toxic pigments (for example, those based on lead and heavy metals) because of health and environmental considerations, paint producers are searching for a new generation of pigments/inhibitors that are more acceptable. Numerous investigations have been performed in an attempt to evaluate promising candidate replacement inhibitors. The need for substitution of toxic pigments can be made on different levels—humanistic, economic, or ecologic. The corrosion inhibition characteristics of many inorganic compounds have been examined for more than five decades with the hope of identifying an equivalent to the excellent corrosion inhibition of chromate pigments inhibitors.

As companies search for a system with equivalent or better properties than the chromates, it is necessary to consider raw material costs. New pigments are usually more expensive than classical pigments. Although such cost difficulties may exist, the use of organic coatings remains as one of the most economical methods of obtaining corrosion protection. This is related to the relatively low application costs in comparison to protection methods such as galvanizing, enamel coating, or the use of finer materials. The true advantage of the use of paints lies in their all-purpose and easy application onto the surface of various materials.

For perhaps the past 20 years, a considerable effort has been focused on developing non-chromate corrosion-inhibiting compounds for protection of aluminum alloys. A number of chromate alternatives have been considered, including molybdates, phosphates, metaborates, zinc oxide (ZnO), vanadates, and silicates [55]. The patent literature suggests the use of sol-gel technology for generating an endless variety of non-chromate pigments. In addition to borate salts, organic acid salts of barium have been considered as corrosion inhibitors. Although barium-metaborate as it exists at *pH* 10 provides very good inhibition of Aluminum

2024, its ability to inhibit decreases with decreasing *p*H and thus decreases as corrosion takes place.

To date, no single compound has demonstrated corrosion/inhibitor potency that is comparable to chromate-based inhibitors. A promising alternative is use of a synergistic combination of two or more compounds, organic and inorganic, as a coating system. The inhibitor synergy is an additive phenomenon wherein the total inhibition provided by the combination exceeds the arithmetic sum of the individual components. However, because of the known release of inorganic pigments from organic matrices [56], and the unpredictable release kinetics of organic additives from organic matrices, the investigations have emphasized use of inorganic compounds for the replacement of chromates. Compared to chromated pigments or zinc dust, modern, environmentally friendly pigments in epoxy-ester primers have shown excellent results, especially in salt spray tests. These systems include zinc phospho-molybdate, ZP modified with organic corrosion inhibitor, calcium hydrogen phosphate, zinc-aluminum polyphosphate, etc. [21]. Reported results of the properties of a wide variety of industrially employed fillers and pigments contained in paints reveal that the formulation of steel protecting coatings can be optimized. For example, this can be accomplished by selecting the optimum filler for an epoxy coating with barrier anticorrosive properties, thickness of coatings, etc. [57].

The inorganic species considered as replacements of chromate can be divided into the following categories [10].

(a) Reducible hypervalent transition metals (compounds of Mo, V, Mn, Tc). The term "hypervalent" as used here refers to the "highest" valence state of the oxoanion, which is typically not thermodynamically stable in aqueous media. Metals, such as Mn, Tc, Mo, and V, that form oxometallates have soluble hypervalent oxoanions that reduce to form insoluble oxides in the same way as chromium. However, Mn, Cr, and Tc compounds exhibit very broad ranges in *p*H around neutral where their reduced oxides are stables, while V and Mo, exhibit relatively narrow ranges in *p*H. On the other hand, vanadium oxide is relatively more stable toward high *p*H and the Mo oxide is more stable toward lower *p*H values. However, as oxides, the elements of Mo and V will never give the same stability as seen in analogous Cr^{3+} oxide. But, they should not be completely ruled out as chromate replacements.

(b) Difficult-to-reduce transition metal oxides (Zr, Hf, Ta, Ti, Y) and covalent oxides (oxides and mixed oxides of Si, Ge, P, Te). Elements such as Nb, Hf, Ti, Zr, and Ta form very stable oxides in their highest oxidation state. Unfortunately, soluble and mobile precursors of these oxides remain difficult to stabilize in aqueous media. It is difficult to imagine how such active precursors could be retained in the resulting films in a manner analogous to the retention of Cr^{6+} in Cr conversion coatings. Both the former group (a) and this group (b) can be carried out using sol-gel methods.

(c) Precipitated coatings. These coatings include boehmite [γ-AlO(OH)] and HT [$Mg_6Al_2(CO_3)(OH)_{16}{\cdot}4(H_2O)$] coatings, and rare-earth metal coatings. The mechanism for the rare-earth inhibition seems to arise from the alkaline precipitation of protective oxide films at active cathodic sites formed on the metal surface. Cerium (Ce) species appear to offer the most effective corrosion inhibition: Ce^{3+} reversibly adsorbs on anodized aluminum, but it acts at much different sites than the Cr^{6+} oxoanions.

In a broad examination of the literature in which the substrate material is not specified, compounds identified as having promising performance include barium metaborate, vanadium-based compounds, rare-earth compounds, molybdates, zinc-based compounds, calcium silicate, thioglycolates, calcium oxide, phosphate salts, calcium silicofluoride, and benzotriazole among others. Additional studies have been made studying synergistic effects achieved by combining promising candidate inhibitors. The corrosion-inhibition efficiency of 27 candidate compounds has been studied and the inhibitors selected for continued testing were: barium metaborate, cerium chloride, cerium oxalate, lanthanum chloride, and sodium metavanadate. Sodium meta-vanadate appeared to be a possible candidate as a chromate replacement [34]. Zinc-molybdenum phosphate could also be a good possibility as a replacement of heavy metal compounds. It is thought that its anticorrosive protection efficiency is similar or superior of that of ZC or ZP.

While all coatings are important in that they protect a wide variety of objects from the harshness of various environments, they also provide us with aesthetic beauty. Studies such as many of those described in this chapter and that are ongoing in many laboratories strongly suggest that new solutions to environmentally and health-acceptable anticorrosion pigments and inhibitors will be found.

Oil Absorption of Pigments[1]

Charles W. Glancy[2]

MIXING A PIGMENT WITH LINSEED OIL AND MAK-ing a paste is a preliminary test applied to pigments that has been in use in a systematic manner for almost a century and perhaps even longer in a less defined manner. This proved to be a practical means to qualitatively characterize the approximate color and texture of pigments quickly with materials and tools readily at hand. The work of mixing and the flow properties of the resulting paste provided an estimate of the rheological impact of a new pigment under consideration or a proposed pigment composition change. Thus, valuable insight of the dispersion performance of a pigment or formulation change in a mill base could be estimated. Further extension of the test was found to be useful in predicting the consistency of finished products. Mills [3] indicated that if equal volumes of "oil absorption paste" are mixed or thinned with equal volumes of thinners, the paints prepared have equal resistance to flow, viscosity, or consistency. While the application of oil absorption values as a formulation tool originated many years ago in the age of oil- and alkyd binder-based paints, the ability to use this information to calculate the binding power index of latex binders, latex porosity index of latex paints, and free binder continues to demonstrate the value of pigment oil absorption data today to solve coatings formulation problems. This is especially true for the field of interior and exterior architectural paints.

If the oil absorption test is conducted in a quantitative manner, the result is a measure of the oil needed to wet the surface area of the pigment and to fill the voids in and among the pigment particles. If this result is achieved, profoundly important information is obtained of high value to pigmented paint and coatings development. A number of relatively simple test procedures have been developed to measure oil absorption of pigments. The difficulty generally to successfully applying these tests has been in two areas. First, great care and effort is required to reach and interpret the oil absorption end point. Secondly, one must obtain particle separation in the test to the same degree as achieved with the formulation in the pigment dispersion manufacturing process to which oil absorption value is to be related.

Two ASTM pigment oil absorption test methods are available, which cover two incorporation methods. The different methods result in different end points and therefore different oil absorption values. Stieg [4] found that if the oil absorption value is determined by the ASTM D281 (Test Method for Oil Absorption of Pigments by Spatula Rub-Out) and expressed on a volume basis, it is proportional to the critical pigment volume concentration (CPVC) of alkyd wall paints. Later he and others demonstrated the extension of oil absorption values to calculate the CPVC of pigment compositions to predict the performance of latex paints and other calculated factors useful in formulating these coatings. Gardner–Coleman oil absorption, ASTM D1483 (Test Method for Oil Absorption of Pigments by Gardner–Coleman Method), values have been related to pigment paste viscosities and found useful in estimating consistencies by comparison to a reference standard pigment behavior in the same dispersion machinery. A number of non-ASTM methods for the determination of oil absorption values have been reported in the literature and a few will be listed below.

MECHANISM

When the oil absorption test is performed, the surface of each pigment particle is wet and saturated to a certain extent with oil and thus is encased in an oil shell that has been estimated to be as thick as eight molecules [4,5]. The amount of oil needed depends on the specific pigment area, which is a function of particle size, roughness, and porosity. With temperature and humidity constant, the oil adsorption value depends on the duration and vigor of the rubbing operation and on the affinity of the oil for the pigment. As oil is added beyond the particle encasement stage, the interstices between the oil-encased particles become filled with oil. The amount of oil required for this stage of the test is a function of the type of packing taken on by the particles [6]. Packing can range from rhombehedral to cubic. In addition, the presence of aggregates, which are clusters of pigment not broken up by the rubbing process, and agglomerates, which are clusters of pigment formed after the pigment has been wet, have an effect on the amount of oil needed. Agglomeration is affected by the nature of the oil, and linseed oil with an acid number of 3 ± 1 and that meets the specifications shown in Appendix A should be used. More extended discussions of oil absorption theory and practice can be found in the literature [7–11].

METHODS FOR DETERMINING OIL ABSORPTION

There are two ASTM methods for determining oil absorption that will be described briefly as well as related methods tabulated and referenced in Table 1.

Spatula Rub-Out Method

This is the classical method and the following directions summarize those of ASTM D281 [12], first published by ASTM in 1928 and updated from time to time with the

TABLE 1—Various non-ASTM methods for determination of oil absorption values

Method	Comment	Ref.
Azam	Method same as ASTM D281 except end point is where paste just adheres to the spatula. See text.	[15]
Bessey-Lammiman	An indirect method. Pore volume of a compressed pigment wafer is determined. From this, an oil adsorption number is calculated.	[9]
British Standards Institution BS EN ISO 787-5:1995 and German Institute for Standardization DIN ISO 787-5	Method is similar to ASTM D281. A defined weight of pigment or extender is placed on a glass plate. Linseed oil is slowly added by burette to the sample and mixed in using a palette knife. The volume of oil required to form a smooth paste-like mass is noted and the oil absorption is expressed as milliliters or grams of oil required per 100 g of sample.	. . .
Density End Point	Assumes density of pigment and oil are additive. Can have void volume errors associated with it.	[16]
National Lead Company	Method is similar to ASTM D281 and Azam methods, but an attempt is made to regulate rubbing pressure and contact area of spatula and rubbing plate	[17]
Smith-Stead	Pigment is added to oil in this method and a mechanical muller is used to better define the rubbing effort.	[18]

latest reapproval in 2007. It is approved for use by agencies of the U.S. Department of Defense. In this test, linseed oil is added in a dropwise manner to the pigment while it is being thoroughly rubbed with a spatula until a stiff putty-like paste is formed. It differs from the Gardner-Coleman Method [13], which requires only gentle folding and stirring, whereas the rub-out test requires a thorough rubbing action of the pigment and oil with a steel spatula.

Raw linseed oil that meets the specifications in Appendix A but with an acid number of 3 ± 1 is slowly added in a dropwise manner to a known amount of pigment. The amount of pigment should be sufficient to require 1 mL or more of oil. After the addition of each drop of oil, the oil is incorporated into the pigment by working or rubbing the two together with the spatula. The end point is taken to be the point where sufficient oil has been incorporated into the pigment to produce a very stiff, putty-like paste that does not break up. The weight of oil is determined by multiplying the volume of oil by its density (0.93 g/mL). The oil absorption value is reported as the grams of oil used per 100 g of pigment. Various stages in the spatula rub-out test are described in Fig. 1.

The test requires extreme care to obtain acceptable precision. The method is very tedious yet requires close attention to avoid over-shooting the end point. Test results by a single operator are often considered satisfactory if within ±5 %, but comparisons between different operators is much more problematic. As reported in ASTM 281, results by a single operator and between different operators in different laboratories that differ by more than 14.3 % and 38.0 %, respectively, are suspect at the 95 % confidence level. Stieg has reported that lack of a clear understanding of the end point accounts for the differences reported between operators [14]. He reported almost perfect correlation between CPVC calculated from oil absorption values and experimentally determined CPVC values when the end point is determined by the very least amount of oil that will cause the pigment mass to cohere while not causing it to wet either the glass plate or the spatula. Then the method is repeated with a slightly smaller amount of oil to be sure that no lower oil value can be obtained. A comprehensive study [7] of oil absorption measurement by the British Standards Institution method found individual operator capable of accuracy of about ±3 %, but results between different operators were of the same order of magnitude as reported in ASTM 281.

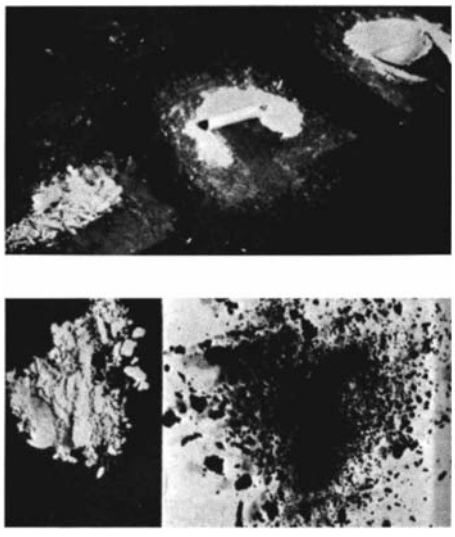

Fig. 1—[1]—A, B, and C in the top photograph represent 1 g of zinc oxide that has been mixed with increasing amounts of linseed oil. Rub-out A (top left) is crumbly and breaks up when an attempt is made to lift it with a spatula. Rub-out B (top middle) is coherent and tends to form a roll when deformed with the spatula. Rub-out C (top right) contains too much oil and does not roll. It can be lifted as a sheet and the mixture is beyond the end point. The bottom two photographs are additional examples of the mixture condition just before the end point is reached. A single drop of oil will convert the crumblings into coherent masses.

The wider range between operators was attributed to the difference in effort expended during the rubbing of the oil into the pigment rather than end point determination, and that the amount of effort that should be expended cannot be rigidly defined. Clearly, where comparisons are to be made between operators, extreme care must be exercised to ensure that the same mixing effort and end point determinations are made. Oil absorption values obtained by this test and the Gardner–Coleman test are given in Table 2.

AZAM METHOD

The Azam Method [15] is essentially the same test as ASTM D281 with the main difference being a more rigorously defined end point. The end point is defined as the point where the paste just adheres to the spatula and the paste was termed a "complete" paste. Azam found that a complete paste absorbed no more oil when immerse in oil, but an "incomplete" paste would absorb oil in an amount sufficient to make it a complete paste. The end point check was made by immersing the rub-out mass in a known amount of oil and then determining the change after two or three days.

Rowland-Stieg Simplification of ASTM D281

This modification [19] of the classical method reports oil absorption volumetrically in terms of milliliter of oil per milliliter of pigment. This simplified procedure eliminates several sources of error and is the logical procedure where the objective is to calculate the CPVC rather than to report the oil absorption value. The abbreviation OA_V was selected to identify the volumetric oil absorption determined by this procedure. The specified pigment sample size in grams equal to 1.25 mL is calculated by multiplying the pigment bulking value in pounds per gallon by the factor 0.15 (the exact value is 0.15006). This provides a sample size of about 5 g for the majority of architectural paint pigment compositions. The measured volume of oil from the titration multiplied by 0.80 (to express milliliter of oil per milliliter of pigment) is OA_V.

TABLE 2—Oil absorption values, grams of oil/100 g of pigment, of some common pigments [1]

Pigment	Gardner-Coleman Test	Spatula Rub-out Test
Barytes	13.5	. . .
Basic carbonate of white lead	18	13.0
Basic sulfate of white lead	30	12.8
Blanc fixe	30	15.0
China clay	51	30.0
Gypsum	33.5	. . .
Lithopone	33	21.5
Silica, crystalline	23	. . .
Silica, amorphous	32	29.0
Talc	60	. . .
Titanox	26	18.5
Whiting	32	17.5
Zinc oxide	52	19.5

Gardner–Coleman Method

This method or some variation of it has been in use for about three quarters of a century. The current method, ASTM D1483 by Gardner–Coleman Method [13], has been in use for over 45 years. In this test, a soft paste is formed from the pigment by drop-wise addition of raw linseed oil that meets the specification in Appendix A but with an acid number of 3 ± 1 from a burette to the gently stirred pigment. As the oil is slowly added, the mixture is continuously stirred and folded so the oil strikes dry pigment as long as any remains. The mixture is not vigorously rubbed as in the rub-out method. Eventually the mixture collects in small lumps that gradually coalesce. The rate of oil addition is reduced as the end point is reached. The amount of oil required to form a paste is used to calculate the oil absorption value. The end point for paste formation is taken to be the point when the lumps of wet pigment form a single ball or when an excess of oil smears the wall of a container (see Fig. 2). This will take place within one or two drops of oil. It is important that there is no rubbing or grinding when this test is carried out. Although the current test calls for use of a steel spatula with particular dimensions and a glass flask for the test, variations of these tools have been used [20,21].

Oil Absorption, *A,* is expressed as grams of oil per 100 g of pigment and is calculated as follows:

$$A = \left(\frac{(M \times 0.93)}{P} \right) \times 100 \quad (1)$$

where *M* is the mL of oil used, *P* is the amount of pigment used in grams, and 0.93 is a constant that represents the density of the linseed oil. Test results by a single operator and between operators in different laboratories that differ by more than 9.9 % and 15.3 %, respectively, are suspect. Oil absorption values obtained by this method and the rub-out method are given in Table 2.

Characterization of Dispersions at the Oil Absorption Point

Examination of the dispersions (pastes) formed between oil and pigment at the oil absorption point is a source of considerable information. Large differences exist in such

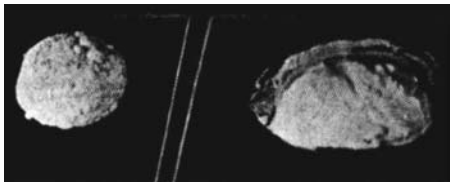

Fig. 2—[1]—Critical states in the Gardner-Coleman test. Left photograph is the oil/pigment mass just before the end point where the mass retains its rigidity. The right photograph is the mixture at the end point where the mass undergoes slight flow and smears the glass.

pastes with some being long, stringy, and soft in character. Others are tough and short, others have a high gloss, others have a dull appearance, others are soft and easy to spread, and still others are stiff and require a large pressure spread or flatten. The amount of oil needed is not closely related to these attributes, and one is led to the conclusion that pigments with essentially the same oil absorption value can yield pastes with markedly different character.

Daniel and Goldman [22] developed a scheme for evaluating dispersion character by using the paste obtained at the end of the spatula rub-out test. The amount of liquid needed to wet the pigment and produce flow is determined. From this information and the types of flow exhibited by the pastes, dispersions are classed as good, fair, or poor. From 10 to 20 g of dispersion is worked with a fairly stiff steel spatula in the test. The oil absorption value is called the *wet point*. From this point, oil addition is continued until the *flow point* is reached. In well-dispersed systems, the flow point is the stage where a substantial portion of the paste flows from a vertically held spatula without leaving jagged flow edges. In poorly dispersed or flocculated systems, the flow point is the stage where the paste drops from a vertically held spatula. Cases intermediate to these two are difficult to define. At the instant when paste drops from the spatula, it elongates at the edge. If a paste does not flow after addition of 10 %–20 % more liquid than is required for the wet point, a portion of the diluted paste is placed on the tip of a horizontally held spatula. The spatula is then tapped near the handle with a finger. The tapping is gentle at first and then more vigorous. The paste may then become glossy and flow over the edge of the spatula, in which case it is passively dilatent, or it may tend to rise or otherwise decrease the interface between it and the blade, in which case it is flocculated. Characteristics of pastes tested in this manner are given in Table 3. A test such as this can yield practical rheological results without sophisticated testing equipment.

Plasticizer Absorption By Pigments

Although linseed oil is used to obtain the oil absorption values, it is obvious that a variety of liquids can be absorbed by pigments. Typical data for selected plasticizers as well as raw linseed oil are given in Table 4.

CRITICAL PIGMENT VOLUME

For a long time, the paint industry formulated on a weight basis. In 1926 Calbeck [23] concluded from a statistical study of house-paint test results that the pigment/binder system should contain at least 28 vol % pigment. Not long after this, Wolff [24,25] related optimum performance of exterior paints to their critical oil contents, and simple graphical methods for determining this parameter were devised [26]. When Elm [27] investigated this concept, he confirmed Wolff's findings, but found it necessary to reverse the point of reference so it expressed the critical composition in terms of pigment content as in the work of Calbeck. Later Vannoy [28] studied the matter and concluded that replacement of certain pigments by others on a volume basis was the manner in which formulating should be approached. From such studies, the relationship known as the pigment volume concentration (PVC) came into use. It is a simple percentage calculated in the following manner:

$$\text{PVC} = \left(\frac{\text{pigment volume}}{\text{pigment volume} + \text{vehicle solids volume}} \right) [100] \quad (2)$$

Studies such as these led to the CPVC concept, and its importance to paint formulation was established by Asbeck and Van Loo [29] in 1949. They illustrated the CPVC concept by relating marked changes in gloss, rust, blistering, and permeability over a relatively narrow (3–6) PVC range. Many other properties including dry hiding, scrub resistance, stain holdout, enamel holdout, and film tensile strength also transition over this range. The CPVC may be defined as the PVC where there is just sufficient binder present to fill the interstices between pigment particles at the densest possible packing and wet the pigment surface in the dry film. The packing characteristics of the pigments determine the void volume to be filled with binder. The surface characteristics of the pigments determine the amount of vehicle that is tightly bound to the surface. Usually the formulator's task for both economic and performance reasons is to define the highest CPVC possible for the raw materials and pigment dispersion processes available. The CPVC relationship is expressed in the following equation:

$$\text{CPVC} = \frac{\text{volume of pigment}}{(\text{volume of pigment} + \text{volume of absorbed vehicle} + \text{volume of void space vehicle})} \quad (3)$$

TABLE 3—Characteristics of pastes from oil absorption studies [1]

Observation Point	Good Dispersion	Fair Dispersion	Poor Dispersion
At wet point	Shines without tapping or with light tapping; dry and difficult to knead	Shines when sharply tapped	Remains dull even when sharply tapped
At intermediate stage	. . .	Flows only on tapping; occasionally has a resistance to suddenly applied pressure	Rises on tapping; has no resistance to suddenly applied pressure; has a high yield value
At flow point	Flows without tapping; offers resistance to suddenly applied pressure	Falls with elongation at breaking line; no resistance to suddenly applied pressure; has visible thixotropy	Falls without elongation at breaking line
Gap between wet and flow points	Very small	. . .	Very large

TABLE 4—Plasticizer absorption for some typical pigments [1].

Pigment	Absorption, g Plasticizer/100 g Pigment		
	Tricresyl Phosphate	Dibutyl Phthalate	Raw Linseed Oil
Barium titanox	27.6	24.2	17.0
Carbon black, super	179.0	147.0	106.0
Calcium titanox	37.2	39.4	22.0
CP cadmium red	26.0	26.2	14.0
CP cadmium yellow	48.4	50.5	37.2
CP Chinese blue	145.0	136.5	41.1
CP chromium oxide	29.5	24.7	17.0
CP chrome orange, med.	19.5	21.0	7.5
CP glen green DD	78.0	72.5	28.9
Chromium hydroxide, green	80.0	76.6	53.0
Lampblack	118.0	126.0	145.0
Lithol toner	65.0	50.5	50.0
Lithopone, high strength	35.4	32.5	24.0
Madder Lake	106.0	81.0	51.4
Titanium dioxide	54.3	47.2	22.5
Toluidine red	31.9	20.0	35.0
Ultramarine blue	65.0	55.0	31.6
Zinc oxide	28.3	25.2	14.5
Zinc sulfide	37.2	34.1	15.7

The CPVC is also the point where the dry coating film transitions from a two-phase system of pigment and binder to a three-phase system with the introduction of air in the voids in the matrix. The discontinuity of the binder phase and presence of voids bring about air interfaces, surface pores, and changes in mechanical, barrier, and optical properties that cause the transition characteristics noted above.

The preference of the industrial coatings segments of the industry where coatings are often well below the CPVC continues to be formulation on the basis of the ratio by weight of pigment to binder (P/B). However, a better understanding of the relationship between changes in pigmentation and performance continues to be derived from formulating on a volume basis. This is especially the case in the architectural segment and other segments of the industry where products are formulated over a very wide PVC range but often above or below the CPVC. Usually this range is broadly defined as a PVC/CPVC ratio of 0.7 to 1.3. The importance of formulation by volume is largely due to the existence of the CPVC, which is largely determined by particle packing on a volume basis. Therefore, the real value of any apparent CPVC as determined by any precise method is as a guide to the relative performance of dissimilar paint systems. From this it follows the ratio of the PVC to CPVC, lambda, is also a valuable reference point in reformulation studies [30]. While the use of oil absorption measurements is very old technology, it is still used today to characterize pigments and to calculate CPVC to determine the PVC for a desired PVC/CPVC ratio in solvent and waterborne coatings [31–35].

CPVC calculated from the pigment linseed oil absorption is a good model for the case of a solution binder coating because of relatively similar viscosity and wetting characteristics. This is not the case with latex binders, which are unable to wet the pigment and flow into voids between the pigment particles to the same degree as linseed oil or solvent-borne binders. Latex paints invariably have lower experimentally observed coatings CPVC values because of physical limitations during the film drying process imposed by polymer particle size and size distribution, polymer modulus characteristics, and possibly inadequate coalescent solvent. However, as will be covered later in this chapter, linseed oil determined CPVC values are useful in formulation studies of latex coating.

Performance properties required of a coatings system determine whether the PVC is above or below the CPVC and to the degree of the difference. Rarely is a system formulated at the CPVC. For economic considerations, the pigmentation should be selected to favor efficient packing to maximize the CPVC and thereby introduce the possibility that less binder may be required above the CPVC for a desired PVC/CPVC ratio and perhaps less hiding pigment may be required in coatings below the CPVC because of superior hiding pigment spacing.

High dry-hiding power resulting from air interfaces in the voids above the CPVC typically is relied upon as a major contributor to hiding power in interior architectural paints requiring the PVC to be above the pigmentation CPVC. While dry hiding increases as the CPVC is exceeded by a greater margin, other desirable properties such as scrub resistance, stain resistance, and enamel holdout decline. For example, a ceiling paint does not need to have excellent scrub resistance, and usually this paint type requires only a very flat appearance, and high dry hiding. Therefore, paint such as this will usually be formulated with a PVC well above the CPVC. Interior flat paints require a balance of competing properties highly dependent upon the void volume ratio to the other two phases. Therefore, the CPVC of the pigment composition is a crucial consideration that the formulator must monitor as adjustments of the pigment composition and binder type and concentration decisions are made to optimize performance and cost. Commonly as the pigment composition and binder changes are made, the formulator will maintain lambda, the ratio PVC/CPVC, as a technique to maintain similar void volume while making composition changes. Exterior flat paints are formulated below the CPVC for adequate durability, but the excess binder must not be too large to avoid dirt pick-up. Therefore, the relationship of PVC to CPVC is an important consideration here as well. Semi-gloss and high-gloss enamels are formulated well below the CPVC, and it is PVC rather than CPVC that has the most significance. However, here proper hiding pigment spacing via small particle size extender often is an issue where the measurement of CPVC of the pigment blends based upon oil absorption measurements can be useful.

Identification of the optimum coatings composition providing the desired performance can be a laborious process involving PVC ladders and testing for many properties. Stieg [14] was the first to propose that pigment oil absorption values could eliminate some of the repetitious laboratory work in developing architectural paints by quickly focusing the work on the region most likely to provide the desired results. As will be detailed later, his approach was first successfully applied to solvent-borne paints and later extended to latex paints. First the oil absorption of proposed pigment blends at various ratios are determined and then the CPVC is calculated. Consequently several proposed pigment blends offering the highest possible CPVC can be identified that can be compared in paints in laboratory test at equal porosity index or free binder based upon calculating the required PVC for the various paints.

Useful Equations Based upon CPVC Calculated from Oil Absorption Data

The porosity index of solvent coatings, latex porosity index of latex coatings, and percent free binder may be calculated using oil absorption measurements of pigments or pigment blends. The recommended method for measuring oil absorption for these calculations is the spatula rub-out test ASTM D281. Stieg defined the end point for his work as the very least amount of oil that will cause the pigment mass to cohere, while not causing it to stick to glass or the spatula. Then the operator repeats the test with slightly less oil to verify that no smaller amount will satisfy this condition [14]. The careful determination of the oil absorption CPVC provides the formulator a ready means to assess the packing characteristics of pigments and pigment blends for use in these calculations or to test CPVC results provided by sophisticated computational means. Although not included below, several articles have been published on a simple computational method using individual pigment oil absorption data of extenders and hiding pigments and an experimentally determined packing correction factor applied to the small particle size fraction (hiding pigment) of the pigment composition to calculate the CPVC of a pigment composition [36,37]. Also a method to calculate CPVC based on pigment particle size distribution and oil absorption data has been proposed, but the necessary particle size data is not widely available [30].

Several assumptions or conditions are implied when Stieg's equations are applied to coatings reformulation work. First it is assumed that CPVC is independent of PVC over the range of the experiments. For practical purposes, this has proven true, probably because the PVC range usually is plus or minus 5 % or less limiting the impact of possible PVC effects. Secondly, although CPVC is a system dependent parameter, the oil absorption derived CPVC of the pigment composition is accepted as a measure of the packing characteristics and thus a pigment property useful for making these relative comparisons with both solvent and latex coatings. Also implied is that the pigment dispersion process and additives that prevent flocculation and maintain stability are equally effective in all cases. By definition the range of pigments to which these equations are useful is limited to inorganic hiding and extender pigments such as those commonly used in architectural paints. A more comprehensive review of the entire CPVC subject including the calculation of CPVC from pigment oil absorption values may be found in Ref. [38].

CALCULATION OF CPVC

Stieg found in 1954 that CPVC [39,40] of a pigment composition calculated from oil absorption values, converted to a volume basis rather than a weight basis, determined by the spatula rub-up method (ASTM 281), provided a useful working approximation of a pigment composition's CPVC. Further he demonstrated that the calculated CPVC of a solution-based paint can be related to the CPVC transition of enamel hold-out and color uniformity over sealed and unsealed surfaces. Also, Stieg showed that oil absorption based calculated CPVC of a number of common pigments is related to the bulk density of the dry pigment establishing a strong correlation between the calculated CPVC value and a basic pigment value depended on packing. The CPVC may be calculated from oil absorption measurements by the following equations:

$$\text{CPVC} = \frac{\text{test volume of pigment}}{(\text{test volume of pigment} + \text{end point test volume of oil})} \quad (4)$$

The equation for CPVC shown below is more convenient and uses the volumetric oil absorption (OA_V) method [19] described earlier. The equation is applicable to solvent systems (x = 1.0) and latex systems where the latex binding power index is known. The determination of the binding power index will be discussed in a following section.

$$\text{CPVC} = \frac{1}{1 + OA_V / x}$$

OA_V = volumetric oil absorption, mL oil/mL pigment

x = latex binding power index (1.0 for solution binder) (5)

The following CPVC equation was published by Ramig [41] and is useful to calculate the CPVC of any latex formulation from binding power index, density and oil absorption of the pigment composition.

$$\text{CPVC} = \frac{(\text{BI})(100)}{(\text{OA})\ \text{Dp} + (\text{BI})(100)}$$

OA = pigment oil absorption in grams/100 g of pigment

BI = binding power index

Dp = density of pigment (6)

CALCULATION OF FILM POROSITY INDEX

The porosity index is a numerical expression of film porosity and can be calculated from the oil absorption CPVC of a pigment composition [42]. The greatest value of the porosity index concept is as a means to guide the optimization of the dry hiding of interior flat paints, while minimizing to the extent possible the negative characteristics of porosity driven paint properties. The porosity index is the fraction of pigment air voids in a paint film *not* filled by the formulation PVC binder volume divided by the binder volume required by the pigmentation at CPVC. It is easily calculated for solution binder systems by the equation

$$\text{PI} = 1 - \frac{\text{CPVC}(1 - \text{PVC})}{\text{PVC}(1 - \text{CPVC})}$$

PI = porosity index

CPVC = pigmentation CPVC calculated from oil adsorption

PVC = formulation PVC (7)

This equation provides a way to balance or maintain constant porosity related properties such as permeability, stain or enamel hold-out, and dry hiding power when making pigment or extender changes. For example, the porosity index of an existing formulation can be calculated from the PVC and the oil absorption determined CPVC. If an extender pigment adjustment is made, the PVC change necessary to maintain equal porosity index can be readily calculated by using the oil absorption of the new pigment mix after rearranging the equation and solving for the PVC required. Frequently a new composition is tested in the laboratory at the same PVC/CPVC (lambda) ratio as the original with a 5 (or more) paint PVC ladder centered on this PVC. Evaluating performance at the lambda ratio of equal porosity index should more accurately provide a center point for further testing.

The equation for latex systems is the same as for solvent systems except that the binding power index, discussed in the next section, is included to take the film-forming capability of the latex into account. Stieg has published several articles that discuss useful graphical methodologies that may save considerable laboratory time when dealing with pigment or latex substitutions with a need to balance dry hiding and porosity-dependent performance properties [19,43]. Plotting the percent pigment, binder and air on a volume basis on triangular co-ordinate graph paper is a convenient means to obtain the porosity index and the percent air volume or porosity of the composition [44]. The porosity index is indicated at the point a line from the pigment apex strikes the pigment-air axis, that also intercepts the point that a line from the air apex to the formulation PVC on the pigment-binder axis crosses the formulation CPVC line. The CPVC line is the formulation CPVC line running from the pigment-binder axis to the pigment-air axis. With latex paints the CPVC line in this graph must be the value determined experimentally (apparent CPVC) or the PVC at zero porosity calculated from the latex porosity equation below where LP= 0. The percent air in the coating film may also be determined by reading from the intercept point on the CPVC line horizontally to the pigment-air axis.

$$\text{LP} = 1 - \frac{\text{CPVC}(1-\text{PVC})}{\text{PVC}(1-\text{CPVC})}(x)$$

LP = latex porosity index

CPVC = pigmentation CPVC calculated from oil adsorption

PVC = formulation PVC

x = vehicle volume fraction = binding power index (8)

Because the binding power index is a primary latex property that does not vary with pigmentation changes [41], the porosity-dependent properties of two different latex paints may be matched by formulating at a constant latex porosity index using the binding power index and the oil absorption CPVC of the pigment blends. The PVC change required to match the latex porosity index of the paints can be calculated by the relationship below:

$$\frac{\text{CPVC}_a(1-\text{PVC}_a)}{\text{PVC}_a(1-\text{CPVC}_a)}(x_a) = \frac{\text{CPVC}_b(1-\text{PVC}_b)}{\text{PVC}_b(1-\text{CPVC}_b)}(x_b) \quad (9)$$

In the case where the same latex is being used and the pigment composition is changed, the above equation may be used omitting the binding power index term on both sides of the equation. With the oil absorption CPVC values of both pigment compositions determined, the PVC adjustment to maintain equal latex porosity index in the new formulation can be calculated. Since the binding poor index is constant x is omitted, and the terms of the equation reverts to the solvent binder form.

CALCULATION OF LATEX BINDING POWER INDEX

Berardi [45] developed the concept that a constant ratio exists between oil absorption and latex polymer concentration required at the CPVC. This relationship can be expressed as

$$\text{BI} = \frac{\text{V}_o}{\text{V}_l} \quad (10)$$

V_o = volume of oil required to bind 100 g of pigment as determined by oil absorption; V_l = volume of latex binder required to bind 100 g of the same pigment as determined by an experimentally determined CPVC.

Stieg [46] eventually concluded the vehicle fraction factor x he had developed to adapt the porosity index (PI) equation developed for solution paints to latex paints was identical to Berardi's binding power index. The formula he developed to calculate the binding power index (x) of a latex may be derived by rearranging the latex porosity equation to solve for x when LP is zero. See Ref. [46] for a detailed discussion of this subject.

$$\text{latex porosity (LP)} = 0 = 1 - \frac{\text{CPVC}(1-\text{PVC})}{\text{PVC}(1-\text{CPVC})}(x) \quad (11)$$

$$\text{For LP} = 0 \quad x = \frac{\text{PVC}_0(1-\text{CPVC})}{(\text{CPVC}(1-\text{PVC}_0))}$$

PVC_0 = apparent CPVC, PVC of zero porosity

CPVC = CPVC calculated from oil absorption

x = vehicle fraction factor = binding power index (12)

PVC_0 may be determined by the detection of dry hiding in a formulation with no or a low concentration of opaque pigment. Schaller [47] published an excellent method for determining the PVC at zero porosity with a PVC ladder in a single extender pigment paint. He determined PVC_0 by the appearance of dry hiding by measuring the contrast ratio. The method is precise and relatively easy to perform and very suitable to determining the binding power index of a latex. Schaller demonstrated in his paper that the PVC_0, the apparent CPVC, of latex paint systems is dependent on the latex particle size and polymer modulus. It was demonstrated that increasing latex particle size and the polymer modulus detract from efficient filming and packing of the latex particles in the pigment matrix leading to latex binders exhibiting a lower apparent CPVC value compared to solution binders in the same pigment composition. Coalescent solvent effective for the latex must be included in the single pigment test to accurately access PVC_0. In systems with high white hiding power pigment, the end point must be determined by tinting a PVC ladder of the formulations with a constant amount of lampblack colorant and determining the break in apparent tintorial strength or *S*-values calculated from the Kubelka-Munk relationship assuming constant *K*-value. The Pierce-Holsworth or the

Cole methods discussed in a later section may be used for determining CPVC of a formulation with a high concentration of opaque pigment.

Ramig [41] provided a proof of the equivalency of Berardi's binding power index and Stieg's vehicle fraction factor x. In the referenced paper he demonstrated that the CPVC in latex systems is more than a basic pigment characteristic and also that the binding power index is a fundamental latex property that remains constant in any pigment composition. Ramig derived another equation to determine the binding power index in terms of oil absorption, pigment density and PVC_0.

$$BI = \frac{(OA)(PVC_0))Dp}{(1 - PVC_0)(100)}$$

PVC_0 = apparent CPVC, PVC of zero porosity determined experimentally

OA = pigment oil absorption in cc/100 g of pigment

D_p = density of pigment (13)

CALCULATION OF FREE BINDER

When making necessary formula adjustments in exterior paints, a means to adjust either the pigment or vehicle to maintain constant durability has long been desired. In the days of linseed oil paints, the concept of free binder was developed as a formulation principle [48,49] that held that if a formula's oil content was adjusted up or down with pigmentation changes to maintain equal viscosity, equal free binder was maintained. Fortunately the optimum viscosity for durability and brushing coincided for oil-based paints. This approach was, of course, not applicable to latex paints. Stieg defined an equation [50–52] below to express the free binder of a paint as the excess vehicle above the amount required for the CPVC of the formula pigmentation calculated as a percentage of the total binder volume. This equation was derived from one published by Dintenfass [53] on the theoretical relationship between the relative viscosity of a dispersion, as compared to that of its vehicle, as a function of the volume occupied by its settled pigmentation. The percent free binder present in any oil-based or soluble binder-system is calculated by the following equation:

$$\%\ \text{Free Binder} = \frac{(CPVC - PVC)}{CPVC}(100)$$

CPVC = Pigmentation CPVC calculated from oil adsorption

PVC = Formulation PVC (14)

The equation indicates that the higher the CPVC of the pigmentation is increased by pigment composition adjustments, the higher the PVC may be for a constant percentage of free binder.

For latex paint systems the binding power index will be less than 1.0 and this must be taken into account to calculate the free binder. The following equation was derived in Refs. [51,52] for latex paints:

$$\%\ \text{free binder} = (1 - PVC) - \frac{PVC(1 - CPVC)}{CPVC(x)}(100)$$

CPVC = pigmentation CPVC calculated from oil adsorption

PVC = formulation PVC

x = latex binding power index (15)

OTHER METHODS FOR DETERMINING CPVC

Asbeck–Van Loo Method of determining CPVC

The Asbeck–Van Loo [10,29] Method of directly determining the CPVC is based on the observation that the packing pattern of a pigment in a paste persists when the dispersion is diluted for sedimentation tests if nonpolar liquids are used for the dilutions. Thus, to measure the voids in a dry paint film, it is only necessary to obtain the pigment in the form of a filter cake and measure the volume of the cake. Then, the cake volume is subtracted from the actual volume of the pigment calculated from density data. The ratio of the actual volume of the pigment to the volume of the cake is the CPVC.

PIGMENT PACKING FACTOR

Asbeck and coworkers [10] proposed the term "pigment packing factor" (PPF) as a name for a pigment parameter that replaces or supplements the oil absorption value. PPF is the CPVC for a single pigment in a standard vehicle with the term CPVC being applied to a single or mixture of pigments present in a paint. The investigators suggested a blend of 4 mL of heat-bodied linseed oil and 50 mL of naphtha as the dispersing vehicle. The PPF is determined by placing 54 mL of the vehicle in a 1/4 pt can or glass jar that is half filled with steel balls. To this, 6 mL of pigment (the weight in grams of pigment equal to the specific gravity times 6) are added. The system is dispersed by machine shaking for exactly 3 min. 20 mL of the dispersion are then used to determine the PPF using the same procedure as that used for CPVC. If the PPF is to be compared with oil absorption values, it must be converted to a weight basis, PPF_{weight}, by means of the following equation:

$$PPF_{weight} = \left(\frac{(100 - PPF)(\text{specific gravity of oil})}{(PPF)(\text{specific gravity of pigment})}\right)(100) \quad (16)$$

The PPF and OA values are compared in Table 5. If values are ranked from highest to lowest, the values calculated from the PPF are highest, those from Gardner–Coleman fall next, and those from the spatula rub-out test are lowest. Explanations for the difference based on conditions existing at the endpoint are tabulated in Table 6.

Cole Method for CPVC

The CPVC depends on pigment particle packing or orientation [10,29], and Cole [54] noted that spherical particles might pack similarly in both liquid and dry films. To demonstrate this, a dry-film method was developed. The method is based on the fact that below the CPVC dry film volume, V, is a sum of the pigment volume, V_p, and binder solids volume, V_b

$$V = V_p + V_b \quad (17)$$

and that above the CPVC the volume of the voids must also be considered with

$$V = PV_p \quad (18)$$

where P is the relative pigment packing factor (the ratio of bulk volume to true volume). Two graphical and calculation methods were used to obtain CPVC.

TABLE 5—Comparison of pigment packing factors, calculated and experimentally determined oil absorption values [1]

Pigment	PPF	Oil Absorption Values		
		Calculated from PPF	Gardner–Coleman Method	Spatula Rub-out Method
Carbon black, medium	10	456	212	124
Chrome green	34	41	33	20
Chrome yellow	27	46	33	24
Iron oxide, light red	37	32	24	19
Lampblack	29	128	70	51
Magnesium silicate	39	50	27	25
Midori blue	33	104	87	51
Phthalocyanine blue	20	225	55	34
Silica, diatomaceous	24	131	105	65
Toluidine red toner B	25	199	62	48
Zinc oxide	27	45	19	12

Pierce-Holsworth Method for CPVC

This method [55] also used paint films, but it treated the data in a different manner by introducing specific volume concepts. The specific volume, v, of a dry paint film can be expressed as:

$$v = \frac{V}{W} = \frac{V}{W_p + W_b} = v_p f_p + v_b f_b \tag{19}$$

where V is the dry film volume, v, v_p, and v_b are specific volumes of the dry film, pigment, and binder, W, W_p, and W_b are weights of dry film, pigment, and binder, and f_p and f_b are weight fractions of pigment and binder, respectively. Since the sum of f_p and f_b is unity, the expression can be arranged to

$$v = (v_p - v_b) f_p + v_b \tag{20}$$

If v is plotted as a function of f_p, a straight line of slope $(v_p - v_b)$ and intercept of v_b should result.

Above the CPVC, the volume of the film is given by

$$V = P v_p W_p \tag{21}$$

where P is a packing factor. If both sides of this expression are divided by W, the expression

$$v = P v_p f_p \tag{22}$$

TABLE 6—Physical conditions that exist at the end points of pigment packing factor and oil absorption test [1,10]

Parameter	PPF	Gardner-Coleman	Spatula Rub-out
Dispersion	Aggregates are completely broken down.	Only a few of the largest aggregates are broken down and the interstices are filled with oil.	More aggregates are broken down than in the Gardner-Coleman methods and the interstices are filled with oil.
Electrokinetic equilibrium	Agglomeration is complete because of high system fluidity.	Agglomeration is incomplete because of low system fluidity.	Agglomeration is incomplete because of low system fluidity.
Pigment surface requirements	Satisfied	Not completely satisfied	Substantially satisfied
Work of dispersion	Defined and very high (approaching maximum)	Undefined but low	Undefined but relatively high
Work of packing	Defined and very low (approaching zero)	Undefined but low	Undefined but relatively high

TABLE 7—Comparison of the critical pigment volume concentration calculated by the Pierce-Holsworth method [28] and comparison with results from physical property measurements [1]

Paint system	Critical Pigment Volume Concentration			
	Pierce–Holsworth Method	Tensile Strength Method	Elongation at Break Results	Water Vapor Permeability Results
Acrylic latex exterior House Paint A	47	47	42	46
Acrylic latex exterior House Paint B	41	42	41	42
Poly (vinyl Acetate) latex masonry paint	44	44	44	45
Acrylic exterior masonry paint (from House Paint A above)	48	47	44	48

is obtained. If dry film specific volume, v, is plotted against the weight fraction of pigment, f_p, a straight line of slope Pv_p passing through the origin results. The intersection of this line with the previously described straight line should occur at a value of f_p corresponding to the CPVC. Results obtained by this method are presented in Table 7 along with the CPVCs obtained by tensile strength, elongation, and water vapor permeability. The good agreement is apparent.

APPENDIX A

Properties of raw linseed oil from Table 1 ASTM D234a

Property	Requirement	ASTM Method
Specific gravity, 25/25°C	0.926–0.931	D1963
Acid value max	4.0	D1639
Saponification value	189.0–195.0	D1962
Unsaponificable matter, max, %	1.50	D1965
Iodine value (Wijs), Min	177	D1959
Loss on heating at 150 to 110°C, max %	0.2	D1960
Clarity	Clear and Transparent At 65°C	D2090
Color (Gardner), max	13	D1544
Foots, volumetric heated oil, max, %	1.0	D1954
Foots, volumetric, chilled oil, max, %	4.0	D1954
Gravimetric foots, max, %	0.25	D1966
Flash point, min, °F	250	D93

[a]ASTM D234-82 (Re-approved 1987). Unfortunately, ASTM D234 Standard Specification for Raw Linseed Oil was discontinued in March 2007. The historical method will still be available from ASTM.org.

In preparation of this chapter, the contents of the 14th edition were drawn upon. The author acknowledges the author of the 14th edition, Vanja King. The current edition will review and update the topics as addressed by the previous author, introduce new technology that has been developed, and include up to date references.

Bactericides, Fungicides, and Algicides

Janet H. Woodward[1]

PREFACE

MANY BACTERIA, FUNGI, AND ALGAE CAN CAUSE problems in the paint and coatings industry. These problems arise during manufacturing, in-can, and post application. To minimize or prevent the growth of these microorganisms, the appropriate microbicide (algicide, bactericide, and fungicide) must be effectively applied. Generally, the microbicides are divided into two general categories: Those used for in-can preservation and those used for dry-film preservation. Knowing the groups of organisms against which a microbicide will target is very important in selecting the best chemical to use. The organisms involved are discussed in more detail elsewhere in this manual.

TECHNICAL TERMS

microbicide—a substance that kills organisms; synonym for biocide; the term is further defined (bactericide, fungicide, algicide) to indicate the target organisms.

microbiostat—a substance that prevents the growth of microorganisms and their spores, but does not necessarily kill them.

aerobes—organisms that grow in the presence of oxygen, utilizing the oxygen as a terminal acceptor.

facultative anaerobes—organisms that grow in the presence or absence of oxygen.

anaerobes—organisms that grow in the absence of oxygen; oxygen can be toxic to these organisms.

efficacy—the effect of a microbicide on the target organism or group of organisms; can be measured in percent kill compared to control, but should be defined in the test method; the result is usually expressed as the minimum inhibitory concentration (MIC) against a specific organism.

spectrum—describes the efficacy of a microbicide.

broad spectrum—microbicide is effective against more than one group of organisms.

narrow spectrum—denotes activity against one group or sub-group of organisms.

DESCRIPTION OF MICROBIAL PROBLEMS

In-can Preservation

Water-based paints are prone to contamination and spoilage by bacteria and occasionally unicellular fungi (i.e., yeast) and filamentous fungi. Bacterial growth requirements include water, a carbon source, an energy source, oxygen for aerobes, and other macroelements, such as nitrogen and phosphorus. The majority of bacteria grow between 10 and 50°C and *p*H range of 3–11. Paint formulations provide an adequate supply of the minimal nutrients at the ideal pH and temperature to maintain bacterial growth.

In-can contamination may originate from a number of sources. The aqueous raw materials, such as defoamers, surfactants, wetting agents, and pigment slurries, are themselves susceptible to bacterial degradation. Powdered materials, including starches, fillers/extenders, and pigments may contain bacterial endospores and fungal spores that can germinate under appropriate conditions. The most common source of contamination is the process water. Along with good housekeeping procedures, proper microbicides must be used in the raw materials and water to minimize bacterial contamination.

The problems commonly encountered in water-based paints are shown in Table 1. These do not necessarily happen at the same time but develop as the microbial population changes due to oxygen requirements. Because of the initial oxygen-rich environment, aerobes and facultative anaerobes will often initiate the degradation. They can utilize a variety of paint components for nutrients. They can produce enzymes, including proteases and glucanases. The breakdown products resulting from numerous enzymatic activities act as nutrient sources for other bacteria. As oxygen is depleted, the facultative anaerobes and strict anaerobes will thrive. The metabolic processes produce acids that can lower the *p*H; produce gasses, such as hydrogen (H_2), carbon dioxide (CO_2), and hydrogen sulfide (H_2S), which can cause bulging cans and odors; and produce organic acids and other metabolic end products that cause odors. Acids will also react with any calcium carbonate to produce CO_2. Anaerobes also produce cellulases. The cellulases catalyze the breakdown of cellulose-based materials such as thickeners. As the thickener is degraded, viscosity is lost. More thorough discussions on these metabolic processes can be found in Refs. [1–4].

To prevent these problems from occurring, the appropriate microbicide must be incorporated into the coating formulation. In addition to being cost-effective, the microbicide should be compatible with all coating components,

TABLE 1—Problems caused by contamination of water-based paints and coatings

Type of Problem	Common Cause
Viscosity Loss	Cellulase enzymes from bacteria or fungi catalyzing degradation of cellulose thickeners
*p*H changes	Acids produced from metabolic processes, typically from anaerobic bacteria
Odors	Organic acids and other metabolic end products, such as hydrogen sulfide from anaerobic bacteria
Gassing—bulging or exploding cans	CO_2 or H_2 production from anaerobic bacteria or yeast
Discoloration	Colored pigmentary moieties from bacterial and yeast metabolism; sulfide from sulfate-reducing bacteria
Foaming	Degradation of antifoam agents via bacteria

be stable within a range of *p*H, temperature, and time period, have no effect on rheology, impart no discoloration or odors to the coatings, be water soluble in concentrations used, and be environmentally acceptable [5–7].

Dry-Film Preservation

Microorganisms involved with dry-film problems include bacteria, algae, and fungi. Bacterial growth requirements are noted in the above paragraphs. In addition to sources of carbon, nitrogen, and hydrogen, most fungi require a relative humidity of 60 % or greater. All filamentous fungi are aerobic whereas the unicellular yeast can be aerobic or anaerobic. The ideal temperature range for fungi is 20–35°C. Although fungi can grow in alkaline conditions, the ideal *p*H range is 4.5–6.5. Algae are photosynthetic; they require light, carbon dioxide and water (i.e., moisture) to produce energy. They survive in alkaline conditions and temperatures of 15–30°C.

The most understood problem associated with dry-film preservation is the defacement and discoloration of the film itself when applied to surfaces such as interior and exterior walls of buildings, bridges, and ships [4, 8–10]. Algae are more of a serious problem in temperate and tropical regions and especially on masonry surfaces because of the alkaline conditions [11,12]. Algal growth may produce minor defacement; however, it will increase moisture retention, which can lead to other problems [10]. In hard, calcium-rich fresh water, algae can also cause the precipitation of calcium carbonate onto submerged surfaces, including antifouling paint [13]. Fungi can produce mycelia and spores that will disfigure dry-film. If the mycelia can grow through the coating, subsequent problems can include the film losing adhesion, the initiation of corrosion, and the deterioration of wooden structures. Table 2 lists problems in paint and coating film preservation.

TABLE 2—Problems in paint and coating film preservation

Type of Problem	Common Cause
Defacement/discoloration/dirt entrapment	Algae and/or fungi; some bacteria growing on film
Loss of adhesion	Fungi growing under film
Deterioration of structure (wooden)	Fungal enzymes catalyzing the breakdown of cellulose, hemicellulose, and lignocellulose
Antifouling paint failures on marine crafts, etc.	Bacteria, algae (including diatoms), fungi, barnacles
Corrosion	Bacteria, such as sulfate reducers, and moisture from fungi initiating corrosion
Destruction of cultural material	Bacteria, algae, and fungi growing on paintings, statues, and buildings

Studies [14,15] have indicated the succession of microbial populations on dry-film as well as surfaces coated with antifouling paint. Initial colonization is from bacteria that produce extracellular capsular material. The resulting conditioning of the surface allows for the subsequent growth of fungi, algae, and other organisms. These studies indicate the need for a dry-film preservative to be broad-spectrum in its activity, i.e., it must be effective against bacteria as well as fungi and/or algae. Other requirements for a dry-film preservative include stability over a wide *p*H range, temperature stability, low water solubility to prevent or retard leaching, UV stability, long-lasting efficacy, compatibility with the other materials in the formulation, no discoloration or odors imparted, and environmental acceptability [6,7].

GROUPS OF MICROORGANISMS RELATED TO BIOCIDAL EFFICACY

It is important to know the activity of a particular microbicide against the types of organisms encountered during in-can or dry-film preservation. For this purpose, the most important groups of microorganisms are:

Bacteria
Aerobic bacteria
  Gram positive bacteria
    endospore-forming bacteria
  Gram negative bacteria
Facultative anaerobic bacteria
  Gram negative bacteria
Anaerobic bacteria
  Gram positive bacteria
    endospore-forming bacteria
  Gram negative bacteria
Oxygenic, photosynthetic
bacteria (Cyanobacteria, formerly called the 'blue-green' algae)

Fungi
Multicellular (molds)
Unicellular (yeasts)

Algae
Green algae
Brown algae

MODE OF ACTION OF MICROBICIDES: SPECTRUM OF ACTIVITY

The spectrum of activity of a microbicide will describe which organisms or group of organisms will be the targeted by the biocide. Typically, microbicides are considered narrow spectrum, i.e., activity against one group or sub-group, or broad spectrum, i.e., two or more groups of organism will be affected. Thus, microbicides can be generally categorized as bactericides, fungicides, and algicides. Because algae and fungi are eukaryotes, their overall cellular structures are different and somewhat more complex than the prokaryotic bacterial cells. Thus, fungicides and algicides are generally more toxic than bactericides.

Concentration will also affect a microbicide's spectrum of activity. At higher levels, some bactericides are effective against fungi. The reverse is also true; some fungicides at lower concentrations will act as bactericides. Another aspect of concentration is the difference of a chemical being microbiocidal (or biocidal) and microbiostatic (biostatic). At low concentrations, some microbicides will be microbiostatic; instead of killing organisms, a microbiostat will react with a physiological activity of a group of organisms to prevent their growth.

Various microbicides used for in-can preservation are listed in Table 3. These agents are incorporated into a paint or coating formulation to prevent microbial contamination of the final product; they are not added at elevated concentrations to treat a contaminated component of the formulation. Therefore, for any in-can preservative to be effective, it is assumed that microbial contamination during the manufacturing process has been kept to minimal levels.

Common microbicides for dry-film preservation are listed in Table 4; most anti-fouling agents are not specifically covered in this chapter. Dry-film preservation actives differ from in-can actives because of two factors. Firstly, as described above, dry-film contamination is typically caused by fungi and algae rather than bacteria alone. Secondly, dry-film preservatives have to be effective for extended periods of time; this can be years as compared with months for in-can preservatives.

Table 5 lists some other microbicides used in paints and coatings, especially during the manufacturing process. As stated above, contamination of raw materials must be kept to a minimum. The process water must also be kept as clean as possible. Disinfection of process vessels and pipes along with general good housekeeping procedures should also help to decrease microbial contamination.

MODE OF ACTION OF SOME ANTIMICROBIAL AGENTS

The following is used to give a general overview of the more common modes of action of the microbial agents listed in Tables 3–5.

Formaldehyde-Releasing Agents

Many microbicides are classified as formaldehyde-releasing compounds. They are produced by reacting formaldehyde with amides (N-formals), with alcohols or glycols (O-formals) or with amines or aminoalcohols (N,O-formals) [7]. As implied by the category, some are biocidal due to the release of formaldehyde. However, under application conditions, certain microbicides in this category do not rely on the release of formaldehyde for their specific mode of action. The liberation of formaldehyde is also related to *p*H; at alkaline *p*H, little or no formaldehyde will be released.

Aldehydes including formaldehyde deactivate protein by interacting with amine groups on the protein. Proteins are found on the outer layers of microorganisms. Also, all enzymes, i.e. catalysts for many metabolic reactions, are protein. The deactivation of protein leads to disruption in cellular metabolism and transportation across cell walls and membranes and ultimately leads to death of the organism.

Formaldehyde can also be classified as an electrophilic agent, i.e., a compound that reacts with the nucleophilic components of a cell.

Agents that React with Nucleophilic Groups

Nucleophilic groups are described as those species that are electron rich. The nucleophilic groups that are commonly found in microorganisms are thiols ($^{-}$SH) and amines (NH_2). Both are found in various amino acids, the building blocks of protein. Proteins are distributed throughout microbial cells, especially in cell membranes and cell walls. Nucleophiles are attracted to electron-poor species, i.e., electrophiles. Thus, microbicides containing electrophilic groups react with the nucleophilic areas of the microbial cells, deactivating the organisms.

Coating components may contain nucleophilic groups and consequently an electrophilic biocide will react with these components. If the typical concentration of microbicide is used in these instances, a portion of the biocide is essentially deactivated and will not be available as a preservative. Therefore, a general knowledge of a microbicide's mode of action will prevent failures in both in-can and dry-film preservation.

Agents that Chelate Metals

Metals are trace elements needed for microbial growth and metabolism. They serve as co-factors for enzymes and are components of some vitamins. Microbicides that are chelating agents will tie up these trace metals; the consequence is disruption in some metabolic processes and eventual microbial death.

STRATEGIES FOR MINIMIZING RESISTANT STRAINS

There are several mechanisms by which microorganisms become less susceptible to microbicides. Reduced susceptibility can be due to intrinsic properties, such as cell structure (e.g., gram positive versus gram negative bacteria), efflux systems that remove various agents [16], and actual deactivation of the microbicides [17]. Organisms can also reduce susceptibility due to acquired mechanisms, including the acquisition of a plasmid or through genetic mutation.

Simple strategies can help minimize the appearance of resistant strains. The most important strategy is general good housekeeping during manufacturing. Allowing water

TABLE 3—Microbicides used for in-can preservation

Chemical Name	CAS Reg. Number	Target Organisms	Putative Mode of Action
4,4-dimethyl-oxazolidine	51200-87-4	Bacteria/fungi	Formaldehyde releaser
5-hydroxy-methyl-1-aza-3,7-dioxabicyclo (3,3,0) octane	56709-13	Bacteria—as a bacteriostat	Formaldehyde releaser
Hexyhydro-1,3,5-tris-(2-hydroxyethyl)-s-triazine	4719-04-4	Bacteria	Formaldehyde releaser
Hexyhydro-1,3,5-triethyl-s-triazine	7779-27-36	Bacteria	Formaldehyde releaser
1-(3-chloroallyl)-3,5,7-triaza-1-azonia-adamantane2[(Hydroxymethyl)amino] ethanol	44080-31-3	Bacteria/fungi	Formaldehyde releaser
	34375-28-5	Bacteria/fungi	Inhibits active transport; coagulates protein; hydrolysis results in release of formaldehyde
4,5-dichloro-2-n-octyl-4-isothiazolin-3-one	64359-81-5	Fungi/algae	Reacts with thiols and amines
([([(2-dihydro-5-methyl-3(2H)-oxazolyl)-1-methylethoxy] methoxy) methoxy] methanol	40382-75-0	Bacteria/fungi	Formaldehyde releaser
Sodium hydroxymethylglycinate 1-hydroxymethyl-3,5-dimethylpyrazole	70161-44-3	Bacteria/fungi	Formaldehyde releaser
	85264-33-1	Bacteria	Inhibits alcohol dehydrogenase and ethanol metabolism
1,2-dibromo-2,4-dicyanobutane	35691-65-7	Bacteria/fungi/algae	Has several highly electron withdrawing centers
5-chloro-2-methyl-3(H)-isothiazoline+2-methyl-3(H)-isothiazoline	26172-55-4 2682-20-4	Bacteria	Inhibits macromolecular synthesis (DNA,RNA, proteins, etc.) plus forms highly reactive radical
1,2-benzisothiazoline-3-one	2634-22-5	Bacteria	Reacts with thiol groups, especially those associated with the cytoplasmic membrane
2-bromo-2-nitropropane-1,3-diol	52-51-7	Bacteria	Reacts with thiol groups, especially those associated with enzymes
Blend of 1,2-benzisothiazoline-3-one+2-methyl-3(H)-isothiazoline	2634-22-5 2682-20-4	Bacteria	Reacts with thiol groups
Blend of 1,2-benzisothiazoline-3-one+2-bromo-2-nitropropane-1,3-diol	2634-22-5 52-51-7	Bacteria	Reacts with thiol groups
Blend of 5-chloro-2-methyl-3(H)-isothiazoline+2-methyl-3(H)-isothiazoline+ 2-bromo-2-nitropropane-1,3-diol	26172-55-4 2682-20-4 52-51-7	Bacteria	Reacts with thiol groups

to remain in pipes and vessels that previously contained treated material will provide diluted microbicide in non-lethal concentrations. This low-level exposure can lead to microorganisms becoming resistant. The same principle applies to the treatment of raw materials; low-level dosages of microbicides can also lead to reduced susceptibility in the microorganisms.

Another strategy commonly used to minimize the development of less-susceptible strains is to change to a biocide with a different mode of action. However, there is some debate as to the usefulness of this practice. Studies have shown that when an organism becomes less susceptible to one biocide, it will also become less susceptible to several chemically unrelated biocides [18].

Whenever the efficacy of a microbicide needs to be determined, organisms from the manufacturing plant or spoiled material should be used rather than stock cultures maintained on artificial media. The microorganism found in the spoiled material or in the production process will have been previously exposed to the existing biocide program and thus be more resistant than stock cultures. Knowledge of microbicides' mechanisms of action will also be useful when determining the appropriate treatment.

TABLE 4—Microbicides used for dry-film preservation

Chemical Name	CAS Reg. Number	Target Organisms	Putative Mode of Action
Diiodomethyl-p-tolyl sulphone	20018-09-1	Fungi	Reacts with nucleophilic cellular components
2-n-octyl-4-isothiazoline-3-one	26530-20-1	Fungi	Reacts with thiols and amines
3-iodo-2-propynyl butylcarbamate	55406-53-6	Fungi/algae	Chelates metals?
4,5-dichloro-2-n-octyl-4-isothiazolin-3-one	64359-81-5	Fungi/algae	Reacts with thiols and amines
1H-benzimidazole-2-ylcarbamic acid, methyl ester	10605-21-7	Fungi	Inhibits mitotic microtubule formation
N-(trichloromethylthio) phthalimide	133-07-3	Fungi	. . .
N′-(3,4-dichlorophenyl)-*N,N*-dimethyl urea	330-54-1	Algae	Inhibits photosynthesis
2-(thiocyanomethylthio)-benzothiazole	21564-17-0	Fungi/algae	Reacts with thiols; inactivates metal enzyme complexes
N-cyclopropyl-*N′*-(1,1-dimethylethyl)-6-(methylthio) -1,3,5-triazine-2,4-diamine	28519-98-0	Algae	Reacts with thiols; inhibits photosynthesis
2,4,5,6-tetrachloro isophthalonitrile	1897-45-6	Fungi/gram positive bacteria	Reacts with amines; chelates metals; interrupts electron transport
2-(thiocyanomethylthio)-benzothiazole+methylene bis(thiocyanate)	21564-17-0 6317-18-6	Bacteria/fungi/ algae/anaerobic bacteria	Uncouples oxidative phosphorylation; reacts with thiols
1-([2-(2,4-dichlorophenyl)-4-propyl-1,3-dioxolan-2-yl] methyl)-H-1,2,4-triazole	60207-90-1	Fungi	Inhibits demethylation of ergosterol in cell membranes
Zinc-2-pyridinethiol-N-oxide	13463-41-7	Fungi/algae	Chelates necessary metals
Barium metaborate	13701-59-2	Bacteria/fungi	Inhibits enzymes
Dodecylguanidine hydrochloride	13590-97-1	Bacteria/fungi/ algae	As a cationic surfactant—disrupts cell walls and cytoplasm
Blend of 3-iodo-2-propynyl butylcarbamate+ 1H-benzimidazole-2-ylcarbamic acid, methyl ester	55406-53-6 10605-21-7	Fungi/algae	Inhibits mitotic microtubule formation
Blend of 3-iodo-2-propynyl butylcarbamate+ 1H-benzimidazole-2-ylcarbamic acid, methyl ester+ *N*-cyclopropyl-*N′*-(1,1-dimethylethyl)-6-(methylthio)-1,3,5-triazine-2,4-diamine	55406-53-6 10605-21-7 28519-98-0	Fungi/algae	Inhibits mitotic microtubule formation and photosynthesis
Blend of 3-iodo-2-propynyl butylcarbamate + *N′*-(3,4-dichlorophenyl)-*N*, *N*-dimethyl urea	55406-53-6 330-54-1	Fungi/algae	Inhibits photosynthesis
Blend of 3-iodo-2-propynyl butylcarbamate+ 4,5-dichloro- 2-n-octyl-4-isothiazolin-3-one	55406-53-6 64359-81-5	Fungi/algae	Reacts with thiols and amines
Blend of 3-iodo-2-propynyl butylcarbamate+-*n*-octyl-4- isothiazoline-3-one+*N′*-(3,4-dichlorophenyl)-*N,N*-dimethyl urea	55406-53-6 26530-20-1 330-54-1	Fungi/algae	Reacts with thiols and amines and inhibits photosynthesis
Blend of 4,5-dichloro-2-n-octyl-4-isothiazolin-3-one+*N*-cyclopropyl-*N′*-(1,1-dimethylethyl)-6-(methylthio)-1,3,5-triazine-2,4-diamine	64359-81-5 28519-98-0	Fungi/algae	Reacts with thiols and amines
Blend of 4,5-dichloro-2-n-octyl-4-isothiazolin-3-one+2-n-octyl-4-isothiazoline-3-one	64359-81-5 26530-20-1	Fungi/algae	Reacts with thiols and amines
Blend of 2-n-octyl-4-isothiazoline-3-one+2,4,5,6-tetrachloro isophthalonitrile+*N′*-(3,4-dichlorophenyl)-*N,N*-dimethyl urea	26530-20-1 1897-45-6 330-54-1	Fungi/algae/gram positive bacteria	Reacts with thiols and amines; chelates metals; inhibits photosynthesis
Blend of 2,4,5,6 -tetrachloro isophthalonitrile+*N′*-(3,4-dichlorophenyl)-*N,N*-dimethyl urea	1897-45-6 330-54-1	Fungi/algae/gram positive bacteria	Reacts with amines; chelates metals; inhibits photosynthesis
Blend of *N′*-(3,4-dichlorophenyl)-*N,N*-dimethyl urea+1H-benzimidazole-2-ylcarbamic acid, methyl ester	330-54-1 10605-21-7	Fungi/algae	Inhibits mitotic microtubule formation and photosynthesis

TABLE 5—Other microbicides used in the paint and coating industry

Chemical Name	Target Organisms	Putative Mode of Action
Glutaraldehyde	Bacterial endospores/ bacteria/fungi/algae	Reacts with amines
Parabens	Fungi	Disrupts membrane activity
Quaternary ammonium compounds	Bacteria/algae	As cationic compounds—disrupt cell walls and cytoplasm
Chlorine and other oxidants	Bacteria/fungi/ algae	Deactivates protein

ANALYSIS AND NEUTRALIZATION OF MICROBICIDES

In many instances, it is important to be able to detect the presence and even the concentration of the microbicide in a raw material or final paint or coating formulation. This may be part of quality control, i.e., documenting that the microbicide was added at the appropriate dosage rate.

The appropriate analytical method will vary according to the microbicide's active ingredient(s). Ideally, the procedure should not destroy the original active molecule(s). For example, it would be preferable to detect the intact molecule of a formaldehyde releaser rather than the formaldehyde that may have already been released prior to analysis or released due to the analytical procedure. Nondestructive methods include nuclear magnetic resonance.

TABLE 6—Factors that positively influence microbicide efficacy

Inclusion of pigments that have antimicrobial activity	Such components could possibly reduce the amount of preservative needed
Inclusion of other materials in the formulation that have antimicrobial activity (e.g., propylene glycol) or resist degradation	Some compounds are not readily used as a food source
Choosing a suitable *p*H range for the microbicide	Because some microbicides are more effective at acid *p*H and others at alkaline *p*H, the *p*H of the formulation could be adjusted to suit the microbicide
Differences in solubility of different microbicides	Combinations of microbicides with different solubilities could increase overall efficacy
Synergism resulting from the combination of microbicides with different modes of action	Antimicrobial agents are frequently complemented in combination, e.g., methylene bis(thiocyanate)/ 2-(thiocyanomethylthio) benzothiazole

Literature from the microbicide supplier, such as the material safety data sheet, will contain information regarding the proper procedure for deactivating a microbicide. If a spill occurs, the chemical will need to be neutralized and cleaned without danger to personnel or the environment.

FACTORS IMPACTING THE EFFICACY OF SOME COMMON MICROBICIDES

Physical and chemical factors not only affect the growth of microorganisms but also impact the efficacy of any microbicide. Some factors are listed in Tables 6 and 7.

METHODS FOR THE DETERMINATION OF MICROBICIDE EFFICACY

There are many standard methods described in the literature for the determination of a microbicide's efficacy for either in-can or dry-film preservation. The ASTM methods include D2574-06, Standard Test Method for Resistance of Emulsion Paints in the Container to Attack by Microorganisms; D3273-00(2005), Standard Test Method for Resistance to Growth of Mold on the Surface of Interior Coating in an Environmental Chamber; and D3456-86(2002), Standard Practice for Determining by Exterior Exposure Tests

TABLE 7—Factors that decrease microbicide efficacy

*p*H	Knowledge of the chemistry of a microbicide should include its activity at various *p*H. Many are less effective at alkaline *p*H. Stability should not be equated with efficacy; a microbicide may be stable at alkaline *p*H but with little efficacy.
Addition temperature	Any biocide will be deactivated to some degree by elevated temperature; MSDS and other literature can provide needed information
Nonionic surfactants	Some biocides are deactivated by these, including the parabens, organic acids, and aromatic alcohols
Low solubility	Preservatives need to be water-soluble to the concentration required for efficacy.
Leachability	A dry-film preservative must maintain an effective concentration throughout the film; leaching of water-soluble actives would lead to reduction in efficacy.
Formulation components	Some biocides are deactivated by these, i.e. protein can deactivate formaldehyde releasers
UV light frequency	UV light frequency decomposes dry-film fungicides and algicides and efficacy is lost

the Susceptibility of Paint Films to Microbiological Attack. A review of industry- and government-mandated methods to demonstrate fungicide efficacy is described in Ref. [19] with testing of algicides for tropical locations described in Ref. [20].

REGULATORY ISSUES

Because of environmental concerns, many heavy metal microbicides are no longer used. In the United States, organo-mercurials were banned from interior paints in 1990 and exterior paints in 1991. The use of various tributyltins was being restricted by several countries, including France [21], Japan, the United States, the United Kingdom, and Germany [22]. In 2001, the International Maritime Organization adopted the International Convention on the Control of Harmful Anti-fouling Systems on Ships (AFS Convention). Effective January 1, 2003, ships would not apply or re-apply organotin compounds. After January 1, 2008, ships would either not have organotin compounds on the hulls, surfaces, or external parts or the ships would have a barrier coating that would prevent the leaching of the organotin compound. The AFS convention entered into force on September 17, 2008. Replacement options include copper-based coatings. However, Canada, the United States, and the Netherlands have regulated copper emissions and/or discharge into their waters [23].

The greatest challenge for microbicide manufacturers worldwide is the Biocidal Products Directive 98/8/EC of the European Union. One aim of this directive is to increase the level of protection to humans, animals, and the environment by establishing a list of permitted active ingredients. The directive was enforced beginning in May 2000 with a ten-year period for the review of all existing actives. Any new active will go through a similar assessment. Because of the anticipated costs associated with this process, it has been speculated that manufacturers may not pursue the assessment of some existing actives. This may have an impact on the actives traditionally used for in-can and dry-film preservation. Instead of introducing new actives, many microbicide manufacturers are registering formulations of blends of approved actives (see Tables 3 and 4).

The current trend in paints and also in microbicides is to produce low-to-no-volatile organic compound (VOC) products. This is being driven by stricter environmental regulations in Europe and North America and by consumers' demand for more environmentally friendly products. Most microbicide manufacturers have low- and no-VOC versions of their actives.

Surfactants

Elvira Stesikova[1] and Heinz Plaumann[1]

INTRODUCTION

SURFACE ACTIVE AGENTS OR "SURFACTANTS" represent a diverse spectrum of chemical compounds capable of modifying interfacial interactions by means of adsorption at interfaces. Since an interface is created when any two phases of immiscible components are present, it is virtually impossible to exclude or ignore interfacial aspects from any practical application. Coatings are no exception, but rather a unique expression of various surface phenomena governing the entire application.

The advent of waterborne and water-based technologies produced more environmentally benign paint formulations, but brought along new technological challenges that did not exist in solvent-based paints. Considering that typical water-based paint consists of an emulsified binder and dispersed pigments, the complexity of paint formulations is caused not only by their multi-component composition but also their multiphase nature and inherent thermodynamic instability. In such complex systems, surfactants play an extremely important role, since they represent additives that facilitate dispersion, provide much desired shelf stability, and destabilize foam. Moreover, surfactants are used in coatings as wetting, coalescent and pigment dispersant agents to aid coating application, film formation and color development.

In addition to the challenges provided by thermodynamic instability of paint systems and kinetics of their phase separation, environmental laws and regulations introduced new standards and additional requirements that will continue to have significant impact on the coating industry. Among many actions taken by state and federal legislative parties, the Clean Air Act of 1970 defines volatile organic contents (VOCs) and stipulates its permissible limits. In addition to the body of federal regulations, an increased consumers' awareness instigated new market initiatives that drive towards alkyl phenol ethoxylate (APEO), free consumer products. All these provide rather stringent guidelines to paint formulators with regard to the selection of dispersing media and functional additives, including surfactants.

Compliance with regulations is compounded with another requirement—ever-growing performance standards. Consumers demand convenience of application, durability, efficiency, and low price. A new trend, contemporary color designs in the architectural coatings, involves deep tones and various textures. This presents new challenges to the chemical community of paint developers that have to deal with more complex issues of pigment stabilization, uniform color development, environmental stability, and potential touch-up applications. Fast-growing and highly demanded do-it-yourself application materials present their own set of challenges with regard to stability and consistency of the paints.

Undeniably, the fundamental technological challenges, legislative regulations, and market trends are the main driving forces behind the developments leading to the introduction of nonvolatile APEO-free surface-active additives on the market. However, the objective of this review is to describe some of the basic properties of various types of surfactants and to develop a rational approach for their use in various coating applications. As elaborated later in this chapter, surfactants in coatings have multiple roles and functions. Initially, surfactants are used as a dispersing aid during the pigment-grinding stage, where they provide better wetting of the pigment particles. Moreover, surfactants are required as primary and/or secondary emulsifiers to produce stable interfaces. Finally, surfactants impart certain physical properties to the water-based coatings, such as better wetting of the substrate, improved stability and film integrity, optimized color acceptance, and minimized film defects.

DEFINITION AND CHEMICAL STRUCTURE

A surfactant is a chemical compound consisting of two well-defined and sufficiently separated moieties of opposite polarity or solubility: oil soluble (lipophilic or hydrophilic) and water soluble (hydrophobic). Fig. 1 shows a general structure of a surfactant molecule possessing those two components of opposite polarity. The hydrophilic "head" group of the surfactant molecule consists of polar ionic or nonionic groups, which interact strongly with water. The hydrophobic "tail" group is non-polar, usually consists of aliphatic or aromatic hydrocarbon residue, and has little or no affinity to the aqueous phase.

This dual nature of surfactants is responsible for their so-called amphiphilic properties, the most significant of which is their tendency to adsorb at an interface and modify interfacial interactions [1,2]. At the interface, amphiphiles are allowed to orient themselves so that the hydrophobic part of the molecule can escape from the aqueous environment, whereas the hydrophilic head group remains immersed in the water phase. This peculiar interfacial orientation of surfactant molecules is responsible for lowering interfacial surface energy. The latter is one of the fundamental properties of the surfactants, which eases the formation of new surface and stabilizes the existing one.

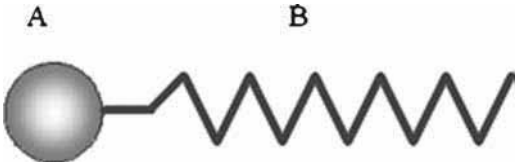

Fig. 1—Basic chemical structure of surface-active molecules with hydrophilic (a) and hydrophobic (b) components.

Owning to their ability to modify interfacial interactions, surfactants are widely used in coatings formulations. In recent times, the term "surfactant" is used as a general term for surface-active agents, which include emulsifiers, wetting and dispersing agents, and foaming and coalescent agents [3,4].

Coating surfactants differ in molecular chemistry, structure, and molecular weight. An assortment of widely used surfactant classifications exists today. This fact could be rationalized based on the diversity of molecular chemistries and the needs of the application community. One classification approach is based simply on the intended use, where surfactants may be classified as emulsifiers and wetting, dispersant, or foaming agents. Another approach is based on physical properties such as water or oil solubility, hydrophilic-lipophilic balance (HLB), cloud point, or viscosity characteristics. Alternatively, classification may be primarily based on the overall chemical structure of the materials. This latter approach provides general guidance for structure-property relationship and develops some rules for the correlation of chemical structure and interfacial activity. Therefore, the following discussion will be focused on the molecular architecture and surface activity of surfactants, whereas subsequent chapters will address physical characteristics and application aspects of surfactants in relation to coatings.

In addition to the above mentioned classifications, it is also important to distinguish between low molecular weight and high molecular weight surfactants. The former exhibit high molecular mobility [1], whereas the latter adsorb forming a thick protective layer that provides steric stabilization [5]. Overall, the molecular weight of the surfactants is relatively high and ranges between 300 and 2,000, which is essential to providing sufficient separation of the structural units and allowing them to reveal their properties.

Surfactant classification, depicted in Fig. 2 and discussed below, is based on the chemical nature of both hydrophilic and hydrophobic groups. Most hydrophilic groups of the surfactants fall into two major categories, ionic and non-ionic. The former, depending on the charge, could be further divided into anionic, cationic or Zwitterionic surfactants.

Anionic

Anionic surfactants are materials of significant practical and economical interest. They contain a negatively charged polar head group, such as sulfonate, sulfate, carboxylate, or phosphate, attached to a hydrophobic moiety, such as alkyl, alkyl phenol, alkyl ether, or alkyl phenol ether chain. The right balance of surface activity is achieved when an anionic group is linked to a hydrocarbon chain containing 10–20 carbon atoms [6]. Shorter hydrocarbon chains render the molecule too water soluble. Longer hydrocarbon

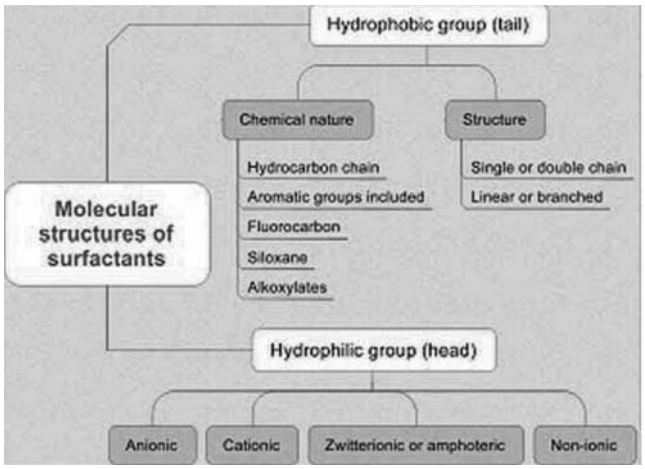

Fig. 2—Surfactant classification based on chemical nature of hydrophilic and hydrophobic groups.

chains contribute to insolubility and limited water-based applications.

These charged molecules adsorb on the surface of a particle, impart a charge, forming the so-called Helmholtz electric layer [1]. The charged layer around the particle creates electrostatic repulsive forces to guard against coagulation. The main disadvantages of anionic surfactants include the fact that they form water-insoluble salts with divalent and trivalent cations (Mg^{2+},Ca^{2+},Fe^{3+}), precipitate from brine solutions, and increase water sensitivity of the coatings.

Cationic

Quaternary ammonium compounds are the most commonly used cationic surfactants that bear a positive charge on the polar moiety of the molecules. The composition of the hydrophobic tail is similar to that of anionic surfactants and includes aliphatic, aromatic, ether chemistries, and combinations thereof. Because of their wider bactericidal activity, the major use of cationic surfactants is found in germicides and fungicides. Despite their high cost, they are also used for pigment dispersion.

Amphoteric and Zwitterionic

The term "amphoteric surfactant" is referred to amphiphilic compound that, depending on the *p*H of the media, is capable of carrying both anionic and cationic charges. *N*-alkyl amino acid is a typical example of *p*H-dependent amphoterics. However, there are amphiphiles that contain both strongly acidic and strongly basic groups and show both anionic and cationic properties independent of the *p*H. Such molecules are specified as Zwitterionic surfactants. Lecitin is an example of a Zwitterionic surfactant that has been traditionally used as a dispersant agent of organic pigments. In general, however, these surfactants are rarely used in the coatings industry since they are unable to provide electrostatic stabilization, and present only 2 % of the world surfactant market [1].

Nonionic

Despite wide utilization of anionic surfactants, chemical coagulation may be avoided by using nonionic surfactants. These molecules have no charge, but incorporate

well-defined hydrophilic and hydrophobic parts. Typically, the hydrophile is composed of ethylene oxide units and can be attached to fatty acid esters of glycerol, sorbitol, or propylene glycol. Widely used and commercially available nonionic surfactants include alkylphenol polyethoxy alcohol, having a series of various degree of ethoxylation and length of alkyl chains. For example, Emulan® (BASF), Triton® (Union Carbide), and Igepal® (Rhone-Poulenc) surfactants are very effective additives having excellent interfacial properties and are used as emulsifiers, dispersants, and wetting agents.

Due to increased environmental considerations, alkyl phenol-free surfactants are getting more attention in the industry and, in some applications, gain enough grounds to replace alkyl phenol-containing additives. Alkyl phenol-free surfactants are rather diverse and are based on EO-PO block copolymers (Pluronic® surfactant series) and alkyl alkoxylates (Lutensol® XP and XL surfactant series). Acetylenic glycols, containing a polar group surrounded by two bulky hydrophobic tails (Air product's Surfynol® surfactant series), is another example of a unique surfactant chemistry that found its applications as an effective wetting agent, defoamer, and surface tension reducer [7].

The main distinction between ionic and nonionic surfactants is the charge and the molecular weight of their molecules. The lack of ionic groups is primarily responsible for lower water sensitivity of nonionic surfactants. Because of their higher molecular weight, the water-soluble segments of nonionic surfactants extend into the water phase, forming a viscous barrier layer. This imparts steric stabilization by inhibiting the approach of another particle and preventing coagulation. Despite their unique advantages, most of the time, nonionic surfactants are used in combination with ionic amphiphiles. Such blends enhance sheer, mechanical and electrolyte stability of the paint in a wider *p*H range, electrolyte concentrations, and temperature conditions. Thus, the presence of anionic surfactant allows compensation for limited solubility of nonionic surfactants at temperatures above their cloud point. Nonionic surfactants, on the other hand, provide additional stabilization to a dispersion when anionic surfactants experience electrolyte "shock" due to shrinking double electric layer at elevated electrolyte concentrations [8].

Hydrophobic Groups

Alkyl benzene and alkylated aromatics, paraffins, and olefins (branched and linear), long-chain alcohols, alkylphenol alkoxylates, fatty acids, and their derivatives are among typical and most commonly occurring hydrophobic groups of various amphiphilic molecules [1,6].

Fluorocarbon surfactants have similar molecular structures to the hydrocarbon molecules except all the carbon-hydrogen bonds are replaced by carbon-fluoride bonds. These surfactants exhibit extremely low surface tension, an average 10–20 mN/m lower than equivalent hydrocarbon [1]. Because of the extremely hydrophobic nature of these molecules, fluorocarbons have a very strong tendency to preferentially adsorb on the interface, reducing the surface tension down to 15–22 mN/m, and provide spontaneous spreading on low surface energy substrates. Despite their unique surface activity and chemical stability, the wide use of these surfactants is limited by their high cost and poor compatibility. The latter could precipitate adhesion problems in the coatings.

Silicone-containing surfactants are another type of nonhydrocarbon-based surfactant molecules. When functionalized to produce water-soluble molecules, their surface activity falls below hydrocarbons and above fluorocarbon-based surfactants. Silicone surfactants effectively adsorb on the interface, act as effective defoamers but do not exhibit aggregation behavior such as micelle formation and solubilization [5].

Polymerizable Surfactants

In recent years, with heightened demands for reduced VOC and improved performance, polymerizable surfactants have received much attention in both academic and industrial circles [9–12]. The attraction of using polymerizable surfactants for lattices is rationalized by the fact that surfactant concentration in the aqueous media and on the surface of a latex particle depends on many factors. These include particle concentration, temperature, ionic strength, *p*H, any of which could be changed during the storage and application affecting the stability of the latex. During the film formation and particle coalescence, the surface area of the particles is significantly reduced, freeing a substantial amount of surfactant to migrate toward remaining coating/substrate and air/coating interfaces. This behavior affects paint adhesion to the substrate and re-coating ability. This could also adversely affect water resistance of the film and its gloss.

It has been shown [9–12] that many surfactant-related problems could be avoided or minimized by using polymerizable surfactants that become covalently bonded to the latex particles during the emulsion polymerization. Several types of ionic and nonionic reactive surfactants have been introduced to the market. Most of them have ethylene and propylene oxide blocks combined with a polymerizable group like allyl (Reasoap™ surfactants, Clariant's Emulsogen® surfactant), vinyl (Emulsogen®) surfactant, diallyl (Plurocoat™ RS surfactants), acrylic (Unichema's Maxemul® surfactants, Eleminol™ surfactants), and styrene (Noigen™ and Hitenol™ surfactants).

THE PROPERTIES OF THE SURFACTANTS

Hydrophile-Lipophile Balance

Solubility, and many other surfactant properties, depends on the specific chemical structure of the amphiphile and the relative contributions of its hydrophilic and hydrophobic (i.e., lipophilic) components. An increase in the length of the hydrophobic portion of the surfactant molecule increases its oil solubility and reduces affinity to water. The reverse is true when the hydrophilic portion of the molecule is increased in proportion to the hydrophobe. The balance of hydrophilic and lipophilic groups in a molecule is known as HLB.

Introduced by Griffin [13,14] and further developed by Davies [15,16], HLB is an attempt to quantify surfactants' properties to determine their affinity to hydrophilic or lipophilic solvents. Griffin [13,14] proposed a scale ranging from 1 to 20. The extremes represent predominantly lipophilic oleic acid and predominantly hydrophilic sodium oleate, respectively, while their mixtures of different compositions represent continuum between these two extremes. The balance of hydrophilic and lipophilic properties (HLB)

TABLE 1—List of hydrophilic and lipophilic moieties of surfactant molecules				
	Hydrophilic		**Lipophilic**	
Ionic	Sulfate	$-OSO_3^-$	Linear or branched	C_6–C_{20}
	Sulfonate	$-SO_3^-$	alkyl	C_6–C_{20}
	Carboxylate	$-CO_2^-$	Alkynebenzene	
	Quaternary ammonium	R_4N^+	Fluoroalkyl	–
Nonionic	Alcohol	$-CR_2OH$	Poly(ethylene oxide)	$(OCH(CH_3)CH_2)_n-$
	Ether	–COC–		$-(OSi(CH_3)_2)_n-$
	Poly(propylene oxide)	$-(OCH_2CH_2)_n-$	Polysiloxane	

is, therefore, expressed in terms of relative amounts of each ingredient in the composition

$$\text{HLB} = 1W_1 + 20W_2 \quad (1)$$

where W_1 and W_2 are the weight fractions of oleic acid and sodium oleate, respectively. Their blends of various compositions dissolved in 50/50 mixture of water/oil serve as reference standards. The state of emulsification of any commercial emulsifier could then be observed and matched to that of a corresponding standard of known HLB that exhibits similar behavior.

Another empirical relation, obtained by Davies [15,16], uses the group contributions:

$$\text{HLB} = 7 + \sum H \text{ (hydrophilic group numbers)} - \sum L \text{ (lipophilic group numbers)} \quad (2)$$

where ΣH is the sum of contributions of hydrophilic groups, and ΣL is the sum of contributions of hydrophobic groups. This equation agrees that the higher the HLB value, the more polar and hydrophilic the surfactant, and stronger its affinity to water. The HLB group numbers are listed in Table 2. Both approaches to HLB calculation [Eqs (1) and (2)] provide satisfactory agreement, especially considering that HLB is only one factor determining interfacial activity of the surfactant.

As a general guideline, HLB > 11 corresponds to a water-soluble surfactant, and HLB > 9 represents an oil-soluble surfactant. In practice, the solubility in water itself may be used to estimate HLB value of surfactants (Table 3).

HLB is an important characteristic for selecting the right surfactant for the application. According to the HLB value, surfactants can be conventionally divided into several groups according to their application potential, as shown in Table 4.

TABLE 2—Davies' HLB Group Numbers (data from Ref. [16])		
Group Type		**Group Number**
Hydrophilic	$-OSO_2^-Na^+$	38.7
	$-CO_2^-K^+$	21.1
	$-CO_2^-Na^+$	19.1
	R_4N^+	9.4

	$-CH_2-$	
	CH_3-	
	=CH–	
	$-(OCH_2CH_2)_n-$	0.33
	$-(OCH(CH_3)CH_2)_n-$	–0.15

Surface Adsorption

Surface free energy is usually associated with disruption of immediate molecular environments of the bulk phases and formation of an interface. The surface free energy per unit area, defined as surface tension σ, is the minimum amount of work required to create new unit area of that interface (ΔA):

$$W_{\min} = \sigma_o \times \Delta A \quad (3)$$

Therefore, a surface active agent is a substance that, at low solution concentrations, adsorbs on the interface and, thereby, changes the amount of work required to expand that interface, i.e., reducing surface tension. Specifically, at the air/water interface, adsorption of the surfactant is driven by unfavorable hydrophobic interactions. The

TABLE 3—Correlation between solubility of a surfactant in water and its HLB value

10–18	Solubilizers

presence of hydrocarbon groups of the dissolved amphiphilic molecule causes distortion of hydrogen bonding network of water molecules and increase of the free energy of the system. This is known as a hydrophobic effect [17]. Once the surfactant is present in the solution, substantially less work is required to bring a surfactant molecule, rather than a water molecule, to the surface. Hence, migration and preferential adsorption of a surfactant on the interface is a spontaneous process. As concentration of the surfactant in the solution increases, the formation of an oriented and densely packed surfactant monolayer with the hydrophobic tails extends away from the water and the hydrophilic head groups submerge into the water phase [Fig. 3(*a*)].

The surfactant's adsorption at an interface is a dynamic process that quickly establishes its equilibrium between two phases: surfactant dissolved in the media and molecules adsorbed at an interface. Classical equations by Gibbs and Langmuir describe quantitative relationships between the equilibrium adsorption and major affecting factors, such as interfacial surface tension and surfactant concentration Thermodynamics of surfactant adsorption from solution are reviewed in detail elsewhere [1,2,6,8,18].

The key property defining surfactant molecules is their ability to adsorb on an interface and reduce interfacial surface tension. The surfactant's ability to reduce surface tension of a solution depends on both its efficiency and effectiveness [2]. Efficiency is related to the minimum concentration of the surfactant required to produce a given surface tension reduction. Effectiveness of the surfactant is the maximum reduction in surface tension that can be obtained regardless the concentration. Efficient surface active agents have relatively low molecular weight and, therefore, high molecular mobility. Surfactants, which diffuse or migrate rapidly, impart to the paint, by definition, low dynamic surface tension and, therefore, reach equilibrium much faster than higher molecular weight surfactants.

Micellization

Adsorption of a surfactant at the interface occurs over a wide range of surfactant concentrations and is typically complete above a well-defined concentration, called critical micelle concentration (CMC). At the CMC, the interface is near its maximum coverage and, to further minimize the free energy of the system, the surfactant is forced to form aggregates in the bulk. Thus, above the CMC, the system consists of adsorbed surfactant monolayer at the air/water interface [Fig. 3 (*a*)], free monomeric surfactant dissolved in the bulk phase [Fig. 3(*b*)] and micelle aggregates in the bulk phase [Fig. 3 (*c*)]. Dynamic equilibrium is quickly

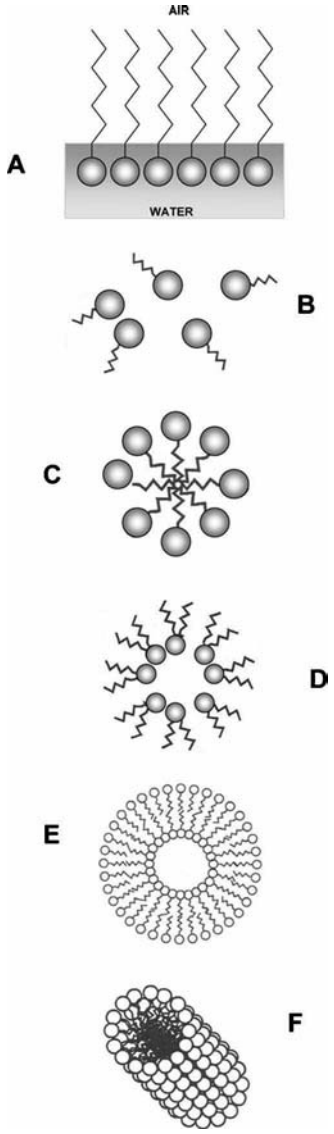

Fig. 3—Schematic illustration of surfactant aggregates: Monolayer (a), monomeric state (b), micelle (c), inverted micelle (d), liposome (e), and rod-like micelle (f).

established between all three states of surfactant existence in the system.

The same mechanism, i.e., "hydrophobic interaction," that causes adsorption of amphiphilic molecules on an interface, also leads to spontaneous association of such molecules to form aggregates or micelles, when their concentration is sufficiently high [1,2,6,8]. Micelle formation occurs over a fairly sharp, well-defined region called CMC. Above the CMC, additional surfactant molecules form the aggregates, whereas the concentration of unassociated surfactant remains fairly constant and equal to the CMC. Most importantly, at much the same concentration, a rather dramatic change in concentration dependence can be observed in common surfactant solution properties (Fig. 4). The sudden change in solution properties is attributed to a significant change in the nature of the solution and formation of aggregates or micelles in solution.

According to Hartley [19], micelles are essentially spherical aggregates with a diameter equal to approximately twice the length of the hydrocarbon chain. The

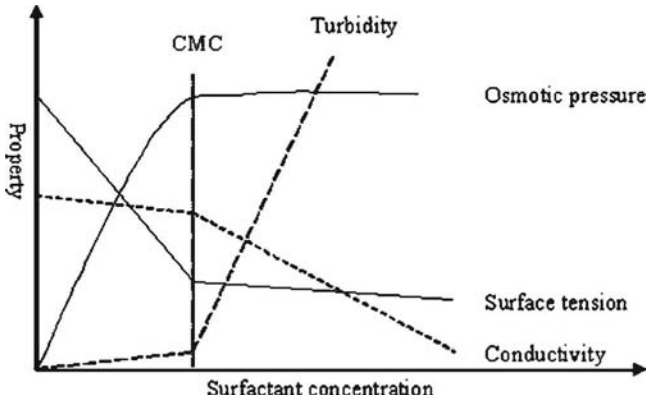

Fig. 4—Schematic representation of the concentration dependence of physical properties of micelle-forming surfactant solutions.

cluster of 50100 surfactant molecules, the core of the micelle, is essentially hydrocarbon free of water or any other polar solvent. The hydrophilic groups remain on the surface of the micelle to allow for maximum interaction with aqueous media. Counter ions are strongly or partially bound to the polar head-groups, thereby reducing lateral repulsive forces between those groups on the surface of the micelle and stabilizing the entire aggregate.

The CMC value of a surfactant depends on many factors, including the experimental method of determining this characteristic [18]. Thus, light scattering techniques are sensitive to the weight average molecular weight and particles size of the micelles. Surface tension and conductivity methods, on the other hand, depend on the number of particles in the solution. Other major factors determining CMC are the nature and structure of the hydrophobic and hydrophilic groups, the nature of counter ion, temperature, and the presence of electrolytes and additives [1,2].

The length of the hydrophobic group is one of the major factors determining CMC. For the homologous series of liner alkyl chains, the CMC decreases logarithmically with increase of carbon number, according to the Klevens equation [20]:

$$\log_{\min}(\mathrm{CMC}) = A - Bn_c \qquad (4)$$

where A and B are constants for a particular homologous series and temperature, and n_c is the number of carbons in the hydrophobic alkyl chain. This equation predicts, rather well, the behavior of linear single-chain surfactants. However, CMC values deviate significantly when alkyl chain branching, double bonds, or aromatic groups are introduced into the hydrophobe moiety. In hydrocarbon surfactants, chain branching increases the CMC value compared to the straight chain surfactant [21]. Presence of a benzene ring in the chain is equivalent to approximately 3.5 carbon atoms [Eq(4)].

Varying the nature of the hydrophilic group from ionic to nonionic has more impact on the CMC of the surfactant than the exact nature of ionic group itself since a major driving force for micelle formation is the entropy factor [1,2]. For a C_{12} hydrocarbon surfactant molecule, the CMC of ionic surfactant occurs in the range of 1×10^{-3} mole/L, while equivalent nonionic surfactant exhibits a CMC in the range of 10^{-4} mole/L.

Since ionic surfactant micelles are formed and stabilized by the interactions of water with the charged head groups, an increase in degree of ion binding (or decrease in electrostatic repulsion between ionic head groups) decreases the CMC. For a given hydrophobic tail and anionic head group, the CMC decreases in the order of $Li^+ > Na^+ > K^+ > Cs^+ > N(CH_3)_4^+ > Ca^{2+} = Mg^{2+}$. For the halide series of cationic surfactants, the CMC decreases in the order of $F^- > Cl^- > Br^- > I^-$.

Presence of electrolytes effectively shields the electrostatic repulsions between ionic head groups, thereby lowering the CMC and increasing aggregation number. Temperature effect on the CMC of ionic surfactants is relatively subtle, owing to the fact that its impact on bonding, heat capacity, and volume is very weak. Nonionic surfactants have more dramatic response to the temperature changes, as elaborated in the discussion of the Krafft and cloud points.

Other aggregates existing in surfactant solutions and described in the literature include rod-like micelles [22] [Fig. 3(*f*)], lamellar [23][Fig. 3(*e*)], and disk or cylindrical aggregates [24]. As the surfactant concentration is increased above CMC, the initially spherical micelles become more distorted in shape and form cylindrical rods and liquid crystals at much higher concentrations.

Solubilization

Solubilization is characterized by the dramatic increase in the solubility of a lipophilic material in the presence of a surfactant at the concentrations above the CMC. This characteristic is frequently used to detect the onset of micellization, even though the lipophilic material itself may affect the value of the CMC [25]. The location of the solubilized species in a micelle is determined primarily by the chemical structure of the additive. In aqueous media, polar molecules are solubilized in the polar surface of the micelle, whereas non-polar additives are strongly associated with the hydrophobic interior of the micelles. More complex molecules containing both polar and non-polar regions may partition between the polar and non-polar regions of the micelles, producing more complex structures. Such complex systems are believed to be stabilized via hydrogen bonding or dipole-dipole interaction between the solute matter and the surfactant [26,27].

Solubilization, similar to the adsorption micellization, is a dynamic process. The average residence time of solubilized molecules have been determined and depend on many factors including temperature, the nature of the solute and its concentration, type of surfactant, concentration, and CMC value [6]. Thus, solubilization increases with increasing surfactant concentration in the region above CMC level. Micelle solubilization capacity is proportional to the length of hydrocarbon chain of the surfactant, which controls CMC and micelle aggregation number. On the other side, the solubilization is expected to decrease with introduction of unsaturation, aromatic groups and hydrocarbon chain branching in the surfactant molecules due to weakened hydrogen bonding, and geometric and packing constraints. Moreover, solubilization depends on the nature of the additive that control its interactions with the surfactant molecules and its molecular size, which determine packing requirements. However, the relationship between the chemical structure of the additive and its ability to be

solubilized by a surfactant solution is rather complex and has not been quantified yet. Temperature has a combined effect on the solubilization process. First, it affects the "parent" process of micellization and may have impact on both CMC value and aggregation number. Second, temperature undoubtedly affects intermolecular interactions, such as hydrogen bonding and hydrophobic interaction, between solvent and solutes.

Cloud Point

Most nonionic surfactant solutions become visibly turbid and cloudy upon heating. Cloud point is defined as a temperature above which the phase separation of surfactant solution occurs. Observed increase in turbidity is the result of increase in aggregation number, augmentation of micelle size, and their more efficient scattering of the light. On the molecular level, more energetic thermal motions available at elevated temperatures weaken specific interactions between surfactant and the media and cause dehydration of the surfactant polar groups. Reduction or complete elimination of hydration shells around surfactant aggregates diminishes or totally eliminates protection against intermolecular interactions. As the result, the micelle-micelle interaction and their subsequent aggregation significantly increase with temperature augmentation. This process occurs in a narrow temperature range and is totally reversible upon cooling.

Cloud point characteristics depend on the chemical structure of the surfactant molecule. For poly(ethylene oxide)(PEO) nonionic surfactants, the cloud point increases with increasing EO content. For a given length of EO block copolymer, the cloud point value decreases by increasing the length of the hydrophobe, broadening the PEO chain length distribution, and introducing branching in the hydrophobe portion of the molecule. However, note that the cloud point could also be affected by the presence of electrolytes [28] and other polar and non-polar additives [29,30] present in the formulation.

The cloud point phenomenon affects many processes including solubilization, foaming, and dispersion. If application temperature is above the cloud point of the surfactant solution, destabilization of dispersion, pigment flocculation, phase separation, and defoaming may occur. The latter could be a very desirable effect since surfactants with cloud points near or below the application temperature are the most effective defoamers.

Krafft Temperature

Solubility of most solutes in water typically increases with increases in temperature. However, for ionic surfactants with low solubility, there is often a temperature at which the solubility suddenly increases very dramatically. This is known as Krafft point or Krafft temperature, T_k, and is defined as an intersection of the solubility and the CMC curves (Fig. 5). Hence, the Krafft temperature is the point at which surfactant solubility equals CMC. Below T_k, surfactant is dissolved only in a single dispersed state and the minimum achievable surface tension will correspond to the concentration of maximum solubility and not the CMC. Above T_k, additional surfactant forms micelles and the solubility rises sharply.

An abrupt increase of surfactant solubility in water with temperature was first noted by Krafft and Wiglow and had since been called "Krafft point" [31]. Originally, due to coincidence of Krafft points and melting points of the hydrocarbon chains, this phenomenon was interpreted as the melting of the hydrocarbon chains of the surfactants. However, current interpretation evolves around the transition between the dissolution of the surfactant to form ions and dissolution to form micelles [2].

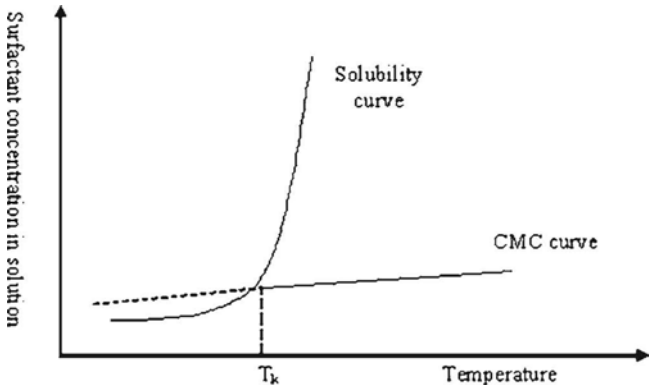

Fig. 5—The Krafft temperature T_k is the point at which surfactant solubility equals the CMC.

T_k varies as a function of both the nature of the hydrophobic group and the character of the ionic interactions between the surfactant and its counter ion. Krafft point is critical for many applications since typical surfactant characteristics such as surface tension reduction and micelle formation cannot be achieved below T_k. Because of their different mechanism of solubilization, nonionic surfactants do not exhibit a Krafft temperature. Characteristic temperature/solubility relationship of nonionic surfactants relies on the delicate balance of specific interactions promoting solubility and thermal motions that destabilize the system. As temperature increases, nonionic surfactants become less soluble and form cloudy suspension (cloud point).

APPLICATIONS

Emulsifiers

The majority of water-based paints consist of aqueous dispersions of water-insoluble polymers made by emulsion polymerization, i.e., lattices. Emulsifiers used for latex preparation are often a combination of both ionic and nonionic surfactants [3,12]. Despite numerous advantages of non-ionic surfactants, they do not completely replace anionic emulsifiers, but rather used in combination for several reasons. First, the presence of anionic surfactants during the synthesis offsets the negative temperature dependence of ethoxylated nonionic surfactants. As elaborated in the discussion of the cloud point phenomenon, temperature increase during the radical polymerization may lead to a decrease in water solubility of the surfactants and a possible phase inversion (from oil-in-water to water-in-oil emulsion). In practice, emulsion polymerizations are often carried out in semi-continuous processes, where the presence of ionic surfactants and adequate reaction cooling circumvent this problem, providing better control over the kinetics and particle size of the resultant latex.

Another reason for using a combination of ionic and nonionic emulsifiers is their enhanced electrolyte stability. Anionic surfactants provide electrostatic stabilization to the latex particles at low and moderate salt concentration.

However, evaporation of water during the storage leads to higher electrolyte concentration and subsequent particle coagulation due to higher ionic strength. Presence of nonionic surfactant provides additional steric stabilization to the latex, preventing it from immediate coagulation upon subtle change in the ionic strength.

Another advantage of using blends of both ionic and nonionic surfactants for emulsification is the fact that adsorption-desorption mechanism is dynamic and driven by many factors including molecular weight of the surfactants, affinity to the surface and media properties. Noteworthy is the fact that nonionic surfactants have a stronger driving force toward the adsorption, which is augmented by the entropy factor. As the result, the ratio of nonionic/ionic surfactants in the adsorbed layer is significantly higher than their ratio in the bulk solution. It is the nonionic surfactant that is responsible for improved sheer and electrolyte stability of the resultant lattices.

Some common ionic surfactants used for emulsification [32] are the sodium and potassium salts of naturally occurring fatty acids, salts of sulfated linear alcohols, salts of alkylbenzene sulfonates and alkylnaphthalene sulfonates, and salts of alkylphosphates. Typical nonionic surfactants may include polyethoxylated alkylphenols and straight-chain alcohols or polyethoxylated polypropylene glycol block co-polymers. Note that the length of the hydrophobic part of the molecule (propylene oxide block, alcohol, or alkylphenol) could be adjusted relative to the hydrophilic part (ethoxylated block) for targeted HLB. While this list is not exhaustive, the combinations of ionic and nonionic surfactants are truly infinite. The primary guideline for selecting the best combination of surfactants is not only the stability of the latex particles, but mainly the application performance of the final product. Since the presence of surfactant in the final dry coating increases its water sensitivity and inadvertently results in surfactant migration to the coating/air and coating/substrate interfaces, the compromise often is necessary in emulsion polymer synthesis.

Wetting Agents

Wetting agents are, by definition, used to improve the wetting of pigment particles and substrate surfaces. Wetting phenomenon involves the displacement of air from a solid surface by a liquid. It also leads to the reduction of the inter-facial surface tension between solid and liquid interfaces.

For a spontaneous wetting to occur, the spreading coefficient of water at a solid surface, $S_{w/}s$, must be positive [1,8],

$$S_{w/s} = \gamma_{s/a} - (\gamma_{s/w} + \gamma_{w/a}) \tag{5}$$

where $\gamma_{s/a}$, $\gamma_{s/w}$ and $\gamma_{w/a}$ are the interfacial surface tensions for the solid/air, solid/water and water/air interfaces, respectively. The presence of surfactant molecules in the system reduces both $\gamma_{s/w}$ and $\gamma_{w/a}$ surface tensions, providing a positive value for the spreading coefficient and prompting spontaneous wetting. Low surface tension of the surfactant solution in the media ($\gamma_{w/a}$) are usually an indication of wetting effectiveness of the surfactant in a given paint formulation.

Wetting is not an issue in the solvent-based paints since their surface tension is usually low enough to spread on any surface. Good wetting agent for a waterborne paint formulation should be a surfactant with a strong ability to adsorb on the interface and ability to reduce surface tension to that of conventional solvent-based coatings, i.e., 25–32 mN/m [3]. These requirements also imply that wetting agents should be hydrophobic surfactants with limited water solubility (HLB 7-9, Table 4). Upon paint application and formation of two new interfaces (coating/air and coating/substrate), the migration of surfactant molecules to these new interfaces is a diffusion-controlled process depending on surfactant availability in the bulk phase. This latter condition is satisfied for surfactants with high CMC, e.g., surfactants containing bulky or branched hydrophobic groups such as Pluronic® WA and Surfynol® products.

Fast surfactant migration is possible for surfactants exhibiting high diffusion coefficient [3]. Since the rate of diffusion decreases with the size of the molecule according to the Stokes–Einstein equation:

$$D = k_B T / 6\pi\eta R_h \tag{6}$$

where k_B is the Boltzmann constant, T is the absolute temperature, η is the viscosity of the solvent, and R_h is the hydro-dynamic radius of the molecule. Large size of the surfactant molecule and corresponding large hydrodynamic radius will prevent it from fast diffusion rendering it a poor wetting agent. Therefore, lower molecular weight surfactants are preferred to achieve more efficient wetting.

Dispersing Agents

Pigments provide various optical properties and special effects, influencing corrosion resistance and mechanical characteristics, adhesion and rheology, and imparting mechanical strength and protective properties. The performance of pigments, however, depends on many factors, including their chemical structure, particle size, and degree of dispersion. The latter is a function of pigment wetting and stabilization and could be largely influenced by the presence of dispersant agents or lack thereof.

Dispersing additives improve the incorporation of pigments and fillers in a coating and ensure their stability during manufacturing, storage, and application processes. Dispersant agents coat suspended pigment particle to form a barrier that, either by ionic repulsion or steric hindrance or both, prevents particle-particle contacts and aggregation [33].

A surfactant's unique ability to adsorb preferentially at the interface is the essence of their application as pigment-dispersant agents. In aqueous systems, the hydrophobic groups of nonionic surfactants are adsorbed on the particle surface, with the hydrophilic groups extending into the bulk of the aqueous media. This partitioning provides not only the reduction of interfacial tension but also steric stabilization around the particles. Such stabilization is the result of steric hindrance created by the chains of the surfactants solvated in the liquid phase. Additional charge stabilization could be provided by ionic surfactants, which adsorb to generate surface charge and repulsive forces, preventing agglomeration of two or more particles with the same charge. Better understanding of the stability characteristics of the colloidal system is provided by the well-known DLVO theory [34] that accounts for attractive van der Waals and repulsive electrostatic forces in suspensions. Both electrostatic and steric (entropic) stabilization may be

combined to achieve maximum stabilization effect in the system. Such electrosteric stabilization is very common for paint formulations.

Pigment dispersion process involves initial particle wetting, particles separation, dispersion in the media, and stabilization against flocculation. Improved pigment dispersion is realized initially by modifying the surface of the pigment. This is typically achieved by adsorbing a surfactant during pigment manufacturing without disclosing particular details of surface treatment. Dispersant agents in the paint formulation adsorb on the particle's interface to form loose assemblies and further prevent agglomeration. Block or graft copolymers are proven to be very effective dispersant agents that adsorb and anchor to the pigment particle and further lower the interfacial surface tension.

The main distinction between dispersing and wetting agents is that a dispersing agent must wet, anchor to the surface of the pigment particle, and provide a connecting link between the particle and the dispersion media. In order to be an effective dispersing agent, a surfactant molecule should meet a number of structural requirements that are somewhat different from those of wetting agents. Thus, a dispersing agent molecule must be long enough to provide adequate wetting by adsorbing on the surface and provide steric stabilization by protruding to the media. Effective anchor groups should have high affinity to the pigment and have little or no solubility in the media. Wetting agents typically have much shorter chain length and are not effective dispersants.

Organic polyelectrolyte dispersants are the most common type of dispersants of inorganic pigments used in waterborne paints [3]. Polymeric phosphates, polyacrylates, polyamines, and other polymers of relatively low molecular weight have the advantage of providing sufficient anchoring at the particle surface. This is favored by polymeric structure of the molecules and quick adsorption rate, which is controlled by keeping the molecular weight of the molecules relatively low.

Organic pigments are generally more hydrophobic than inorganic pigments and require the use of various types of ionic and nonionic surfactants for their dispersion. Alkylbenzene sulfonates and alkylphenol ethoxylates with relatively long poly(ethylene oxide) chains of 20–30 ethylene oxide units are the most commonly used dispersant agents. However, with the increased attention to the perceived environmental effect of alkylphenol ethoxylate surfactants and their slow biodegradation, they are gradually being replaced by linear and branched alkyl alcohol ethoxylates. Unfortunately, even after matching the HLB values of alkylphenol ethoxylate, fatty alcohol ethoxylate are still lacking the benzene moiety that provides additional electron donor-acceptor mechanism of interaction with pigment surfaces.

Due to vast diversity of pigment structures, particle size, and paint formulations designed for different applications, there is no universal wetting or pigment dispersant agent that would work in every formulation. Preference is given to a particular surfactant based on performance and environmental considerations, cost, and availability.

Foaming and Antifoaming Agents

Foam is created when air is introduced into paint during manufacturing or application. Complex paint formulations include several vehicles that promote foam stabilization, i.e., wetting agents, dispersants, and emulsifiers. These surfactants stabilize the foam due to one or several mechanism available to them including hydrogen bonding, ionic, and van der Waals forces. Foaming is highly undesirable and almost unavoidable. It reduces manufacturing efficiency and causes film defects. This necessitates the use of foam control agents—surface-active additives that prevent, reduce, or eliminate foaming during manufacturing and application.

Physically unstable foam composed of thin lamellae-structured film of surfactant with water molecules trapped inside. Foam stabilization mechanism is associated with well-known Marangoni–Gibbs effect [3,18]. The thinning of the foam lamellae leads to a surfactant's concentration gradient, which, in turn, establishes a surface tension gradient. The surface transport of the surfactant molecules from low to high surface tension region (Marangoni flow) will eliminate the gradients, but will also pull water molecules in the process, thus restoring the width of the lamella and preventing it from complete drainage. Ionic surfactants assist in foam stabilization by creating electrostatic repulsion between the two sides of the film. Additionally, they provide high osmotic pressure due to the presence of high concentration of counter ions. Since none of these mechanisms are available in the absence of ions, nonionic surfactants produce less foam and less stable foam, thus offering a substantial benefit of utilizing nonionic surfactants in coatings.

Foaming is resolved by creating inhomogeneities in the surface tension of the foam lamellae to cause instability and ruptures. Such effects can only be achieved if defoaming additives have a very limited compatibility with the aqueous media. These molecules also must have a positive entering (E) and spreading coefficients (S) to enter the foam lamellae and spread at the interface, and be able to adsorb the surfactant and drastically reduce lamellae stability [18],

$$S = \sigma_f - \sigma_{a/f} - \sigma_a \tag{7}$$

$$E = \sigma_f + \sigma_{a/f} - \sigma_a \tag{8}$$

where σ_f is a surface tension of the foaming medium (such as aqueous), $\sigma_{a/f}$ is an interfacial tension between media and antifoam, and σ_a is the surface tension of the antifoam. Typically, foam control agents are hydrophobic molecules with low surface tension in the range of 20–25 mN/m [3], present in the small amounts, less than 5%.

In addition to quantitative calculations, the simple and most straightforward method for defoamers' evaluation is simply to shake a measured amount of surfactant solution in a graduated cylinder or other suitable container, under controlled conditions (rpm, temperature, time, and concentration), and note the amount of the foam generated and the rate of its disappearance. Defoaming effectiveness is rated in comparison to the control solution with no defoamer present [35].

There are two types of foams—macrofoams and microfoams [36]. The former consists of polyhedral foam bubbles that, once they rupture and dry, produce craters in the coating films. The latter is revealed by the existence of small spherical air bubbles dispersed throughout the paint that produce pinholes. Foam control agents are called antifoams

if they prevent or retard foam formation, or defoamers if they destroy already existing foam. All antifoams are defoamers but not all defoamers are antifoam agents.

Defoamers generally fall into two main categories: silicon-based and silicon-free organic defoamers. Silicon defoamers are based on polydimethylsiloxane chemistries and combine non-volatility with low surface tensions. They proved to be outstanding "universal" defoamers, but find limited application due to high cost and substantial contribution to coating defects, such as fish eyes, poor recoatability or loss of adhesion. Moreover, with the increased general pollution of siloxanes in Nordic countries, less toxic non-silicon defoamers are promoted by the manufacturers. For example, surfactants based on propylene oxide (Pluronic® L101 and 25R1 surfactants), silicone backbone (Gold-schmidt's Tegopren® surfactants), and fluorochemical backbones [37] are very effective "foam killers."

Unfortunately, there is no single universal defoaming agent that would prevent foam formation in all systems. Paints are very complex formulations and potentially any constituent could affect either foam behavior or the effectiveness of the defoamer [38].

Coalescent Agents

Coalescing agents aid film formation, improve leveling, gloss, adhesion, and scrub resistance. Prior to the VOC regulations, high-boiling solvents were used as coalescing agents to provide better coalescence or fusion of polymer particles by reducing the T_g in polymer particles below minimal film formation temperature (MFFT). Examples of these additives include Union Carbide's Carbitol®, carbitol acetate, Butyl Cellosolve® acetate, butyl carbitol acetate, and hexylene glycol products.

In contrast to coating resins dissolved in a solvent, latex paint undergoes several steps during the film-forming process [39,40]. Initial stages of this process involve water evaporation accompanied by significant reduction of inter-particle distances. In order to achieve direct contact, the electrostatic repulsion forces between the spheres, which originally provided for the stability of the dispersion, must be overcome. Upon further reduction of the total volume beyond the point of inter-particle contact, sufficient deformation and interdiffusion of the particles is required for true film formation. This is possible when the capillary forces and the surface tension forces are larger than the deformation resistance,

$$pressure\ of\ deformation = C\gamma_{PA}R \tag{9}$$

where γ_{PA} is the polymer/air interfacial tension, R is the particle radius, and C is a constant. Capillary forces are equally important for particle deformation. Thus, Eckersley and Rudin [41,42] illustrated that even though the capillary forces cannot cause coalescence, the combination of capillary and interfacial forces gives enough coalescing force. Later, this theory has been challenged by Dobler [43], who studied core shell latexes. The theory, describing the interdiffusion of particle surfaces, was further developed by Winnik et al. [44], who proved that PEO stabilization also promotes interdiffusion and possibly plasticization.

Deformation pressure is related to physical properties and glass transition temperature of the resin and frequently assessed in terms of MFFT. In practice, film formation process can only occur at a temperature above glass transition (T_g) of the polymer, or, more precisely, above the MFFT. As the result, the processing temperature (T_p) could be controlled either by a corresponding selection of monomers or by the addition of external plasticizers to meet the following condition:

$$T_p \geq \text{MFFT} \tag{10}$$

This theoretical and practical limitation is circumvented by the addition of film-forming or coalescing agents. Their behavior could be explained by the so-called three-phase model [45]. This model takes into consideration the fact that a coalescent agent is distributed among three phases: Water, particle nucleus, and particle shell. Only its presence in the shell of the particle is essential for the film formation. The plasticizer effect and impact on the film formation is marginal, if the coalescent agent is too hydrophobic, and predominantly located in the nucleus of the particles, or too water soluble and, thus, primarily located in the water phase.

Organic solvents, in general, are very effective coalescing aids due to their small molecular size, high diffusion coefficient, and closely matched interaction parameter. They successfully and temporarily lower the T_g of the polymer and affect polymer diffusion rate in the film prior to their complete evaporation. Alternatively, nonvolatile coalescing aids remain in the film and impart more permanent change to the polymer physical properties. Examples of nonvolatile coalescing aids used in coatings include alkylphenol ethoxylates ($C_nPhO–EO_x$), particularly NP20 ($n = 9$, $x = 20$), which was shown to increase the rate of PBMA polymer diffusion [46]. Pluronic® surfactants EO-PO-EO or PO-EO-PO of approximately 2,000 molecular weight and 50 % copolymer compositions also reduce T_g of the PBMA polymer by 3 and 8°C, respectively [47].

Coating Defects

Most common coating problems could be attributed to one of the two main causes: defects driven by surface tension and pigment dispersion problems. The former includes cratering, telegraphing, sinks and bumps, crawling, and beading. The latter manifests itself in flooding, floating, poor color development, and insufficient gloss, which could be solved, at least partially, by carefully selecting a dispersant agent better suited for a particular application.

Surface-tension-driven defects are formed in the presence of and in the vicinity of surface tension gradients caused by contaminants, such as oil, or by temperature and surfactant concentration gradients across the surface of the coating. An established surface tension gradient will cause the material to flow from low to high surface tension area until the driving force is diminished or the materials cure and resist the flow.

Poor initial wetting of the substrate and subsequent dewetting could yield crawling defects. Solution to this problem involves a better cleaning of the substrate surface or addition of wetting agents to the paint. Surfactants, however, do not differentiate and could migrate to both substrate/coating and coating/air interfaces. When used in excess, surfactants could improve wettability of the

substrate but also weaken the adhesion and cause difficulties during touch-up and re-coating applications.

CONCLUSIONS

In summary, it is important to emphasize that surfactants remain to be the key paint additives. They enable water-based paint technology to reduce paint surface tension, wet the substrates, aid in film formation, disperse pigments, and emulsify polymers. The term surfactant is used as a general term for surface active agents. In paint applications, these include wetting agents, dispersants, emulsifiers, coalescent agents, and defoamers. In addition to numerous and frequently conflicting functions of surfactant additives in paints and coatings, high paint performance standards and growing environmental concerns are important practical considerations for paint formulators. Volumes of publications and decades of experience do not change the fact that surfactants applications in coatings, although based on strong scientific foundation, mainly rely on empirical guidelines and remain to be an art. Where wetting agents are used to improve surface wetting and assist pigment dispersion, foam issues may arise and contribute to coating defects. Likewise, anionic surfactants, useful for electrostatic stability of dispersions and freeze/thaw stability of the lattices, yield excessive water sensitivity that shortens the longevity of the coatings.

Because of the complex interactions of surfactant molecules with multi-component paint systems, it is practically impossible to design universal additives, or accurately predict their impact on a particular formulation. As a result, a particular choice of surfactant additives depends on many factors including the nature of the coating formulation and its intended use. However, it also represents a delicate balance of desirable and undesirable properties for the final coating.

Coalescing Aids

Kevin W. McCreight[1]

LATEX PAINTS CONTAIN FINE DISPERSIONS OF high molecular weight film-forming resins in water. Common film-forming resins include vinyl acetate-acrylic co-polymers, vinyl acetate-ethylene copolymers, acrylic copolymers, or styrene-acrylic copolymers although many other types of systems are also commercially available. Formulations of latex paints are complicated by the presence of pigments, surfactants, dispersants, biocides, defoamers, thickeners, freeze-thaw stabilizers, and coalescing aids. Paints must be formulated such that good stability and excellent coating properties can be achieved over a wide range of application conditions. Many important paint properties, including scrub resistance, porosity, and gloss, are linked to the quality of film formation that is achieved. Film formation in latex paints is promoted by the addition of coalescing aids, which enable the latex particles to consolidate and yield a continuous film.

HISTORY

Latex paints based on styrene and butadiene copolymer were first commercialized in about 1946 and rapidly developed wide acceptance in the marketplace [1]. Other film-formers of this period included vinyl acetate, acrylates, styrene, and vinyl chloride copolymers [2]. Since many of these latexes had relatively high glass transition temperatures, it was understood early on that plasticizers, such as phthalates or phosphates, were required in order to achieve good film formation. In a paper written by Green in 1953, it was noted that plasticizers should be liquids that are solvents for the film-forming resin and exhibit low color, mild odor, non-flammability, and minimal toxicity [3]. These comments were echoed in a paper written by Sullivan in 1954, which also stated that the primary function of the plasticizer is facilitation of film formation through solvation of the resin in the paint [4]. Subsequent work illustrated that overuse of plasticizers could lead to paint films with poor scrub resistance and increased dirt pickup [5]. These issues arose from the extremely low volatility of the plasticizers, which caused them to persist to a significant degree after film formation had occurred. In order to overcome the problems that had been encountered with plasticizers, the concept of coalescing aids was introduced. Coalescing aids have higher volatility than plasticizers, which enables them to facilitate film formation and then evaporate such that scrub resistance and dirt pickup are not negatively impacted. Early coalescing aids included hexylene glycol, ethylene glycol monoethyl ether, diethylene glycol monoethyl ether acetate, ethyleneglycol monobutyl ether acetate, and diethylene glycol monobutyl ether acetate [5]. In 1963, a patent was issued for 2,2,4-trimethyl-1,3-pentanediol monoisobutyrate (Tex-anol® Ester-Alcohol) [6], which became the most widely used coalescing aid for latex paints [7]. Coalescing aids that are currently used include glycol ethers, ester-alcohols, glycol ether-esters, esters, and glycols. These materials vary widely in evaporation rate and hydrophobicity.

INTRODUCTION TO COALESCING AIDS

In relation to latex paints, coalescence may be defined as the process by which latex particles come into contact with one another and unite to form a continuous homogeneous film. The process of coalescence is governed by the glass transition temperature (T_g) of the paint system (including coalescing aids and other additives). T_g may be defined as the temperature at which the onset of cooperative segmental backbone motion occurs in a polymer chain. In other words, a polymer below its T_g acts "glassy" since the molecules have no short-range mobility, while a polymer above its T_g is "rubbery" and the molecules are free to move. In order for film formation to occur, the polymer molecules in the latex must have sufficient mobility to interdiffuse across the boundaries between latex particles under a range of application conditions (temperature and humidity). A coalescing aid acts as a temporary plasticizer to reduce the T_g of the latex below that of the application or drying temperature to enable good film formation. Fig. 1 provides a simplified illustration of the impact of a coalescing aid on the T_g of a paint. In section A, it is seen that T_g of the paint is significantly higher than the desired minimum application temperature. Under these conditions, the latex particles cannot coalesce since the polymer molecules that compose the latex are in the glassy state and do not have sufficient mobility to enable film formation. Section B illustrates the same paint after the addition of an appropriate amount of a coalescing aid. The coalescing aid reduces the T_g of the paint below that of the minimum application temperature and enables mobility of the polymer molecules in the latex such that particle coalescence can occur. After application of the paint, the water and the coalescing aid begin to evaporate from the coating (section C). Although Fig. 1 illustrates the evaporation of the water and coalescing aid as discrete events, they actually evaporate simultaneously (although the rate of evaporation of the coalescing aid is generally much slower than that of the water, as indicated). While the coalescing aid evaporates,

the T_g of the paint film increases and returns to approximately its uncoalesced value. As T_g increases, the polymer molecules become much less mobile and a well-coalesced block resistant film is formed. Plasticizers may be added to a paint formulation to enable film formation, but since they tend to evaporate extremely slowly, they must be used judiciously in order to prevent the coating from remaining tacky, which may manifest itself as problems with block resistance and dirt pickup.

AN OVERVIEW OF FILM FORMATION

There have been numerous studies on the mechanism of film formation [8–19] and while there is some disagreement as to the detailed driving forces for coalescence, there is general agreement in a three-step depiction of the process. Fig. 2 provides a general model of the stages that proceed as a latex paint dries. Initially, water evaporates from the system and the latex particles become more closely packed—also known as consolidation. As the coating continues to dry, the particles begin to contact one another, deform, and compact. This process is believed to be driven by capillary pressures or van der Waals forces that occur in the interstices between adjacent latex particles as drying proceeds. [8,9] Coalescing aids facilitate compaction by reducing the elastic modulus and yield strength of the particles. [10] Finally, coalescence occurs by the diffusion of polymer molecules across the latex particle boundaries and a strong, continuous film is formed.

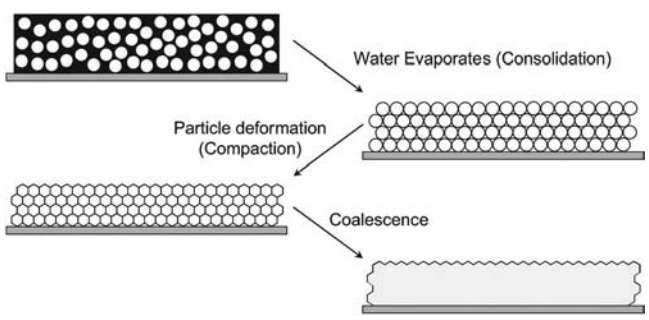

Fig. 2—A simplified view of the film formation process.

REQUIREMENTS FOR EFFECTIVE COALESCING AIDS

Coalescing aids must meet several important criteria in order to be considered for use in latex paints. The issue of primary importance involves the compatibility of the coalescent with not only the common film-forming resins, but also all of the other paint components including pigments, thickeners, surfactants, and freeze-thaw stabilizers. The coalescing aid must also efficiently reduce the T_g of the system. Many coalescing aids are considered to be volatile organic compounds (VOCs), and therefore selection of an efficient coalescent minimizes the amount of VOC that must be added to a formulation in order to meet minimum application temperature requirements. Evaporation rate of coalescing aids is important since the majority of the water needs to leave the paint system prior to the coalescent, regardless of the conditions of temperature and humidity. As a result, most coalescing aids tend to have relatively low evaporation rates in order to ensure that film formation can be achieved. Coalescing aids must also exhibit reasonable hydrolytic stability under the relatively high *p*H conditions that are common in latex paints. Hydrolysis of a coalescing aid can lead to reductions in coalescing efficiency and shelf stability. The water solubility (or insolubility) of a coalescing aid impacts the extent to which it partitions between the latex and the water. It has been found that relatively water insoluble coalescing aids function very effectively since they partition largely to the latex, which enhances their efficiency [20] Other important properties for coalescing aids include a low freezing point (so that the coalescent does not solidify at low application temperatures), low odor, low color, reasonable cost, and acceptable properties from a health, safety and environmental (HSE) perspective.

PERFORMANCE EVALUATION OF COALESCING AIDS

Coalescing Efficiency

One of the most important properties of a coalescing aid is how efficiently the material can reduce the T_g of a latex. Since measurement of the impact of a coalescing aid on the T_g of a latex is not straightforward by use of differential scanning calorimetry, a minimum film-forming temperature (MFFT) instrument is used in accordance with the ASTM Test Method for Minimum Film Formation Temperature of Emulsion Vehicles (D2354, withdrawn in 2007 but still available). MFFT may be defined as the lowest temperature at which a system can form a coherent film, and generally has a value relatively close to T_g. A MFFT instrument consists of a stainless steel plate with a specified temperature gradient along its length. By preparing mixtures of a latex and coalescing aid at various coalescent concentrations, a determination may be made as to the MFFT of a system as a function of coalescent level. Fig. 3 provides an illustration of a typical MFFT bar set with a temperature gradient of 0–18°C. Five coalescing aid/latex mixtures have been drawn down on the bar under controlled conditions of temperature and humidity, with coalescent concentration increasing from the front (near side) of the bar to the back. The part of the film that appears to be white is not coalesced since in that temperature range, the polymer molecules have insufficient mobility to interdiffuse. The

Fig. 3—Minimum film-forming temperature apparatus (temperature range of 0–18°C).

point at which the film changes from white to clear is designated as the MFFT for that particular blend. As more coalescing aid is added to the latex, the MFFT of the system decreases since the additional solvent allows sufficient molecular mobility for lower temperature film formation. From this type of test, a plot can be made of MFFT as a function of coalescent concentration for a given latex and coalescing aid combination. Fig. 4 demonstrates the impact of three different coalescing aids in a typical latex with a MFFT of about 15°C. Coalescent **A** is more efficient than coalescent **B** since at a given MFFT, a given quantity of **A** yields a lower MFFT than an equivalent amount of **B**. If a manufacturer specifies a minimum application temperature of 10°C, in order to have a reasonable margin of safety, a MFFT of 5°C might be selected. From Fig. 4, it can be seen that 3.2 parts per hundred parts of resin (phr) of **A** is necessary while 4.7 phr of **B** is required. Coalescent **C** is ineffective in conjunction with this latex since it provides no reduction in MFFT regardless of the level of incorporation. An estimate of the overall efficiency of a coalescing aid may be obtained by preparing blends of a given material with a wide range of latex types and determining the total amount of coalescent necessary to achieve a target MFFT. Paints that contain high T_g industrial maintenance type latexes require a significantly higher quantity of coalescing aid compared to the low T_g latexes that are used for interior flat paints. In addition to MFFT measurements, atomic force microscopy (AFM) proves to be a useful technique for observation and quantification of the extent of coalescence. Fig. 5 demonstrates the appearance of a high T_g (~40°C) acrylic latex with two different amounts of a typical coalescing aid—5 phr for **A** and 10 phr for **B**. The left side of each image represents the height in the vertical direction and gives a feel for surface roughness, while the right side of the image provides phase contrast between the hard and soft sections of the latex particles. Note that in **A**, there is insufficient coalescing aid to form a homogeneous film, while in **B** there is a marked decrease in surface roughness, and the particle boundaries are less well-defined.

When considering coalescing efficiency, it is important to consider the impact of substrate and substrate porosity on paint performance. Since water soluble coalescents partition predominantly to the water phase, it has been suggested that porous substrates could absorb both the water as well as some of the solubilized coalescent [21]. In this case, the residual coalescing aid in the paint may be insufficient to provide for adequate film formation, especially under adverse conditions (see illustration in Fig. 6). Perera has examined the potential for selective penetration

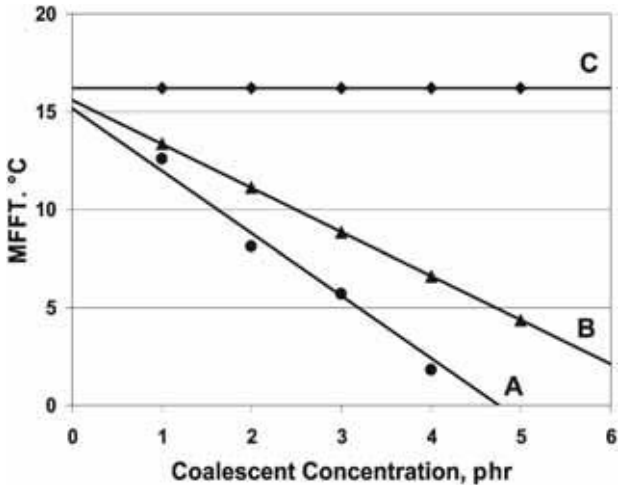

Fig. 4—Impact of coalescing aid concentration on MFFT of a typical latex.

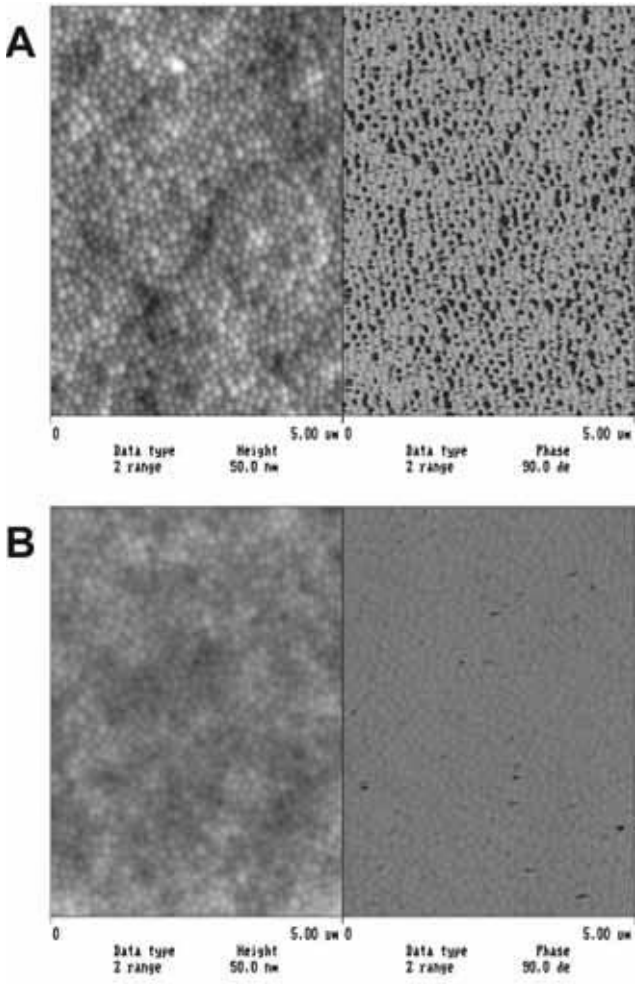

Fig. 5—AFM images of a high Tg acrylic latex with coalescent levels of (A) 5 phr and (B) 10 phr—the height image is on the left, and the phase image is on the right.

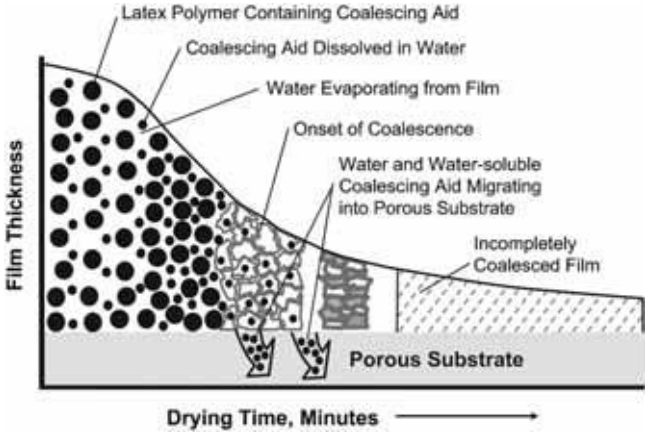

Fig. 6—Impact of using a water soluble coalescing aid in paint applied over a porous substrate [21].

of paint components into common substrates by evaluating paint T_g and the concentration of coalescent and binder in the substrate for several types of paint [22]. His work suggested that penetration of the binder and coalescing aid into porous substrates leads to increases in both the T_g and pigment volume concentration.

Evaporation Rate

The evaporation rate of a coalescing aid is measured relative to a standard such as *n*-butyl acetate in accordance with the ASTM Test Method for Evaporation Rates of Volatile Liquids by Shell Thin-Film Evaporometer (D3539). As stated previously, the evaporation rate of the coalescing aid needs to be significantly slower than that of water regardless of temperature and humidity conditions. Fig. 7 provides an illustration of the variation in the evaporation rate of water as a function of relative humidity at 25°C. A coalescent with a fast evaporation rate may not adequately coalesce a paint under high humidity conditions, while a very slow evaporating coalescent has the potential to remain in the coating too long, which may result in poor hardness development, blocking problems, and dirt pickup.

Hydrolytic Stability

Hydrolytic stability of a coalescing aid may be evaluated by combining the material with a high *p*H latex (generally above 9.0) and holding the system at elevated temperature (usually 50°C). The *p*H of the system is then monitored over a period of four weeks. Dramatic reductions in *p*H are often associated with hydrolysis of a coalescing aid, which can negatively impact paint performance.

Water Solubility

Water solubility of a coalescing aid may be determined by preparing a 50/50 v/v mixture of coalescent and distilled water which is agitated. If separation occurs, samples can be taken from each of the layers to be quantified using a technique such as gas chromatography (GC). Alternative measures of water solubility are the ASTM Test Method for Partition Coefficient (N-Octanol/Water) Estimation by Liquid Chromatography (E1147) and the ASTM Test Method for Measurements of Aqueous Solubility (E1148). In general, water insoluble coalescents function with maximum efficiency since the majority of the solvent partitions to the latex particles where it can effectively act to reduce the T_g of the film former. The extent of partitioning may be expressed by means of the distribution coefficient, which is the ratio of the concentration of coalescent in the water to its concentration in the latex. Distribution coefficients may be determined experimentally by a centrifugation/GC technique [20]. In addition, models have been developed to predict partitioning behavior of coalescents [23]. There is some data to suggest that hydrophobic coalescing aids (which partition more extensively to the polymer) lead to an increase in latex particle size while hydrophilic coalescents can actually lead to slight reductions in particle size [24]. A simple model for the location of a coalescing aid in a latex paint has been developed by Mercurio [25]. As shown in Fig. 8, the location of a coalescent in a paint system can be characterized by location **A** (the interior of the latex particle), **B** (the surface of the latex particle), **C** (the aqueous phase), or a combination. The most efficient coalescing aids tend to reside in the **AB** region, which encompasses the most critical region for film formation.

Odor

Although odor is becoming an increasingly important property in paints, particularly for institutional use, it also tends to be very subjective. Coalescing aids can contribute to odor in latex paints, but the impact a single raw material on the odor of a paint formulation is not easily quantified. A paper has recently been published by researchers at the

Monell Chemical Senses Center that addresses the impact of a common coalescing aid on odor perceptions in formulated paints [26].

STRUCTURES AND PROPERTIES OF COMMON COALESCING AIDS

Fig. 9 illustrates the names and structures of some of the more widely used coalescing aids. The most common coalescents are ester-alcohols and glycol ethers. Table 1 provides a summary of the evaporation rate, water solubility, and partitioning behavior of these same coalescing aids. The majority of these materials have slow evaporation rates relative to n-butyl acetate (0.002–0.006). In the case of ethylene glycol monobutyl ether, the evaporation rate is 0.06, which is close to the evaporation rate of water at about 85 % relative humidity and 25°C. Under hot, humid conditions, a fast evaporating coalescing aid, such as ethylene glycol monobutyl ether, may evaporate at a comparable rate to the water, which may leave insufficient coalescent for complete film formation. An appropriate coalescing aid should be selected so that (1) coalescence can be achieved under the most adverse conditions of temperature, humidity, and substrate and (2) the coalescing aid will evaporate from the film at a rate that will allow adequate property development. Coalescing aids are commonly blended to provide an optimized evaporation rate for a given paint and the associated application conditions. Table 1 demonstrates that the majority of common coalescing aids have relatively minimal water solubility and partition predominantly to the latex particle and its surface (the AB region). More hydrophilic glycol ethers, such as ethylene glycol monobutyl ether and diethylene glycol monobutyl ether, are completely water soluble and partition in the **BC** region. Although these water soluble coalescing aids may not provide optimum efficiency in systems applied to porous substrates, they may improve freeze-thaw stability and open time since they have a significant presence in the aqueous phase of the paint [25].

GUIDELINES FOR INCORPORATING COALESCING AIDS

Although a properly selected coalescing aid should be compatible with the remainder of the paint components, some care must be exercised during formulation to prepare a paint with the expected performance properties. Most hydrophobic coalescing aids can be successfully added directly to the letdown, assuming the latex is relatively stable. In contrast, certain highly hydrophilic coalescents, such as ethylene glycol monobutyl ether, can "shock" or destabilize the latex if added directly to the letdown. These coalescents can be successfully incorporated by premixing with some water prior to being added to the paint. In some cases, a portion of the coalescent may be added to the grind, where it may reduce surface tension and may function as a pigment dispersant.

INFLUENCE OF COALESCING AIDS ON PAINT PROPERTIES

Coalescing aids have significant impact on the properties of paints due to their function in film formation as well as their interaction with other additives in the formulation. Not surprisingly, coalescing aids have major effects on properties that relate to the quality of film formation, such as scrub resistance, gloss, color development, and weathering.

Scrub Resistance

Scrub resistance of a coating may be evaluated according to the ASTM Test Method for Scrub Resistance of Wall Paints (D2486). This method simulates the resistance of a paint to cleaning with an abrasive cleaner and a nylon bristle brush. Scrub resistance is generally measured after the paint is allowed to dry for at least a week, during which time the majority of the coalescing aid evaporates from the coating. In common architectural coating for-

TABLE 1—Physical properties and partitioning characteristics of common coalescing aids

	Evaporation Rate (*n*-BuOAc=1)	% Solubility in Water	Partitioning Properties[a]
2,2,4-trimethyl-1,3-pentanediol monoisobutyrate	0.002	Insoluble	AB
Ethylene glycol monobutyl ether	0.060	100 %	BC
Ethylene glycol mono 2-ethylhexyl ether	0.003	0.2 %	AB
Diethylene glycol monobutyl ether	0.003	100 %	BC
Dipropylene glycol monobutyl ether	0.006	5 %	ABC
Propylene glycol monophenyl ether	0.002	2 %	AB

[a]See Fig. 8 for description of partitioning designations.

mulations, paints with no coalescing aid have minimal scrub resistance while the addition of increasing amounts of coalescent increases scrub resistance up to a point. If an excessive amount of coalescing aid is used, the latex can be softened to the point that the scrub resistance of the paint is reduced. Although plasticizers can aid in film formation, their use in paints has the potential to reduce scrub resistance since they evaporate extremely slowly, which may cause the paint film to remain soft. Early block resistance (hardness development) of a latex paint can also be reduced by overuse of plasticizer or slow evaporating coalescing aids.

Gloss

Gloss of a paint film is also related to the quality of film formation. In general, smoother coating surfaces yield higher gloss. Specular gloss is most commonly measured using a glossmeter in accordance with the ASTM Test Method for Specular Gloss (D523). A poorly coalesced film will have lower gloss than a well-formed film. Proper choice of coalescent is critical to the development of acceptable gloss under harsh conditions (for example, low temperature and high humidity). Under adverse conditions, a very volatile coalescing aid may not allow development of good gloss since the coalescent may evaporate before it can function to enable film formation.

Color Development (Low Temperature Coalescence)

Film formation may also be analyzed by comparing the color obtained from a slightly tinted paint at two temperatures (room temperature and 4.5°C) by the ASTM Test Method for Low Temperature Coalescence of Latex Paint Films by Porosity Measurement (D3793). To achieve similar color development under two temperature conditions, a coalescing aid must provide equivalent film formations in both cases. If an insufficient amount of coalescent or a coalescent that does not provide adequate film formation under adverse temperature conditions is used, the color may not match. This could be an issue if part of a room is painted under a given set of environmental conditions, and the rest of the room is painted at a later time and the temperature and/or humidity have changed drastically.

Block Resistance

Block resistance testing provides insight as to the tendency of two painted surfaces to stick together when they come into contact with one another, such as in the case of doors and windows. Testing is carried out in accordance with the ASTM Test Method for Blocking Resistance of Architectural Paints (D4946), which specifies that the painted surfaces be placed face to face at 50°C for a set period of time and applied weight. The degree to which the painted surfaces can be separated from one another to one another after testing is referred to as the block resistance. The ASTM method is sometimes referred to as a "heated block" test, and in some cases variants such as the "room temperature block" or "wet block" may also be reported, although under different conditions of sample preparation, applied weight, paint cure time, and temperature of the testing. If a paint film is too soft or poorly coalesced when tested, block resistance will be poor. Appropriate selection of coalescing aids is critical when working with high T_g latexes, which may require significant amounts of coalescent and can lead to a balancing act between achieving low temperature coalescence and maintaining block resistance. Overuse of slow-evaporating coalescents or plasticizer can lead to poor block resistance, but appropriate choice of coalescent type and level will yield complete film formation and excellent block resistance.

Exterior Durability

Exterior durability of paints is impacted by the quality of film formation as well as the composition of the latex. A well-chosen coalescing aid will reduce the porosity of a latex paint while increasing the film strength. Both of these effects can increase the potential for a paint film to withstand the forces of wood expansion or contraction without cracking and to minimize the water vapor transmission that can lead to delamination of paint from a substrate. Solvents or additives that remain in the paint film have the potential to bloom to the surface and lead to dirt pickup. As a result, it is important to select a coalescing aid with an appropriate evaporation rate at a use level that will ensure timely hardness development. Dirt collection on coated exterior panels may be evaluated by the ASTM Test Method for Quantifying Dirt Collection on Coated Exterior Panels (D3719).

Rheology

Coalescing aids interact with associative thickeners and different types of coalescent can significantly modify the viscosity of a latex paint formulation. Relatively hydrophobic coalescing aids can interact with the hydrophobic modifications present in associative thickeners, which increases viscosity and effectively increases thickener efficiency [27]. In contrast, more water soluble coalescing aids can actually interfere with the function of associative thickeners and may lead to a reduction in the viscosity of a formulation. If alternate coalescing aids are "dropped into" a formulation as a direct substitute, there is a potential for the paint rheology to be altered such that the application characteristics of the paint change.

Freeze-thaw Stability

Architectural coatings are evaluated for freeze-thaw stability by cycling paint samples between room temperature and 0°C as outlined in the ASTM Test Method for Freeze-Thaw Resistance of Waterborne Coatings (D2243). Freeze-thaw stability is often achieved through use of completely water soluble diols, such as ethylene glycol or propylene glycol, which serve as freezing point depressants. Since the most efficient coalescing aids tend to be relatively hydrophobic, these materials do not improve and may actually reduce freeze-thaw stability. Wegmann suggested that the mechanism for this reduction in freeze-thaw stability stems from the coalescing aid increasing the solubility of the surfactant in the water, which destabilizes the latex [28].

Wetting and Defoaming

Many coalescing aids effectively reduce the surface tension of water. In latex paints, this property serves to aid in the process of both pigment and substrate wetting [29]. It has been reported that hydrophobic coalescing aids can be used to activate silicone defoamers in aqueous systems [29].

IMPACT OF VOC REGULATIONS ON COALESCING AIDS

VOC Regulations and Test Methods

Over the past 10 years, there have been significant changes in the regulations governing the use of VOCs in architectural and industrial maintenance (AIM) coating applications. In the United States, several regulatory bodies have restrictions in place, including SCAQMD (South Coast Air Quality Management District), OTC (Ozone Transport Commission), CARB (California Air Resources Board), and the U.S. EPA. Table 2 provides a summary of the historical, current, and proposed regulations for these four organizations. From this table, it is evident that the usage of VOCs has been and will continue to be curtailed by these new regulations. The European Union (EU) is covered by the Decopaint Directive 2004/42/CE of the European Parliament, which was issued on April 24, 2004. Annex II of this directive outlines two sets of VOC limits for paints and varnishes, one that was implemented on 1/1/2007, and a more stringent standard that will come into force as of 1/1/2010. The reader is cautioned that U.S. and EU limits are not directly comparable, as both VOC definitions and test methods are different. In the United States, VOC is evaluated according to ASTM Standard Practice for Determining Volatile Organic Compound Content of Paints and Related Coatings (D3960), which is analogous to EPA Federal Reference Method 24. At low VOC, EPA Method 24 has significant error [30], and a newer method is described in the ASTM Test Method for Speciation of the Volatile Organic Compounds in Low VOC Content Waterborne Air-Dry Coatings by Gas Chromatography (D6886), although this method has not yet been adopted for regulatory purposes by the EPA. The European Union uses test methods from the International Standards Organization (ISO) titled Paints and Varnishes—Determination of Volatile Organic Compound Content Part 1: Difference Method (ISO 11890-1, for use with VOC contents above 15 % by weight) and Part 2: Gas-Chromatographic Method (ISO 11890-2, for use with VOC contents less than 15 % by weight). As more restrictive rules are implemented, significant research has been carried out in order to determine the most effective approaches to maintain paint properties within the guidelines of these regulations.

In addition to the changes observed with respect to VOC limits in paints and coatings, there has begun to be more interest in long-term emissions from painted substrates, both from the regulatory and research perspectives. Some recently published work focused on obtaining a better understanding of the fate and availability of coalescing aids in latex paints. Corsi studied the partitioning of 2,2,4-trimethyl-1,3-pentanediol monoisobutyrate in flat and semi-gloss paints over aluminum, gypsum board, and concrete substrates [31]. His work led to mass balances of coalescing aid in the substrate, paint film, and air over the period of about 1 year, which revealed that airborne recovery of 2,2,4-trimethyl-1,3-pentanediol monoisobutyrate ranged from <25 % to 90 % and was dependent on both paint type and substrate type.

Reformulating to Reduce VOC

Regulations have led to the need for extensive reformulation in the coatings industry, which has in turn spawned a desire for new lower-VOC components for latex paints. The main VOCs in latex paints are the freeze-thaw stabilizer/open time additive and the coalescing aid. Several approaches to meet lower-VOC limits have been espoused, generally including a resin modification, a coalescing aid modification, or both.

Low-VOC Coalescing Aids

From the perspective of VOC reduction through use of alternative solvents, possible solutions involve more efficient coalescents, low-VOC coalescing aids or plasticizers, reactive coalescing aids, or elimination of the freeze-thaw stabilizers. The premise for VOC reduction based on efficiency stems from the fact that if less coalescent is required to meet a target MFFT, VOC will be reduced accordingly. Lower-volatility coalescents have been considered for use in formulations based on the fact that the VOC contributions of very nonvolatile materials may be much less than 100 % according to EPA Federal Reference Method 24 (Determination of Volatile Matter Content, Water Content,

Density, Volume Solids, and Weight Solids of Surface Coatings). Some of these materials may be classified as having nearly zero VOC contribution based on the U.S. definition. Low-VOC coalescents often share similar chemistry with conventional coalescing aids, but are less volatile since they are higher molecular weight esters, glycol ethers, or ester-alcohols. As described previously for plasticizers, careful formulation is required when using low-volatility coalescents in order to avoid issues with block resistance, scrub resistance, and dirt pickup. The concept of a reactive coalescing aids involves a coalescing aid acting to promote film formation in the traditional manner and then crosslinking to become a permanent part of the coating. One approach to reactive coalescents involves esterification of relatively nonvolatile unsaturated materials that can crosslink through an oxidative cure mechanism [32]. The benefits for this technology are twofold: VOC is reduced and these products may be viewed as renewable, since many of the unsaturated materials are of natural origin. Potential shortcomings for this approach include slow hardness development due to the minimal crosslinking from the low level of coalescent incorporation, the potential for color development, and the fact that driers may be required to promote cross-linking.

Reducing VOC through Resin Modification

Alternative technology based on resin modifications includes reduction of latex T_g to limit the coalescent requirements, manipulation of latex composition or morphology (core-shell or power feed processes) to reduce coalescent requirements, or copolymerization of reactive monomers that allow cross-linking subsequent to film formation. By reducing T_g of the base latex, the paint film can form a film without using as much (or any) coalescent. While this reduces VOC, it can also lead to a softer film that is less durable and more prone to dirt pickup and blocking problems, as demonstrated by Testa in a study comparing the performance of coalesced versus coalescent-free paints [33]. There has been extensive work on cross-linking latex systems in which a functional monomer is polymerized into the latex and which may or may not require use of an additional crosslinker. These systems were initially directed more extensively toward the industrial maintenance market, but are beginning to gain some traction in the architectural area, although cost considerations are more significant in this market. Taylor and Winnick have written a comprehensive review of the technologies in the functional and thermoset latex field [1].

Currently, although there are many technologies under examination from both the additive and resin standpoints, it is clear that maintaining excellent paint properties while meeting future VOC regulations will continue to be a significant challenge.

ACKNOWLEDGMENTS

Thickeners and Rheology Modifiers

Gregory D. Shay[1]

LIST OF ABBREVIATIONS

ASE = Alkali-swellable and/or soluble emulsion
ATRM = Associative thickener and/or rheology modifier
BP = Biopolymer
CMC = Carboxymethyl cellulose
CTRM = Conventional thickener and/or rheology modifier
DS = Degree of substitution
DUEV = Dynamic uniaxial extensional viscosity
EHEC = Ethylhydroxyethyl cellulose
EMHEC = Ethylmethylhydroxyethyl cellulose
GG = Guar gum
HASE = Hydrophobe modified alkali-swellable/soluble emulsion
HEC = Hydroxyethyl cellulose
HEEASE = Hydrophobe modified ethoxylate ester alkali-swellable/soluble emulsion
HEG = Hydroxyethyl guar gum
HEMC = Hydroxyethylmethyl cellulose
HENN = Hydrophobe modified ethoxylate nonionic non-urethane
HEUR = Hydrophobe modified ethoxylate urethane
HEUUR = Hydrophobe modified ethoxylate urea urethane
HEURASE = Hydrophobe modified ethoxylate urethane alkali-swellable/soluble emulsion
HMC = Hydrophobe modified cellulosic
HMNS = Hydrophobe modified nonionic synthetic
HMEHEC = Hydrophobe modified ethyl hydroxyethyl cellulose
HMHEC = Hydrophobe modified hydroxyethyl cellulose
HPG = Hydroxypropyl guar
HPAPE = Hydrophobe modified polyacetal polyether
HPMC = Hydroxypropylmethyl cellulose
HSV = High-shear viscosity
ITRM = Inorganic thickener and/or rheology modifier
LIQ = Liquid
LSV = Low-shear viscosity
MC = Methyl cellulose
MCC = Microcrystalline cellulose
MS = Molar substitution
MSV = Medium-shear viscosity
NA = Data not available
ORG = Organo or organic
PAA = Polyacrylic acid
pEO = Polyethylene oxide
PG = Propylene glycol
PN = Pre-neutralized
PVC = Pigment volume concentration
RM = Rheology modifier
SOLV = Solvent
T = Thickener
TRM = Thickener and/or rheology modifier
VOC = Volatile organic components
XCPS = Xanthamonas campestris polysaccharide (Xanthan gum)

INTRODUCTION

THE PERFORMANCE EXPECTATIONS OF COATINGS have grown substantially over the past few decades, and the rheological requirements for storage, handling, application, and post-application flow properties have become more demanding. Thickeners and rheology modifiers (TRMs) play a key role in many coating performance properties, and consequently, they are among the most important components in coatings systems. Although TRMs are used in minor amounts in most formulations and are generally considered additives, aqueous coatings usually contain at least one and sometimes two or more TRMs to obtain the desired balance of performance properties. Due to present-day environmental concerns and the use of TRMs predominantly in aqueous coatings, the focus of this chapter is on water-borne coatings where TRMs are used extensively in architectural, construction, elastomeric, and industrial applications. TRMs also find utility in some solvent-borne coatings—discussed later in this chapter, where they function primarily as flow modifiers and thixotropes. A list of some coating properties controlled or influenced by thickeners are found in Table 1. A recommended overview of coatings rheology and rheological test methods is found in Chapter 36 on "Rheology and Viscometry."

Thickeners

Thickeners, as traditionally defined, are chemical components that substantially increase the viscosity (resistance to flow) of fluids at relatively low concentration. The viscosity of a fluid, as discussed later in more detail, is a function of shear rate (the rate of fluid deformation), and most coatings formulations are shear thinning. That is, they decrease in viscosity as increasing rates of shear are applied. Thickeners tend to increase viscosity at all shear rates when incorporated, but for coatings, thickeners are most often incorporated to increase viscosity at moderate shear rates approximating those encountered during pouring, pumping, stirring, or mixing. The applicable shear rate (in reciprocal seconds) during these medium shear processes is in the range of about 10–1000 s^{-1} and more typically about 100 s^{-1}. The coating viscosity in this shear rate range is often referred to as the coating "consistency" or medium-shear viscosity (MSV). To be effective, a thickener should produce the desired coating consistency at a low-use level. The amount of thickener required to obtain a desired coating consistency is the "thickener efficiency," which is often expressed in units of lb thickener solids per 100 gal of liquid coating (or g/L where metric units are used). By example, for architectural coatings the total amount of thickener

- Scrub resistance
- Wet and dry adhesion

required (thickener efficiency) is typically less than about 15 lb/100 gal (~ 18 g/L), more typically less than 10 lb/100 gal (~ 12 g/L) and can be as low as 3 lb/100 gal (~ 4 g/L) or even less depending on several factors. Among those factors are the inherent thickening ability of the thickener, coating formula solids, pigment volume concentration (PVC), vehicle type, and other components present in the formulation. As discussed later, the selection and interaction of other coating components is of particular importance when associative thickeners are used.

A coating's consistency can sometimes be sensed subjectively. For example, the depth of fluid vortex in a container at a given mixing speed provides an indication of the consistency by visual observation, or the resistance to flow can be felt during hand stirring of the coating fluid. The consistency of the coating can also be measured using an appropriate viscometer or rheometer that operates in the medium shear rate range. The high end of this range (near 1000 s^{-1}) also correlates with "pumpability," which is critical in some automated manufacturing operations. Several popular instruments for measuring consistency are described later in this chapter.

Rheology Modifiers

Rheology is the study of the flow and deformation of matter, and various rheological measurements are used to define the flow characteristics of a fluid. Many fluids including most coatings cannot be described rheologically by a single viscosity measurement. Rheology modifiers are often used in coatings to alter viscosity at low and/or high shear rates. However, there is no universally accepted definition of the term "rheology modifier" as it relates to coatings. In fact, the terms "thickener" and "rheology modifier" are often used interchangeably in commerce. The rheology modifier term is frequently used to refer to associative thickeners or to low molecular weight conventional thickeners, which are effective for modifying low or high shear viscosity. The thickener term is more often used to refer to relatively efficient conventional (non-associative) thickeners. The distinction between associative and conventional thickeners is discussed in more detail later in this chapter.

Upon close examination, all thickeners modify rheology in some way or to some degree when incorporated into a coating. Consequently, all thickeners are technically also rheology modifiers whether that is their intent or not. The converse is also generally true—most materials described as rheology modifiers are also thickeners since they increase the consistency of a coating to some degree though they may be relatively inefficient in doing so. Consequently, a true rheology modifier will usually require a higher concentration to significantly affect coating consistency. However, that same rheology modifier can be an inefficient thickener in one formulation but an efficient thickener in another depending on formulation parameters and other coating components present in the formulation. This is especially true for associative rheology modifiers. For instance, a rheology modifier that is efficient for consistency in one formulation may require only 5 lb/100 gal, but in another formulation it could be very poor for consistency requiring as much as 60 lb/100 gal (~ 35–75 g/L). Rheology modifiers are often used as secondary thickeners in a coating formulation to influence viscosity at high and/or low shear rates (generally above 1000 s^{-1} or below 10 s^{-1}). They may be very efficient for controlling rheology at the shear-rate extremes while contributing little to coating consistency. Rheology modifiers may also influence the elastic or elongational (extensional) properties of coatings, which are properties that can be measured on some high-performance rheometers. Sometimes, a single thickener or combination of thickeners is effective in meeting all of the low-, medium-, and high-shear rheological requirements of a coating formulation. If the rheological requirements cannot be met with thickeners alone, a rheology modifier is often included to augment flow properties especially at low and/or high shear rates. A common example of this is the incorporation of a rheology modifier to raise the high-shear viscosity (HSV) of a coating to increase film build (film thickness) for improved substrate protection or one-coat hiding. Another common example is the incorporation of a rheology modifier to reduce the low-shear viscosity of the coating for improved leveling of brush marks and roller pattern. In some situations, a rheology modifier is efficient enough to function as an effective thickener such as in the presence of a small-particle-size latex, water-insoluble coalescing aids, at high binder concentrations, or at high-volume solids. This effect, which will be discussed in more detail later, especially applies to associative rheology modifiers where strong interactions occur between the TRM and other coating components.

Terminology Convention

The definitions for thickeners and rheology modifiers as they apply to coatings in this chapter are shown in Table 2. Because most thickeners modify rheology and most rheology modifiers thicken coatings to some degree, these terms will be used interchangeably in this chapter with little distinction and are collectively referred to as TRMs. The term thickener is used extensively hereafter and is meant to mean either a thickener or rheology modifier.

INCORPORATION OF TRMs

Coating manufacturing operations generally consist of several stages of processing, and TRMs are often important in each. Some common stages of coating production are the "premix" (where ingredients are added prior to pigments), "grind" (where pigment is added and reduced in

TABLE 2—TRMs defined in this chapter
Thickener—any material added to a coating formulation to increase coating consistency (mid shear viscosity). Note: Most thickeners also modify coating rheology to some degree when incorporated into a coating formulation.
Rheology Modifier—any material added to a coating formulation to alter one or more rheological characteristics (e.g., low-shear viscosity, high-shear viscosity, extensional viscosity, visco-elasticity, thixotropy, yield point, or relaxation time etc.). Note: Most rheology modifiers also increase coating consistency to some degree when incorporated into a coating formulation.

size for optimum dispersion), and "letdown" (where the polymer or latex binder is normally added). Some, but usually not all, of the thickener is often added to the premix to increase viscosity in the grind for improved pigment dispersion (deagglomeration). Under laminar flow conditions, the rate of shear during grinding is set by the tip speed of the impeller and the depth of the shear gradient. One theory suggests that increased viscosity (such as from thickener addition in the grind) allows better energy transfer by decreasing turbulence at the impeller. This, in turn, increases the shearing collisions that attrite the pigment agglomerates. However, too much thickener at this stage impedes mixing and actually slows down the grinding process. The remaining thickener in a coating formulation is usually added to the letdown to provide proper suspension and product consistency. Finally, post-adjustments with additional thickener or rheology modifier may be required to bring the product "into specification" for consistency and application properties.

RHEOLOGY AND VISCOSITY

Because viscosity and rheology modification are the very essence of primary TRM function, a basic understanding of rheological concepts is helpful to fully appreciate differentiation in product performance. The rheological characterization of paints and coatings has been extensively investigated [1–14], and thorough treatment of this subject is found in Chap. 36. The following subsections provide a general overview of the two primary types of flow encountered during the preparation, storage, and application of coatings that are affected by the choice and amount of TRM present.

Viscosity is defined as "resistance to flow" and is mathematically equal to the ratio of two rheological parameters (shear stress τ/shear rate γ), where shear stress is the force exerted per unit area in the fluid shearing plane and shear rate (rate of fluid deformation) is the fluid velocity divided by the gap between shearing planes. For the case of simple shear, shear rate is just the gradient of velocity in a flowing fluid. At constant shear rate, viscosity increases with increasing shear stress. Shear rate increases with increasing fluid velocity or with a decrease in the gap between shearing surfaces. If either the shear rate or shear stress is known, the other parameter can be measured to obtain viscosity. Often, the geometry of the viscosity measurement system allows the shear rate to be known or approximated, and by plotting the measured viscosity of a fluid at several shear rates, a viscosity flow curve (i.e., rheology profile or rheogram) is obtained. Nearly all waterborne architectural coatings are shear-thinning fluids. That is, the viscosity of the coating decreases with increasing shear rate. Some coating processes operate at lower rates of shear, while others operate at moderate or higher rates of shear. Consequently, the rheology profile of the coating fluid defines the relative performance of several coating processes.

Shear Flow

Most low, medium, and high shear rate coating phenomena involve shear flow that is characterized in the laminar regime (where the shear field produces Reynold's numbers below the critical characteristic for the fluid). Shear flow in the turbulent regime (high Reynold's numbers) is not normally characterized, since most parameterizing equations fail in this regime. The vast majority of viscometers and rheometers produce laminar shear flow and measure the ratio of shear stress to shear rate (viscosity). With coatings, it is useful to determine viscosity at several shear rates to obtain a complete rheology profile (rheogram), which is normally represented in log-log form. These profiles are also conveniently divided into three shear rate regions—"fluid at rest," "fluid during processing," and "fluid during application," which correspond to the low-shear, medium-shear, and high-shear regions, respectively, as depicted in Fig. 1. A coating fluid at rest could be either a stationary fluid in a container or a liquid film after application before it dries. A rheometer is a convenient instrument for obtaining a coating fluid rheogram. The viscosity profile for a coating can also be approximated by single-point viscometer measurements of low-shear viscosity (LSV), MSV, and HSV. Some of the coating processes and properties affected in each region are shown in Fig. 1 and are further discussed later in this chapter in "TRM Functions."

Time-dependent shear thinning (thixotropy) and zero-shear yield value are two other rheological coating properties that may be very important in the rheological characterization of coatings. For example, a thixotropic fluid with high yield value may exhibit good leveling if the time required to rebuild viscosity is long compared to the time needed for flow out of brush marks or roller pattern. The viscoelastic properties of a coating may also be important, particularly in spray and roll applications. The elastic component of shear can be determined on some advanced cone-plate or parallel plate rheometers either by measuring the shear storage modulus (G') in oscillatory simple shear mode or by measuring normal forces (e.g., first normal stress difference, N_1), which is a force produced perpendicular to the plane of shear.

Elongational Flow

In addition to the simple shear flow fields generated during the mixing and application of coatings, elongational (extensional) flows may also be induced during the coating application processes of spray, roll, or blade. The study of extensional flows and their importance in coatings has been widely examined [15–17] and especially as it applies to roll coatings [18–20] and spray applications [21,22]. During these application processes, the fluid is accelerated as it approaches the applicator orifice or nip, and the polymer molecules of the thickener become stretched and aligned. The viscosity related to the induced elongational flow is termed by Glass [15] as the "dynamic uniaxial extensional

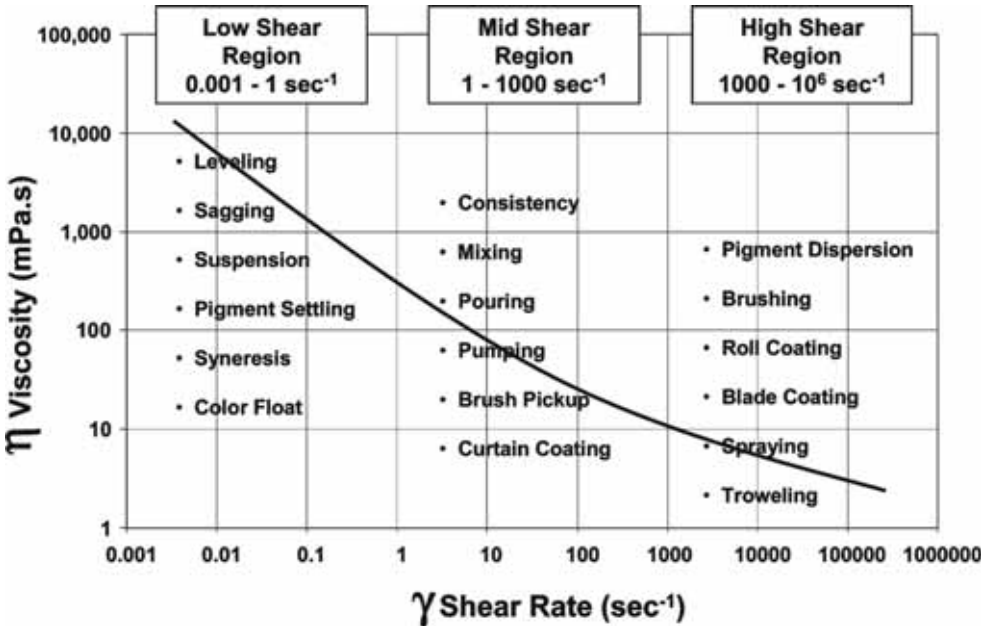

Fig. 1—Three shear-rate regions and related performance properties for architectural coatings.

viscosity" (DUEV). One coating property that has shown some correlation with DUEV is roller spatter in architectural coatings [23–25], and this undesirable phenomenon may actually be due to a complex combination of DUEV and viscoelasticity [25]. The degree of spatter can be rated using ASTM Test Method for Measurement of Paint Spatter Resistance to Roller Application (D4707-87). Other properties that have shown some correlation with DUEV are ribbing, web formation, misting in roll coatings, and atomization in spray coatings. Many viscometers and rheometers are available for the characterization of shear flow, but there are only a few instruments for the measurement of DUEV on disperse phase coating systems. Two such instruments are the Rheometrics RFX (no longer in production) and the Haake Caber 1 Extensional Rheometer. As a class, associative thickeners tend to impart lower DUEV than conventional (non-associative) thickeners, which improves some of the application properties described. Comparative representations of shear and elongational (extensional) flow are depicted in Fig. 2.

TRM CLASSIFICATION

Polymeric organic thickeners for aqueous media are often classified into two basic types: "conventional," which thicken predominately by hydrodynamic and flocculative mechanisms, and "associative," which thicken substantially by hydrophobe associative mechanism. Associative thickeners may also have some hydrodynamic thickening contribution depending on their molecular size. These mechanistic definitions are subject to some variability and ambiguity; however, a more clear distinction can be made for purposes of classification based on chemical architecture.

Conventional thickeners are defined in this chapter as viscosifying water-soluble polymers lacking hydrophobic groups capable of association. They are non-associative thickeners. Higher molecular weight conventional polymers are more efficient as thickeners, while lower molecular weight polymers of similar or different composition may function more as rheology modifiers. Associative thickeners are defined here as viscosifying water-soluble polymers that contain hydrophobic groups capable of association. The hydrophobes may be located at the ends of the polymer chains, within the polymer chains, or pendent to the hydrophilic polymer backbone The hydrophobes in these polymers are capable of nonspecific hydrophobic associations similar to those of conventional surfactants, and these associations are primarily responsible for generation of viscosity with these thickeners. Because they provide much of their thickening ability by hydrophobe association, these polymers can be much lower in molecular weight than conventional thickeners but they may also have some thickening contribution due to their molecular size. Regardless of their size, most associative thickeners are effective rheology modifiers at low and/or high shear rates and also due to their ability to modify elastic and elongational flows. Variation in chemical architecture, the number of hydrophobes present, and a further reduction in molecular weight can produce associative polymers that function primarily as rheology modifiers. It becomes readily apparent that, with proper hydrophobe modification, virtually any conventional polymer can be converted to an associative polymer, and this is what has been done in the design of several commercial associative thickener products.

The acronyms used hereafter for conventional thickeners and rheology modifiers and for associative thickeners and rheology modifiers are CTRMs and ATRMs, respectively. The various advantages and disadvantages of CTRMs and ATRMs have been extensively investigated and reviewed in the literature [26–32] and will become more apparent in

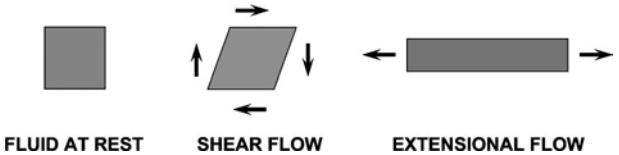

Fig. 2—Types of flow in coatings rheology (shear flow and extensional flow).

the following sections. A clearer distinction between these two major classes of thickeners will be apparent on examination of the thickening mechanisms involved. Although nearly all inorganic thickeners are conventional thickeners with respect to their thickening mechanisms, these TRMs will be treated separately later in this chapter.

THICKENING MECHANISMS

Three primary thickening mechanisms for polymeric waterborne thickeners are "hydrodynamic," "flocculative," and "associative." Each of these mechanisms may be further divided into subclasses, if desired, which have their own individual rheological and coating characteristics. Consequently, it is important to consider these mechanisms when making TRM selection for increasing coating consistency, for rheology modification, or for their effect on other coating properties.

Thickening is often a complex process. For example, the flocculation mechanism is frequently a byproduct of hydrodynamic thickening but may also occur in associative coating systems that are improperly formulated or in those systems where a controlled degree of flocculation is desired. Some associative thickeners (for example, alkali-swellable types) are sufficiently high in molecular weight that an appreciable hydrodynamic component of thickening is present. Depending on their chemical architecture, strength of the hydrophobic associations, and other formulation components present, some ATRMs actually function to varying degrees with both associative and non-associative mechanisms at the same time. Outlined in Table 3 are some possible thickening mechanisms for conventional and associative thickeners.

The Hydrodynamic Mechanism

Prior to the introduction of associative thickeners, nearly all organic thickeners used for aqueous coatings were water-soluble polymers of relatively high molecular weight (MW) or stiff backbones without hydrophobe modification. As previously defined, these are conventional TRMs as depicted in Fig. 3. The molecular weights of the conventional polymers that function as thickeners are generally greater than about 10^5 and can be as high as 10^6 or more. Polymers with stiff backbones (e.g., many cellulosics) at the lower end of the MW range are as effective in thickening ability as polymers in the high end of this range with flexible backbones (e.g., polyethylene oxide). When conventional thickeners dissolve in water, the polymer chains occupy a large hydrodynamic volume in solution and immobilize large volumes of water within the coils of their backbones. This increases viscosity of the continuous water phase dramatically. For a given polymer type, higher molecular weight molecules take up more space and produce higher viscosity. In fact, the solution viscosity of conventional polymers in water or nonaqueous solvents is one of the common methods used for determination of molecular weight when the Mark-Houwink constants ("K" and "a") are known. As previously stated, sufficiently low-molecular-weight polymer analogs (e.g., LMW HEC) can function more as true rheology modifiers since they do not contribute appreciably to consistency (MSV). However, these lower molecular weight conventional polymers have been mostly replaced or augmented with associative rheology modifiers in many coatings applications.

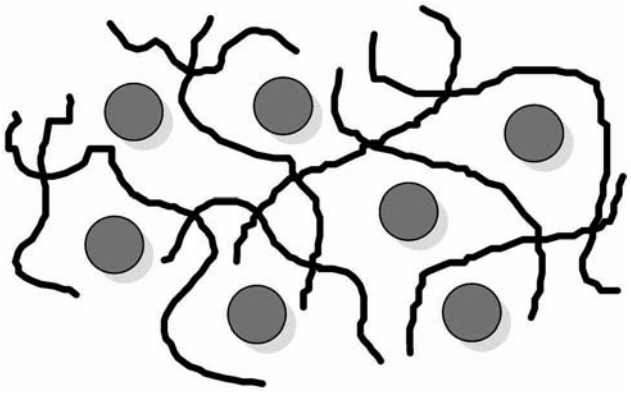

Fig. 3—Depiction of conventional (non-associative) polymer thickening in aqueous media.

Some conventional thickeners typically made by emulsion polymerization are addition copolymers that contain a substantial amount of carboxylic acid functionality. When neutralized, these polymers become water soluble and expand into the water phase providing thickening. Some of the copolymers are lightly cross-linked to make them water-swellable rather than water-soluble. On neutralization in aqueous media, these polymers may swell to many times their original particle diameter to produce viscosity by a hydrodynamic mechanism. Some of the neutralized copolymers contain both swellable (gel-fraction) and soluble polymer, but both contribute to thickening.

Examples of conventional water-soluble or water-swellable thickeners used extensively in coatings are hydroxyethyl cellulose, hydroxypropyl methyl cellulose, and alkali-swellable/soluble copolymer emulsions (ASEs). These and some other CTRMs are discussed later in this chapter under "Conventional TRMs (CTRMs)".

Flocculative Mechanisms

Because conventional thickener molecules take up significant volume in solution, they often induce flocculation in coatings, forming latex-rich, pigment-rich, and thickener-rich domains by a mechanism commonly referred to as "volume restriction," "volume exclusion," or "depletion" flocculation. This process is depicted in Fig. 4 and is now

TABLE 3—Thickening mechanisms for conventional and associative TRMs in aqueous media

Hydrodynamic—molecular size, chain entanglement, swelling, and chain stiffness
Depletion Flocculation—mostly conventional thickeners and promoted by hydrodynamic size
Bridging Flocculation—polymer bridging of particles
Structure Formation—moslty inorganic thickeners
Hydrophilic Interactions—ion dipole, and electrostatic interactions
Hydrophobe Association—associative thickeners only, intermolecular and with hydrophobic particle surfaces
Note: associative thickeners may also have one or more of the other mechanisms operating to some degree

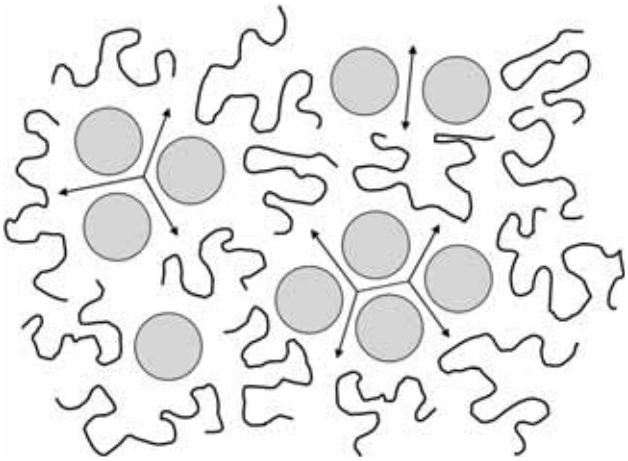

Fig. 4—Depletion flocculation—A conventional thickener occupies space, which results in flocculation of latex and pigment particles. This is facilitated by osmotic pumping of water from between particles interstices.

recognized as a primary mode of thickening for conventional polymeric thickeners in disperse phase systems such as in coatings with pigment or latex particles present. This flocculative mechanism has been examined in both experimental [33–36] and theoretical treatments [37–39], and also modeled by computer simulation [40,41]. The process begins when latex or pigment particles randomly approach each other. When they are close enough (on the order of a random-coil thickener molecular diameter), the thickener molecules in the coating are "excluded" from the interparticle region. The concentration gradient formed causes water to be osmotically "pumped" from between the latex or pigment particles driving the particles even closer together, which further concentrates the thickener molecules in the aqueous phase. Eventually, the latex or pigment particles touch, forming flocs that are readily observable on microscopic examination. This mechanism of thickening can adversely affect gloss and hiding and also may impart more shear thinning character and more viscoelasticity to the coating. Since these polymers are typically of high molecular weight, they also tend to impart high extensional viscosity to coatings and one consequence of that has already been identified (roll spatter and rib pattern in roll coatings).

Another flocculative mechanism that may occur particularly with conventional thickeners is "bridging" flocculation. In this mechanism, the polymer molecules partially adsorb onto latex or pigment particles. If the thickener molecules are sufficiently long and have a strong affinity for other particles, bridging can occur, forming flocs.

ASSOCIATIVE MECHANISMS

The primary thickening mechanism for ATRMs is via intermolecular hydrophobic association between thickener molecules, and more predominately by association of the thickener hydrophobes with disperse phase (colloidal phase) hydrophobic components in a coating formulation [42–47]. This mechanism is depicted in Fig. 5. When a water-soluble polymer contains both hydrophilic and hydrophobic moieties, the potential for associative interaction exists. Among the simplest associative molecular

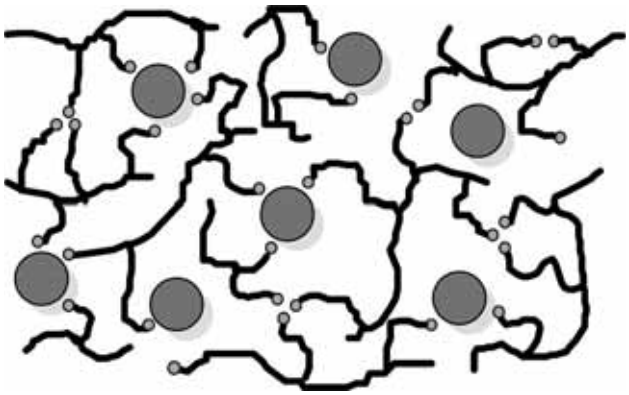

Fig. 5—Depiction of associative polymer thickening in aqueous media.

structures are nonionic surfactants. These molecules have a hydrophilic polymer segment (usually polyethylene oxide) on one end and a hydrophobic group (typically a long chain alkyl or alkyl aryl group) on the other end. At a sufficiently high concentration known as the critical micelle concentration (CMC), surfactants spontaneously form micelles in aqueous solution. At or above the CMC, the hydrophobes aggregate at the interior of the micelle, and the hydrophilic tails orient outward into the water phase. The key driving force for micellization is not the London Van der Waals attractive forces between hydrophobes, but rather the change in free energy on transfer of a hydrophobe in the aqueous phase to a more oil-like environment at the interior of the micelle. Water excludes the hydrophobes in the micellar process.

If a hydrophobe is chemically attached to the other end of a nonionic surfactant, a simple associative thickener is formed. However, because the thickener has a hydrophobe at each end, micelle formation is not a favorable process and is not observed except for certain chemical architectures at extremely low concentrations. Instead, the associative molecules aggregate into a more favorable three-dimensional structure of hydrophobes associating with other hydrophobes. The hydrophobe network structure that forms inhibits flow and raises the viscosity of the aqueous solution or coating. The driving force for association is similar to that for surfactant micelle formation—exclusion of the hydrophobes by water. To be viable in commerce, ATRMs usually have a few repeat hydrophile-hydrophobe units within the polymer backbone or in side chains to increase molecular weight, thereby increasing the hydrodynamic contribution and also the association efficiency. Although each associative polymer type has an optimum molecular weight, high molecular weight is not a requirement for associative thickeners, and most are significantly lower in molecular weight (typically <50,000) than conventional thickeners. Lower molecular weight has some advantages for supply of the thickener in aqueous solution, for the thickener's ease of incorporation, and for the rheology imparted to a coating. Another aspect of ATRMs is their interaction with colloidal components in a coating formulation. Whenever latex particles or hydrophobic pigments are present, the hydrophobes on the associative thickener can adsorb onto the hydrophobic particle surfaces. This results in a further increase in system viscosity and may result in coating rheology modification. The strength of the association is impor-

tant, and depending on the degree of association, a polymer can induce several types of equilibrium phase behavior including non-associative volume restriction flocculation and especially associative bridging flocculation [48–50]. Because associative thickeners are much lower in molecular weight than conventional thickeners, depletion flocculation is reduced or eliminated, resulting in advantages in coating gloss and more Newtonian rheology.

Although hydrophobe interaction is the predominate associative mechanism for ATRMs, some evidence suggests an additional associative mechanism, which is hydrophilic rather than hydrophobic in nature. Almost all latex particles possess carboxyl groups on their surfaces to impart stabilization. The proposed hydrophilic association is an ion-dipole interaction between the latex surface carboxyl groups and the polyethylene oxide (pEO) segments in the associative thickener present [51]. When the ATRMs contain both carboxyl and ethoxylate functionality in the same molecule (for example, associative alkali-swellable/soluble polymers), both intermolecular and intramolecular ion-dipole associations are theoretically possible.

TRM FUNCTIONS

Formulating for optimum performance with TRMs can be challenging, but the resources available are many [52–63]. The primary function of TRMs are the control of coating viscosity and rheology throughout the applicable shear rate spectrum: consistency is measured and adjusted in the medium-shear-rate range, application properties in the high-shear-rate range, and film formation and container storage properties in the low-shear-rate range. The viscosities associated with these ranges may be referred to as MSV, HSV, and LSV, respectively. ASTM Standard Practice for Rheological Characterization of Architectural Coatings Using Three Rotational Bench Viscometers (D7394) describes a procedure for obtaining a three-point rheology profile for prediction of performance properties. Background and discussion regarding this method are detailed in the following TRM function subsections. Several film properties are also affected and may be manipulated by the appropriate choice and amount of TRM in the coating. Two examples of architectural coatings formulated with TRMs to obtain very different rheology profiles are shown in Fig. 6. A clear understanding of the rheology profiles depicted in this illustration and their impact on application and film properties will become more apparent in the following subsections.

Coating Consistency MSV

The MSV is a measure of a paint's consistency (resistance to flow on mixing), and it is often determined on a viscometer operating in a shear rate range of 10–1000 s^{-1}. A common formulating practice is adjustment of coating viscosity in the medium-shear range by varying the amount of thickener in the coating. The "target" viscosity is normally based on prior experience or on a previously established specification range for a particular type of coating. For architectural coatings, the preferred instrument for determining coating consistency and for making thickener adjustments is a paddle type viscometer that measures viscosity in Krebs units (KU) as shown in Figs. 7 and 8. This instrument is sometimes referred to as a "Krebs viscometer" or more commonly a "Stormer

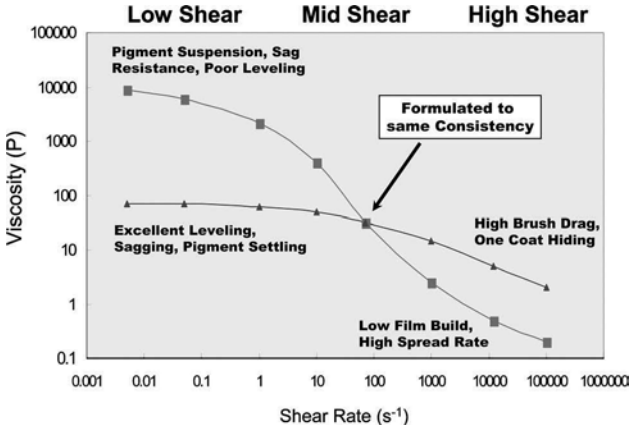

Fig. 6—Two examples of very different coating rheology in architectural paints.

Viscometer" (genericized trademark). Viscosity determination with this instrument is conducted in accordance with ASTM Test Method for Consistency of Paints Using the Stormer Viscometer (D562). The Krebs viscometer's rotor paddle geometry imparts mixing action during measurement similar to hand stirring or stirring on a lab mixer. The measurement range capability is 60–140 KU. Most architectural coatings fall within the range of 80–120 KU and more typically within 90–110 KU for coatings applied by roll or brush. A typical house paint might have a Krebs viscosity specification of 100±3 KU (±3% in this example). When a series of similar coatings are being compared for rheology, they ideally should have the same or similar KU viscosity. This is important for meaningful comparisons of their LSVs and HSVs because raising or lowering the consistency of a formulation will normally result in a corresponding increase or decrease in its LSV and HSV (i.e., the viscosity curve is shifted up or down). As some paints are thixotropic, it is a good practice to pre-stir the paint with a spatula or lab mixer to break up any structure prior to making a viscosity measurement.

The earliest and most well-known Krebs viscometer is the Stormer® Viscometer, and references on this instrument go back to the beginning of the 20th century [64–66]. The paddle spindle used on this viscometer is driven by mechanical coupling of suspended brass weights over a

Fig. 7—Manual Krebs type viscometer for measuring the MSV, otherwise known as the "consistency."

Fig. 8—Digital Krebs type viscometer for measuring the MSV, otherwise known as the "consistency."

pulley system (Fig. 7). The weights are adjusted until a constant paddle speed of 200 rpm is obtained, and from the weight required, the Krebs viscosity of the paint is computed. The latest version of the Stormer viscometer is the Thomas Stormer® Rotational Shear Viscometer (with Calibrated Paint Testing Outfit) from Thomas Scientific, as shown in Fig. 8. This instrument is calibrated by the Krebs Pigment and Color Corporation to give readings that will duplicate those obtained with other similarly standardized analog and digital instruments.

Today, modern digital Krebs viscometers are often used for obtaining Krebs viscosity. Three such digital instruments are the Thomas® ETS-2000 Digital Viscometer from Thomas Scientific, the Brookfield® KU-1 or updated KU-2 viscometer from Brookfield Engineering, and the Sheen 480 Krebs Viscometer from Sheen Instruments (Fig. 7). These viscometers provide digital readout in Krebs units, grams, or centipoise/poise. Like the Stormer and Thomas Stormer analog viscometers, the digital Krebs viscometers have the same paddle rotor geometry, obtain viscosity measurements at the same 200 rpm rotor speed, and also read out in Krebs units. Their main advantages are ease of use and easy-to-read LED display.

LSV and HSV for architectural coatings, as discussed in later sections of this chapter, are measured using instruments that typically provide viscosity in centipoise (cP) for LSV and poise (P) for HSV. The centipoise values are easily converted to poise by 100 cP = 1 P. However, consistency as measured in Krebs units is not directly convertible to poise for non-Newtonian fluids such as paints. To compare MSV with LSV and HSV in the same units, it would be advantageous to know the mid-shear viscosity of a paint in poise. It would also be desirable to know the shear rate of the Krebs viscometer for the paint tested, which would then allow the generation of a three-point flow curve of LSV, MSV, and HSV at the respective shear rates of each viscometer. A determination of this type has been made and reported previously for a semi-gloss latex coating. The determination was accomplished by first preparing a series of paints with different rheology modifiers to the same target viscosity of 95 KU. This was accomplished by adjusting the thickener concentration in each paint as measured on a Brookfield KU-1 Krebs viscometer. The coatings were then analyzed with a high-performance controlled shear rheometer over a wide shear-rate range. The average crossover point of the rheology spectra is the apparent mid-shear viscosity indicating that a Krebs viscosity of 95 KU was equivalent to ~20 P at a shear rate of ~ 70 s^{-1} (Fig. 8).

As an option to using a Krebs viscometer for determining coating consistency, a standard Brookeld® type spindle viscometer can be used when operated at the higher speed selections (20–100 rpm) to give the appropriate shear rate. However, the measurement readout is in cP rather than KU. As discussed later in the next section, this same instrument is also useful at lower speeds (0.3 or 0.5 rpm) for determination of low-shear viscosity and processes related to LSV.

The Rotothinner® is another viscometer that can be used to determine consistency. This instrument provides an even greater mixing action than a Krebs viscometer and is capable of stirring the entire container contents while the viscosity measurement is being made. While this instrument can be used for more conventional coatings, it is ideally suited for breaking down the structure of thixotropic coatings to obtain a sheared viscosity.

Leveling, Sag, Syneresis, Settling (LSV)

Besides MSV, there are also low-shear and high-shear process viscosities important in coatings that may also have target values when paints are formulated, and sometimes rheology modifiers are added to meet these targets. Once a paint's coating consistency (KU viscosity) has been appropriately adjusted or approached, a common next step for a paint formulator is to determine the LSV and HSV of the paint to make adjustments in these shear-rate regimes if needed. In this section, the low-shear coating processes are considered, and in a following section, the high-shear process are addressed.

Among the important low-shear processes for coatings are in-can pigment suspension [67], leveling [68–71], syneresis [72], and sag resistance [73]. The measurement of LSV can give an indication of performance for these processes. A properly formulated paint will typically have a sufficiently high LSV to prevent pigment settling on storage and to impart sag resistance on vertical surfaces when applied, but it will at the same time be low enough to provide leveling of brush and roller marks. Sometimes it can be difficult meeting all rheological requirements, and formulating becomes a compromise. The applicable shear rates for LSV processes are generally less than about 10 s^{-1} and more often in the range of 10^0 to 10^{-3} s^{-1}. The low shear applied in these processes is primarily due to the effects of gravity for container separation and sagging, and due to capillary pressure (generated by surface tension and surface curvature) for leveling. In architectural coatings, LSVs that are too high result in poor film leveling, and brush or roller

Fig. 9—Sag bars used for determining sag resistance of films in vertical orientation.

pattern can be very apparent. In contrast, LSVs that are too low may allow sagging on vertical surfaces and in-can settling or syneresis. Container settling can be assessed subjectively using ASTM Test Method for Evaluating the Degree of Settling of Paint (D869). Sag ratings are often conducted in accordance with ASTM Test Methods for Sag Resistance of Paints Using the Multinotch Applicator (D4400) as shown in Fig. 9. The degree of leveling is often determined by simple inspection of the brush marks or roller pattern, if any, after the applied film has dried. Optionally, a notched applicator on a horizontal surface may be used in accordance with ASTM Test Method for Leveling of Paints by Draw-Down Method (D4062).

A variety of viscometric techniques has shown some correlation with leveling. Among these is the Beeferman stress-relaxation procedure [68]. In this method, the coating is first sheared at a moderately high rate on a viscometer or rheometer to break down structure to simulate what would be accomplished during brushing or rolling. The shearing on the viscometer is then stopped to simulate secession of brushing or rolling, and the declining shear stress versus time for the paint is recorded. The area under the relaxation curve is then integrated to obtain a "leveling viscosity" that is the product of shear stress (dyne/cm^2) and time (s) with the dimensions of viscosity.

To obtain LSV in architectural coatings, a simple one-point viscometer technique is often used, which generally provides good correlation with leveling and other LSV processes. In this method, viscosity is measured at low rpm on a rotational bench spindle viscometer (e.g., at 0.3 rpm on analog or digital Brookfield® or similar viscometer) and can be conducted in accordance with ASTM Test Method for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield) Viscometer (D2196). Analog and digital instruments of this type are shown in Fig. 10.

With this spindle geometry and the instrument operating at its lowest speed, low-shear rate in the 10^0 to 10^{-3} s^{-1} range is imparted to the fluid being measured (Fig. 8). As with some other viscosity determinations, it is preferable to first stir the paint with a spatula or mixer. This is done to break up structure (e.g., thixotropy) if present and to obtain a uniform sample by redispersing any pigment that may have settled on storage. Ideally, the same viscometer spindle

Fig. 10—Digital spindle viscometers for determination of LSV conducted at lowest speed (0.3 rpm).

should be used for all paints being measured. However, this is not always possible as some coatings may be out of the preferred torque range of the viscometer. A recommended practice is to select the spindle that gives a torque reading between 10–100% of full scale for each coating tested. If that is not possible, a spindle change can be made, but the rotational speed should remain the same (0.3 rpm) to keep the shear rate relatively constant. The spindle should turn in the sample for about 60 s (or a longer fixed time period) before taking the reading, and the same time period should be used for all measurements. With this technique and assuming a pre-adjusted MSV of about 95 KU for each paint tested, the following guidelines provide low-shear performance predictions: excellent leveling for viscosities of less than about 250 P (25 Pa·s) as might be obtained with an associative thickener; too much flow for viscosities below about 100 P (10 Pa·s) and with sagging predicted on vertical surfaces; poor leveling at about 1000 P (100 Pa·s) as might be obtained from a moderately high MW conventional thickener; and little or no flow at 2000–3000 P (200–300 Pa·s) as might be obtained using some very high MW conventional thickeners or some unconventional associative thickeners. Another useful method that can be conducted on a Brookfield spindle type viscometer is the measure of "pseudoplastic index." This is a two-point determination that is the ratio of two viscosities a decade apart in shear rate (for example, 10/100 rpm). LSV is probed by extrapolation of viscosity to lower shear rates (lower rpm).

From the prior discussion, high LSV is a facilitator for pigment suspension and low flow coating characteristics, while a low LSV is desirable to promote flow and leveling. Some coatings have a prominent yield stress that can also be a factor in leveling. Due to their associative mechanism,

most, but not all, ATRMs provide low LSVs to impart excellent leveling characteristics. However, some alkali-swellable associative thickeners and even some nonionic associative thickeners impart uncharacteristically high LSVs, and like very high MW CTRMs, these thickeners have utility as antisag or antisettling agents for use in highly structured coatings (for example, texture paints). Their unusual behavior in coatings may be due to their ability to impart a degree of flocculation resulting from bridging or depletion mechanisms. Although gloss development is higher than most CTRMs with these thickeners, the gloss levels are not as high as most typical associative thickeners, which supports this conclusion. However, some alkali-swellable thickeners actually produce very high gloss levels, which suggests that aqueous phase networking has a larger influence on rheology than expected and/or that the dispersant character for these thickeners is greater than expected. Conventional thickeners, on the other hand, nearly always are highly shear thinning with high LSVs due to the hydrodynamic and flocculative mechanisms operating. Consequently, the gloss and hiding imparted from these thickeners tends to be lower.

Application Properties (HSV)

Most brush, spray, or blade coating operations are relatively high-shear processes. This is also true for roll coating applications when the circumferential velocity of the roll is significantly different than the linear velocity of the substrate. The shear on application for these operations is generally greater than about 10^3 s^{-1} and is typically about 10^4 s^{-1} for brushing and as high as 10^6 s^{-1} for some high-speed roll coating, blade coating, and spray operations. Many high-performance rotational rheometers are capable of measuring the HSV and most use cone/plate or plate/plate geometry. One general purpose instrument that is popular for laboratory and quality control of HSV measurement of architectural and other coatings is the ICI cone-plate viscometer as described in ASTM Test Method for High-Shear Viscosity Using the ICI Cone/Plate Viscometer (D4287-88). This instrument as shown in Fig. 11 has a fixed shear rate of 10^4 s^{-1} and the viscosity measured is a good predictor of film build when a coating is applied by brush and sometimes by paint roller [3,11–14]. The higher the ICI viscosity, the more resistance a brush encounters on application, which results in a thicker applied film. HSVs at this shear rate are typically from about 0.5–2.5 P (50–250 mPa s) for architectural coatings. If the HSV is too high, the coating will require too much effort to apply, will have a low spread rate, and may sag. If the HSV is too low, a second coat may be required to hide the substrate. Subjective brush drag by actual application is often conducted in accordance with ASTM Test Method for Comparison of Brush Drag in Latex Paints (D4958).

Conventional thickeners generally produce coatings with low HSV, while most associative thickeners and particularly associative rheology modifiers (lower efficiency associative thickeners) produce high HSV. Although less common, some associative thickeners produce low HSV and that may be advantageous depending on the application and film thickness desired. These thickeners tend to be very efficient in the medium-shear region, and the low HSV is primarily a consequence of less thickener being used. As a general rule for a given thickener type, the more thickener

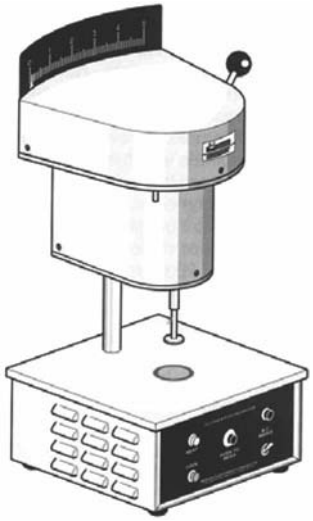

Fig. 11—Digital ICI cone/plate high-shear viscometer for determination of HSV.

required to obtain desired consistency (MSV), the higher the HSV will be. Therefore, if an increase in HSV is desired, a less-efficient thickener or rheology modifier may be needed so that more thickener is incorporated. As an option with associative thickeners, efficiency in the medium-shear region can be suppressed or enhanced by adjustment of other components in the coating formulation. By proper TRM selection or TRM blending, the desired HSV can be obtained without adversely affecting MSV or LSV.

Other TRM Test Methods

Although traditional viscometers and rheometers are very useful in providing coatings rheology, some nontraditional rheology characterization methods have been developed. Among these is a nondestructive technique for assessing rheology during film formation by measuring amplitude decay by optical two beam interference [74]. Surface tension was identified as an important factor for leveling by this method. Besides rheological characterization, other useful procedures have been developed for evaluation of some other properties for thickeners and rheology modifiers. Among these are a method for quantitative determination of thickener equilibration in coatings using a Krebs viscometer [75], and another for determining the relative water sensitivity of thickeners in neat form or in coatings by water vapor sorption [76]. Differences in water take-up between various classes of thickeners were revealed.

CONVENTIONAL TRMS (CTRMs)

In the broadest definition, CTRMs are non-associative water-soluble polymers, water-swellable polymers, or inorganic water dispersible materials that are capable of thickening or modifying the rheology of aqueous media. As defined, CTRMs are efficient thickeners or rheology modifiers without associative hydrophobe modification. For conventional polymeric viscosifiers, higher-molecular-weight polymer analogs within a given polymer type function primarily as thickeners, while lower-molecular-weight analogs function more as rheology modifiers. The primary thickening mechanisms of CTRMs are hydrodynamic and flocculative. Although there are many different chemical

types of these water-soluble polymers that could be used as TRMs in architectural, industrial, and other type of coatings, only a few have been accepted for use due to factors relating to economics, bio-stability, water sensitivity, compatibility, production quality, ease of handling, or the type of rheology imparted.

The CTRM polymers that are used in coatings are either synthetic or of biological origin. The synthetic polymers are derived from oil or natural gas feedstocks and are typically produced by addition or condensation polymerization. The biopolymers are either naturally occurring (rarely used in coatings), or are semi-synthetic including natural biopolymers that have been chemically modified, or biopolymers produced by a fermentation process. For classification herein, the polymeric CTRMs fall into three main categories: biopolymers (mostly modified polysaccharides), anionic synthetic ASEs, and nonionic synthetic polymers. The biopolymers may be further subdivided into modified cellulosics, guar derivatives, and fermentation biopolymers. The synthetic fermentation bipolymers, though less used in coatings, are of more recent vintage origin and employ microorganisms as a means of production. Several conventional polysaccharides are commonly used in architectural coatings (mainly house paints). ASEs are infrequently used in house paints but are often used to formulate adhesives and sealants. Conventional nonionic synthetics polymers are also seldom used in architectural coatings, but some polymer types are utilized in specialty applications such industrial roll coatings. Table 3 lists conventional water-soluble polymers used as thickeners in both coatings and noncoatings applications. As mentioned, nearly all of these thickener types have been tried in coatings, but only a few have found commercial acceptance. Table 4 details some important international suppliers of CTRMs and some of their respective products.

Cellulosic Polysaccharide Thickeners

Prior to the introduction of associative thickeners, conventional cellulosic thickeners were by far the most commonly used TRMs in aqueous coatings. Cellulosic thickeners for waterborne coatings were introduced in the 1950s, and they are still widely used today and are preferred as sole thickeners are in combination with associative thickeners in many formulations [77–81]. Some historical milestones during the development of cellulosic thickeners were enzyme-resistant grades in the 1970s, hydrophobe modified associative cellulosics in the 1980s, and fluidized (liquid) grades in the 1990s. Some of the conventional cellulosics are now being replaced or augmented in coatings by associative thickeners. Among these associative thickeners are hydrophobe modified cellulosic and galactomannan polymers, which are discussed later in this chapter. Cellulosic polymers are used in both interior and exterior architectural paints as thickeners and rheology modifiers, but they also are preferred for some other paint properties. One of these is the water-holding ability (water retention) of cellulosic polymers, which slows down evaporation and also retards penetration of water into the substrate. This property also helps to provide good "open time"—the time interval available for easily lapping back into a freshly coated architectural paint film with a brush or roller, and a new ASTM work item (WK13360), New Test Method for Open Time of Latex Paints, to measure this paint property is being developed.

Cellulose $(C_6H_{10}O_5)_n$ is a naturally occurring polysaccharide composed of repeating anhydroglucose units. Because of its relatively straight and stiff polymer chains and its strong intermolecular and intramolecular hydrogen bonding, cellulose is highly crystalline and consequently is insoluble in water. However, with appropriate chemical modifications, cellulose is readily converted to a variety of amorphous water-soluble polymers. The cellulose ether polymers are the most important for coatings and among those that have been used extensively are hydroxyethyl cellulose (HEC), methyhydroxypropyl cellulose (HPMC), sodium carboxymethyl cellulose CMC, and ethylhydroxyethyl cellulose (EHEC). Some standard terminology for cellulose and cellulosic polymers is provided in ASTM Standard Terminology of Cellulose and Cellulose Derivatives (D1695). The reactions used to produce water-soluble cellulose polymers are relatively uncomplicated. They typically involve treatment of cellulose with alkali to swell the polymer, followed by the chemical addition of the appropriate substituent. Each of the commercial cellulosic polymer types is available in a variety of grades that are differentiated by molecular weight, levels of chemical substitution, uniformity of substitution, and treatment for ease of dispersion. The chemical modifications are defined in two ways: the degree of substitution (DS), which is the average number of hydroxyl groups that have been substituted per anhydroglucose unit, and the moles of substitution (MS), which is the average number of moles of substituents per anhydroglucose unit for those substituents that generate repeating units (such as ethylene oxide in HEC).

In pure water, the more common cellulosics such as HEC, EHEC, HPMC, and HEMC at similar molecular weight have very similar rheology flow curves. The differences between these products become apparent in formulated products with respect to rheology and other properties. There are also regional preferences governed by production locations, cost, climate, formulating practices, and other factors.

In general, as molecular weight increases for conventional water polymers (e.g., polysaccharides thickeners), the amount of thickener required for constant MSV decreases (thickening efficiency improves). At the same time, LSV typically increases and HSV decreases, resulting in a more shear-thinning fluid. The effect on film build is predictably lower and with reduced leveling. However, some investigators have actually reported improved leveling with higher MW cellulosics, but this may be system dependent. Each type or grade of cellulosic thickener has a characteristic hydration time, which is defined as the onset of viscosity build. Some cellulosic grades (especially for coatings) also have surface treatments such as glyoxal to slow down the rate of hydration. This is called "retardation," and the result is improved incorporation of the thickener. The glyoxal reacts with hydroxyl methyl groups on the polymer to form hemi-acetal crosslinks. The dissolution time of the thickener is defined as the time to reach equilibrium viscosity (maximum viscosity).

One inherent liability with many cellulosic polysaccharide polymers is poor biostability [82–85]. Cellulase enzyme attacks the biopolymers, degrading them with resultant viscosity loss in coatings. Much research has been dedicated to finding reagents that would deactivate cellulase enzyme. Unfortunately there are dozens of different types of

naturally occurring cellulase enzyme, and a deactivator that is effective for one enzyme is often ineffective for another. A cocktail of deactivators would be required, and to date, this has been an impractical solution because of cost, toxicity, interaction with other components in a coating formulation, and issues with persistence in the coating over time. However, in another approach, chemical modification of the cellulosic polymers has resulted in the development and commercialization of bioresistant grades of HEC and some other cellulosics. The chemical modification that imparts enzyme resistance (for at least on a major producer of HEC) is the DS and uniformity of ethylene oxide substitution. To achieve the enzyme resistance, the glucose repeat units in HEC are substituted with pendent ethylene oxide on at least every other alternating anhydroglucose unit. The uniformity of substitution effectively blocks the attachment of the enzyme to the polymer backbone. Cellulosic polymer may also be subject to degradation by oxidant/reductant impurities that are carried over from the emulsion polymerization of latexes used in the coatings formulations [86]. This has mostly been solved on the latex side by ensuring that only low levels of those impurities remain in the latex products.

HEC

Of the cellulose ether polymers available, HEC has been by far the most popular cellulosic thickener used in waterborne coatings, and it is also the most popular coatings thickener regardless of chemical type [81]. HEC is a semi-synthetic nonionic polysaccharide manufactured by reacting ethylene oxide with the reactive hydroxyls on the anhydroglucose units of cellulose. The ethylene oxide also reacts with previously substituted hydroxyls resulting in short pEO side chains of usually two or three units in length. The ratio of molar substitution (MS) to DS defines the number of EO groups per side chain. The most popular products have MS values in the range of 1.5–3.0 and DS values of about 0.85–1.35. Optimizing reaction conditions results in a more uniform distribution of substitution to produce bio-resistant polymer grades. Commercial products are available in several regular and enzyme-resistant grades. Microrganisms such as bacteria, molds, and fungi can produce enzymes that degrade cellulosic thickeners. These microorganisms are often introduced into paint through contaminated raw materials or poor in-plant housekeeping. Although in-can preservatives will kill the microorganisms present, there are no additives effective against the enzymes that might have been produced in the paint. Consequently, bioresistant grades of HEC with unique structures were developed that have resistance to cellulose enzyme. Of the various grades of HEC available, the medium- and high-molecular-weight bio-resistant grades have been of greatest utility in coatings as thickeners. Low-molecular-weight grades are occasionally used as secondary TRMs to modify rheology (improve flow or film build).

Some cellulosic grades also have surface treatments to slow down the rate of hydration, thereby reducing the tendency for lumping. HEC is most often used in solid powder form, but moderately viscous "fluidized dispersions" are also available, which improve handling and may also improve the rate of incorporation. To minimize the dispersion viscosity of the supplied product, proprietary salts are incorporated. Various test methods for HEC are found in ASTM Test Methods for Hydroxyethylcellulose (D2364).

EHEC AND EMHEC

EHEC and ethymethylhydroxyethy cellulose (EMHEC) are two related cellulosic thickeners used in coatings with regional preferences [78–80]. In this more common naming convention, these cellulosic polymers are considered derivatives of HEC. Of the two, EHEC is more widely used in coatings, and mostly because of its favorable economics, EHEC has become competitive with HEC in North America and is the dominant cellulosic thickener in some other geographies. EHEC and EMHEC are inherently somewhat more bioresistant than HEC, but the respective bioresistant grades tend to be similar in enzyme resistance. To avoid lumping on addition of the powder to aqueous media, all paint grades of EHEC and EMHEC are treated with glyoxal for ease of incorporation. Increasing hydroxyethyl substitution along the cellulose backbone increases water solubility, improves salt tolerance, and decreases the tendency for gellation on heating. EHEC is used in several architectural coatings applications including textured paint, chemical plaster, flat paint, satin paint, and semi-gloss paint. The general performance in paint is typically somewhere between HPMC/HEMC and HEC. As is typical with other cellulosic thickeners, lower molecular grades impart less spatter and impart better leveling, while higher MW grades are more efficient with more pseudoplastic rheology.

EMHEC was developed to impart the combined properties of both HEC and HPMC. This high-efficiency thickener has particular application in flat paints where it provides good color acceptance and water resistance. Another attribute of enzyme resistance EMHEC is its low surface activity resulting in low foaming relative to HEC and HPMC.

HPMC AND HEMC

Another water-soluble nonionic cellulose polymer is methyl cellulose (MC). This polymer is mainly used in food and cosmetic applications but also has major industrial application in construction materials, where it is used in cement or gypsum-based mortars to control workability, slump, open time, water retention, substrate adhesion, and viscosity. The industrial construction grade is modified with glyoxal for increased dispersibility Although MC is not typically used as a thickener in coatings, some water-soluble derivatives of MC with hydroxyethyl or hydroxypropyl substituents have found acceptance in coatings. Two of the principal derivatives are hydroxypropylmethylcellulose (HPMC) and, used to a lesser extent, hydroxyethylmethylcellulose (HEMC) [87,88]. An alternative naming for these polymers in some literature is based on their being derivatives of HPC and HEC. In this convention they are MHPC and MHEC. These polymers have a modest degree of surface activity, which is advantageous in cementitious compositions, but this characteristic can be problematic in coatings for color development and color acceptance. For coatings, HPMC and HEMC are mainly in Europe and particularly in Northern European formulations. They are used as viscosifiers in interior and exterior emulsion paints to control in-can consistency, rheology, and storage stability. Some binder systems that seem to work well with these thickeners are styrene-acrylics and VA/VEOVA emulsions. Standard grades of HPMC and HEMC are more bioresistant to enzymatic degradation than standard grades of HEC or EHEC; however, the bioresistant grades of HEC and EHEC are considerably more resistant than HPMC and HEMC. There

is some controversy regarding the relative performance of these products for spatter resistance. HPMC has some niche applications and is especially recommended for Italian Tempera type paints because of its compatibility with certain types of calcium carbonate used in those formulations. HPMC tends to impart less pseudoplastic character than similar grades of HEC in some formulations.

Grades of HPMC vary in molecular weight, the ratio of methyl to hydroxypropyl substitution on the cellulose backbone, and the degree of substitution. Commercial grades of HPMC have average DS for the methyl groups in the range of 0.9–1.8 and MS for hydroxypropyl groups in the range of 0.1–1.0. Variations in these parameters affect solubility, thermal properties, and resistance to enzymes. Both MC and HPMC exhibit lower critical solution temperatures (i.e., they possess the somewhat unusual property of being soluble in cold water and insoluble in hot water). Solutions of these polymers form gel structures on heating. With modifications in processing, the DS, MS, gel temperature, and gel texture are altered. Because of its structure, HPMC is also inherently more resistant to bio-organisms compared to some other polysaccharides. Various test methods for the characterization of HPMC may be found in ASTM Test Methods for Hydroxypropyl Methylcellulose (D2363).

HEMC is another MC derivative, but it is used to a lesser degree in coatings than HPMC. For reasons of economics and product line extension, the same producers that make MC also conveniently make HPMC and HEMC. The HEMC grades are generally fewer for HEMC than HPMC, but they are prepared in a similar fashion regarding variation of DS for methyl groups and MS for the hydroxyethyl groups on the polymer backbone.

CMC

CMC is an anionic water-soluble polymer that has been of limited use in coatings because the modification constituent (sodium carboxylate) leaves the dried films more water-sensitive than most non-ionic polysaccharides [78–80]. However, in some lesser-developed countries and where lowest cost is a primary consideration, this polymer as a thickener in coatings is quite popular. CMC is prepared by reaction of cellulose with monochloroacetic acid after treatment with alkali. Commercial grades have DS for carboxylate substitution ranging from 0.4–1.4, and the most popular products are with MS 0.7 to 0.8. As with most other conventional polysaccharides, the viscosity is primarily controlled by varying the molecular weight of the cellulosic chain. Some technical grades of CMC contain by-product salts (primarily sodium chloride and sodium glycolate) that further limits their use in coatings applications. One application of utility for CMC is in dry-mix paints where the CMC functions to control viscosity and wet edge. A purified grade of CMC referred to as cellulose gum is preferred for use in latex paints. Various procedures for characterization of CMC may be found in ASTM Test Methods for Sodium Carboxymethyl-cellulose (D1439).

MCC

Microcrystaline cellulose (MCC) is a nonionic form of cellulose that is typically coprocessed with carboxymethyl cellulose and supplied in powder form for use in paints and coatings [89,90]. MCC forms a three-dimensional stabilizing network after high shear dispersion in water resulting in millions of insoluble microcrystals. The viscosifying network is shear thinning and forms very stable thixotropic gels. This provides stability at low shear rates for improved pigment suspension and reduced color float in tinted gloss paints co-thickened with nonionic associative thickeners. For proper incorporation, it is recommended that the MCC be the first component dispersed in water with high shear.

Galactomannan Polysaccharide Thickeners

GUAR GUM AND LOCUST BEAN GUM

Guar gum (GG) and locust bean gum (LBG) are two galactomannan polysaccharides with different mannose/galactose ratios [91,92]. These polymers are widely used in many industrial sectors including food, textiles, paper, paint, adhesives, cosmetics, mineral processing, and pharmaceuticals. Of these two polymers, guar, and especially modified guar, is more important in paints and coatings though used less than many other polysaccharides. Guar (guaran) is a naturally occurring, high-molecular-weight galactomannan polymer obtained from the guar plant *(Cyamopsis Tetragonalobus)*. Also known as clusterbean, guar is a drought-tolerant annual legume with major crop production and processing in India, Pakistan, and the United States (mainly Texas and Oklahoma). The polymer backbone of guar is a linear chain of β1,4-linked mannose residues to which galactose residues are 1,6-linked at every second mannose, forming short side-chain branches. The polymer, with molecular weight of over 1×10^6, takes on a rigid rod-like conformation because of the beta linkage between the monomer units. Guar gum is sometimes used as a thickener for coatings in its natural unmodified form, but more often it is derivitized for industrial applications. The primary derivative is hydroxypropyl guar.

HYDROXYPROPYL GUAR (HPG)

Guar is often chemically modified similar to cellulosics with akly and hydroxylakyl ether substituents. The most common derivitized product is hydroxyproply guar (HPG). Although natural and derivitized guar are sometimes used in coatings, they are more commonly employed as efficient viscosifiers in food and in non-cementicious construction products [93–95]. Solutions of galactomannan polymers exhibit strongly pseudoplastic behavior, excellent heat stability, good cold water solubility, high salt tolerance, and lubricity. Of the non-cellulosic polysaccharides thickeners available in commerce, only hydroxypropyl guar has found any significant application in coatings. Like the synthetic biopolymers described below, HPG produces coating rheology that is more shear thinning (more pseudoplastic) than most of the cellulosic polymers previously described. Consequently, HPG tends to have better suspension and antisag characteristics than some cellulosics but produces more roll spatter and is less bio-resistant. Another limitation for HPG is that it is available in only a few grades for coatings. Compared with its parent (guar gum), solutions of HPG are more bioresistant, less electrolyte sensitive, and have improved solubility and clarity. The biostability is typically less than enzyme-resistant cellulosics. Utility of HPG is primarily as a secondary thickener for sag and suspension control in flat, texture, and dripless paints such as spray ceiling paints

Fermentation Biopolymer Polysaccharide Thickeners

The cellulosic thickeners previously described are all semi-synthetic biopolymers. However, the terms "semi-synthetic biopolymer" or "synthetic biopolymer" sometimes imply biopolymers produced by a non-traditional chemical method—fermentation. However, fermentation is a mostly natural process; therefore, it is more appropriate to refer to these polymers as biopolymers by fermentation or simply fermentation biopolymers [26,96]. These polymers are often referred to as gums or biogums. The use of fermentation biopolymers in paints and coatings has been quite limited; nonetheless, at least two products are being used as either primary or secondary thickeners, some to provide suspension characteristics. Like commercial cellulosic thickeners, commercial fermentation biopolymers are also polysaccharides; however, they are enzymatically produced rather than being made by chemical modification. The biopolymer synthesis is typically conducted in a fermentation broth with naturally occurring bacterium or yeast. Some common traits of biopolymers are their superior ability to suspend or gel, their inherent salt tolerance, and their stable viscosities over a wide temperature range. Biogums also tend to have better enzyme resistance than non-enzyme resistance grades of cellulosic thickeners. As with HPG, a limitation is that there are only a few grades available from suppliers. Among the commercial biopolymer products which are available for use in coatings are xanthan gum, rhamsan gum, welan gum, gellan gum, and diutin gum. Biogums have a naturally occurring cellulose enzyme that must be controlled for paint applications. Because of that factor and cost, most biogums find little use in coatings.

XANTHAN GUM

The most well known and commercially important synthetic biopolymer is Xanthomonas campestris polysaccharide (XCPS), better known as xanthan gum [97,98]. This "cultured" biopolymer was initially discovered in USDA laboratories in 1959 by fermentation of glucose with the bacterium *Xanthomonas campestris* [30], a microorganism found in nature mainly on the leaf surfaces of green vegetables. The discovery of Xanthan gum was brought into first commercial production by the Kelco Company under the trade name Keltrol in the early 1960s. In the optimal fermentation process, aeration, temperature, pH, and agitation are carefully controlled, resulting in a tan-colored, free-flowing powder on drying. Though xanthan is produced by fermentation, this polymer is made up of β-1,4-linked D-glucose residues producing a backbone that is identical to the cellulose molecule. A trisaccharide branch with one glucuronic acid unit between two mannose units is linked to every other glucose unit in the main chain. This high-molecular-weight (approximately 2×10^6), branched polysaccharide is characterized as having high yield stress values and a high degree of pseudoplasticity (high LSV and low HSV). The rigid structure of the Xanthan polymer matrix immediately dissociates on shear and instantly recovers to the original viscosity when the shear is removed. This immediate recovery of viscosity after shearing is a key characteristic for pigment suspension and sag resistance in coatings, but it does inhibit leveling. Other features of xanthan gum are its relative insensitivity to *p*H, temperature, enzyme attack, the presence of most salts, and good compatibility with other coatings ingredients. Applications for Xanthan are similar to those for HPG but with somewhat better thickening efficiency and even more shear thinning rheology (higher LSV). Grades of xanthan gum are available to provide a range of dispersibility and hydration.

OTHER FERMENTATION BIOPOLYMERS

There are several other biopolymers produced by fermentation that have gained commercial importance in some industries such as food, pharmaceuticals, and personal care, but these polymers currently have very limited use in coatings [26,96]. However, they do have potential in certain types of coatings and for some specific properties. Cost is often a deterring factor though, as there are more cost-effective options with cellulosics and other thickeners. Among these fermentation biogums are rhamsan gum, gellan gum, welan gum, and diutin gum.

Rhamsan gum has some very minor application in coatings. One of the more outstanding characteristics of this polymer is its exceptional suspending power (produces very high LSV in coatings). In approximate order of decreasing suspending ability are Rhamsan gum > Xanthan gum > HP guar > CMC > HEC. Rhamsan gum also is reported to have good salt tolerance and improved stability to high-shear mixing.

Gellan gum is a water-soluble anionic polysaccharide produced by microbial fermentation of the *Sphingomonas elodea* bacterium. This gum is a very efficient thickener and forms gels with even minor levels of mono or divalent cations. Its principal application is in food. The repeating unit of the gellan polymer is a tetrasaccharide with repeating units of glucose, L-rhamnose, and D-glucuronic acid. The polymer is available with both low- and high-acyl content to provide hard non-elastic and soft elastic gels, respectively. The high-acyl polymer has ester side groups, and the low-acyl polymer is produced by alkali treatment of the high-acyl polymer.

Welan gum is an anionic polysaccharide with excellent thermal stability and retention of viscosity at elevated temperatures (greater than 90°C) in aqueous media. This microbial polysaccharide is produced by fermentation with *Alcaligenes* sp. bacterium resulting in a tetrasaccharide repeating unit backbone with single sugar branches of either L-mannose or L-rhamnose. Welan gum is considered a first-generation thickener for cementitious systems (cements and concrete). It is also recommended for oilfield, foundry coatings, pigment suspensions, and paint.

Diutan gum is considered a second-generation product to welan gum and was designed specifically for cementitious systems. This polymer imparts pseudoplastic rheology with virtually instantaneous response to either the application or removal of shear. Consequently the fluid is easy to pump or process but then provides instant suspension. Some applications include grouts and mortars with limited use in coatings.

Alkali-Swellable/Soluble Emulsions (ASEs)

Alkali-soluble and alkali-swellable emulsions (ASEs collectively) are among the few conventional synthetic hydrocarbon thickeners used in coatings [99–102]. Conventional ASEs are carboxyl functional copolymers produced by the free-radical emulsion polymerization of ethylenically

unsaturated monomers [31]. They are low-viscosity water-insoluble latexes at low *p*H as produced and commercially supplied, but they exhibit thickening on dissolution or swelling of the latex particles when the *p*H is raised (generally above *p*H 5.5) with full viscosity development on the alkaline side of *p*H. Copolymers of methacrylic acid and ethyl acrylate are by far the most common pair of primary monomers used, and they often include a small amount (generally less than 1 %) of a polyfunctional monomer to lightly cross-link the polymer to enhance swellability. Since most coating formulations are finished on the basic side of *p*H, the ASE polymers are fully neutralized in most applications. They achieve their maximum viscosities above about *p*H 7, and ideally, the maximum viscosity should be relatively constant from about *p*H 8–10 so that slight changes in *p*H on storage will have little or no effect on coating consistency. Although ASEs impart viscosity and pseudoplastic rheology similar to some other conventional thickeners, their primary advantages compared to the powder form polysaccharides and fermentation biopolymers are in ease of handling and bio-stability ASEs may be more water sensitive than most nonionic polysaccharides; however, unlike CMC, which is supplied as a water-soluble sodium salt, neutralization of ASEs is normally conducted with ammonia or volatile aminoalcohols, which eventually leave the film on drying. The ASE polymer is insoluble before neutralization, soluble after neutralization, and again insoluble after the volatile base leaves the paint film thus producing a film with relatively low water sensitivity. Hydrophobe modification of conventional ASEs to produce associative products (HASEs) has greatly increased the popularity of alkali-responsive emulsion thickeners. The HASE associative thickeners are discussed later in this chapter under "Hydrophobe Modified ASEs (HASE)."

A current list of conventional commercial thickeners suppliers and their products are compiled in Table 4.

ASSOCIATIVE TRMS (ATRMS)

Because of the increasing importance of rheology modification in coatings, the use of ATRMs continues to grow with many product offerings now available. The study of associative thickeners, their performance, and formulating with these products has been examined extensively over the past 20 years [103–124]. Presently, three broad classes of commercial ATRMs represent many older and newer products: hydrophobe-modified nonionic synthetics (HMNS), hydrophobe-modified cellulosics (HMC), and HASE. Contained within these major classes are important subclasses, all of which are discussed in detail hereafter. Table 5 summarizes the commercial product classification scheme for CTRMs and ATRMs used in coatings. Included in this table are the principal thickener classes, subclasses, conventional/associative analogs, and the designated acronyms. Those acronyms that are prominent in the literature as well as those which are assigned here are indicated.

Coating components and coating formulation variables are known to affect the rheological performance of associative thickeners [125,126]. Some specific parameters that have been examined are volume solids [127], type of latex binder [128–130], latex binder particle size [131], particle surface acid groups [132], surfactants and cosolvents [133–135], coalescing aids [136], and some clay pigments [137,138]. The steady shear, linear viscoelastic, and extensional rheological properties of associative thickener solutions have also been characterized. The classes of associative thickeners will be discussed below in no particular order. However, the three most significant products commercially have been hydrophobe modified nonionic synthetics (mainly HEUR), hydrophobe modified alkali-swellable emulsions (HASE), and hydrophobe modified polysaccharides (mainly HMHEC).

Hydrophobe Modified Nonionic Synthetics (HMNS)

The HMNS ATRMs are nonionic condensation polymers of synthetic origin. Most of these polymers are amphiphilic and therefore contain distinct polar (hydrophilic) and non-polar (hydrophobic) regions in the molecules that can promote micelle formation in very dilute solution. The hydrophilic regions are usually pEO segments that alternate with hydrophobic (usually alkyl, cycloacyl, or aromatic hydrocarbon) groups. The ends of main chains and any side chains of these polymers are also typically terminated with hydrophobic groups.

The HMNS polymers tend to be much lower in molecular weight than conventional thickeners, and the repeat units (pEO segment plus hydrophobe) are generally less than about 20 units. The most well-known HMNS subclass of which there are many commercial representative examples are the hydrophobe-modified ethoxylate urethane (HEURs). You will note that the M (for Modified) is dropped in this accepted acronym and in several other commonly accepted associative acronyms to follow. Another prominent HMNS subclass includes the hydrophobe-modified ethoxylate ethers (HEET) that are sometimes designated in literature as hydrophobe modified nonionic non-urethanes (HENN), or hydrophobe modified ethoxylate ethers (HEET). Other sub-classes include hydrophobe modified ethoxylate aminoplast thickeners (HEAT), and hydrophobe-modified urea/urethanes (HEUUR), which are sometimes designated PEUPU (polyether urea polyurethane). On examination, differentiation between HMNS subclasses mainly reflects the linkages between the hydrophobes. However, the size of the polymer, the macro structure of the polymer (linear, comb, branched), and the length of pEO segments are important elements for relative performance. Among the attributes of HMNS thickeners are excellent flow and leveling in coatings and high film build for increased coating thickness or one-coat coverage. These thickeners also tend to give better corrosion resistance in coatings. However, the low-shear viscosity that gives excellent leveling can be a liability for sag resistance on vertical surfaces. One issue with these thickeners has been viscosity loss on tinting due to the disruption of the associative thickening network by surfactants present in the tinting material. This is a research area where there as been much recent development to correct this problem [139–141]. Another area of recent activity for improvement is color acceptance with associative thickeners [142–144]. The subclasses of associative thickeners are discussed below.

HEUR (SUBCLASS OF HMNS)

As mentioned, the HEUR polymers are the major subclass of the nonionic synthetics (HMNS) [145–153]. They were the first HMNS polymers commercialized and are still among the most popular ATRM products with several

[a] HASE usually contain ester linkages to associative side chains.
[b] HEURASE contain urethane linkages to associative side chains—they are sometimes considered a subclass of HASE.
[C] HEUR are sometimes designated PEPU (polyether polyurethane) or simply PU Thickener (polyurethane thickener).
[d] HEUUR are sometimes designated PEUPU (polyetherurea polyurethane).
[e] HEET are sometimes designated HMPE (hydrophobically modified polyether) or PEPO (polyetherpolyol).
[f] HPAPE is designated HMPAPE by supplier with same text description.
[g] HMPAM is used mainly in oilfield applciations.

domestic and international suppliers. Common to all HEUR polymers are the presence of three chemical components: hydrophobes within and at the ends of side or main chains, hydrophilic pEO segments, and urethane linkages that join the pEO segments to the hydrophobes. Most HEUR polymers are formed by the reaction of mono- and di- or tri-isocyanates with the hydroxyl groups on the pEO segments—the reaction of an isocyanate with a hydroxyl group is a urethane group. The HEUR and some other HMNS subclass polymers are generally considered to be among the most effective of the associative products with respect to rheology modification. Being low in molecular weight and highly associative, they tend to provide the most Newtonian rheology (low LSVs and high HSVs) for superior flow/leveling and film build. They also impart low extensional viscosity and low viscoelasticity for superior spatter resistance.

Many HEUR polymers are supplied as moderately viscous solutions in a combination of water and cosolvent such as Butyl Carbitol® or propylene glycol. The cosolvent is present to suppress viscosity for ease of handling. Like conventional surfactants, these cosolvents have polar surfactant-like character that can disrupt the intermolecular association of the HEUR hydrophobes thereby reducing viscosity. Without the cosolvent, the viscosity of the HEUR thickener in water alone would be too high for practical

use. HEURs are now available that are 100 % aqueous (without cosolvent). Ordinarily these polymers would be extremely viscous in solution, but low viscosity is achieved with the addition of cycloextrin that effectively traps the HEUR hydrophobes to minimize their association. Since HEURs are non-ionic, they should have inherently low water sensitivity. However, they are generally less efficient than cellulosics or ASEs and they are also much lower in molecular weight, which may limit their use in some exterior applications. Because the HEUR products have very low LSVs for superior flow, they may permit sagging, syneresis, or pigment settling, particularly when used as the sole thickener. They are also very sensitive to other coating components, and proper formulation balance is necessary for optimum performance.

Other Nonionic Synthetics

As mentioned, one of the key differentiating features of the associative nonionic synthetic thickeners is the linking functionality joining the internal and terminal hydrophobe groups to the polyethylene oxide segments. In HEUR polymers, the linkage is urethane. In some other similar associative polymers the linkage can be ether, urea, or a combination of linkages, and some of the other commercial HMNS subclasses are discussed below [154,155].

HEET (SUBCLASS OF HMNS)

Synthetic nonionic associative thickeners with hydrophobe-pEO linking groups other than urethane are among the newer products in the HMNS arena. These polymers as a group are sometimes referred to as HENN thickeners. One of the subclasses in this group are the HEET. One major difference that defines the HEET subclass compared to HEURs is that urethane linkages are replaced with ether linkages. Another difference is that polyether segments may not be limited to ethylene oxide alone (that is, EO-PO blocks may be present).

HEUUR (SUBCLASS OF HMNS)

Another recent HMNS subclass is the HEUUR. In literature, the acronym PEUPU is sometimes used. As the names imply, these associative polymers are similar to HEUR except that some urea segments are present. That would suggest that at least some of the ethoxylate segments initially contained amine functional end groups—the reaction of an amine with an isocyanate results in the formation of a urea group. The HEUUR would be expected to have rheological properties similar to the HEUR and HEE polymers.

HEAT (SUBCLASS OF HMNS)

Another HMNS subclass is HEAT. This thickener subclass contains the usual hydrophobes and pEO segments, but it uses an aminoplast linkage to join the components. At this time there is only one commercial supplier of these products. Like the HEUR polymers, HENN thickeners contain cosolvent and are supplied as moderately viscous aqueous solutions. Little information is currently available; however, based on advertising claims for chemical composition and performance, the rheological characteristics of these products are expected to be similar to HEUR ATRMs. The chemical composition and physical form would also suggest that the handling and performance limitations are similar to those of HEURs. Improved color acceptance, color stability, and block resistance are claimed for the commercial product, and improved shear stability due to lower molecular weight is claimed for the developmental products but at the expense of thickening efficiency.

Hydrophobe Modified ASEs (HASE)

The HASE polymers were among the first ATRMs to be developed and their commercial significance dates back to the late 1960s, and since then, these polymers have been extensively studied in both academic and industrial settings [102,156–159]. The popularity of these products continues due to their relatively good economics, bio-stability, rapid viscosity equilibration, lack of cosolvents (0 or low VOC), and low-viscosity liquid form as supplied. Like ASEs, the HASE products are synthetic addition polymers produced by emulsion polymerization of carboxyl functional monomers. Consequently, they are of relatively high molecular weight (higher than HMNS but lower than conventional thickeners) and thicken by a hydrodynamic mechanism in addition to the associative mechanism. The predominate mechanism operating depends on several factors, including the molecular weight and the amount and type of associative functionality.

Typically, HASE products are terpolymers of ethyl acrylate, methacrylic acid or itaconic acid, and an associative macromonomer. The effects of monomer types, monomer ratios, and the types of associative side chains have been examined [160–165]. The macromonomer usually contains pEO units (typically 10–100 mol ethylene oxide) terminated with a hydrophobe (typically alkyl or alkylaryl). The associative side chain linkage to the main chain backbone is pre-dominately either ester (HEEASE) or urethane (HEURASE) per the classification scheme of Table 5. The patent literature does describe other linkages and although some have been used in the past, they are not commercial today (for example, products with ether linkages and products with anhydride ester linkages were marketed in the 1960s, but they were later discontinued). Like ASEs, the HASE polymers may also be cross-linked to varying degrees with small amounts (typically less than 1 %) of a polyfunctional monomer to increase swellability. Although HASE polymers are anionic and, therefore, predicted to be more water sensitive than non-ionic ATRMs, many HASE products are more efficient (less thickener is required for consistency), which minimizes the effect of the anionic character. Additionally, performance of HASEs in exterior coatings can be improved with ZnO or zinc complexes, which cross-link the carboxyl functionality present [157], which is lacking in the HMNS polymers. Being polyanionic, the HASE polymers also have dispersant character that contributes to hiding and gloss. The carboxyl groups in HASE polymers can also covalently cross-link with melamine, urea, and epoxy resins in thermoset coatings, and being acidic, they catalyze the cross-linking process. Some structural depictions of the three most polular associative thickeners are shown in Fig. 12.

HEEASE (SUBCLASS OF HASE)

Hydrophobe modified ethoxylate ester alkali-swellable/soluble emulsions (HEEASE) are one of two major HASE subclasses [166–168]. Although the HEEASE acronym is not often used, it helps to differentiate between associative ASEs that contain ester linkages and those that contain

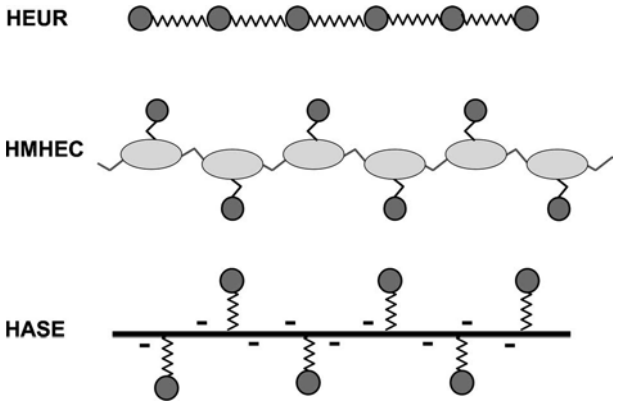

Fig. 12—Relative polymer architecture of three popular associative thickeners used in waterborne coatings.

urethane linkages. Prior to the introduction of HASEs containing urethane linkages, the HEEASE polymers were the only lasting commercial representatives of the HASE class. Consequently, HASE often implied HEEASE in the literature. Since there are now several commercial urethane functional HASE polymers, subclassification was needed, and like the HEUR and HENN polymers, differentiation here relates to the presence or lack of urethane linking functionality. The associative side chains of HEEASE polymers contain ester linkages, and like most other ATRMs, some HEEASE polymers function more as rheology modifiers and are often lower in molecular weight while others function as primarily thickeners to produce efficient mid-shear viscosity. Because of the dual thickening mechanisms, the molecular weight and type and amount of associative functionality are among the processing variables that can be altered to effect change in performance. With respect to rheology, the HEEASE thickener rheological performance is generally similar to the associative cellulosics.

HEURASE (SUBCLASS OF HASE)

The second major subclass of HASE thickeners are the hydrophobe modified ethoxylate urethane alkali-swellable/soluble emulsions (HEURASE) [169–173]. These ATRMs are of more recent vintage and were designed to combine some of the chemical architecture and performance attributes of anionic ASEs with the chemical architecture and performance attributes of nonionic HEUR thickeners. Like conventional ASEs, HEURASE polymers are prepared by emulsion polymerization and supplied as low-viscosity, low-*p*H latexes. However, the associative side chains in HEURASE contain the same three functional components found in HEUR thickeners (terminal hydrophobes, pEO segments, and urethane linkages). Because of this and the relatively high level of associative monomer present in these terpolymers, rheology modification approaching that of the premium HEUR thickeners is claimed without many of the HEUR and HENN limitations. Although most HEURASE thickeners provide the expected Newtonian rheology, some atypically impart suspension characteristics (high LSV) for use in antisag, antisettling, or texture paint applications. The extensional viscosity imparted by HEURASE products is low and comparable to some HEUR thickeners.

Hydrophobe Modified Cellulosics (HMC)

Like the HMNS polymers, hydrophobe-modified cellulosics (HMC) are nonionic condensation polymers but of biological origin. These polymers are prepared by modifying standard or special grades of conventional cellulosics such as HEC or EHEC with hydrophobes, and like the other ATRMs described above, the hydrophobes are typically alkyl or alkylaryl, but the pEO chains are comparatively very short. Presently there are two commercial subclasses of HMC: HMHEC and HMEHEC. Although the acronyms for associative thickeners are usually unhyphenated, the hyphen is included in the sections for polysaccharides to avoid confusion where H often means hydroxyl (rather than hydrophobe) and M means methyl (rather than modified). These HMC are non-ionic; however, the potential exists for other cellulosic associative products, which may be either nonionic [for example, hydrophobe-modified hydroxypropyl methyl cellulose (HMHPMC) and the like] or anionic [for example, hydrophobe-modified carboxymethyl cellulose (HMCMC) and the like]. One non-cellulosic hydrophobe modified polysaccharide recently commercialized is based on hydroxypropl guar gum, discussed later.

HMHEC (SUBCLASS OF HMC)

The first commercial associative cellulosic thickener on the market in the late 1980s was a HMHEC introduced by Hercules/Aqualon. At least three grades of this product are still available at this writing under new umbrella ownership. Another competitive HMHEC product was introduced later from Dow Chemical. HMHEC thickeners have overcome many of the limitations of conventional HEC, including improved film build, improved leveling, and better spatter resistance [174–180]. The associative behavior (adsorption onto latex and pigment particles) and the rheology of this polymer have been characterized along with various solution properties. The improvement in rheology (more Newtonian for better leveling and increased film build) over HEC is generally similar to the HASE type thickeners, but since HMHEC is nonionic, the early water sensitivity of coatings made with it tends to be better. The methods of preparation and solution properties of HMHEC have also been described. HMHEC is prepared by attaching hydrophobes to conventional HEC via the hydroxyl groups along the polymer backbone. The degrees of substitution and molecular weight grade of HEC chosen for this modification are important. Unlike other classes of ATRMs, the ethoxylate content between hydrophobe and HEC backbone is small (generally one to a few units). Because HMHEC is a solid, the handling limitations are similar to those of HEC and other solid thickeners. To improve on this, developmental fluidized aqueous dispersions of HMHEC were introduced but with limited success. The viscosity of the fluidized products as supplied is still moderately high and similar to that of the HEUR and HENN products.

HMEHEC (SUBCLASS OF HMC)

Associative EHEC polymers were introduced in 1992 and are among the most recent commercial HMC products [181,182]. Their chemical construction and performance is somewhat similar to HMHEC but based on EHEC. As with the unmodified cellulosic analogs, use is often geographically driven. At this writing, there is currently only one supplier of HMEHEC products.

HMHPG (SUBCLASS OF HMC)

A relatively recent entry into the polysaccharide associative thickener category is hydrophobe modified hydroxypropyl guar gum (HMHPG) [183–185]. This polymer is somewhat similar to the hydrophobe modified cellulosics but is of course a galactomannan derivative. Like HMEHEC, this thickener is used primarily in certain geographies and the success in coatings is somewhat limited. Anti-spatter properties with improved flow and film build are expected.

In Table 6 a current list of principal associative thickener suppliers, their products, and the thickener classification for each is compiled.

INORGANIC THICKENERS FOR AQUEOUS AND SOLVENT-BORNE COATINGS

Most inorganic thickeners and rheology modifiers (ITRMs) are supplied as powders and are mainly either modified clays or fumed silicas. When they are properly dispersed into a coating, they usually function as suspending or gelling agents and some may have secondary utility as extender pigments. Rheologically, ITRMs tend to have high yield values and are characterized as "thixotropes." The viscosity of the coating decreases with time under constant shear as its gel structure is broken down. When the shear is removed, the coating gradually recovers to its original viscosity. The rate of recovery can be very rapid (complete within seconds) or can take several minutes or even hours depending on the degree of thixotropy and prior shear history. Certain grades or mineral types of ITRMs are useful for thickening aqueous systems and others for solvent-borne coatings. Utility in one media or the other is mostly a function of the thickener. Table 7 lists and catagorizes the various types of inorganic thickeners used in waterborne and/or solvent-borne coatings. Included are synonyms, chemical type, and the type of thickening mechanism.

Particle surface is often modified with organic treatments to render it hydrophilic (usually for waterborne coatings) or hydrophobic (usually for solvent-borne coatings). ITRMs are also sometimes added to aqueous formulations as secondary thickeners to impart some degree of antisag, antisettling, or antisyneresis to coatings containing primary conventional or associative thickeners. The most common types of modified and unmodified ITRMs are attapulgite clays, bentonite clays, organoclays, and treated and untreated synthetic silicas.

Clay Thickeners

The term "clay" or "silicate clay" refers to minerals that are rich in alumina, silica, and water. The main building blocks of silicate clays are layers of silica tetrahedron and aluminum octahedron. Many clays also contain magnesium in their crystal lattice (magnesium aluminum silicates), and some also contain one or more other cations including iron, zinc, sodium, calcium, or lithium. The five primary silicate clay mineral groups are kaolinite, illite, vermiculite, smectite, and chlorite, which are differentiated by their layer type, layer charge, and by chemical formula [186]. Of these five main clay groups, only smectite clay (and some related clays) are commercially significant as thickeners in waterborne and/or solvent-borne coatings [186–188]. Smectite means "expanding lattice," and refers to a family of thickeners that undergo an increase in effective volume (swelling) during incorporation into coatings. This is also the only clay group that swells with water. Two important types of swelling smectite clays are bentonite and hectorite. Also commercially important as thickeners are the non-swelling organoclays derived from bentonite and hectorite. Another non-swelling clay containing some smectite is attapulgite. This clay and the organoclays thicken by structuring rather than by swelling. The other four main clay groups (kaolinite, illite, vermiculite and chlorite) do not function as thickeners, but they are important in commerce as pigment extenders, insulation materials, fillers, and the like. Although smectites and attapulgite clays work very well as viscosifiers, they can be challenging to incorporate into coatings. They typically must be predispersed under high shear, may require some time for full equilibration, and their water demand sometimes limits formulating latitude. However, some dispersible grades are available for ease of incorporation. Each of these clay thickeners is discussed in more detail below and they are identified as being either swelling or structuring clays.

BENTONITE/MONTMORILLONITE CLAY—SWELLING

As mentioned, the two main commercial classes of smectite clay for swellable coatings thickeners are bentonite and hectorite. Bentonite is by far the most abundant of these two minerals in nature, and the term bentonite is commonly used generically to mean smectite. The principal bentonites are sodium bentonite and calcium bentonite. Although bentonite and hectorite are similar in their mechanism of swelling behavior, they differ in their crystal lattice composition. Bentonite is an absorbent, naturally occurring hydrated aluminum silicate originally deposited by volcanic ash and metamorphosed into rock over time [189,190]. This clay consists mainly of the mineral montmorillonite, which is named after its discovery location in Montmorillon, France.

There are actually several types of bentonites, and their names depend on the dominant elements present, such as K, Na, Ca, and Al. Bentonite is typically described as colloidal hydrated aluminum silicate with varying degrees of aluminum replacement with magnesium, calcium, and sodium. The crystal lattice of montmorillonite contains mainly aluminum with the chemical formula $(Na,Ca)_0$, 3(Al, $Mg)_2Si_4O_{10}(OH)_2 \cdot n(H_2O)$. Wyoming bentonite is considered a relatively pure form of montmorillonite, and often montmorillonite means Wyoming bentonite. The vast majority of natural bentonite is calcium bentonite. When sodium ions are substituted for calcium ions, sodium bentonite is obtained and the swelling ability is enhanced. Natural sodium bentonite has a very high swelling ability, and this bentonite gets its name from its discovery near Fort Benton, Montana.

The crystal structure of bentonite is a three-layer sheet that forms flake-like colloidal particles of less than 0.5 μm. In aqueous media, bentonite is naturally hydrophilic and readily dispersible. The water is taken up between the mineral laminae, causing the lattice structure to stretch and swell. Thickening is due to a combination of swelling and particle network interaction, and purified forms of un-modified bentonite are highly effective as thickeners in aqueous coatings. Although the thickening mechanism is rather different than attapulgite clays, most bentonite clays also require wetting, high-shear for dispersion, and time for complete hydration. Some modified grades are,

TABLE 7—Inorganic thickeners for waterborne and solvent-borne coatings: their classification, synonyms, composition, type of thickening, and where they are used

Inorganic Thickeners for Waterborne (WB) and Solvent-borne (SB) Coatings					
Class	**Clay or Silica**	**Synonyms**	**Chemical Composition**	**Type**	**Primary Use**
Smectite clays	Bentonite	Montmorillonite[a]	aluminum phyllosilicate	Swelling	WB
	Hectorite	—	magnesium lithium phyllosilicate	Swelling	WB
Organoclays	modified bentonite and hectorite	—	smectite clays modified with quaternary ammonium hydrophobes	Structuring	SB/WB
	mixed mineral thixotropes	MMT	composite of several different types of clays and modified with QAH	Structuring	SB/WB
Other clays	Attapulgite	Palygorskite[b]	magnesium aluminum phyllosilicate	Structuring	WB
	Sepiolite	Meerschaumc[c]	hydrated magnesium silicate	Structuring	WB
Synthetic silicas	Precipitated Silica	—	hydroxylated sodium silicate	Structuring	WB
	Fumed Silica	Pyrogentic Silica	silicon dioxide	Structuring	WB
Hydrophobic silicas	organo modified silica	—	made from organo treatment of precipitated or fumed silica	Structuring	SB/WB

[a] Depending on the reference, montmorillonite is the principal mineral in bentonite, or bentonite is the principal mineral in montmorillonite.
[b] Palygorskite is the principal mineral in attapulgite—also some smectite present.
[c] Meershaum (meaning sea foam) was the previous name for sepiolite.

however, readily dispersible with conventional agitators. For effective incorporation, *p*H must be carefully regulated. If it is too high, excessively rapid hydration occurs, and if it is too low, hydration times are long with loss in thickening efficiency. The presence of salts (electrolytes) may cause flocculation, rendering bentonite ineffective in highly ionic environments. The bentonite and hectorite clays are often organically treated with hydrophobic quaternary amines to produce "organoclay" thickeners as discussed later.

HECTORITE CLAY—SWELLING (NATURAL AND SYNTHETIC)

Hectorite is a rare soft, greasy smectite clay mineral that occurs with bentonite. Like bentonite, hectorite is derived from volcanic ash and tuff but with relatively high glass content. Hectorite is often associated with hot spring activity and is an alteration of the mineral clinoptilolite. This smectite group mineral gets its name from a mining location near Hector, California, and it is one of the two primary swelling smectite clay thickeners, the other being bentonite, Na_0, $3(Mg,Li)_3Si_4O_{10}(OH)_2$. Hectorite differs from bentonite in that it contains lithium in its crystal lattice with absence of aluminum. Of these two similar clays, natural hectorite is a relatively more scarce mineral in nature. When it is mined and purified it is an effective swelling thickener similar to bentonite but is somewhat more efficient. To compensate for its natural lack of abundance, synthetic hectorite was commercially developed. This synthetic hectorite produces relatively clear solutions in water, is a more efficient thickener for suspension than natural purified hectorite, and is also significantly more efficient than bentonite as determined by measuring yield stress values [191–193].

ATTAPULGITE CLAY—STRUCTURING

Attapulgite clay is the most commonly used inorganic thickener in latex paints because it is economical and can also function as an extender pigment [194–196]. Attapulgite is a magnesium aluminum phyllosilicate with formula $(Mg,Al)_2Si_4O_{10}(OH)\cdot4(H_2O)$ which occurs in a type of clay soil common to the Southeastern United States. Attapulgite was named after the town Attapulgus in Georgia where it is very abundant, but the primary mineral in this clay is palygorskite, which was originally discovered in the Ural mountains and is given its name for the mining location there. Attapulgite is not a single mineral, but is actually a composite of smectite and predominately palygorskite. Attapulgite clays found in the Meigs–Quincy district of Georgia are bundles of palygorskite clay particles surrounded by a matrix of smectite clay, which is slightly swellable. Georgian attapulgite clay particles consist of a palygorskite core surrounded by smectite. Unlike pure smectite, the palygorskite component is an acicular bristle-like crystalline form that does not swell or expand. Attapulgite in its natural form consists of lathe-shaped colloidal particles called "spicules," which are typically less than 0.5 μm in diameter. These particles form a crystal chain-like structure in which the spicules attract each other, become entangled, and result in entrapment and suspension of solids. It does this by establishing a lattice structure of particles connected through hydrogen bonds.

In an aqueous environment, attapulgite is nonswelling and essentially inert. Unlike bentonite, which is sensitive to the presence of salts, attapulgite will form gel structures in both fresh water and salt water systems. Taking advantage of this characteristic, attapulgite is widely used in special salt water drilling muds that are used for drilling through brine formations. Coatings containing attapulgite clay thicken not by swelling, but instead by the structured reflocculation of the pigment particles into a colloidal interaction network after shearing. In coating preparation, attapulgite clays can be added as powders or as pregelled dispersions throughout the formulation process. However, they are normally added

in the grind using high-speed mixers for dispersion and hydration. The thickening power of these clays is high, and salts have little or no effect on viscosity. However, like many other ITRMs, the amount of attapulgite clay required for thickening is generally higher than for organic TRMs, and the water demand is high (water is pulled from the aqueous phase to wet the particle surface, thereby increasing effective coating solids). Attapulgite can be used for solvent-borne systems with a cationic surfactant. Some advantages of attapulgite clay are compatibility with a wide range of formulations, use over a broad *p*H range, insensitivity to presence of salt, and resistance to attack by microorganisms.

SEPIOLITE CLAY—STRUCTURING

There are many specialty clays in nature, but only a few have commercial significance for coatings. Sepiolite is a light, porous, high-surface-area clay that was formerly known as Meerschaum (sea froth) [197]. This is an unusual form of non-swelling clay that functions as a thickener in a manner similar to attapulgite. Sepiolite is relatively rare with few commercial deposits, mostly located near Madrid, Spain. This mineral is unique in that it has the highest surface area of all the clay minerals. Chemically, it is a hydrated magnesium silicate with chemical formula $(Si_{12}Mg_8O_{30}(OH_2)_4 \cdot 8H_2O)$ or $Mg_4Si_6O_{15}(OH)_2 \cdot 6(H_2O)$. Unlike smectites, sepiolite is not a layered phyllosilicate but instead is described as a quincunx of five talc sheets separated by parallel open channels within its crystal structure. It has a chain-like structure of needle particles rather than the plate-like particles of many other clays. Although sepiolite is a non-swelling clay, the needle particles have an exceptionally large surface area. This provides a high degree of hydrogen bonding to produce structure in fluids including waterborne and solvent-borne coatings. This structure entraps the mobile phase liquid, thereby increasing viscosity and suspension of the fluid. The structure is stable even in high salt-content fluids.

ORGANOCLAYS—STRUCTURING

Many different grades of organoclays are available for both solvent-borne and aqueous coatings [198–202]. Although these products differ in their chemical modification, the mechanism for thickening and rheology control is substantially the same. Bentonite and hectorite clays are the principal minerals used to prepare organoclays. Because these clays initially are both hydrophilic and oleophobic in their natural form, they must be modified for dispersion in organic solvents. Only after a sophisticated purification process followed by cation exchange with organic ammonium bases is the surface rendered sufficiently organophilic for use in nonaqueous media. As supplied, organoclay thickeners are in the form of agglomerated platelet stacks. Conventional organoclays require wetting and shear for deagglomeration and the addition of a chemical polar activator for full rheological development. The chemical activator serves to disperse the organoclay and also carries water into the hydrophobic organic solvent to insure full hydrogen bonding. Some newer products still require wetting and shear but are functional without the chemical polar activator. Although not essential, elevated temperatures are preferred for efficient processing. High-performance organoclays have recently been developed with greater thixotropy and improved sag resistance. Special grades of organoclays (organophilic clays) have also been designed for aqueous coatings. Some of these depend on shear, wetting, and hydration for full rheological performance, while others are available in readily activated slurry form. The efficiency of these products is generally independent of *p*H.

MIXED MINERAL THIXOTROPES (MMT)

Mixed mineral thixotropes (MMTs) are essentially non-conventional organoclays [203]. The most widely used thixotropes (mainly for solvent-borne systems) are organoclays, fumed silicas, and castor waxes. Although the base materials for MMTs and organoclays are both clays, the particle structure is significantly different than the laminar organoclays that are based on the smectites (bentonite and hectorite). MMTs differ by being made up of many different types of clay minerals that are condensed to give particles with multi-shaped architecture, including platelet-shaped, ribbon-shaped, and pipe-shaped clays. This allows them to be separated more easily than conventional organoclays. Like organoclays, the surface of MMTs is covered with quaternary ammonium compounds to render it hydrophobic. In organic media, the platelets of MMTs interact with each other by hydrogen bonding to form a three-dimensional network producing thixotropy in coatings that is similar to that of fumed silica. Two advantages of MMTs are the possibility to produce pregels at higher concentrations and the reduced shear required for their dispersion.

Synthetic Silicas

Another class of inorganic thickeners are certain types of synthetic amorphous hydrophilic and hydrophobic silicas [204]. Both are widely used in solvent-borne coatings; however, excessive hydration generally limits the utility of the hydrophilic silicas to aqueous media. Two forms of amorphous hydrophilic silica are commercially available and get their names, "precipitated silica" and "fumed silica," from the respective manufacturing processes. A proposed thickening mechanism for these silicas is based on hydrogen bonding between the silica particles and with other coating components to form a three-dimensional structure. High water demand may also contribute to thickening with these products.

PRECIPITATED SILICA

Precipitated silica is obtained in a wet process by the neutralization of sodium silicate solution [205]. This results in a polar, fully hydroxylated surface. Consequently, hydrogen bonding is strong, and excellent thickening comparable to that of fumed silica is obtained especially in nonpolar media. However, because of the competition between hydroxyls on the silica and those in the continuous phase, precipitated silica tends to be less efficient than fumed silica in polar media.

FUMED SILICA

Fumed silica (pyrogenic silica) is amorphous, non-porous, low-density, high surface area silicon dioxide prepared by vapor phase hydrolysis of silicon tetrachloride in a hydrogen-oxygen flame [206,207]. An optional process is the vaporization of quartz sand in an electric arc. Particle size of fumed silica is on the order of 5–50 nm with surface area of 50–600 m^2/g. First discovered in a Degussa laboratory in 1941, this synthetic product gets its name from the smoke-

TABLE 8—Commercial inorganic-based thickeners and rheology modifiers for WB and SB coatings

Company	Trade Name	Thickener Type	Thickener Product Codes
Active Minerals Int.	MIN-U-GEL®	400, 500	Attapulgite clay for waterborne
BASF/Engelhard	ATTAGEL	40, 50	Attapulgite clay for waterborne
Cabot Corp.	CAB-O-SIL	M-5	untreated Fumed Silica

Rockwood/SCP	GELWHITE®	GP, H	High bright Smectite
Rockwood/SCP	LAPONITE®	RD, RDS, S482, SL25, RD	Synthetic Smectite/Hectorite
Rockwood/SCP	MINERAL COLLOID®	BP, MO	Purified montmorillonite
Rockwood/SCP	PERMONT	SX 10A, SC 20	Synthetic Smectite
Wacker	WACKER HDK®	H15, H18, H20, H30	Hydrophobic fumed silica for Polar Systems
Wacker	WACKER HDK®	N20, N20P, T30, T30P, T40	Hydrophylic fumed silica for Non-Polar Systems

like appearance as it forms in the flame. In the fuming process, the particles formed have a partially hydroxylated surface containing hydroxyl, silanol, and siloxane groups. The resulting particle surface is somewhat less polar than that of precipitated silica. Fumed silicas primarily provide thickening through the formation extensive network structures generated by hydrogen bonding via the silanol groups, which can interact with a number of functionalities including hydroxyl, carboxylic acids, carboxylic esters, and other silanol groups. The structuring is accomplished by the creation of relatively large silica particle chains, which associate via interparticle hydrogen bonding. Because fumed silicas have both hydrophilic (hydroxyl and silanol) and hydrophobic (siloxane) functionality, they are effective in producing thickening in both polar and non-polar media. To take full advantage of their thickening potential, the proper incorporation of the silica is very important. Like some clay thickeners, suboptimal dispersion can impact coating gloss. *p*H does have a significant effect on the thickening efficiency of fumed silica in aqueous systems. To be effective, *p*H must be below about *p*H 7.5. Above this *p*H, electrostatic repulsion keeps the particles far enough apart to inhibit hydrogen bonding. Some fumed silicas have very small surface area, which results in very high thickening efficiency even in non-polar media. Some performance properties claimed for fumed silica are improved sag resistance, crack resistance, film hardness, and dirt pick-up resistance. To improve on incorporation into coatings, aqueous fumed silica dispersions have been developed. This liquid form provides advantages in handling, health, ease of dispersion and speed of thickening equilibration. The liquid form also has the potential to reduce VOCs since the dispersions are solvent free and surfactant free.

HYDROPHOBIC SILICA

In less-polar environments, the silica hydroxyls of precipitated silica or the silanol groups of fumed silica are encouraged to interact with each other through hydrogen bonding for development of the thickening network. To make precipitated silica and fumed silica particles more hydrophobic, they are often reacted with organophilic groups on the silica surface to produce hydrophobic silica grades [208,209]. The reactants are typically either organosilane or organosiloxane compounds, which replace many of the surface hydroxyl groups with the organic functionality. Various patented processes are used and the following are representative. Fumed silica can be reacted with chlorosilanes in a fluidized bed reactor to produce hydrophobic fumed silica. Precipitated silica can be hydrophobized with alkylchlorosilanes or trimethylsilanol in precipitated solution to produce hydrophobic precipitated silica. After treatment, these products have few surface silanol groups left for hydrogen bonding, and the amount of carbon incorporated onto the surface is typically on the order of 1–5 %. Hydrophobic silicas are generally superior to hydrophilic silicas in water-reducible systems.

Compiled in Table 8 is a current list of commercial suppliers of inorganic thickeners and rheology modifiers used in waterborne and solvent-borne coatings. Some close-up photomicrographs showing the diversity of particle shapes for four different inorganic thickeners are shown in Fig. 13.

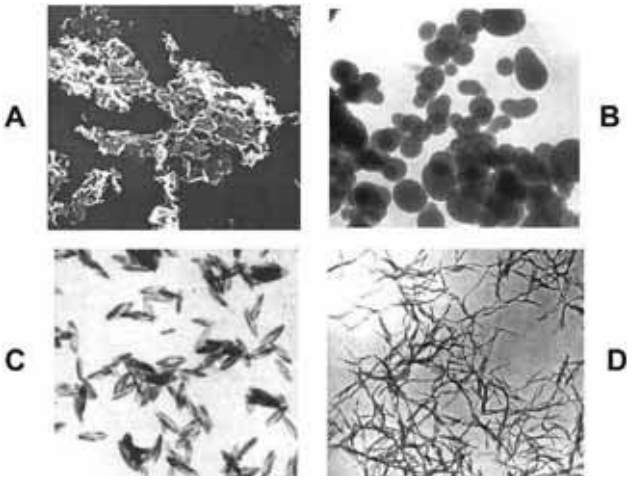

Fig. 13—Photomicrographs of various dispersed thickeners particles: A=clay, B=fumed silica, C=polyolefin, D=polyamide.

Thickener Blends

Often, one or more different thickener types are used in coatings formulation to obtain a desired combination of performance properties. This is usually not an issue when conventional type thickeners are combined with other conventional types. However, care must be taken when combining thickeners with thickening mechanisms that may compete with each other [210–214]. One such combination is a high molecular conventional hydrodynamic thickening polymer with a highly associative polymer which can, on occasion, result in syneresis, loss of hiding, and loss of gloss. However, the thickeners can often be made compatible with the appropriate addition of surfactants and/or optimum dispersant selection.

ORGANIC TRMs FOR SOLVENT-BORNE COATINGS

Besides the inorganic products described above, a variety of organic additives also function as thickeners, rheology modifiers, and mainly thixotropes in solvent-borne systems [215–217]. These products are available in liquid paste and powder form. Many require some dispersion and activation for thickening, and the recommended process temperatures often depend on the strength of the solvent present in the coating formulation. Careful formulation procedures are required to avoid seeding, "false body," or loss in thickening efficiency. Among the many types of organic products available for use as thickeners and flow control agents for solvent-borne systems are castor oil derivatives, polyethylene glycol, polyamides, polymerized oil derivatives, organic esters, complex polyolefins, and aramid pulp fibers, overbased calcium sulfonate. Some of the materials that are very effective are waxes with melting points. Among these are the polyamides and polyethylene glycols. The waxes are favored for their performance in many formulations. Because of the number of products, their diverse nature, and the fact that little information is available on many due to their proprietary status, only a few of the principal TRM types for solvent-borne will be discussed—castor oil derivatives, polyamides, and overbased calcium sulfonate. In Table 9, a list of commercial suppliers of organic thickeners for solvent-borne coatings, the products of each, and the chemical class type is compiled.

CASTOR OIL DERIVATIVES (CASTOR WAXES)—STRUCTURING

One of the main classes of thickeners for solvent-borne systems are castor oil wax derivatives [218,219]. As the name implies, these products are produced by modification of castor oil, including their sulfonation, hydrogenation, and esterification with polyols. These materials provide thickening by structure formation due to hydrogen bonding of the pendent hydroxyl groups in the castor derivatives with each other and also with the hydrophilic entities within the solvent-borne binders. Often heat activation is recommended for effective incorporation.

POLYAMIDES—STRUCTURING

Polyamides are another widely used TRM class for solvent-borne coatings [220,221]. Polyamides are high molecular weight polymeric waxy solids typically produced by the reaction of diamines with dicarboxylic acids. The internal segments of these polymers contain amide functionality while the terminal ends usually do not. These polymers create structure viscosity in coatings by swelling in the coating solvents, which increases the effective volume and provides chain entanglement. The structure formed is weakly associated and thus easily disrupted (shear thins) by mixing and also for high-shear application processes such as spraying and roll coating. Like some of the clays and silicas used as thickeners, polyamides require high shear for incorporation. One issue with polyamides is migration to interfaces in the coating films that can result in a blotchy appearance on the surface or intercoat adhesion at the substrate.

OVERBASED CALCIUM SULFONATE—STRUCTURING

Overbased calcium sulfonate gels are a complex matrix of calcium carbonate in its calcite crystalline form stabilized by sulfonate dispersants [222,223]. The dispersants typically used are alkyl benzene sulfonates. In the overbasing process, calcium hydroxide is formed *in situ* to provide colloidal stability. In the preparation of this thickening component, the calcium carbonate undergoes a change to its calcite crystalline form, and the alkali-metal portion of the sulfonate dispersant adsorbs onto the hydrophilic carbonate particles with the hydrophobes extending into the continuous solution phase. The carbonate crystals interact with the polar heads of the dispersant, producing ionic crystal flocs to provide structure and colloidal stability. Additional structure is generated through Van der Waals interactions of dispersant hydrophobe tails with the nonpolar phase components in the coating. Good suspension and anti-sag properties are conferred to the coatings, and since they are supplied in pre-gel form, they do not reduce coating gloss. The structure is easily broken down with shear and reforms rapidly after shear is removed. These thickeners do not require heat for activation and are typically incorporated at the pigment dispersion stage.

MODIFIED POLYUREA—STRUCTURING

Modified ureas function by their selective insolubility, which results in a controlled separation of fine needle-like particles [224,225]. The mechanism of thickening is by strong cohesive hydrogen bonding interactions of these particles to form a three-dimensional network and by association with binder molecules producing gel structure and rheology modification. Solvent-borne coatings with

TABLE 9—Other commercial thickeners for solvent-borne coatings: producers, product trade names, product codes, and thickener type

Company	Trade Name	Thickener Type
OMG Borchers	Borchi® Gel	Aluminum Soaps
BYK-Chemi	BYK®	Polyamide, Modified Urea
Chattem (Elcat)	Cyco-Gel®	Aluminum Compounds & Soaps
Chattem (Elcat)	Gel-Wei®	Aluminum Compounds & Soaps
Chattem (Elcat)	ViscoMaster®	Aluminum Compounds & Soaps
Cognis	Dehysol®	Polyamide
Cognis	Rilanit®	Polyamide, Hydrogenated Castor, Mod HCO
Cray Valley	Antisettle	Castor Waxes
Cray Valley	Flowtone®	Castor Waxes/Inorg. Mod. Castor Wax
Cray Valley	Crayvallac®	Oxidized Polyethylene
Cray Valley	Crayvallac®	Pure Amide/Polyamide Blends/Amide Castor Waxes
Cray Valley	Crayvallac®	Modified Urea
Evonik/Degussa	Aerosil®	Hydrophilic & Hydrophobic Fumed Silica
Elementis	M-P-A®	Oxidized Polyolefin
Elementis	Post 4®	Sulfonated Castor Oil
Elementis	Suspend-Ayd®	Not Specified
Elementis	Thixatrol®	Polyamide
Elementis	Thixin®	Hydrogenated Castor Oil
Elementis	Nuvis®	Surfactant, Polyamide
Ferro	Synpro®	Aluminum Stearate
King Industries	Disparlon®	Polyamide, Oxidized Polyethylene
King Industries	Kstay®	Overbased Sulfonate
Lubrizol	Ircothix®	Overbased Calcium Sulfonate
Lubrizol	Ircogel®	Overbased Calcium Sulfonate
Lubrizol	SOLTHIX®	Undefined RM for Solvent-Borne
Lubrizol	SOLPLUS	Undefined Two-Pack RM for Solvent-Borne
Poly-Resyn	Suspeno®	Oxidized Polyolefin
Poly-Resyn	Polythix®	Hydrogenated Castor Oil
Poly Resyn	Polytrol®	Hydrogenated Castor/Amide Co-melt
Rockwood	Rheocin®	Hydrogenated Castor Oil
Rockwood	Advitrol®	Hydrogenated Castor/Amide Co-melt
Rockwood	Rheotix®	Hydrogenated Castor Oil Based
Rockwood	Adjust®	Sulfonated Castor Oil
Rockwood	Y-Type	Oxidized Polyolefin
Troy Corporation	Troythix®	Polyamide, Polyester, Hydrogenated Castor Oil

1) Chattem Chemicals is an ELCAT Company.
2) Cognis was formerly Henkel.
3) Elements acquired Rheox & Servo Deldin.
4) Lubrizol acquired Avecia Additives.
5) Rockwood acquired Southern Clay Products and Sud Chemie.
6) Borchers was acquired from Bayer by OMG.
7) Lubrizol acquired Langer & Co.

these thickeners form very shear thinning flow and thixotropy The effective typical concentration is about 0.5 % using high-speed dispersion for incorporation. However, the modified ureas are not recommended for dispersion in the grind as it breaks down the polymer, resulting in lower efficiency.

Part 8: Physical Characteristics of Liquid Paints and Coatings

34

Density and Specific Gravity

Raymond D. Brockhaus[1] and Ben J. Carlozzo[2]

INTRODUCTION

Why Concern Ourselves with Density? The World of the Producer and the Customer

MATERIALS ARE EXCHANGED FOR AN AGREED upon value based upon a "cost per unit material." The "unit of material" is in terms of what the user wants to do with the material expressed in physically measurable units such as volume or weight. The customer does not want to be shorted, and the provider does not want to give away material. Accurate measurements are expected to keep both parties happy. When a customer wants a gallon of paint, the manufacturer blends the component materials together by weight and fills out by weight. Balances are easy devices to place and use with filling lines. Delivery of constant volumes, on the other hand, is not an easy task, as will be explained later. Measurement of the weight of a known volume of the paint generates a relationship defined as density. With this relationship, the producer can fill by weight and then sell to the customer on a by-volume basis. The customer wants volume; the producer wants to work in weights. The relationship—density—enables the transformation to make life easier for both groups.

MEASURE OF QUALITY

In the open marketplace, the business person and the customer have this rule of thumb—let the buyer beware. Testing for quality of the shipment is best done on-the-spot, quickly, and in a way that is highly reliable. If you are in charge of the wine and ale stocks of a restaurant, one method of determining the quality of the goods obtained would be verification of the density with flotation probes called hydrometers. Similarly, the purchasers of metals such as gold, lead, silver, and copper could use various methods of determining density to keep from being cheated and assuring quality.

In our more modern world, with instruments capable of assaying individual chemical compounds in complex mixtures, verification of density has become a manufacturing tool for in-process control. Density measurement becomes an indirect assurance that the ingredient(s) of interest exists in the material of exchange at the proper concentration. For paint, ingredients such as solvents, polymers for binders, and pigments have a different range of density typical of that material. Partial omission of a major component, for example, a solvent, can make the paint density change from the formula loading target. Quick approximate determinations of density can be done with an inexpensive piece of equipment that acts as a screening tool, catching special-case errors like wrong material shipped. Common errors of minor contamination are usually not caught this way.

While the use of density measurements as the sole or major measure of quality is declining in favor of testing designed to provide ingredient concentrations and chemical functionality, it still remains as a typical, routinely performed quality control test method and is almost always found in tests run to certify contents (Certificates of Analysis). There is often a balance between spending time, money, and manpower on testing and risking the liability of inadequate product performance.

REGULATORY CONCERNS

In addition to customers and producers, government can express concerns in the exchange of materials. Government's concern is for regulation. Paints or other similar heterogeneous materials are mixtures in which only the nonvolatile portion of the bulk material being exchanged is of true value to the customer. The "carrier" portion of the bulk material must be accounted for because it is a discarded material and thus a "pollutant." The carrier portion, solvents, and viscosity reducers are used to aid in transporting the solids to the work surface to form a thin film. These can pose disposal problems and have a significant impact on landfills, air, and water quality, which are all regulated by federal, state, and local governments. Paint volume solids and critical pigment volumes are two significant concepts which require the use of raw material and finished product densities for their determinations and must be understood and accounted for when dealing with modern government regulations [1].

Definitions: Density—Static and Dynamic Mathematical Models

STATIC MODEL

ASTM D16 Standard Terminology for Paint, Related Coatings, Materials, and Applications defines density as the mass per unit volume of a substrate at a specified temperature and pressure, usually expressed in g/ml, kg/L, g/cm^3, g/L, kg/m^3, or lb/gal [2]. In other texts, "in vacuo" is specified because measurement of weights in gaseous or liquid environments may require a buoyancy correction. If the volume of the mass being weighed is large, a correction must be made for displacement of the environmental media (air or a liquid).

For some samples, however, vacuum conditions will cause vaporization of the sample. Therefore, "in vacuo"

[1] *E. I. Du Pont, Automotive Products, Mt. Clemens, MI 48043.*
[2] *DCA Coatings, Cleveland, OH 44139.*

Copyright © 2012 by ASTM International

is usually a theoretical condition rather than a normally experienced one and deals with the surrounding environment. The balance used to weigh the sample must also be in vacuo.

The Greek letter ρ (rho) is used to denote density.

$$\rho = (m/V) \tag{1}$$

where m is mass, and V is volume expressed in units consistent with the mass units.

$$\rho = (W/V) \tag{2}$$

where W is weight (a function of mass), and V is volume expressed in units consistent with the mass units.

DYNAMIC MODEL

Density is a mathematical value describing a balance of physical forces acting on a material called mass occupying a known volume of space under known temperature conditions. This equation is identical to that given in the static model. Density is expressed as a single value, but is really an average value of forces dynamically fluctuating, both internal to the material and external as the surrounding environment.

The first model (static) is the traditional model. It has changed only slightly over the ages, being upgraded with the terms "mass" in place of weight and "in vacuo" after vacuum bell jars were developed. The second model (dynamic) is a more fundamental model, dealing with materials on a molecular level, where the concepts of chemical functionality, kinetic and potential energy, and interfacial boundaries come into play. With the second model, we can understand and deal with mixtures of chemicals and mathematically deal with how a single component's densities interact when mixed. For most practical determinations the static model will suffice. However, in some cases, the need for truly accurate determinations of density in situations where molecular interactions of chemical ingredients can create errors, the dynamic model is a must.

The attractive forces exerted on a primary mass or collection of particles by a second mass much larger than the first mass is called weight. This is an attractive action, resulting in compression and increasing the density of the primary mass. The dispersing forces are caused by thermal energy absorption, resulting in particles of increasing motion or kinetic energy. This manifests itself as temperature of the material.

The volume of space occupied by a mass of particles that exists at an average kinetic energy level expressed as the temperature of the physical material is defined as the volume. This total quantity includes the voids of space between the particles on a molecular level.

The average kinetic energy level of the material is expressed in the motion of the particles of the material. That is, the material is made up of many small particles that are independent in their motion. These motions are random, such that the overall motion in the X, Y, and Z directions cancel each other and the net motion of the total mass is zero. As the kinetic energy level, expressed as temperature, increases, the distances between particles increase and the material is identified as expanding.

TABLE 1—Density of water (g/cm³) at various temperatures (°C) [15]

Temperature, °C	Density, g/cm³
15	0.999 127
16	0.998 971
17	0.998 772
18	0.998 623
19	0.998 433
20	0.998 231
21	0.998 020
22	0.997 798
23	0.997 566
24	0.997 324
25	0.997 072
26	0.996 811
27	0.996 540
28	0.996 260
29	0.995 972
30	0.995 684

Special cases used as standard measurement reference points:

- One cubic centimeter (cm^3) of pure water (H_2O) at 4.0°C is defined to weigh 1.0000 g.
- $Density_{water}$ = 1.000 g/1.000 cm^3
- 1.000 mole of a gaseous compound occupies 22.4 L of volume at 0°C (273 °K) at 1.000 atmosphere pressure (a molar volume).

For air, whose composition is 22 % by weight oxygen and 78 % by weight nitrogen (ignoring other gases), 1 mole weight = (32 g × 0.22) + (28 g × 0.78) = 28.88 g. Density = 28.88 g/22 400 cm^3 = 0.001 29 g/(cm^3) or 1.29 g/L [3].

Relative density, also referred to as specific gravity, is the ratio of a density determined for Material A at Temperature T_1 divided by the density of a reference material at some temperature, T_2. For solids and liquids, and of particular concern to us, for paints and coatings, the reference material is pure water. For gases, the reference material is air.

$$\text{Density}_{\text{Relative } A} = \frac{\text{Measured Density } A \text{ at } T_1}{\text{Measured Density at 0°C}} \tag{3}$$

If a Liquid A has the same density as water at T_1 when determined by a buoyancy device, then the density can be determined from a table of known density values established for pure water over a range of temperatures.

When T_2 equals 4.0°C, the relative density for pure water equals the measured density. As temperature increases, water expands. For a constant volume, the mass of water must be decreased to fit into a given volume. Thus, water's density value, Table 1, must decrease with increasing temperature. Relative density is a ratio of two values carrying the same units. Therefore, relative density is a dimensionless number.

Specific gravity is an old term but still widely used today, particularly when the density determination is of a liquid such as paint; the term *relative density* is identical and may be less misleading [4].

Apparent density—This term refers to a density value widely used for powders and macroscopic particulate solids, which are compacted by vibration, such as pigments and extenders. Air is still present in the voids between the particles and in pockets or voids at the irregular surface of the macroscopic particles. This means the volume is greater than just for the solids, and the density is smaller in value than if the material was a liquid or compacted such that no voids existed. Pigments used in paint are mechanically worked with solvents and resins to fill in these voids. The true density of the pigment, which is needed in paint calculations, is that obtained without any of the air (void) contribution.

Fundamental Concepts—Material, Objects, Volumes, Masses, and Weights—What Really is Density?

Density is more than just the mathematical numerical value identified above. It also incorporates units of measure which are, in turn, based upon more general and fundamental concepts. These units of measure assume a set of definitions that will be explored in very general terms. These units are crucial to understanding the dynamic model of density and in allowing microscopic concepts to be explored.

Material—Anything (a physical entity) that exists for a period of time, occupies space, and has mass. Mass is a stable configuration of atoms individually loosely organized as elemental atoms or joined together chemically to form molecules.

Object—A collection of materials, homogeneous or heterogeneous, localized to a portion of volume (space). The material can be in any one of three states: solid, liquid, or gaseous. The shape of the volume of space occupied by the object plays a role in dealing with density but does not define the object itself.

Volume is based upon measurement of distance in three directions at right angles to each other as in Fig. 1. The physical universe in which we live is often described in three dimensions in terms of distance, which is a scalar property. When dealing with three dimensions, the term distance is described as length, width, and depth.

An object having all three is described as having volume. The mathematical value for volume is the product of multiplication of the three scalar values. Volume can exist without objects occupying that space. This condition is called a vacuum. Vacuum's volume and object's volume can both be of very irregular and non-matching shapes, yet they can equal in the scalar value of the volumes. Examples are shown in Fig. 2.

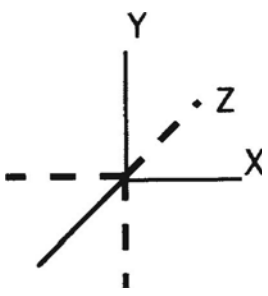

Fig. 1—Coordinated in three dimensions.

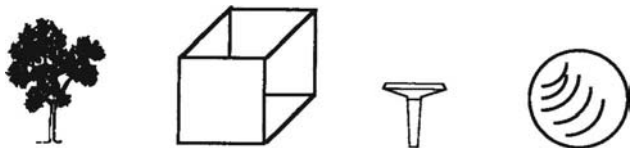

Fig. 2—Examples of physical objects.

PROBLEMS WITH VOLUME MEASUREMENTS

Customers often make use of material based on volume as applied and want to purchase these products in containers recognized to hold standard volumes. Materials have the property of responding to temperature changes with expansion or contraction of their volume. Products that experience wide temperature ranges during filling, shipping, storage, or in use must also have extra unfilled volume to accommodate expansion or the material forces leak and material is lost. This problem is most severe with liquid materials. Material suppliers use containers with larger than exact volume required to allow for expansion. These vessels must be marked in some way to indicate the volume increments if they are to be used for filling by volume. Producers seldom can or want to control temperature during packaging. Temperature control devices will add expense without making a difference in the material's performance. Without temperature control, filling at a constant volume will produce units of varying amounts of material. Use of density overcomes these problems and permits correct volumes to be filled out.

Weight and Mass

A fundamental attribute of a physical entity is mass. This is one of the indefinable mechanics [4]. Two physical objects exhibit an attraction for each other in proportion to the quantity of mass in each object. The greater the mass, the greater the attractive force. When the ratio of two masses is grossly unequal, such as the planet Earth and an object on

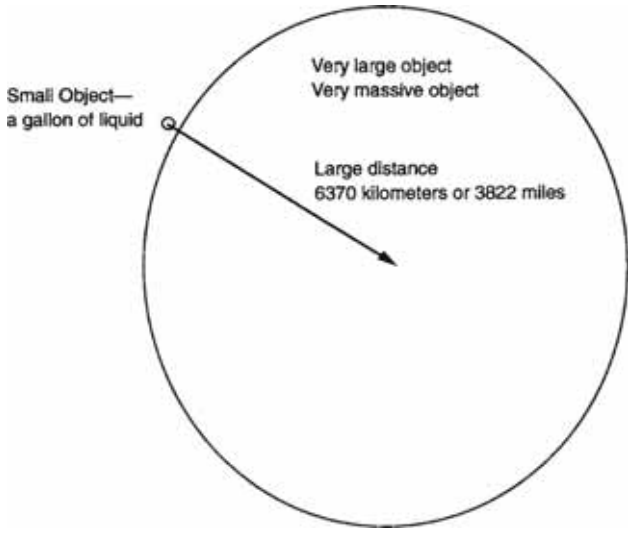

Fig. 3—Moderate distance to large body center.

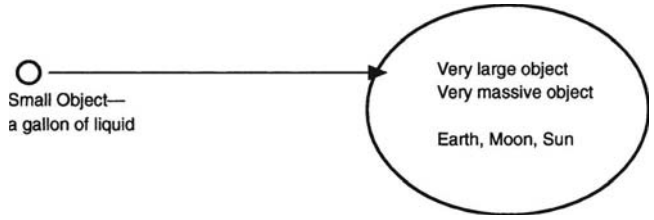

Fig. 4—Vast distance to large body center.

its surface, the larger mass is assumed to be constant and the second object is described to have a "weight" relative to this larger object. The mass of the planet is effectively unchanging and thus constant. Our moon is also a very large object, but smaller than Earth, thus its attraction to a second object would be weaker than for Earth. Mass is the unchanging, fundamental property.

But we are human, and we deal in the measurement of weight, which is a force. While weight is a vector quantity having both scale and direction, the direction portion is taken for granted and weight is usually treated as only a scalar value. Fig. 3 and 4 graphically depict this issue.

Weight, *w,* is defined as a force of gravity, F_g, [4].

$$w = F_g = G\frac{mm_E}{R^2} = mg \tag{4}$$

where:

G = a gravitational constant for Earth
= 6.670×10^{-11} N·m²/kg·m²,
m_E = mass of the Earth = 5.98×10^{27} g,
R = the radius of the Earth = 6370 km,
m = mass of a second body (Newton's law) [5],
g_E = 9.80 m/s² or 32.0 ft/s²,
g_{Moon} = 5.333 ft/s² or 1 /6 that for Earth,
$g_{Distance\ from\ Earth}$ = 1.0×10^6 km= $g_E/[(1.0064 \times 10^6\ km)^2/(6370\ km)^2] = 0.004g_E$

These values are given as constants in physics calculations but actually represent average values. In the real world, the value of *g* varies from location to location for a variety of reasons. Table 2 shows that variation present in the value of *g*, the acceleration due to gravity, is greatly influenced by the distance that point on the earth is to the center of gravity of the earth. Mountains many miles above sea level and deserts below sea level have an effect, not to mention the varying densities of the composite materials which make up earth itself [5].

Example 1: A gallon of paint produced in Galveston, Texas, has a weight of 10.000 lb/gal. The product then finds its way to Eagle City, Alaska. Here it has a gallon weight of 10.03 lb/gal. The difference is minor but real.

If the paint specification is a density in the range of 9.90 to 10.10 lb/gal, the +0.03 lb leaves only 0.07 lb for testing errors before the material is identified as out of specification. As environmental regulations on the volatile organic content (VOC) increase in importance, these minor differences will play a larger role and should not be overlooked for their contributions to relationships such as density.

The pull of gravity is not as strong at a mountaintop as it is on the plain. The reason is because the mountaintop is at a greater distance from the center of gravity than the plain. A plumb line might not point exactly to the Earth's center of gravity, however, if it is attracted to a large deposit of denser material beneath the earth's crust that is not in line with the Earth's center of gravity [5].

TABLE 2—Values of *g*, the acceleration due to gravity [5]

Place	Value[a]	Place	Value[a]
Cambridge, Massachusetts	980.398	Denver, Colorado	979.609
Eagle City, Alaska	982.183	Galveston, Texas	979.272
Greenwich, England	981.188	Honolulu, Hawaii	978.946
Madras, India	978.281	New Orleans, Louisiana	979.324
Punta Delgada, Azores	980.143	Reykjavik, Iceland	982.273

[a] Centimeters per second per second. Use of centimeters emphasizes the differences that are occurring in the second through sixth numerical place.

Example 2: The weight of a gallon of paint in New York City is recorded at 9.5 lb. The distance from the center of the Earth is 6370 km at this location. At a distance of one million kilometers from the earth, the same gallon of paint would weigh 0.003 78 lb.

Has the amount of mass changed? No. Has the weight changed? Yes, because of distance. Has the volume of the material changed? Possibly. If the gallon container is surrounded by air at 1 atm, the container shape is retained and the material in it will not overflow. But, in the new location, the fluid does not want to remain together. It forms droplets and wants to float off in all directions. It has lost the cohesiveness provided by gravity. Has the density of the material changed? By definition, yes, drastically! By fact, little. The same physics rules apply in both locations, but the environment has changed and with it our appreciation for the term mass.

Example 3: A 1.00 m³ Styrofoam cube of material is created on Earth in our atmosphere (air) at 20°C and 1.0 atm. This is a heterogeneous material because it has trapped air in the foam. Let us say it weighs 900 g on a balance on an open desktop.

$$Density_{earth} = 900\ g \div 1.00\ m^3 = 900\ g/m^3$$

Next, this cube is taken to the moon (gravitational factor = 1/6 Earth) and kept inside a building with 1.0 atm at 20°C:

$$Density_{moon} = (900 \times 1/6 \div 1.00\ m^3 = 500\ g \div 1.00\ m^3 = 500\ g/m^3$$

Next, the cube is taken out onto the moon's open surface, where there is no atmosphere (vacuum conditions). Now, two things happen to this cube.

1. There is no air to displace when weighing the cube. It can thus exhibit a heavier weight since there is no buoyancy correction: 1 m³ of air weighs 1.29 g on Earth and 0.215 g on the Moon. So the weight would be 150.215 g.

2. The material can also lose the air entrapped in the foam. This may be a slow process, but it can happen. Now the cube will appear to lose weight. Let us say it loses 0.050 g by moon weight and now weighs 150.215–0.050 g.

$$\text{Density}_{\text{vacuo,moon}} = 150.165 \text{ g} \div 1.00 \text{ m}^3 = 150.165 \text{ g/m}^3$$

Return the cube back into the building on the moon with 1.0 atm and the weight might now be 149.95 g if the foam structure is strong enough to retain the cubic shape without crushing from the external pressure. Its density is now 149.95 g/m^3.

Density is a very simple, straightforward concept and relationship. Still, as noted before, physical reality can and does impact on it, adding subtle perturbations that should be understood. What appears to be homogeneous may not be. Physical reality is a source of variability, and affects must be taken into consideration when arriving at results we will share with one another.

Solids, Liquids, and Gases—As Concepts, Under Ideal Conditions

Materials exist in one of three states: solids, liquids, or gases. For an equal amount of weight, solids usually occupy less volume than liquids, which occupy much less volume than a gas. Solids also retain a shape and flow or distort very slowly. Liquids take on the form of a containing vessel. Gases have no shape and are bounded and shaped by their container. Techniques exist to determine densities for all three states.

Solids—Fig. 5 is a depiction of a solid in which the particles are atomic or molecular in scale. The distance between particles is a regular, repeatable distance. Most kinetic energy is gone. Only external pressure can shorten the distance between particles. This shortening is called compression and affects the ratio of weight present and the actual volume occupied by that mass of material. If the solid remains compressed after the external pressure is released, the material is called inelastic. If it returns to the original volume, it is elastic. Density of solids can depend on the processing history.

Liquids—In a liquid as depicted in Fig. 6, the particles are molecular or atomic in scale. Distances between particles are not constant. Kinetic energy is greater than in solids. External pressure can shorten the distance between particles. Each material has a characteristic compressibility factor. All liquids behave elastically, flowing back and filling in. The population of particles has a distribution of kinetic energy values, with some being greater than the surface energy. The portion of the population that has a kinetic energy greater than the surface energy escapes, and is called vapor.

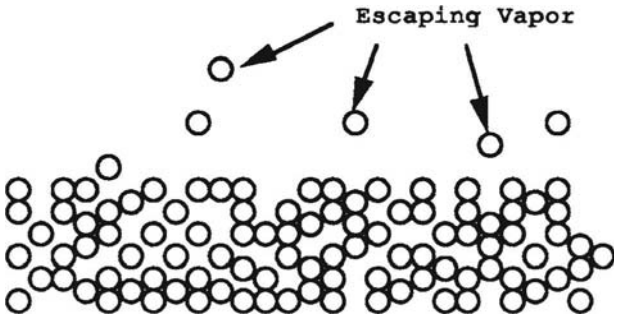

Fig. 6—Simple model of particles of matter in liquid state.

For ideal conditions and "conceptual" materials, no interactions occur between the materials, the testing containers, and the surrounding environment. The material investigated is well behaved. When such materials are mixed together, the weight of each material times the individual material's density will add together as a linear sum. For a majority of coatings this is a good approximation and allows formulating programs to give useful density values for the finished products. These include older solvent-borne technologies, as well as waterborne latex formulations. Exceptions to this rule are two component systems where the separate ingredients begin to react with each other forming various intermediates. Some of these will eventually be lost as VOCs. Densities measured of the different parts can be useful for filling operations, but determining the density of the mixed materials may not give reliable numbers. Other exceptions involve highly ionic mixtures in waterborne formulations. (Salts of amines, and acids designed to improve water solubility as well as anionic and cationic surfactants, are usually nonlinear additions, although the small amounts used of the later can still allow for close approximations to actual density.)

Gases—In a gas, as depicted in Fig. 7, the particles are molecular or atomic in scale but more widely separated. Distance between particles is irregular. Kinetic energy is even higher than in liquids. External pressure can shorten the distance between particles. Each material has a characteristic compressibility factor.

Weighing solid or liquid material in a container or as a solid object is an easy task. Instruments for this task keep improving in accuracy, precision, ease of use, and lower cost. For gas-phase material, vessels of accurately determined volume can be purchased and used. Materials of

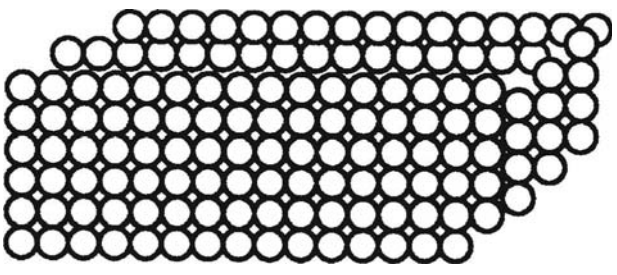

Fig. 5—Simple model of particles of matter in solid state.

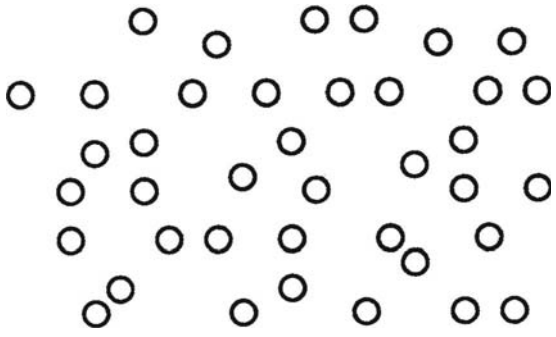

Fig. 7—Simple model of particles of matter in gas state.

construction for durability and reuse are of concern. If the temperature of testing is controlled within the tolerance of the calibration of these vessels, expansion is not a concern. Since gases are seldom incorporated into a paint system (on purpose, although entrapped air manifested as foam can throw off measurements and in most cases is removed before the material is deemed finished), this topic will be skipped.

Further Discussion of Liquids and Solids

For liquids, containers can be constructed to hold a known volume. These vessels can be mass produced with adequate accuracy to allow large numbers of users to have access. These are called liquid pycnometers. Some are also called Weight per Gallon Cups. Within the temperature range of 1°C and 99°C, the density of water can be determined. More detail will be given in the section entitled "Liquids." Devices that can float in water can be calibrated to show a scale calibrated directly in density. When these floats are used along with a scale for weighing, the volume of material can be determined [6,7].

Fig. 8 contains drawings of several pycnometers as seen in a commercial scientific supplies catalog. The catalog text descriptions for two pycnometers have been included to inform you as to sizes, capacities, materials of construction, etc. The features discussed identify attributes of importance to the end user.

Liquids have other properties that can be used to test for density. One of these is sound transmission. Replacement of air with a liquid in a container will cause that container to shift a tone impulse to higher frequencies. The extent of the shift is related to the liquid's density and can provide a direct measurement with different degrees of accuracy depending on the sophistication of the instrument.

For solids, the task is more complex. Two paths are available. Either shape the solid into a known geometric figure and calculate the volume or use the solid to displace a material, such as a liquid or a gas, which has a known density. The solid can be shaped by mechanical, thermal, or chemical means. Mechanical means can be employed to cut, carve, and shape, then weigh. Thermal shaping is changing the solid into a liquid using heat to melt the solid, pouring the liquid into a mold, cooling to form a solid, and then weighing. Chemical shaping is dissolving the solid in a "carrier" liquid (solvent), pouring the solution into an open mold, and evaporating the solvent, leaving behind a solid properly shaped to accommodate testing. The drawbacks of this technique are:

- Complete solvent removal is often difficult.
- Chemical reshaping of solids can cause problems if the original solid had small air pockets or if the solvent used is trapped in these voids, thus actually changing the solid and affecting its apparent density. Solids which demonstrate the latter behavior have a bulk density different than their skeletal density.

The principle of buoyancy, discovered in the third century by Archimedes, provides a means to determine volume [5]. Determination of volume by displacement requires acquiring a weight in air and a weight in a liquid of known density at the testing temperature. Complete submersion of the solid object or a representative portion of the material in a liquid of known density is required while determining the material's apparent weight. The weight difference is equal to the weight of the volume of liquid displaced. Knowing the liquid's density and the weight difference, the volume for the tested portion can be calculated. The practical application of Archimedes' Principle is used in the following discussions to describe the determination of specific gravity of pigments and other solid ingredients in paint.

Solids, Liquids, and Gases as Concrete Materials in a Physical World—A Practical Guide to Density

A vast variety of materials exist, and interactions are possible between any of the different types of materials. When an attribute, like density, can be directly measured, it is possible to identify two types of these interactions.

The first is ideal behavior with respect to the attribute under investigation and the amount of mass used. These interactions are well behaved and produce predictable attribute changes. The second type is non-ideal and means that other interactions are taking place than just that of mass-to-mass attraction. Materials are ideal if when mixed together the sum of the weight fraction of each material multiplied by the material's density equals the density determined for the entire mixture. Materials are non-ideal if when mixed together the sum of the weight fraction of each material multiplied by the material's density does not equal the density determined for the entire mixture.

Some solids can exist with varying degrees of crystalline domains incorporated into their solid form. As temperatures cycle up and down in the surrounding environment of

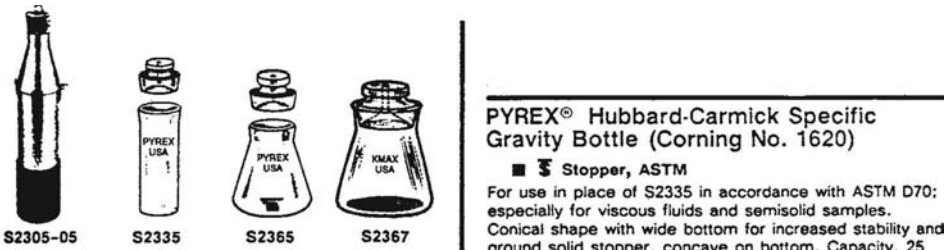

Fig. 8—Specific gravity testing pycnometers. (Courtesy of Sargent-Welch.)

these solids, the solids will change density as these domains increase or decrease and they move toward a thermodynamically stable form of the solid.

Finally, as we alluded to earlier, materials can chemically interact when mixed, producing or absorbing heat and generating an entirely new material with its own unique attributes. These actions are not bad or good, but they basically exist and must sometimes be taken into consideration when dealing with mixtures such as liquid paints and solid coatings.

When a material (A) is homogeneous, the density is a fixed value for a fixed temperature. When a material (B) is heterogeneous, the density is also a fixed value for a fixed temperature. When two different materials, homogeneous or heterogeneous, are mixed together, they become a new, heterogeneous material, and the resultant density is a new fixed value for a fixed temperature. Depending on whether the interactions are ideal or non-ideal, the density can be predicted by calculation or a deviation in the density will result. Paints are formulated as ideal mixtures, but they don't always follow this assumption. The relationships between these values are given below [8].

$$\text{A + A has A's density which is } \frac{W_{A\rho A} + W_{A\rho A}}{W_A + W_A} \tag{5}$$

$$\text{B + B has B's density which is } \frac{W_{B\rho B} + W_{B\rho B}}{W_B + W_B} \tag{6}$$

A + B has a new density which may be =, >, or < that of A or B and is:

$$\frac{W_{A\rho A} + W_{B\rho B}}{W_A + W_B} \tag{7}$$

where:

W = weight of component,
ρ = density of the component.

Many important materials are available as complex mixtures in today's world. These mixtures can be heterogeneous in terms of phase. Gasoline for the car and lawn mower can contain butane dissolved into the heavier hydrocarbons. Paints, inks, and cements contain liquids and solids, with the liquid phase either neutral or reactive. If the liquid's role is neutral, it can be a solvent or carrier or plasticizer. If the liquid's role is reactive, it is called a binder, reactive diluent, or catalyst.

Modern paints contain chemically reactive, low-molecular-weight polymers that, when heated, produce a crossed-linked solid and usually volatile by-products. When chemical changes occur, the linear density addition model is correct only by chance. Usually the volume is reduced from chemical bonds forming, and as a result, the density goes up.

Theoretical volume solids have been calculated for years in the coating industry using the linear model. This model has worked well for lacquers, varnishes, and other systems where chemical reactions took place at low levels and were of the oxygen uptake type, making the final film heavier from oxygen addition. Modern paints react internally, generate by-products of low molecular weight, and actually lose weight during cross-linking and film formation. But, because there has been no good way to determine the volume of paint films that is repeatable and reproducible, the practice of calculating volume solids is still used in 2010. (Repeatable means in the same lab, with the same instrument, time after time, and reproducible means between different sites or labs using similar but physically different instruments like balances, ovens, etc.)

Definitions Related to Density and Specific Gravity

BULK DENSITY

$$= \frac{\text{Total weight of object including air or water}}{\text{Total volume occupied including air or water}} \tag{8}$$

SKELETAL DENSITY

$$= \frac{\text{Total weight of object less air or water}}{\text{Total volume of actual material less air or water}} \tag{9}$$

Surface interactions—These interactions involve wetting of solid surfaces by liquids during liquid displacement testing. In determining the volume of a material due to displacement of a liquid, the liquid must come in close contact with the material surface. When the liquid meets or wets the surface without penetration into the bulk of the material, the volume of liquid displaced is equal to the bulk volume of the material being tested. When the liquid does not contact and wet the surface, a thin layer of air exists between solid and liquid. This also displaces liquid, making the apparent volume of the material larger. In tests like ASTM D2965, where the volume of paint film being tested is very low, this error can be significant. Materials called surfactants can be added to increase wetting, but they affect the density of the liquid. Where surfactants cannot be used, another liquid must be used.

Permeation—When the liquid meets or wets the surface with total penetration into the bulk of the material, the volume of liquid displaced is equal to the skeletal volume of the material being tested. If there are molecules with low molecular weight left inside the bulk of the solid, these can migrate out, leaving the testing liquid in its place. These will change the bulk testing liquid's density as they accumulate.

MEASUREMENT SYSTEM UNITS, CONVERSIONS, DENSITY, AND RELATIVE DENSITY

Today's world uses three systems of measurement [4]:

1. International System of Units (SI), previously referred to as the metric system, based upon powers often. This was called the MKS system, standing for meters (distance), kilograms (force), and seconds (time). A common form of this system uses millimeters, grams, and seconds as the units. By universally accepted definition, 1.0000 g of distilled water occupies 1.0000 cm^3 (or 1.0000 ml) at 4.00°C.
2. The British system uses the British yard (distance), pound (force), and second (time).
3. The United States (U.S.) system uses the U.S. yard (distance), pound (force), and second (time).

The British and U.S. systems use the same basic linear distance and force units, but, when measuring volumes, the systems do not have equivalency. A British gallon of water

Precision Hydrometers for Light and Heavy Liquids—175 mm

A series of short range hydrometers with an accuracy of 0.001, calibrated 60° /60°F. Design corresponds with ASTM specification E100 for plain hydrometers. With smooth, easily cleaned shapes, solid metal ballist, and cemented paper scales. Subdivisions, 0.001.

Cat. No.	Range		
S41885-F	1.000	to	1.070
S41885-G	1.060	to	1.130
S41885-H	1.120	to	1.190
S41885-I	1.180	to	1.250
S41885-K	1.240	to	1.310
S41885-L	1.300	to	1.370
S41885-M	1.360	to	1.430

Fig. 9—Hydrometers—specific gravity scale—plain design [6].

(volume) weighs 9.993 lb at 77°F (25°C), while a U.S. gallon of water weighs 8.321 lb at 77°F (25°C) [7]. Conversion between the three systems can be accomplished using the following relationships:

$$2.54 \text{ cm} = 1.00 \text{ in.}$$
$$231 \text{ in.}^3 = 1.00 \text{ U.S gallon}$$
$$453.6 \text{ g} = 1.00 \text{ lb}$$

or

$$277.4 \text{ in.}^3 = 1.00 \text{ British (Imperial) gallon}$$

From SI to U.S.:

$$(2.54 \text{ cm/in.})^3 \times (231 \text{ in.}^3/\text{U.S. gal})/453.6 \text{ g/lb} = 8.345 \text{ cm}^3\text{lb/U.S. gal. g} \quad (10)$$

$$(2.54 \text{ cm/in.})^3 \times (277.4 \text{ in.}^3/\text{British gal})/453.6 \text{ g/lb} = 10.02 \text{ cm}^3 \cdot \text{lb/British gal} \cdot \text{g} \quad (11)$$

These are conversion factors, which carry particular units. They are used to convert density values for a material at any temperature into a second set of units at that same temperature. The 8.345 factor for converting to U.S. lb/gal is sometimes confused with the 8.321 value for a U.S. gallon of water at 25°C (77°F) [9].

Density (in the SI system) at any temperature = density (in the U.S. system) × 8.345 at the same temperature.

Example for pure water at 4°C (39.2°F):

$$\frac{1.000 \text{ g}}{1.000 \text{ cm}^3}(\text{SI}) = 1.000 \times 8.345(\text{conversion}) = 8.345 \frac{\text{lb}}{\text{U.S. gallon}} \text{ at } 4°\text{C} \quad (12)$$

For pure water at 25°C (77°F):

$$\frac{0.997\,04 \text{ g}}{1.000 \text{ cm}^3}(\text{SI}) = 0.997\,04 \times 8.345(\text{conversion}) = 8.321 \frac{\text{lb}}{\text{U.S. gallon}} \text{ at } 25°\text{C} \quad (13)$$

Note in these examples that the volume of space (container internal volume) has not changed with temperature. But, the amount of material which can fit into that volume has changed with temperature! Using known volume devices provides only density values. Temperature must be stated as a significant variable.

LIQUIDS

Densities of Liquids—Methods of Determination

BUOYANCY-HYDROMETERS

Hydrometers are flotation devices that are calibrated using water at various temperatures. When placed in clear liquids, the relative density is read directly from the scale on the hydrometer. The hydrometers range from low-cost, low-precision versions, to expensive, high-precision devices. Higher-grade hydrometers also have thermometers incorporated for temperature correction and greater independence of reading liquids in an as-is condition. A balance or a known volume device is not needed with this technique. Simplicity is the advantage of this technique. Shown in Figs. 9 and 10 are two types of hydrometers. The catalog text has been included to explain ranges and features unique to these devices.

ASTM methods using hydrometers are [10,11] Standard Test Method for Density, Relative Density (Specific Gravity), or API Gravity of Crude Petroleum and Liquid Petroleum Products by Hydrometer Method (D1298) and Standard Test Method for Calculation of Volume and Weight of Industrial Aromatic Hydrocarbons (D1555).

DISPLACEMENT-SUBMERSION—SPECIFIC GRAVITY BALANCES

A specific gravity balance is similar to the hydrometer. It is actually a balance that measures the counterweight applied to balance a plummet submerged in the liquid sample. The weight and volume of a mercury-filled elongated glass bulb (plummet) is determined by comparison with standards established by regulatory agencies and traceable back to well-characterized standards, referred to as primary standards, established by national scientific bureaus. The plummet is attached to a balance and submerged into a liquid to displace some of the liquid's volume. The change in weight is attributed to the weight of the displaced liquid. The plummet's volume is known, and it is related to

Sugar Hydrometers with Brix Scale and Enclosed Thermometers—380 mm

Hydrometers are similar to S42436, but provided with a thermometer, range 0° to 50°C in 1° subdivisions, and with scale of correction values in red.

Cat. No.	Range
S42440-B	0 to 12
S42440-C	9 to 21

Fig. 10—Hydrometer–Sugar with Brix scale and enclosed thermometer [6].

displacement of water. These are related back to water as a calibration liquid, so they provide a relative density rather than a true density. With this device, the sample does not need to be clear because there are no markings on the plummet. The devices also allow the liquid to be at temperatures other than 4.0°C. This type of device is good for solvents and low-volatility materials. Two balances are shown in Fig. 11 and are from recent scientific lab supplier catalogs [12]. The catalog descriptions have been included because they are concise statements about the devices, their operating principles, ranges, and other relevant information.

ASTM method using submersion [13], Standard Test Method for Specific Gravity (Relative Density) and Density of Plastics by Displacement (D792).

Displacement—Fluid External Media

This is a device where the sample-holding chamber is not of a known, calibrated volume. A helium gas pycnometer can be used to determine the volume of a liquid in a metal or glass container. The pycnometer's test chamber volume is first established by determination of gas pressure differences in a sample chamber and after expansion into a connecting expansion chamber. Then an independent, empty sample container is introduced into the gas pycnometer test chamber and tested. The reduction in volume is allocated to the empty sample container. The independent sample container's weight is measured on an analytical balance. The sample is added to the sample container and weighed. The container and sample are tested again to establish a new volume. The sample volume is (sample + container volume) – (container volume). The sample weight is (sample + container weight) – (container weight). Density is (sample weight/sample volume). The test is fairly fast. Containers of predetermined volume can be kept available to help shorten testing time. Precision and accuracy are good.

The ASTM method for using a helium gas pycnometer [14] is Standard Test Method for Percent Volume Nonvolatile Matter in Clear or Pigmented Coatings Using a Helium Gas Pycnometer (D6093).

Displacement-Known Volume Devices-Fluid Internal Media

These are devices of known, internal volume. They have many names such as liquid pycnometers, U.S. standard weight-per-gallon cups, U.S. mini weight-per-gallon cups, British standard weight-per-gallon cups, "featherweight" type weight cups, and Monk cup [7,9,15]. Liquid pycnometers come in a variety of sizes, shapes, volumes, and materials of construction. For precision, glass (inert, light weight, and transparent) is usually used. For testing conditions that require demanding repeated use, other materials with reasonable inertness or resistance to chemical attack, such as stainless steel, are used. To combine both the lighter weight of glass and the ruggedness of metal, a "featherweight" construction of anodized, high-tensile aircraft alloy is employed at a cost consistent with the use of specialized materials of construction. The Monk cup is a special design (Fig. 12) and discussed under the topic of handling entrapped air in samples.

Liquid pycnometers or weight-per-gallon cups are built with a main body or container volume, a cap or lid with a vent hole, and sometimes a tare weight object. The tare weight is used as a counterweight for dual pan balances. The weight read after correcting for the tare weight is attributed to the material contained in the vessel at a level which reaches the top of the vent hole in the cap (see Fig. 13).

Both the vessel and a sample of the material to be tested are equilibrated to room temperature or a constant temperature bath temperature. Common temperatures for

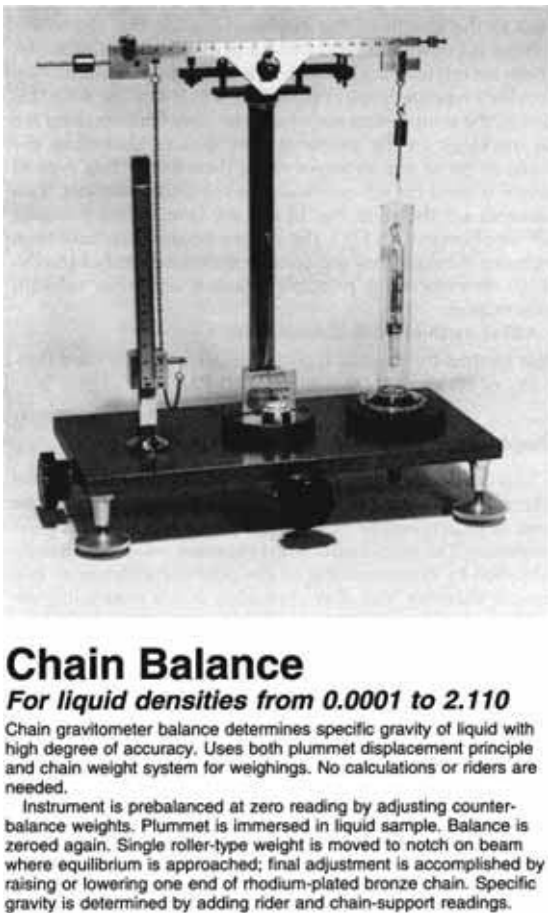

Fig. 11—Specific gravity balances—chain balance and Mohr Westphal balance with catalog text instruction and comments [11]. (Courtesy of Fisher Scientific.)

STAINLESS STEEL

MINI WEIGHT PER GALLON CUPS

METHOD OF USE

1. Determine the weight of a clean cup in grams. As an alternative, the cup may be supplied with an accurate tare weight for use with two-pan laboratory balances. Note: Do not interchange tare weights between cups as each cup and tare weight is matched.
2. Remove cover and fill to within 1.7mm of rim with material to be tested.
3. Carefully replace cover so that the air and excess material is expelled through vent.
4. Wipe over cover to remove surplus and reweigh. By subtracting the original weight of the cup, the weight of the contents will be found. If a tare weight was used at the start, the balance will show the weight of the contents. Clean thoroughly immediately after use.

TEMPERATURE		WEIGHT
C.	F.	Grams
21	69.8	8.329
22	71.6	8.327
23	73.4	8.325
24	75.2	8.323
25	77.0	8.321
26	78.8	8.319
27	80.6	8.316

DETERMINING ACCURATE CUP FACTOR

Comparative results on different materials measured in the same cup are accurate to within the limits of sensitivity of the balances used. Comparative results between cups may be improved by determining a cup factor as follows: Divide 99.925 by the gram weight of distilled water held by the cup at 25°C to determine the cup factor. For example, if the weight of water held by the cup is 99.800 grams, divide 99.925 by 99.800 which is 1.0013. Multiply all cup readings by this factor. In the same manner, if the cup holds 100.200 grams, divide 99.925 by 100.200 which is 0.9973 and all cup readings should be multiplied by this factor.

Fig. 13—Mini weight per gallon cups [7].

paint and solvent testing are 20°C (68°F) and 25°C (77°F) because these are temperatures in the human comfort range. Using temperatures greater than these would drive off solvents. Moisture is not likely to condense out on surfaces from being too cool (weight gain drift during weighing), and volatile materials will not evaporate at a rate that significantly affects the weight readings taken (weight loss drift during weighing). Temperatures colder than these are easily obtained, but are less comfortable for the tester. However, any temperature can be used if the temperature is noted and the vessel volume is corrected for that temperature. If the bath is used, the vessel exterior must be dried off. This has to be done with minimum handling to prevent temperature changes from heat exchange by hands or drying materials.

Next, a portion of the tempered sample is poured into the vessel up to the top rim. The lid is carefully placed on the vessel so that the excess liquid is forced up through the vent hole in the lid without coming out around the lid lip. The excess is carefully cleaned off the surface of the lid and from around the lid lip. This is a cleaning, not merely a wiping off. Wiping leaves residues, which affect the results obtained. The sample-containing vessel is then carefully weighed.

Afterwards, the vessel and lid are cleaned as soon as possible and as well as possible to prevent buildup of residues, which will change the vessel's volume. A verification test should be performed at frequent intervals with distilled water to catch inaccuracies from poor cleaning or damage to the vessel surfaces. For improved accuracy, the vessel can be calibrated using pure water at normal reading temperatures. Divide the gram weight of water by the weight determined by direct testing. This produces a correction factor. This factor number is multiplied by the weight of the gallon weight found for an unknown liquid or mixture. If the determined density of water was less than expected, a factor greater than 1.000 is generated. As a result, the vessel's volume is less than expected. Tracking the factor value will alert the tester to problems arising from poor cleaning or rough handling that can damage and alter the testing vessel.

Sample sizes range from 10 to 84 ml. The combined weight of the vessel, lid, and sample affect the type of balance that can be used to provide good repeatability and reproducibility. The larger the size, the easier it is to get a sample representative of the bulk material. But the larger the size, the harder it is to remove entrapped air bubbles from the sample introduced during sample collection or preparation. For very volatile solvents, use of larger size vessels offsets the weight drift seen during weighing.

The problem of entrapped air can be countered in two ways:

1. The Monk cup is designed to pressurize the sample to 150 lb/in.^{2} in a known volume of space. This pressure compresses the entrapped air in the sample to such an extent that occluded air bubbles are reduced to a negligible volume. Entrapped air of up to 10 vol % can be dealt with by this technique. The volume produced is still larger than the true volume, and a density error is still present. Entrapped air should not be accounted for if the air escapes before use or the air is an artifact of sample mixing before testing. The Monk cup is large and heavy and requires use of non-analytical balances. Fig. 12 is a schematic diagram and picture of a Monk pressure weight-per-gallon cup.
2. An alternative technique is to mix a measured weight of the unknown density material with the weight of a known diluent from a full weight per gallon cup. The blend is then placed back into the cup and weighed. The following, enclosed in quotes, is copied directly from the GARDCO mini catalog Number 9, including the diagrams, with permission from GARDCO [7].

$$X = \frac{W_{unknown} B_{lend\ wt\ per\ gallon}}{(W_{unknown} + W_{diluent\ cup\ weight} - 10 B_{lend\ wt\ per\ gallon})} = \frac{WB}{(W + A - 10B)} \quad (14)$$

where $A = W_{\text{diluent cup weight}}$.

"Heavy-bodied materials which entrap air present a problem in true weight per gallon (density) measurements. Air entrapment causes the apparent volume of a material to be greater than actual and density or weight-per-gallon calculations are low and erroneous. The practice of measurement under pressure does reduce the error but the error is far from eliminated as the entrapped air is normally not removed, but only compressed, as shown in Figs. 14 and 15.

Most materials that are difficult to evaluate can be simply and accurately measured by the following depicted procedure.

"A measured weight of the unknown material is thoroughly blended with the weight of a known diluent from a full weight per gallon cup. The blend is then placed in the cup and the weight per gallon is determined. The value of

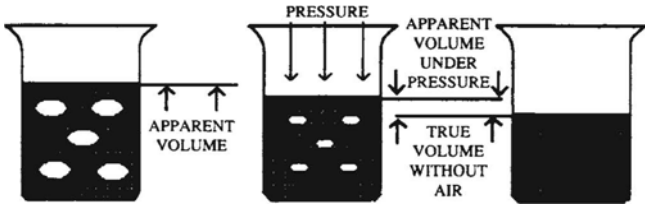

Fig. 14—Liquid with entrapped air [7]. Figure provided by Paul N. Gardner Co., Inc.

the unknown material is calculated from the formula given above. The diluent liquid must be compatible with the material containing the entrapped air and it must be thin enough in viscosity to allow entrapped air to rise to the blend's surface and escape. In the case of particulate, such as pigment, the liquid must be able to wet the particle surfaces and displace air in pockets or depressions on the surface."

ASTM methods using known volume devices are [15,16] Standard Test Method for Density or Relative Density of Pure Liquid Chemicals (D3505) and Standard Test Method for Density of Paint, Varnish, Lacquer, and Related Products (D1475).

Sonic Frequency Shifts

Waves of air reaching a human ear are recognized as sound. The pitch of a sound is related to how many waves reach our ear per unit of time. This unit of time is referred to as frequency. Waves are made by an object moving in the media: air or liquids or even solids. The media touched by the wave can pass this movement through itself. When a boundary between two media of different densities is encountered by the wave, two actions occur: (1) some waves are reflected back; (2) a portion of the waves are passed into the new media but with their frequency changed.

Changes in density also lead to changes in frequency. This can be demonstrated by filling a matched set of water glasses to different levels with water, then striking each glass lightly to produce a sound. The higher the water level is in the glass, the higher the tone. Just as the frequency changes from an empty glass (air, less dense) to a high frequency tone when filled with water (more dense), the replacement of liquids of differing densities also shifts the frequency for glasses filled to the same level. This is the principle for several digital density meters commercially available today.

Measuring devices have been devised using a glass tube, an oscillator, and a sensor. The oscillating frequency

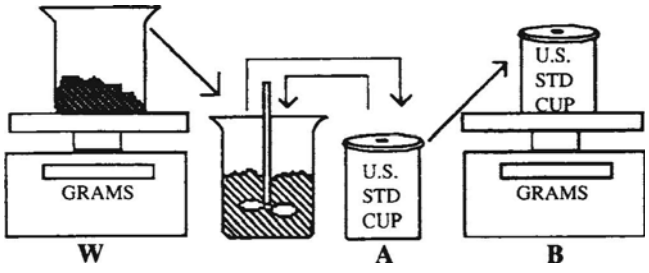

Fig. 15—Diagram for mixing known- and unknown-density materials [7]. Figure provided by Paul N. Gardner Co., Inc.

of the tube changes when air is replaced with a liquid. The instrument can use air and water to establish a set of constants, called *A* and *B*, for the following relationships [17]:

$$A = (T_w^2 - T_a^2) \div (d_w - d_a) \tag{15}$$

$$B = T_a^2 - (A \cdot d_a) \tag{16}$$

where

T_w = observed period of oscillation for cell containing water,
T_a = observed period of oscillation for cell containing air,
d_w = density of water at test temperature,
d_a = density of air at test temperature,
t = test temperature expressed in degrees Kelvin,
p = test barometric pressure expressed in Torr,
d_a (g/ml) = 0.001 293 × (273 ÷ t) × (p ÷ 760)
d_w (g/ml) = 0.997 04 at 25°C (273°+ 25° = 298°K)

Constant A is used by the instrument's computer to calculate constants K_c and K_{cr}. Constant *B* is used by the instrument's computer to return the reading for air density.

Modern digital density instruments are equipped with heating and cooling devices internal to the instrument, such that the sample can be equilibrated within the instrument in a matter of seconds. This leaves the pressure term, *P*, as a visible variable. Pressure changes can occur over a period of time due to weather changes.

The sample tube must be cleaned after each use. The tube's condition needs monitoring to verify that it is at original condition. Frequent calculation of the instrument cell constant K_c overcomes both of these problems.

For density values

$$K_c = \frac{1}{A} = \frac{d_w - d_a}{T_w^2 - T_a^2} \tag{17}$$

$$d_{\text{material}} = d_w + K_c \cdot (T_a^2 - T_w^2) \tag{18}$$

For relative density values

$$K_{cr} = \frac{1.0000 - d_a}{T_w^2 - T_a^2} \tag{19}$$

$$d_{\text{material}} = 1.0000 + K_{cr} \cdot (T_s^2 - T_w^2) \tag{20}$$

where:

T_w = observed period of oscillation for cell containing water,
T_s = observed period of oscillation for cell containing sample,
K_c = instrument constant for density,
K_{cr} = instrument constant for density,
d_w (g/ml) = 0.997 04 at 25°C (273 + 25 =298°K) density of water at test temperature, and
t = test temperature expressed in degrees Kelvin.

Small process computer chips built into commercially available instruments handle all the necessary calculations. Small sample volumes (1.0 to 2.0 ml) are used so heterogeneous samples like paint must be well mixed. The samples

must be free of entrapped air. Small amounts of air cause fluctuations in the readings. Use of dilution with a compatible solvent (of known density) to thin the sample can be used if the thinning does not cause pigment dropout. The contribution of the thinner solvent can be calculated and backed out.

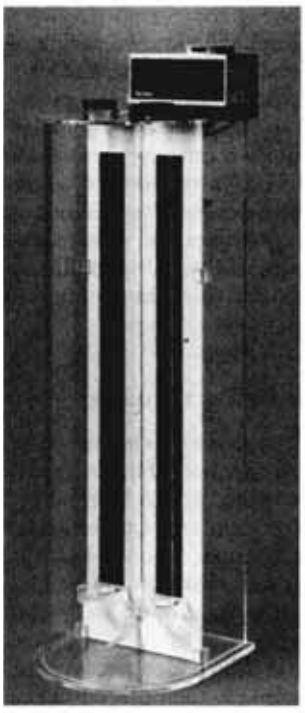
The ASTM method using the digital density meter is [17] Standard Test Method for Density and Relative Density of Liquids by Digital Density Meter (D4052).

SOLIDS

Densities of Solids—Methods of Determination

With solids, determining the volume for a known weight of the material is a challenge for several reasons. First, the form is fixed and direct, accurately known volumes are the exception rather than the rule. Second, solids are seldom homogeneous in their density. Processing often introduces voids or regions of differing degrees of crystallinity, both of which affect density. For large objects, displacement techniques as well as sonic shifts are useful. For powders and small particles, displacement and density by mixing with liquid diluent are the most common techniques. For thin films, only displacement techniques are useful.

Direct Volume Measurement by Pycnometer



Pigments are insoluble, solid particles used to impart color or light reflectance in paints. To provide more than an apparent density, special steps must be taken. ASTM Method for Specific Gravity of Pigments (D153) is a set of three variations on the diluent pycnometer technique described in Fig. 15. It uses a vacuum pump and vacuum dessicator or bell jar to reduce the pressure on a sample of solid pigment. Variation A places a weighed sample of pigment in a dry, weighed glass pycnometer. White kerosene is then added to cover the pigment. The pycnometer and sample is then placed in the dessicator or bell jar and slowly evacuated to remove air entrapped on the irregular surfaces of the pigment. This is a method to wet the pigment surface and remove the contribution of entrapped air in the pigment. After all bubbling stops, air is let back into the jar and the pycnometer is filled to the top with kerosene and weighed. Variation B evacuates the pycnometer before the kerosene is added. Most of the kerosene is added to the pycnometer while it is under vacuum. The pycnometer is topped off with kerosene after returning to normal pressure. Variation C uses a measuring burette to add the kerosene so that volume of kerosene added is known [9,18].

ASTM methods using a pycnometer are [18,19] Standard Test Methods for Specific Gravity of Pigments (D153) and Standard Test Method for Density (Specific Gravity) of Solid Pitch (D2320).

Displacement of Liquids

This was discussed in the section "Solids, Liquids, and Gases—as Concepts" Under Ideal Conditions.

Density gradient column systems (Fig. 16) are another form of submersion test methodology, inverted from the plummets of the density balances. Here the fluid is the calibrated, known test media, and the solid is the unknown. A vertical column tank with black background is carefully filled with a mixture of liquids in a very strict order to establish a heavy-to-light liquid density gradient. Measurements

For accurate density determination of small solid samples to 0.001g/mL. Conform to ASTM D1505-68 for testing plastics. Measurements are made with reference to standard glass floats calibrated within ±0.0001g/mL. Fibers, irregular fragments, pieces of film, powders and glass are suitable. Several determinations can be made at same time.

In wide use for testing polyolefins, fluorocarbon polymers, nylons, PVC. Can separate natural and synthetic fibers. Can assay factors affecting density such as degree of crystallinity of plastics, concentration of isotopic content, presence of trace amounts of boron in silicon.

Fig. 16—Density gradient column systems with text from supplier catalog [6]. (Courtesy of Fisher Scientific.)

are made by adding in both unknown solid materials such as fibers, film pieces, powders, and glass particles and reference materials of known density. The particles will sink to the level of their own density. Using the proper reference materials, exact matches can be established within 0.0001 g/ml. There is a problem when the sample interacts with the fluids and absorbs them or interacts in other chemical ways that perturb the normal test action as with inert materials such as glass or plastics. Powders with irregular surfaces can also experience surface wetting problems and air pocket entrapment. Densities can be determined from 0.79 to 2.89 g/ml with this technique [26].

The test is of long duration, requiring a settling time of usually several hours. Several caution notes are included concerning thin film samples and their handling, which could change the density. Potential users should review ASTM D1505 to assess the applicability of this technique to their own personal needs and use.

ASTM methods using displacement of liquid and gases are [13,20,21] Standard Test Method for Specific Gravity (Relative Density) and Density of Plastics by Displacement (D792), Standard Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings (D2697), and Standard Test Method for Density of Plastics by the Density-Gradient Technique (D1505).

Displacement—Gases

Helium pycnometers have been available for a number of years with many people expressing interest in using these devices to determine the volume of solids of known weight. These instruments are usually relatively expensive and only recently have become sufficiently automated to reduce the

intense manual labor required to do a good job. The main problem is to provide a sufficient amount of free paint film to test at a valid film thickness. Films that are too thick can retain solvents. Films that are too thin are very hard to handle. Free films develop static charge buildups, which further complicate the testing procedure.

Dry powders are a second candidate for this technique. Helium gas displacement eliminates the need for the vacuum pump and the kerosene used in ASTM Method D153, Test Methods for Specific Gravity of Pigments, to replace the air in the voids and available surface cavities. The drawback is that the fine powder is easily blown around. The instrument must be designed to eliminate powder travel and to keep the fine particles from the valves and seals. Hopefully most of these drawbacks have been addressed [14].

ASTM methods using Helium Pycnometry are [14,22] Standard Test Method for Percent Volume Nonvolatile Matter in Clear or Pigmented Coatings Using a Helium Gas Pycnometer (D6093) and Standard Test Method for Density of Solid Pitch (Helium Pycnometer Method) (D4892).

Sonic Frequency Shifts

The sonic frequency shift, principle and equations, has been discussed previously. Use of the sonic technique is limited to continuous objects that can be cut and shaped. Powders and small particles can be suspended in liquids and tested using the equipment discussed previously and using the equations noted earlier under Sonic Frequency Shifts. When the instrument uses solids instead of liquids, several considerations change. A glass tube is no longer used. The solid specimen must be cut into a rectangle with a smooth surface. Surface flaws will introduce errors in the readings.

A sonic sensing head is attached to the solid specimen (approximately 75 mm in thickness), and measures the velocity of sound transmitted through the specimen. Solid specimens require a minimum conditioning time period under controlled temperature and humidity conditions before testing. A calibration curve can be established using materials of known density. The published use is limited to polyethylene plastics. Alternative methods are probably cheaper or less time/labor consuming.

ASTM method using ultrasound [23] The Standard Method for Density of Polyethylene by the Ultrasound Technique (D4883).

Apparent Density

Many pigments or powders are tested without regard to the air entrapment on the particle surfaces or in the voids between where the particles touch. These materials are placed in a graduated transparent container, and a vibrator is touched to the container wall. The particles pack down and a weight is taken. This is referred to as apparent density.

ASTM methods based on apparent density include [24–26] Test Methods for Methylcellulose (D1347), Standard Test Methods for Sodium Carboxymethylcellulose (D1439), and Standard Test Methods for Hydroxypropyl Methylcellulose (D2363).

PAINT VOLUME SOLIDS

Paint is a mixture of materials that is designed to protect and beautify a substrate. When paint is sold, it is sold by volume as gallons or liters. What the consumer wants is the most coverage for the money. Commercial painters and original equipment manufacturers paint surfaces to a minimum thickness called "hiding." They know the square footage or square meter surface area they need to cover. With the thickness for hiding known, a volume of solids needed for painting a house or an automobile can be calculated. Government regulators would like to know the volume of volatile organic material included in a gallon of paint. A ratio of volume volatiles to volume solids would be a measure to compare paint products in terms of pollution contribution.

Theoretical Calculations of Paint Volume Solids

For many paint systems in commercial use today, a straight calculation of solids content can be performed with good results using the densities and weight percent content of materials that contribute solids to the final product. For many other systems, however, this calculated answer does not account for additional reaction by-products or provide information about how the density of the material has changed when cross-linking occurs. For these systems an analytically tested answer is needed. For the last revision of this book, the major document in force by the U.S. Environmental Protection Agency (EPA) was Reference Method 24: Guidelines of Testing for VOCs at 110°C for 1.00 Hour Bake [1]. This was the document to which all methods development related to VOCs relied. In the last 15–20 years, several ASTM test methods have been developed to address the concerns associated with how and when a VOC is occurring, be it the slight amount of solvent introduced via a minor additive, or a reaction product of a catalyzed system. All of the methods referenced in this manual that deal with paint and coatings raw materials and finished products reference EPA Method 24. These analytical methods are appropriate regardless of whether the composition of the coating is a known or an unknown.

Analytical Determination of Paint Volume Solids

Standard Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings (D2697) [20] is commonly used. The test is based on displacement of liquids, usually water or kerosene. Perhaps a more reliable test is Standard Test Method for Percent Volume Nonvolatile Matter in Clear or Pigmented Coatings Using a Helium Gas Pycnometer (D6093) based on volume determination by gas (helium) displacement [14]. The helium is a pervasive gas that behaves closely to an ideal gas. Where paint surfaces are hard to wet with water, the helium has no problem getting very close to the paint surface and displacing air residing at the surface. The test chambers are usually from 5.0 to 30 cm^3 in volume. The paint sample is introduced as a free film or attached to a carrier such as a metal disk or aluminum foil. When the film is a free film, static charges can build up and cause sample loading and handling problems. The test instrument is not inexpensive, but it is highly automated and minimizes the human labor required to about 5 min per test. The fact that the test specimen is a solid film is very beneficial in the case of reactive systems, which are not chemically the same before and after cure. This may be the only means to ascertain the reactive elements (by difference), which should be included in VOC determinations.

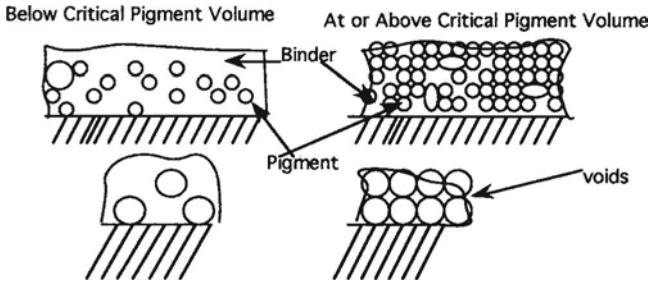


Fig. 17—Pigment volume relationships.

CRITICAL PIGMENT VOLUMES

The pigment volume concentration is a physical property of paint that can help indicate its performance. The definition of Pigment Volume Concentration (PVC) is the ratio of the pigment volume divided by the pigment volume plus resin solids (and sometimes additive solids) volumes. The reader is directed to chapter 28 of this book where this concept is discussed in greater detail.

Pertinent to our discussion is a volume concentration of pigment known as the Critical Pigment Volume Concentration (the CPVC or cPVC). At this ratio, several things happen to the properties of the paint. At this point, there is just enough resin or binder to completely fill the spaces between all the pigment particles. As the PVC increases past the cPVC, the dried paint film will contain voids. The porosity will increase, the moisture vapor transmission will increase, the stain resistance will decrease, the wet hiding will decrease, but the dry hiding will increase. As the paint dries, a condition will exist where the paint has too much pigment and too little polymer such that the internal voids created will entrap air or solvent in the vapor phase [1]. Paint companies actually take advantage of one of these properties to make inexpensive paints that can still hide in the dry state. By formulating above the cPVC, the coating can contain much less pigment, while still performing sufficiently well enough for noncritical applications (ceiling paints and the interior low-performance application). For our discussion it is enough to say that a solid is created that has a higher apparent volume than really exists (see Fig. 17).

If a volume solids test is used that uses strictly liquids to determine displacement solids, they may be unable to penetrate into the void areas. A larger volume of water will be displaced and the apparent weight loss will be greater in water. The bottom line is that all the tests that rely on an accurate determination of specific gravity will be in error. It is exactly in this situation where the ability to accurately determine the volume solids of a paint film, such as the Standard Test Method for Percent Volume Nonvolatile Matter in Clear or Pigmented Coatings Using a Helium Gas Pycnometer (D6093), really shows its worth.

Characterizing Particle Size and Size Distribution

George D. Mills[1]

INTRODUCTION

CHARACTERIZING THE SHAPE, SIZE AND SIZE-distribution of particles that go into liquid paint or coating formulations as well as dry formulated powdered coatings are very important. These materials may vary from being ground mineral fillers to crystalline epoxy cross-linkers and catalysists used in finished powdered paint products. There is a significant effect on the coating's density, mechanical strength, electrical, thermal as well as sound and small molecule transmission properties as a function of the included average particle size and shape.

An example of the importance of particle size is the inclusion of crystalline dicyandiamide (dicy) as a cross-linker in fusion bonded epoxy (FBE) powder coatings or the blowing agent in "fire resistive" paints. Dicy is not stable after melting and decomposes to gaseous products if not consumed in a curing reaction with epoxy. The use of the standard commercial particle size dicy in FBE formulations leads to an unusual type of coating failure. In this case, to remedy the problem, a separate step is performed on the standard commercial-sized powdered dicy used in FBE coatings to produce a "micronized" powdered dicy. If "micronized" dicy is not used, it cannot be fully incorporated into the un-cured FBE matrix during the short time in the extrusion process. This leads to very small regions of the crystalline dicy cross-linker remaining after cure. Because of its slight water solubility, tiny osmotic blisters are formed causing the coating failure. This same material, dicy, is used as a "blowing agent" in the formulation of intumesant paints. In this case the dicy particle size incorporated into the paint dictates the foam density produced on heating and decomposition. This impacts the thermal transfer value of the fire resistive paint.

Particle-size measurements associated with the paint and coatings industry has broadened in scope considerably over the past few decades. Not only must we evaluate the size, shape, and size distribution of the pigments, fillers, and emulsified resin particles used in the formulation of the coating system, but major efforts are now put forth to address environmental and applicator's health problems that are specific to particle size, nature, and morphology. Environmental and economic concerns have been a substantial driving force in the development of powder coating technology, which requires monitoring finished powder size and size distribution to ensure consistent application parameters.

We have learned that the size, shape, and nature of dust particles in the air we breathe during the manufacture, application, and abrasive removal of paints are of utmost concern to our health. Airborne dusts of silica and asbestos, as well as lead- and chromium-laden paint debris generated during abrasive blasting, are serious health threats. In an effort to protect the general public, government regulations now address the monitoring of small reparable dust particles of less than 10 μm ("R10" particles) during the abrasive removal of certain coatings.

In the production of electronic microcircuits, chips, and semiconductors, photo-resist coatings are applied to silicon wafers with line-to-line resolution of fractions of a micron. Dust particles, which are a fraction of this size, if allowed to contaminate the coated surface, will cause the production of defective chips. Dust has forced the development of more sophisticated clean-room technology in recent years. The reject rate of produced microchips caused by defects in the coating as a result of ultra-small particles of dust is a major problem.

As technology advances in the evaluation of smaller-size particle systems, materials used to standardize and calibrate the measuring/monitoring equipment must be developed. The necessity for standard traceable test materials, i.e., from the National Institute of Standards and Technology (NIST), formerly National Bureau of Standards (NBS), which are required to ensure the reliability of the measurements, has led to secondary industries that produce these standards from various materials.

Due to pressing global concerns with solvents emissions as well as the associated economic benefits, powder coatings as a class have grown at a very fast rate over the past 30 years. Many properties impacting the production, delivery, application, and film-forming characteristics are related to the average particle size of the manufactured powder coating. Often, of equal importance, is the amount of very small particles present. These "fines" impact fluidization and electrostatic application characteristics of the powder coating.

With the exception of physically sieving a powder sample using different sized screens, particle size analysis usually employs laboratory instruments. These lab instruments employ various physical principles. Current technology instrumentation has the ability to determine particle size as small as 0.003 μm utilizing "Quasi Elastic Light Scattering"

[1] *Ph. D., President, George Mills & Associates International, Inc., Foley, AL 36535.*

Copyright © 2012 by ASTM International

to 1200 μm using "electrical resistance zone sensing." These technologies are addressed later.

Particle characterization methodologies currently employed include:

- Physically sieving using various screens having different size openings;
- Sedimentation (using centrifugal and gravity forces);
- Surface area determination (employing both gasses and liquids surface adsorption);
- Individual particle sensing (light blocking and electrical resistance);
- Direct microscope measurements (static and dynamic image microscopy, visual light microscopes and electron microscopes);
- Light attenuation and scattering;
- Liquid paint draw-down gage.

There are currently emerging techniques that employ the physical principle of ultrasonics. The specific instrumental techniques include Acoustic Attenuation Spectroscopy having a measurable size range of 0.05 to10 μm. With this technique concentrated colloids, emulsions, and suspensions can be analyzed. When the transmission of light through the sample is required to affect the particle size analysis, the sample must be diluted considerably. Unfortunately, some of these particle systems are not stable at these dilutions. The use of ultrasonic waves of a range of frequencies directed through the dispersed medium and accurately measuring the attenuation at each frequency allows collecting an attenuation spectrum that can be converted to a particle size distribution as well as a measure of the concentration of the dispersed phase. This has been made possible by the recent development of ultrasonic transducer and advancements in digital signal processing [1].

Another developing technique using ultrasonics is Electroacoustic Spectroscopy (Electrokinetic Sonic Amplitude) having a measurable size range of 0.1 to 10 μm. Single Frequency Colloid Vibration Current and Electrokinetic Sonic Amplitude have a measurable size range of 10 nm to more than 10 μm. A major benefit is the ability to accept samples as concentrated as slurries [2].

Although an understanding of the relationships of powder properties to product application characteristics and performance is important, quality assurance/quality control (QA/QC) requirements demand high-speed, on-line (real-time) monitoring. This demand for rapid, accurate analysis of particle characteristics has been a driving force in the development of current instrumentation. The availability of low-cost computers and pertinent software as well as highly reliable and stable energy power sources and detectors have allowed the development of fast, accurate, broad spectrum, and "in-process" instrumentation. The development of robust solid-state laser diodes has allowed the replacement of bulky gas lasers, which required optical table stability. Further, the development of fiber optics, as well as the technology associated with its ease of alignment, has assisted in downsizing the footprint of some current generation instrumentation.

A major objective of this chapter is to provide an understanding of many of the various methodologies available for evaluating particle size, shape, and distribution. The hiding power and light transmission characteristics of coatings are greatly affected by the particle size of included pigments and fillers. Tensile strength of the cured system, water and gas vapor transmission coefficients, chemical resistance, and interface anticorrosive activity are only a few areas impacted by the size, shape, nature, and size distribution of the pigments and fillers formulated into the coating.

This chapter will allow an educated choice of technologies based on the size-dependent measurement most related to the desired property of importance. An appreciation of the mathematics involved will aid in determining and understanding the limitations and potential errors inherent in the measurement.

History of Particle-Size Analysis

The earliest reported particle sizing was about 150 B.C. in Greek and Roman mining manuals using sieves made of leather, woven hair, and planks. The Germans introduced wire-woven screens in the 15th century. Microscopes were reportedly used in the 1700s for size analysis. Automated machinery was developed in the 1800s for weaving metal-wire sieve fabric. In the late 1800s to early 1900s, standards were developed defining sieve sizes. The first apparatus of record used for classification of pigment particles into different sizes was reported by Thompson [3] in 1910. Oden proposed the use of gravity sedimentation as early as 1916 [4,5].

Energy sources of various wavelengths, employing many different configurations, have been used to measure particle size. Visible light photometry was reported by Stutz and Pfund [6] in 1927. Gamble and Barnett [7] employed radiation in the near-infrared region. Atherton and Peters reported using light-scattering techniques in 1953 [8]. The electron microscope found use in the 1940s for characterizing very small particles as well as to define the corresponding surface topography. After the laser light source was invented, light scattering technologies were expanded. The development of better diode array detectors opened the way for developing the fast light-scattering and blocking instruments now widely used since the 1990s. The recent advancements in transducer technology and digital data collection are opening the way for the instruments using ultrasonics mentioned above.

The latest technology since 2010 includes laser diffraction spectrometry, ultrasonic extinction, and photon cross correlation spectrometry. There have been improvements in image analyses, both static and dynamic. These technologies allow a particle size measurement range of 1 nm to 10 mm [9].

Importance of Particle-Size Analysis

As the physical properties of paints, coatings, and polymers in general are impacted by the size, shape, and size distribution of the fillers included in the formulation, it is imperative that characterization of the pigment and filler system be correlated with the physical properties of the coating.

Because of the early importance of zinc oxide as a pigment in oil-based paints and its existence in multi forms and shapes, this material was studied in the 1920s and 1930s. Bunce [10] found that as the average diameter of zinc oxide in paint increased from 0.19 to 0.31 μm, the elongation of the film increased and the load at the breaking point decreased (Fig. 1). Eide [11] showed that coarse acicular zinc oxide imparted greater durability to a paint than did "round" zinc oxide. In related studies, Morris [12] and Nelson [13] found evidence that acicular asbestine of

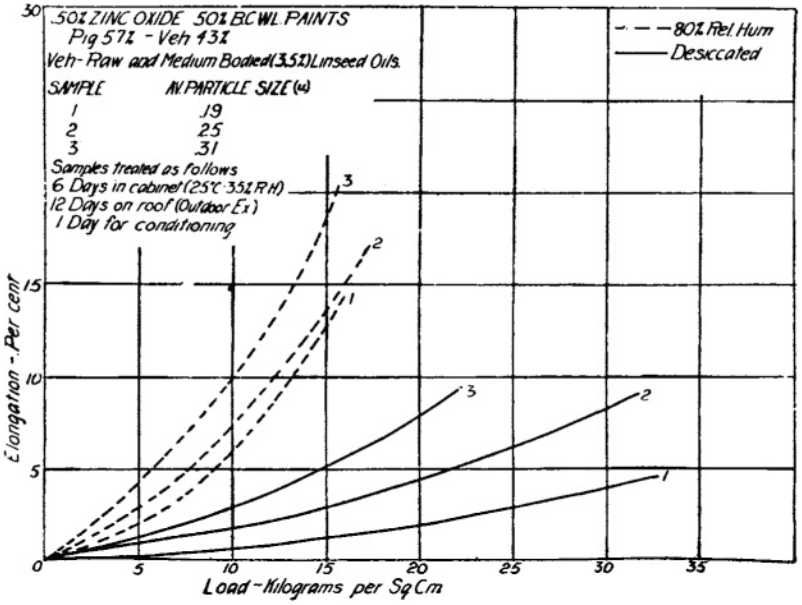

Fig. 1—Stress-strain curves of some paint films. These illustrate the effect of the particle size of zinc oxide on the strength of paint films.

a wide distribution of sizes favorably influenced the durability of paints, and a review by Jacobsen [14] cites many examples of the significance of particle size and shape of pigments and extenders on the optical and physio-chemical properties of coating systems.

Many surface properties are impacted by the pigment's and filler's particle size and nature of which gloss is one of the most prevalent. While the larger-size particles can "protrude" through the surface of the coating, causing a surface roughness related to the size of included particles, extremely fine particles can affect gloss by adsorbing binder to a point that the gloss is decreased due to a lack of available binder at the coating surface. The "oil adsorption" of the pigment is a function of its surface area and increases as the average particle size decreases. ASTM D1483 presents a standard test method for determining the oil absorption of a pigment [15]. The "critical pigment volume concentration" (CPVC) exists at a pigment loading such that there are just enough binder solids to completely wet out the included filler and pigment particles. Coatings formulated above the CPVC cannot be glossy. Abrasion resistance of the coating may be increased by the addition of hard fillers such as silica. The relationship between particle dimensions and film properties is depicted in Fig. 2. The National Paint, Varnish, and Lacquer Association has published a Pigment Index that gives information on the particle size of many of the pigments available on the American market [16].

Other coating properties impacted by variations in particle size and shape include the efficiency of contained ultraviolet (UV) blockers and absorbers such as carbon black pigments. The use of acicular (needle-like) pigments such as Wollastonite (asbestos free) is popular in many types of coatings. The tensile and compressive strength of coatings also can be modified by judicial choice of particle size and shape, and gas vapor and molecular water vapor transmission of a coating can be altered with the proper choice of pigment loading, shape, and size.

The coalescent and film-forming characteristics of emulsion binders are impacted by the particle size of the dispersed resin particles. Cold "touch-up," brush ability, and mechanical stability during pigment dispersion are a function of properties that are related, in part, to polymer particle size. Surfactant demand and effectiveness are a function of polymer particle size (as well as other binder variables). Because of the importance (dependence) of many coating properties on the small finite size of the pigment, fillers, catalysts, and polymers formulated into the coating, the demand for rapid, accurate analysis of particle characteristics has led to the refinement of many techniques.

CONSIDERATIONS IN SAMPLING TECHNIQUES

Normally, when a particle-size determination is made, one will not work with the total collection of particles comprising the bulk sample. A "representative" collection of particles is usually chosen. This sample is then reduced in size a few more times until only a few milligrams remain for the actual instrumental testing. The assumption is usually made that the fraction actually evaluated is, in fact, "identical" in particle size, size distribution, shape, and nature to the total of the bulk material. This, essentially, is never true. This sample test fraction, which usually does not exactly represent the bulk, can be a major source of error, introducing considerable bias and distortion to the results. The reliability of any measurement depends on the degree of "representativeness" of the test sample. Thus, the sampling technique is often more important than the actual particle-size measurement.

Theoretical Considerations of Variance in Sampling

To obtain a representative sample, the sampling process is usually divided into several steps during which a conscious effort is made to reduce bias. The bulk material is usually obtained in huge, ton lots. The first sample reduction

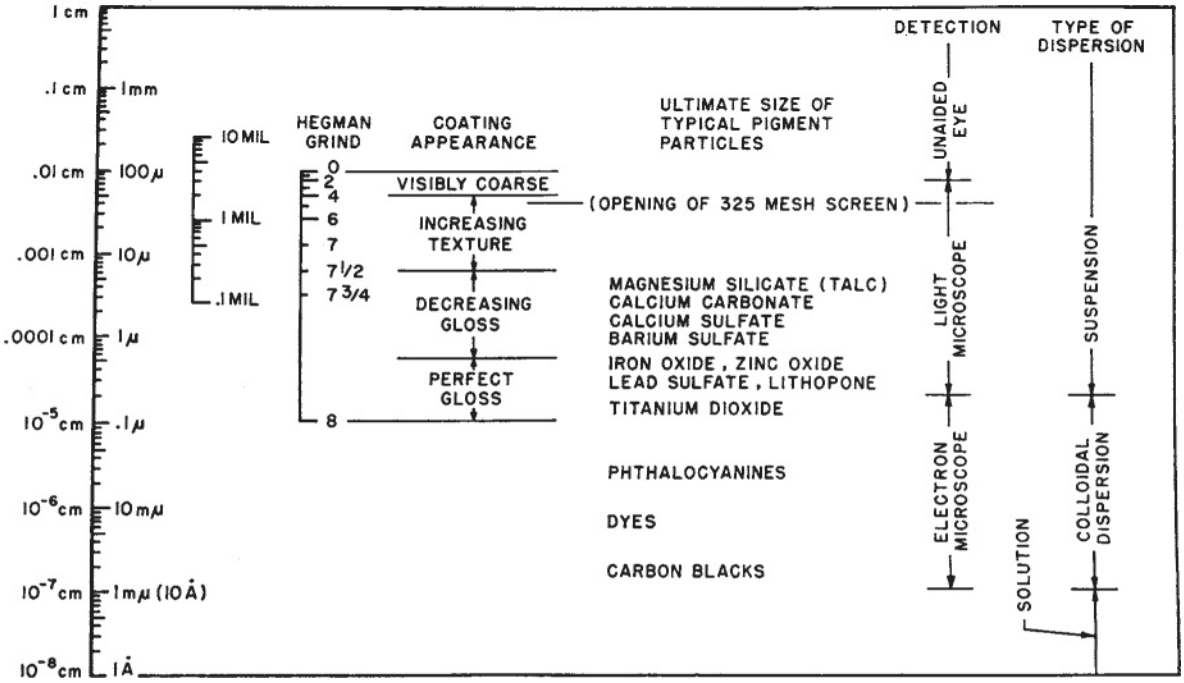

Fig. 2—Dimensions of granular pigments and their relation to surface properties (from Ref. [12]). (Courtesy of the *Journal of Paint Technology.*)

provides the "gross" sample, which is on the order of kilograms. This sample is then reduced to the "laboratory" sample, which is on the order of grams. The actual evaluation sample introduced to the instrument is on the order of milligrams. The reduction process, almost always, will introduce some bias, depending on the actual spread in the distribution. This bias will diminish as the consistency approaches unity, i.e., all particles approach being identical. The bias exists because the physical forces acting on the particles in a collection are not the same, but are, in fact, size dependent. The "fines" act differently in a pile than will the coarse particles. Their angle of repose is different, often resulting in particle stratification and some segregation.

There are some established rules that must be followed to minimize this bias. The "perfect" sample is one in which the differences seen between the evaluated characteristics and those that actually exist in the bulk can be ascribed to the expected number variations described by statistics. For a sand (A) and sugar (B) mix, the probability that the number fraction, *p,* of (A) in the bulk actually is represented by the number fraction (*pi*) in the sample is computed from the number of actual particles in the bulk *(N)* and the reduced sample *(n)* [17]. The equation is as follows:

$$\mathrm{Var}(p_i) = \frac{p(1-p)}{n}\left(1-\frac{n}{N}\right) \tag{1}$$

Theoretically, the expected deviation (i.e., standard deviation), σ_i, is the square root of the variation. Since the use of the weight fraction is often more convenient, the equation for variance is given by

$$\mathrm{Var}(P_i) = \frac{P(1-P)}{w}[Pw_B + (1-P)w_A]\left(1-\frac{w}{W}\right) \tag{2}$$

where the weight fraction in the sample and bulk are *P*; and *P,* respectively, *W* and *w* are the bulk weight and sample weight, respectively, and w_A and w_B are the weights of individual grains of A and B, respectively.

Even with the "perfect" sample, there is a finite probability that the measured sample will deviate from the actual bulk by some predictable value. To minimize this "guaranteed" deviation, a minimum sample size is required. One may calculate the minimum sample size required to yield values within preset statistical limits [18]. The equation relating the minimum sample weight of a gross sample is given by

$$M_s = \frac{1}{2}[\rho/\theta^2][1/w_\lambda - 2]d_\lambda^3 \times 10^3 \tag{3}$$

where:

M_s = the limiting weight in grams,
ρ = the powder density in g/cm³,
θ^2 = the variance of the tolerated sampling error,
w_λ = the fractional mass of the coarsest size class being sampled,
d^3_λ = the arithmetic mean of the cubes of the extreme diameter in the size class in cm³.

The collection methods used in obtaining the sample are important. Depending on the nature of the material being tested, samples should be gathered so as to minimize the introduction of bias. There are two "golden rules" of sampling that should be followed when possible [18]. These are:

- The sample should be collected while in motion.
- All of the stream should be collected for a short period of time rather than a portion of the stream for a longer period of time.

TABLE 1—Standard deviation in particle size determination of a sugar-sand mixture as a function of sampling techniques

	Standard Deviation (σ)[a]	
	Sugar-Sand	Sand-Sand
Cone and quarter (worst)	5.762	6.812
Scoop sampling	6.312	5.142
Table sampling	2.11 %	2.09 %
Chute riffler	1.10 %	1.01 %
Spinning riffler (best)	0.27 %	0.132 %
Random variation	0.09 %	0.08 %

[a] Binary mixtures of sand-sand and sand-sugar were used, and all particles of one component and none of the other would pass through a designated sieve. Density of sand and sugar, respectively, is 2.65 and 1.64 g/mL From Allen, T., and Khan, A.A., 1970, *Chemical Engineering,* Vol. 238, pp. 108–112.

This procedure will assist in minimizing the probability of error generated by stratification and segregation due to differing weights of the particles within the stream and of the way they act within the collective mass of the sample during transport. Special collection devices are available for affecting the sample collection.

Sampling Techniques and Equipment

Sampling techniques have been developed to minimize the systematic errors introduced both in collecting the gross sample and in reducing its size to the analytical sample. In the work done by Allen and Khan [19] using sand-sugar and sand-sand, mixtures were evaluated utilizing different collection techniques. These techniques included (1) cone and quartering; (2) scoop sampling; (3) table sampling; (4) chute riffling; and (5) spinning riffling. The data presented in Table 1 show the values obtained via each method as well as the expected standard deviation from the known sample.

Cone and quartering is a procedure in which the powders are piled into a cone. The cone heap is then carefully pushed down flat and divided into four equal sections. The assumption is that the cone will be symmetrical about its central axis and the flattened sections will all be representative of the bulk mixture. A problem exists as it is very difficult to produce perfect symmetry, which results in some size segregation from the center out. The technique is also operator dependent, and tests showed this technique to give the largest standard deviation of the five techniques evaluated (see Table 1).

Scoop sampling entails randomly dipping into and pulling a scoopful of powder from a pile of the material to be evaluated. Because the pile is usually not totally symmetrical and evenly distributed throughout, the technique is prone to errors. Since in this procedure the powder is not caught while moving, it will not be typical of the bulk lot of material.

Table sampling (Fig. 3) utilizes a tilted surface over which a powder sample is allowed to slide. A series of splitting wedges cut the sample into numerous sections where some portions fall through openings and are discarded. Ultimately, a decreased quantity of sample is collected, although it is necessary that the incoming powder be uniform and consistent.

Chute splitting utilizes a funneling or channeling device capable of alternately placing the powder sampling stream into one of two collection hoppers. The technique is subject to error and operator bias if segregation is allowed to occur in loading the bulk sampling trough. Such error is present when the two collected portions are not the same

Fig. 3—Table sampler: A 16 to 1 reducer with removable legs for portability. (Courtesy of Gilson, Inc.)

Spinning rifflers (Fig. 4) utilize a series of smaller collection tubes or holders mounted in a way to collect a flowing powder stream over a very short time period. This technique was found to be the most reliable method for sampling and, when tested with different operators, showed little operator bias. Such was not the case for the other techniques investigated.

PARTICLE CHARACTERIZATION METHODOLOGY

As indicated above, the size and size distribution characterization of powders utilize various physical principals and methodologies. These methodologies range from the simple as with physically sieving the powders using screens with different known size openings to very sophisticated instrumental ultrasonic attenuation.

Particle Size by Sieving

Sieving appears to be a simple means for separating pigments into fractions according to size. A significant addition to the physical laws governing the process has been made by Whitby [20], who investigated variables such as size distribution, mesh size, sieve loading, sieve motion, sieve material, and relative humidity. A comprehensive manual on sieving methods has been published by ASTM [21] and the W. S. Tyler Company [22].

For routine testing, sieves conforming to ASTM Specification for Wire-Cloth Sieves for Testing Purposes (E-11) are useful. These sieves are made of woven wire cloth, supported in frames of up to 12 in. (30 cm) in diameter. A skirt protrudes slightly below the sieve, allowing it to nest

Fig. 4—The spinning riffler. (Courtesy of Brinkman Instruments, Inc.)

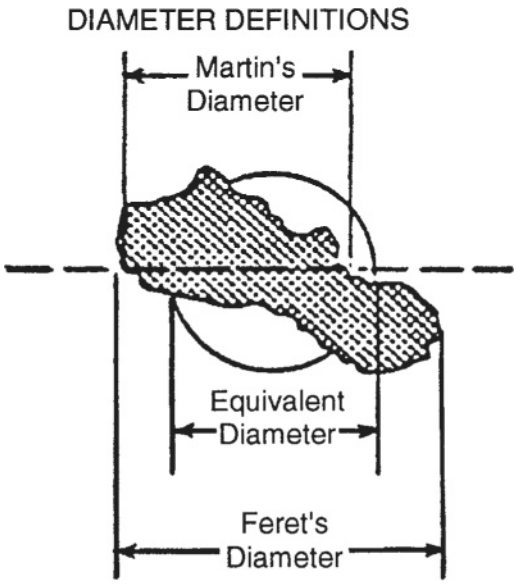

Fig. 5—The relationship of some stated diameters and the physical size of the particle.

into the frame of the next size sieve. The openings in successive sieves progress from a base of 1.00 mm in the ratio of the square root of 2 to 1 (i.e., 1.414:1). When selecting a range of sieves from the series, it is recommended that each sieve, each alternate sieve, or each fourth sieve be taken. In this way, the basic ratio between successive sieves remains constant.

The U.S. Series of sieves is patterned after the Tyler Series that was introduced in 1910. In fact, the two are now interchangeable, the only difference between them being the designations of the individual sieves. Those in the U.S. Series are identified preferably by the sizes of the openings in millimeters or micrometers, while an alternate means is by a number approximately equal to the mesh. Tyler sieves are identified by mesh. Equivalent sieves are available in both series. The sieves proposed as standard by the International Standards Organization (ISO) correspond to many of the sieves in the U.S. Series. Especially useful for sizes under 100 μm is a sieve made by a photoengraving and electroplating process [23]. Such sieves are intended to serve mainly as primary reference standards [see ASTM Specification for Precision Electroformed Sieves (Square-Opening Series) (E-161)].

HAND SIEVING

If the sieves are used singly, the following directions that appear in several ASTM test methods, among them D546, Sieve Analysis of Mineral Filler for Road and Paving Materials, may be used. After transferring the specimen to the sieve, "Hold the sieve, with pan and cover attached, in one hand in a slightly inclined position so that the specimen will be well distributed over the sieve, and at the same time gently strike the side about 150 times per minute against the palm of the hand on the upstroke. Turn the sieve every 25 strokes about one sixth of a revolution in the same direction each time. Continue the operation until not more than 0.05 g passes through the sieve in 1 minute of continuous sieving."

Sources of error in hand sieving are operator fatigue and casual attention to directions. While machine sieving eliminates these errors, some specifications still require hand sieving unless it can be shown that machine sieving gives the same results.

MACHINE SIEVING

Machine sieving has the advantages of uniformity of treatment and saving time since the operator is free to perform other tasks while the machine is working. Several types of machines are available. The conventional ones impart an oscillating or rotating motion (or both) to the sieve, with regular tapping. None appear to reproduce the motions of hand sieving.

Ro-Tap Sieve Shaker. This machine (Fig. 6) has been in use since the early 1900s and the company now has five models. The machine manipulates a series of sieves, graduated with respect to mesh size, so as to permit separation of a specimen into sizes. As the name implies, the sieves are given a special rotary motion accompanied at regular intervals by a tap. The nature of the specimen dictates the size of the sieve openings and the timing cycle. This type of machine is recommended in ASTM Test Method for Particle Size or Screen Analysis at No. 4 Sieve (4.75-mm) and Finer for Metal Bearing Ores and Related Materials (E-276). See www.wstyler.com/html/ro_tap.html for various models having one or two stacks of sieves.

Sonic Sifter. In the Allen-Bradley sonic sifter [24] (Fig. 7), the sieves are stationary, and agitation is imparted to the particles by an oscillating column of air. Sieve wear and particle attrition are said to be minimal. The sonic sifter consists of a sieving chamber, a diaphragm at the top vibrating at 60 Hz, and a motor with the necessary controls. The amplitude of vibration is adjustable to the nature of the specimen. A determination may require no more than 60-s operation of the machine.

Fig. 6—Ro-tap testing sieve shaker. (Courtesy of W. S. Tyler Co.) http://www.wstyler.com/html/ro_tap.html.

To make an analysis, the sieves, in descending order from top to bottom, are assembled in the holder, and the specimen (not more than 30 *g* or 10 ml) is transferred to the top sieve. The cone, coupling unit, and the diaphragm are added, and the stack is latched within the chamber. The complete assembly is positioned in the machine, the power level and the time interval are set, and the operation is started. After the sift interval, the stack is removed and opened, and the fractions are weighed and computed in the usual manner.

Air-Jet Sieve. A cross section of the air-jet sieve [25] is shown in Fig. 8. A specimen is seen being processed through the component parts. The complete operational unit includes a vacuum cleaner. The hose of the vacuum cleaner is fastened to the outlet at the lower left. The specimen is placed on the sieve, and the air, which comes from the rotating split nozzle on its way to the vacuum cleaner, agitates the specimen. The finer particles pass the sieve and are collected in a tared filter bag; the coarse particles are retained on the sieve. Sieves with different meshes are used for additional fractionations, and the procedure is repeated. New tared filter bags are used for each fractionation if retention of the fractions is desired. Air velocity must be regulated, and a manometer is used to indicate the vacuum in the housing.

Particle Size by Sedimentation

The use of the principle that a particle will "fall" through a liquid medium at a rate dependent on its diameter (as well as other variables) is a popular sizing technique. By this method, the pigment particles are dispersed in a liquid and then allowed to settle under the influence of gravity or centrifugal force. The rate of particle movement through the liquid then gives the particle diameter. Among the methods for measuring the rate of particle movement in a fluid are: (1) collecting the particles on a balance pan suspended in the dispersion, (2) analyzing specimens withdrawn with a pipette from different levels, (3) determining density with hydrometers or "divers," and (4) measuring attenuated light transmission through the dispersion. With low-cost computers and extremely stable rotational control provided by advanced electronic feedback circuits, the sedimentation methods using centrifugal acceleration have become popular.

A prerequisite to analysis by the sedimentation process is that the particles must be at their primary size. Vigorous stirring, usually with a dispersant agent or surfactant, both with and without ultrasonics, is often necessary. Agents to prevent flocculation may be required, and adjustments in solution pH may be necessary to stabilize the system. These additives must be evaluated at different levels to determine impact on the derived values.

STOKES' LAW

For essentially spherical particles, one assumes that Stokes' law will be followed when particles are falling in a fluid under some accelerating potential such as gravity or centrifugal force. This assumption requires that the particles will fall freely under laminar flow conditions [26]. For a perfect sphere, the diameter can be calculated simply from the Stokes' equation

$$D = \left[\frac{18_{\mu\nu}}{g(\rho_p - \rho)}\right]^{1/2} \tag{4}$$

where:

D = diameter of sphere,
μ = medium viscosity,
ν = velocity of fall under influence of gravity,
g = gravitational constant,
ρ_p = sphere density, and
ρ = medium density.

Most often, the particles are not exactly spherical. Because of this, it is difficult to relate a particle's dimensions directly to the observed settling rate. The usual procedure is to use Stokes' equation to determine the values for d from the sedimentation distance and its corresponding time. The value so determined is then the "Stokes' diameter" of the particle. The definition then becomes "the diameter of a sphere that has the same density and free falling velocity (in

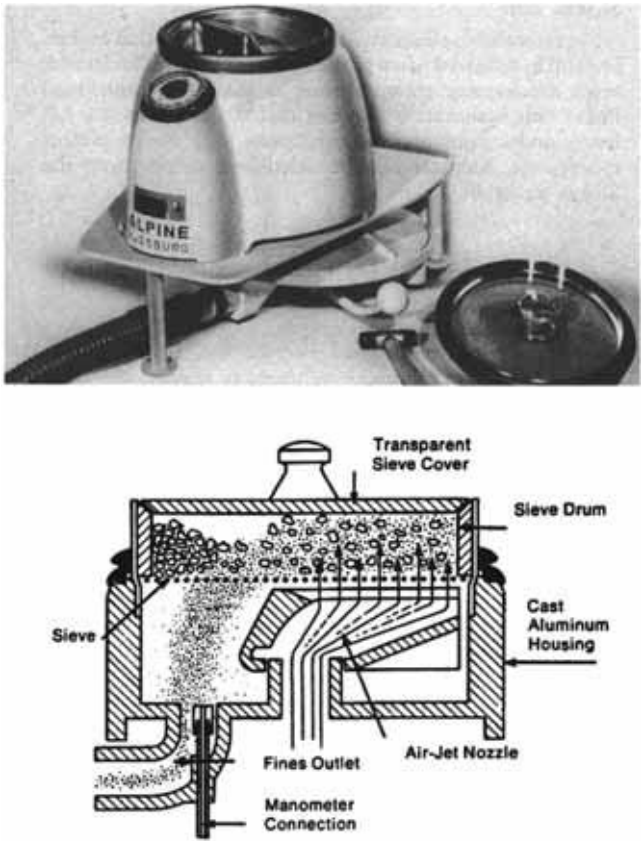

Fig. 8—Alpine air-jet sieve. (Courtesy of Gilson, Inc.)

a given fluid) as the particle being investigated (within the range of Stokes' law)".

This practice avoids the problem of variations in free fall velocities caused by shapes that differ from being a sphere. The assumption holds and permits useful comparisons of the size distributions when similar types of materials are evaluated. The size distribution of particles of different shapes may be compared provided that the phenomenon being studied is dependent on its behavior in the fluid.

While the concept of the Stokes' diameter is useful, it is necessary to appreciate its limitations. One should not equate the Stokes' diameter to a sphere of equal volume or other related quantity. Two types of errors may be introduced. In the first case, errors arise when the particle's movements depart from Stokes' law and, in the second case, errors are introduced by the experimental technique itself.

Departure from Stokes' law can occur when flow conditions are not met. Stokes' equation is valid under laminar flow only. Consequently, there is an upper limit to the size of a particle that can be evaluated in a given liquid. Large particles can experience too high a velocity in the liquid and create turbulent flow. Vortexes in the liquid in the vicinity of other particles also introduce errors. Laminar flow is determined by the Reynolds number experienced by the particle/ fluid system at the fall rate. The Reynolds number, *Re,* is defined as

$$Re = vd\rho/\eta \qquad (5)$$

where v is the velocity in the fluid, d is the diameter in centimeters, ρ is density of the particle in grams per milliliter, and η is the viscosity in poise. According to British Standard (B.S.) 3406 [27], the value of *Re* cannot exceed 0.2 if the introduced error from Stokes' law deviation is to be less than 5 %. This would imply that the upper limit of particle size would depend on both the viscosity and density of the fluid. For water, this value would place an upper limit of about 60 μm. However, as might be anticipated from the Reynolds equation, this limit may be stretched somewhat when using either more dense or more viscous liquid media than water.

Another problem arises when the concentration of particles is too great. The Stokes' equation assumes single particles having no influence from the wall of the vessel or other particles in close proximity. Wall effects are minimized by employing properly sized vessels. While some investigators have recommended that the volume concentration should be kept less than 0.05 %, others recommend concentrations of up to about 0.5 to 1 % by volume. Certain investigators feel that this compromise introduces systematic errors and renders the method inappropriate as an absolute measure, although it is suitable as a routine control method. The flocculating nature of the powder in the test fluid will impact the maximum concentration that can be used. B.S. 3406 recommends a concentration of 1 % by volume, although it cautions that, under certain circumstances, a small interference may occur. Because of the potential introduction of systematic errors at higher concentrations, efforts to refine the technique so that reduced concentrations are used are underway. Precision with differentials no more than 4 % are usually expected.

Another problem that must be addressed is the temperature stability of the liquid. Not only is there a change in the liquid viscosity, but thermally produced convection currents grossly impact the sedimentation process. Because of the difficulty in maintaining thermostatic control over the long periods required for gravitational settling, there is usually a lower particle-size limit of about 2 μm when water is used as the suspending liquid.

GRAVITY SEDIMENTATION

The analysis of particles by sedimentation is possible because of Stokes" law, which states that the time of fall of a particle through a viscous medium is proportional to the particle's density (the difference between it and the medium) and its diameter. Of course, if the density of the medium were greater than the particle, the particle would float. Another requirement is that all of the particles must have a common density. This rules out mixtures of different minerals and pigments having different densities since they cannot be determined together.

Because of the time required for sedimentation to occur, the simple gravimetric method and the photometric method appear to be limited to pigments of sizes above 0.5 to 1.0 μm. Cadle [28] and Orr and Dallavalle [29] have reviewed the many variations of the method. Gravity settling was first proposed by Oden [30,31]. Calbeck and Harner [32] were among the first to use the technique for paint pigments; Jacobsen and Sullivan [33] brought the method to a higher degree of refinement by using an analytical balance with one of the pans replaced with a cup submerged in the suspension.

Hydrometer Method. The density of a dispersion is proportional to the concentration of the dispersed material, and methods for particle-size analysis based on the use of

the hydrometer have been developed. One such method is ASTM Method for Particle-Size Analysis of Soils (D422). Another, developed in large part by Bauer [34], is Technical Association of the Pulp and Paper Industry Method T649sm, Determination of Particle Size of Clay. Included in the method is a nomograph by Casagrande [35] to aid in the calculations. The same nomograph is found in Test Method for Particle Size Distribution by Hydrometer of the Common White Extender Pigments (D3360) [36].

Radioactivity Method. Connor and Hardwick [37] report on this method for determining the height of the sedimentation. The radioactivity is either induced in the specimen or is used as an external probe. The technique avoids disturbing the suspension by periodic sampling and can be used with both gravity and centrifugal sedimentation.

CENTRIFUGAL SEDIMENTATION

The centrifuge is used to provide an accelerating force for sedimentation analysis. Configurations exist using rotating disks with "see-through" ports as well as holders of small see-through cells.

Disk Centrifuge. The technique for the disk centrifuge was developed by Atherton et al. [38]. The apparatus might be considered to be a direct descendant of the single cell centrifuge of Donoghue [39] and the scratch start technique of Marshall [40]. The range is from 0.01 to 0.5 μm.

The apparatus consists of a centrifuge unit, a sampling unit, and an electronic control unit [41]. The rotor of the centrifuge is a cell (hollow disk) of plastic or glass that rotates on a horizontal axis (Fig. 9). The back wall is attached to the shaft of the rotor. The front wall has a hole in the middle that serves as an access port. The inside diameter of the standard cell is 10 cm, and the width is 1 cm. In operation, the cell takes liquid up to a minimum radius of 2.3 cm. The speed ranges from 500 to 8000 rpm.

The sampling unit (Fig. 10) consists of a probe connected to collection flask and a clock motor. The probe is an L-shape thin-wall steel tube arranged to rotate about the axis of one arm. The other arm terminates in a sharp bevel for scooping up the contents of the cell in a manner analogous to that of an inside cutter in a lathe. The center of rotation of the probe lies below the center of the rotor.

To make a test, an appropriate volume of "spin fluid," typically a 4 % sucrose solution, is transferred to the rotating cell. After swirling stops (20 to 30 s), the specimen—usually 0.5 ml of a 0.5 % dispersion—is expelled from a syringe against the back wall near the center of rotation. The specimen flows outward over the wall unit it reaches the free surface of the spin fluid, where it forms a band about 1 mm thick. The spin fluid and the dispersion do not mix because of the higher density of the former. Thus, zero time for the measurement is defined rather accurately.

After the desired time, spin fluid is withdrawn from the cell with the probe, which is driven by a clock motor at 1 rpm. With the pickup end of the probe in the 12 o'clock position, the motor is started automatically. All but 5 ml of the spin fluid is removed for measurement of the undersized fraction of the dispersed powder.

The development of detector systems must consider the action on a transmitted light beam. Light-scattering theory dictates that when light of intensity I_0 attempts to pass through a dilute suspension (i.e., no multiple scattering) of particles, it is lost or extinguished to an extent that I_t makes it through. Mathematically [42,43], the transmitted light is given by

$$I_t = I_0 \exp(-\alpha_{ext} L) \tag{6}$$

where L is the length through the suspension, and α_{ext} is the attenuation coefficient (turbidity). The value of α_{ext} is related to the number concentration of particles, N per unit volume, by

$$\alpha_{ext} = NC_{ext} \tag{7}$$

where C_{ext} is the extinction cross section of the particles. The extinction efficiency of a particle of cross-sectional Area A is conveniently expressed as

$$A = C_{ext}/Q_{ext} \tag{8}$$

This yields the relationship

$$\alpha_{ext} = N\pi d^2 Q_{ext}/4 \tag{9}$$

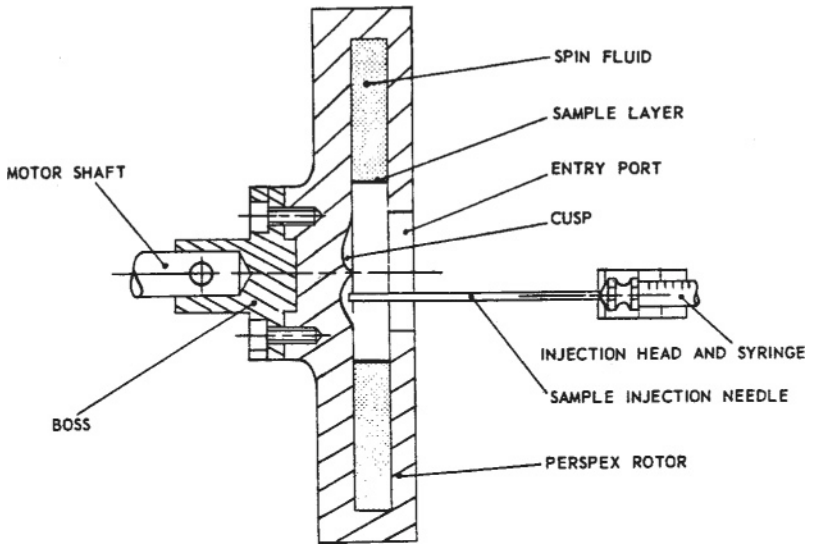

Fig. 9—Diagram illustrating the principle of the disk centrifuge. (Courtesy of Joyce, Loebl & Company, Ltd.)

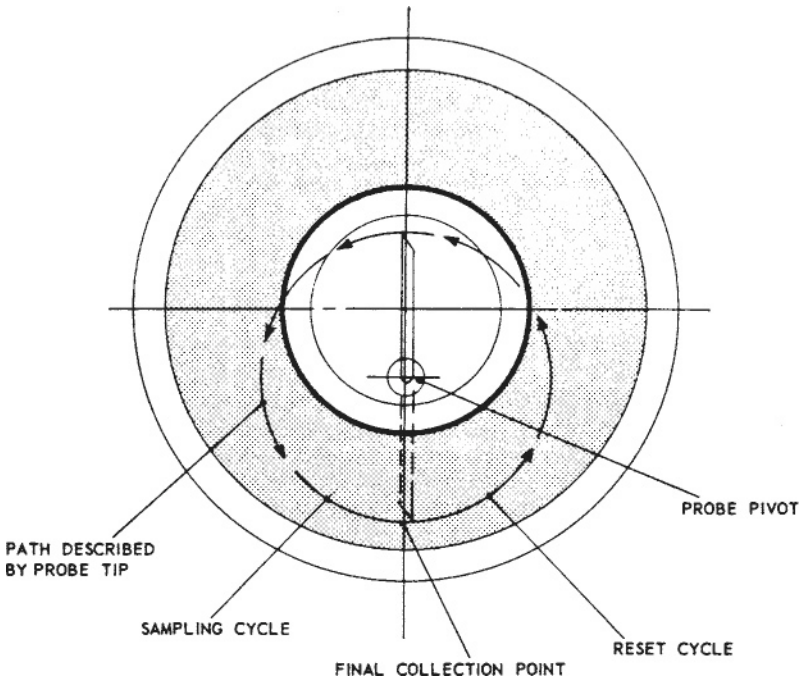

Fig. 10—Relationship of disk and probe of disk centrifuge sampling. (Courtesy of Joyce Loebl & Company, Ltd.)

Photo extinction detectors on modern turbidity instruments essentially determine α_{ext}. The internal calculation of Q_{ext} requires knowledge of the particle refractive index, size, shape, orientation, state of polarization, and wavelength of the scattered light as well as the refractive index of the suspending liquid. Using Mie theory [44,45], size may be deduced. Oppenheimer [45] has pointed out that a source of potential error is that the refractive index of the suspending liquid and particles must be known for each wavelength.

Rotating Cell Holder Centrifuge. Real time monitoring is provided on some instruments and is advantageous when irregular measurements force an abort. One such instrument can perform centrifugal as well as gravity analysis using the same on-board computers. With ten different rotor speeds switchable from 300 to 10,000 rpm, an accelerating potential of up to 9000 *g* is available. Particles as small as 0.01 μm are reported to be measurable.

The instrument uses two small, transparent rectangular cells (Fig. 11) mounted opposite each other on the balanced rotor. While they counterbalance each other, one serves as a reference for the suspension liquid, and the other holds the particle suspension system under analysis. Three photocells in the top monitor three opposite light-emitting diodes (LED) on the back side of the rotor. This allows real-time monitoring of the reference cell, the sample cell, and the rotor speed (Fig. 12). Data are displayed in real time on a built-in computer monitor as well as printed out on tape after the analysis for a permanent record. Graphs are presented indicating the absorbance versus time, frequency distribution, and cumulative distribution (either percent undersize or percent oversize).

Particle Size from Surface Area Employing Both Gasses and Liquids

It is often useful to use the approximation of size from surfaces to evaluate other parameters derivable from the volume function, such as specific surface area and density. The basic equations that describe a sphere's surface area and volume are given by

$$\text{Area of a sphere} = \pi D^2 \tag{10}$$

$$\text{Volume of a sphere} = \pi D^3/6 \tag{11}$$

These relationships allow determination of the mean particle diameter if the specific surface (area) is known. Particle-size characterizations that employ surface area techniques in the size determination yield average diameters. The surface area of a powder may be determined from gas adsorption experiments. By assuming uniform-size non-porous and spherical particles, the mean particle size may be determined from the surface area data. The "specific surface" obtained equals the determined surface area divided by the product of the particle volume and density. With appropriate units conversion

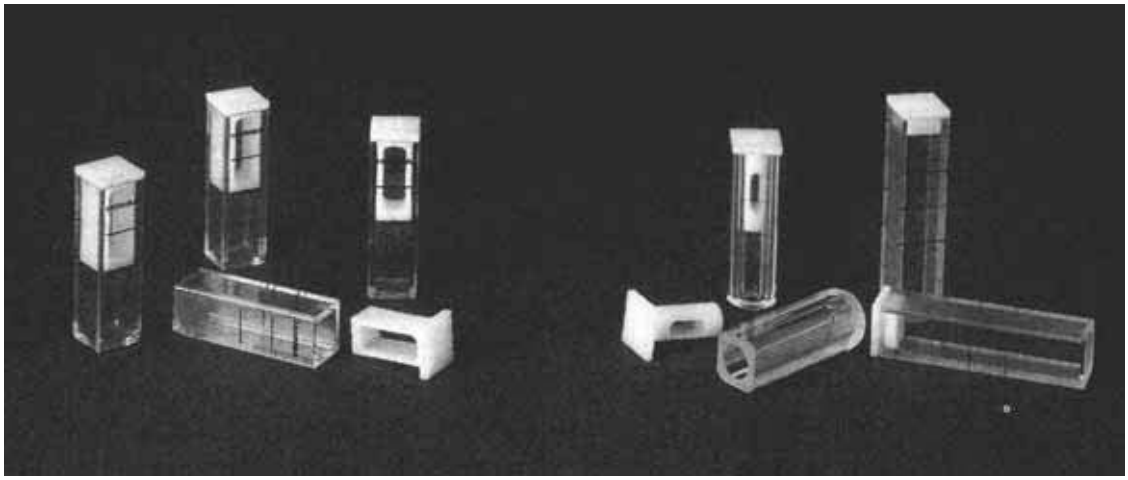
$$D = 6/[\rho A] \tag{12}$$

where:

D = particle diameter, μm,
ρ = particle density, g/cm^3, and
A = specific surface area, m^2/g.

Any shape other than a sphere, either regular or irregular, has a greater ratio of surface to volume, and consequently the particles will be smaller than calculated. Cracks, crevices, and pores are other factors leading to an increase in specific surface area and to a corresponding decrease in calculated particle size.

Perfectly spherical particles are seldom encountered in mineral pigments and fillers used in paint and coating applications since these particles result from shattering by crushers and high-speed pulverizers. Crystalline materials fracture along crystal planes, while some pigments are acicular (like needles). With the many shapes



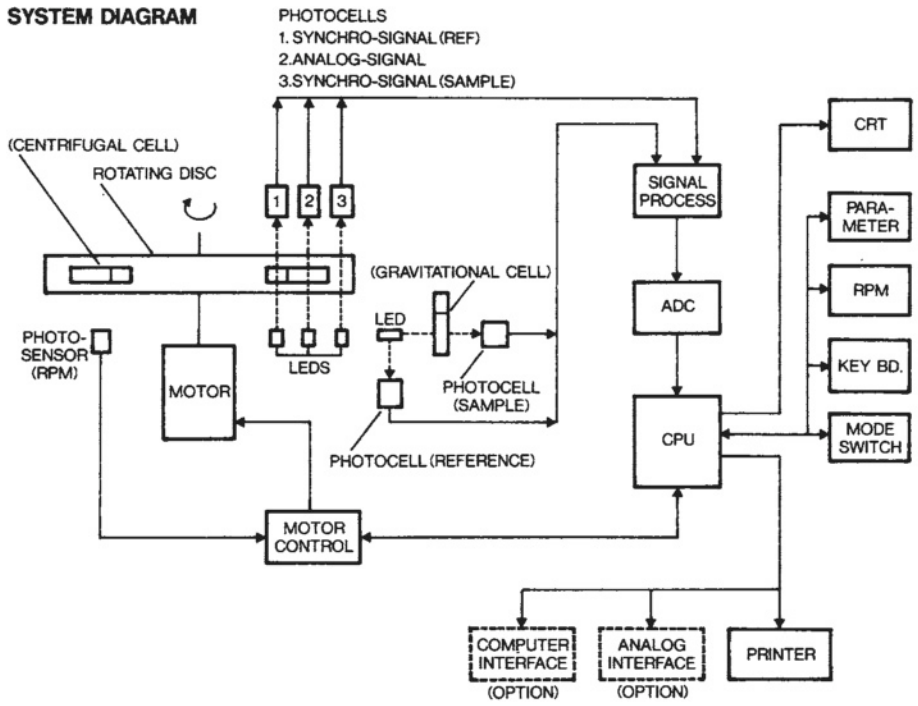


Fig. 11—Reference cells used in a centrifuge. (Courtesy of Horiba Instruments, Inc.). www.horiba.com/us/en/scientific/products/particle-characterization/particle-size-analysis/.

of particles to be evaluated and characterized, instruments that operate on different principles "see" different values of the size-dependent variable being monitored. As a result, a sample characterized by one machine may yield a somewhat different value when evaluated using a different technique. For this reason, the practitioner must be aware of the size-dependent variable to which his machine is sensitive.

The CAPA-700 system is comprised of an optical system, a centrifuge, computation circuitry and input/output functions. The rotating disc in the horizontally mounted centrifuge is connected directly to the motor to minimize gravitational effects, and electronic control keeps the rotational speed stable at the set value. The CPU monitors and controls automatic checking for fluctuations in rotational speed, computation formulae and deterioration of the light source and detector, assuring precision data at all times. In the optical system, a reference cell guarantees both optical and mechanical balance for each revolution, which, after CPU processing, gives even higher precision particle size distribution analysis.

Fig. 12—A modern instrument for determining particle size in real time.

Methods [46] for determining specific surface include adsorption of gases by the pigment, adsorption of solutes from solutions by the pigment, and permeability of pressed pigment particles to gases or liquids.

Adsorption of Gases

This method is based on determining the number of gas molecules that will adsorb as a monomolecular layer on the surface of the particles. Knowing the area occupied by one molecule and the number of molecules, the specific surface area of a specimen of pigment may be calculated from

$$\Sigma = nNA \tag{13}$$

where:

Σ = specific surface area in cm^2,
n = number of moles of gas per gram of pigment,
N = Avogadro's number, 6.02×10^{23}, and
A = area covered by each molecule.

Knowing the specific surface, the surface mean diameter may be calculated.

Brunauer-Emmett-Teller (BET) Method. The general procedure for this method [47,48] includes introducing the specimen into an enclosed space of known volume followed by degassing with heat and evacuation. A known amount of gas is admitted to the system, and its pressure is determined. The gas is then compressed to a new volume, and the corresponding pressure is determined. The procedure is repeated until enough data for the preparation are obtained. By means of the BET equations, the surface area is found, and from it the average particle size may be calculated.

Continuous Flow Method. This method makes use of the BET equation, but the adsorbed gas is determined by concentration measurements in a continuous flow system [49]. Nitrogen gas is adsorbed by the specimen at liquid nitrogen temperature from a stream of nitrogen and helium gas and is later eluted by warming the specimen. The amount of nitrogen liberated is estimated by thermal conductivity. For detecting changes in the amount of adsorbed nitrogen, Beresford et al. [50] used the Perkin-Elmer-Shell sorptometer with conductivity bridge and potentiometric recorder.

Gravimetric Method. In addition to the volumetric methods, a gravimetric method using balances patterned after that of McBain and Bahr [51] can be used. The procedure is much simpler but requires care as the apparatus is very fragile and the changes in weight are very small.

An essential part (Fig. 13) of the gravimetric method is a fused silica spring balance from which a small glass "bucket" for the specimen is hung. The balance assembly is located in a glass housing connected to a source of gas and to a manometer for determining the pressure. The bucket is hung on the balance, the housing is closed, and the specimen is degassed by evacuation. The zero point of the balance is recorded. Gas is admitted to the housing, and the change in weight of the specimen is determined by noting the change in the elongation of the balance with a traveling microscope. Details are set forth in Ref. 17.

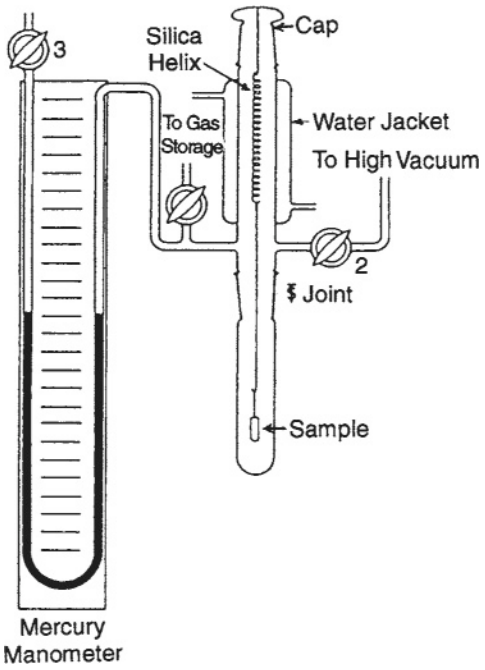

Fig. 13—The components of a basic gravimetric adsorption apparatus.

ADSORPTION OF NONGASEOUS MOLECULES

Adsorption of molecular species other than typical gaseous molecules is possible also. These include the adsorption of solvents and surfactants in special cases.

Adsorption of Solutes onto Pigments. This method depends on the adsorption of solute molecules onto a particle when it is wet out by a solution containing the dissolved surface active solute [52]. The process requires that the adsorbent be thermodynamically more active than the solvent and the kinetics be such that wet-out times be reasonable. Typical systems used are stearic acid in benzene, dyes in benzene, and wetting agents in water. The amount adsorbed will asymptotically approach a constant value with time. At this value it is assumed that the surface of the particles is covered with a mono-molecular layer of solute. The area occupied by a single molecule of solute may be obtained from tests made with solids of known areas. The amount adsorbed is obtained by analysis of the solution before and after adsorption.

A disadvantage of the method is uncertainty about the size and orientation of certain types of molecules. On the other hand, the method is rapid and easy to perform. For this reason it is suited to routine tests where its reliability has been established.

Soap Titration of Emulsion Particles. Maron et al. [53] determined surface area and particle size of a synthetic latex by titrating with a soap until the critical micelle concentration of the soap in the solution was attained. From the effective molecular surface area of the adsorbed soap and the amount adsorbed, surface area and particle size are calculated. The method is calibrated with electron micrographs. Brodnyan and Brown [54] also studied the technique.

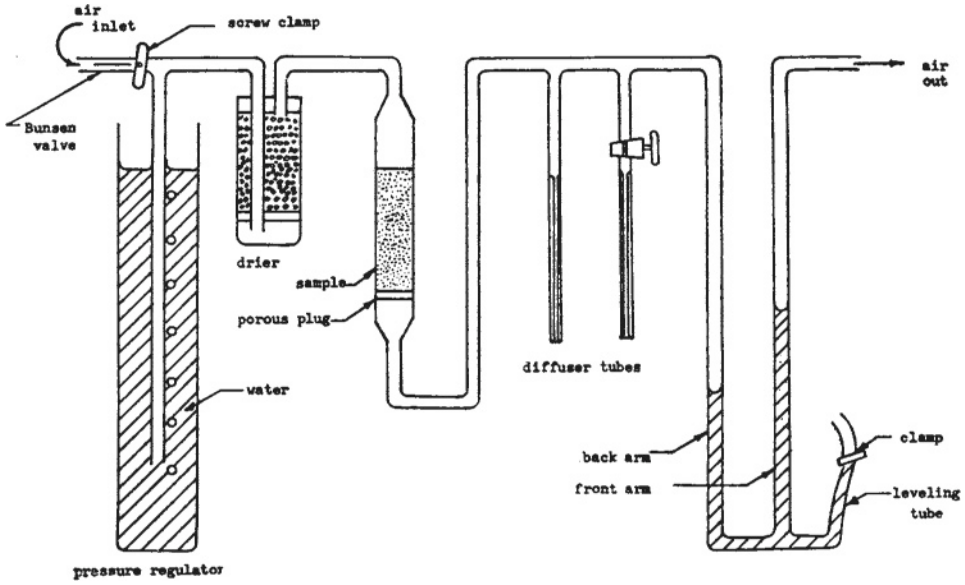

Fig. 14—Gooden-Smith apparatus for surface area. (Courtesy of *Official Digest.*)

Permeation Through Packed Powders

In this method, a gas, usually air, is forced through a compacted bed of the pigment. The rate of flow is a function of voids (pore space), pressure drop through the bed, specific surface of the pigment, and viscosity of the gas. Knowledge of all the other factors allows calculation of the specific surface area and, from it, the mean surface diameter. The method is fairly simple and is suitable for routine determinations of spherical or near-spherical particles.

Gooden-Smith Method. Using air as the gas, Gooden and Smith [55] designed a permeation method with two special features: (1) the weight of specimen used in grams is numerically equal to its density and (2) every specimen is packed to the same volume (Fig. 14). Together with a graphic calculator, these features greatly simplify the test and make it attractive for routine testing or research in the particle-size range 0.2 to 50 μm.

Hutto-Davis Method. The principal differences between this and the preceding method are: (1) the weight of the powder used to make the compacted pellet is calculated to give a definite porosity, and (2) the volume of air is kept constant for all plugs.

Hutto and Davis [56] modified the apparatus of Carman and Malherbe [57] by providing an improved manometer, better control of the volume of air, and an improved press for preparing the specimen. They also designed a nomograph for calculating specific surface and surface area. The apparatus consists of: (1) a U-tube with legs of unequal length and closed at each end with a sintered glass disk, (2) a manometer, (3) a capillary specimen tube, and (4) a leveling bulb containing mercury.

To provide the constant volume of air, the U-tube is inverted and filled through the stopcock at the bend. Then, with a capillary eyedropper, a weight of mercury equivalent to 1 ml is removed, leaving an equal volume of air after which the stopcock is closed and sealed. The mercury does not pass through the sintered glass disk at the pressure used in the test. To make a test, a plug of pigment is formed inside the specimen tube using the special press. The weight of the specimen is a function of its density and the desired porosity of the plug (usually about 0.5). With the leveling bulb in the lower position, the specimen tube is attached to the side arm of the apparatus, and a vacuum is applied by opening the stopcock at the upper right-hand corner. The vacuum is adjusted, and simultaneously the stopcock is closed, timing is started, and the leveling bulb is raised to its upper position, which forces the 1 ml of air into the system. The timing is stopped when the manometer returns to zero. The stopcock is then opened, and the bulb is returned to its lower position for another run.

Individual Particle Sensing by Light Blocking and Electrical Resistance

In this technology, individual particles are separated from each other by a diluted suspension in either air (by fluidization followed by entrainment in a flowing stream) or a constantly stirred conductive solution. The particles are then forced to pass through the sensing zone. In one air-fluidized instrument, the time of flight between two precisely placed laser light sources and detectors is used to calculate size. In another, the attenuated light as detected by a photodiode is used to calculate a size. In the liquid suspension instrument, a change in the established electrical resistivity through an electrolyte circuit is measured as a particle passes through a small orifice.

TIME OF FLIGHT FROM LIGHT BLOCKAGE

An instrument based on aerodynamic time-of-flight (TOF) technology was developed by Dahneke [58]. The measurement range is reported to be from 0.2 to 200 μm, with 150 channels per decade and a count rate of up to 100,000 particles per second. Output may be reported in either geometric or aerodynamic diameter. In this instrument, a gas (usually air for pigment particles) is used to break down agglomerate material and entrain them in a controlled flow; a specially designed "pulse-jet dispenser" is used where a

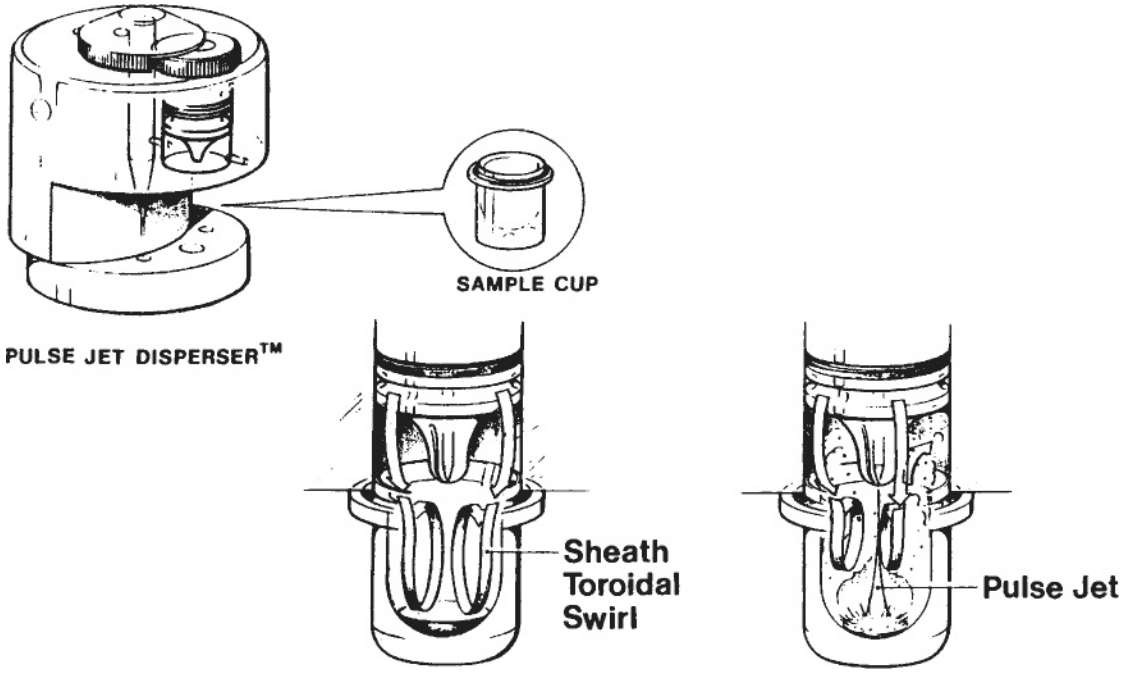

Fig. 15—A diagram of the operation of the dry-powder pulse jet disperser. (Courtesy of Amherst Process Instruments, Inc.)

controlled flow of air is directed down onto a sample placed into a small cup (Fig. 15). Depending on the nature of the sample, the operator sets the computer values for particle count rate, flow pressure, and pulse pressure. The disperser flow pressure controlling the carrier gas usually remains constant. The disperser pulse pressure determines the number of particles fed through the analyzer.

Measurements are made over 2 s intervals to ensure that the minimum count rate is met. Should the count rate fall below the predetermined count rate, the pressure is increased. Should the count rate exceed the maximum allowed, the pressure is dropped by a factor of 2, thus maintaining the number of counts between the allowed maximum and minimum.

The particles are deaggregated to primary size and fed into the injection tube of the sonic nozzle suspended as single particles in the air stream moving at about 6 L per minute. There is no operator involvement during the 1 to 5 min determination. Two laser beams set at a discrete distance apart and directed onto two photomultipliers make up the "sensing zone" (Fig. 16). As the particle passes through the set of laser beams, light that is attenuated and scattered is monitored by the detectors. Signal analysis using cross-correlation techniques give the particle's TOF with a resolution of 25 ns. The technique is reported to be able to discriminate between particles with only a 10 % size difference. Attachments to the instrument also allow the investigation of sprayed aerosol droplets as well.

ELECTRICAL RESISTANCE

According to the Coulter principle [59,60], when a particle suspended in an electrically conductive liquid enters a constricted path between electrodes, it changes the pathway electrical resistance between the electrodes. This change produces a fluctuation in the applied voltage that, under proper conditions, is inversely proportional to the volume of the particle. When the dispersion is made to pass through a hole small enough to pass the particles one by one, the resultant series of voltage fluctuations may be electronically amplified, scaled, and counted [61].

A functional diagram is shown in Fig. 17. The beaker and tube contain the suspension. When the stopcock is opened, a controlled vacuum starts flow of the suspension from the beaker into the tube and also unbalances the mercury in the manometer. The stopcock is then closed, and the mercury siphon continues the flow of the suspension. Electrical contacts in the manometer start and stop the counting of the particles. The volume of the manometer tube between the contacts determines the volume of the

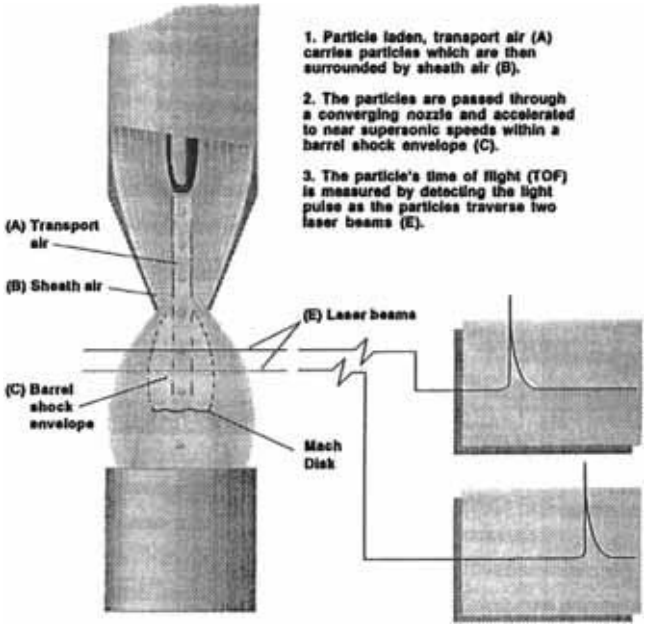

Fig. 16—Schematic of the aerosol beam generator and detection mechanism. (Courtesy of Amherst Process Instruments, Inc.)

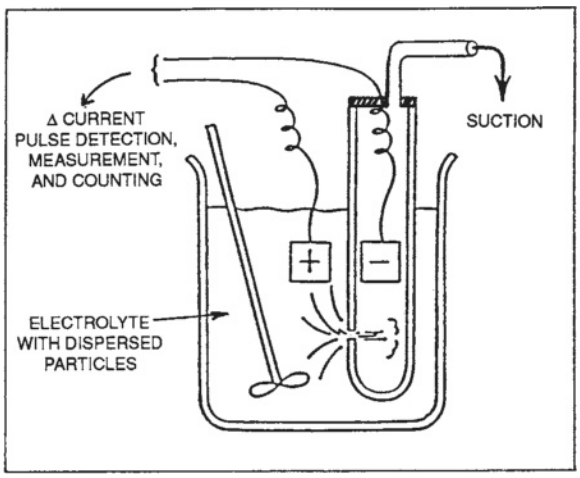

Fig. 17—The Coulter principle: A fluctuation in current flow occurs when a particle partially blocks the small opening between the electrodes. The size of the particle is related to the amount of change in current flow.

specimen. This ranges from 0.02 to 5 ml. A fresh volume is drawn for each count. A typical count requires from 3 to 30 s, depending on the size of the hole and the volume between the contacts in the manometer. The Coulter counter was found to be useful by Princen et al. [62] for particle-size determination of emulsified oil systems.

The principle utilized to determine individual particle size is the electrical resistance of the particle as it is forced to pass through a small hole in a glass envelope through which an electrical potential exists.

Direct Microscopic Measurement Using Visual Light Microscopes and Electron Microscopes

Microscopes, both optical and electron as well as automated image analyzers, are used to measure particle size directly. Optical techniques suffer somewhat from an inability to focus on the "edge" of a particle at very high magnifications due to a depth of field problem. The lower limit is set by its resolving power and the upper limit by its depth of focus. The microscope is especially useful for measurement of plate-like and needle-shape particles that do not obey Stokes' law, on which the sedimentation methods are based. Disadvantages of the method are that it is slow and laborious. Hence, it is used chiefly for the calibration of the more rapid relative methods. ASTM Practice for Particle-Size Analysis of Particulate Substances in the Range of 0.2 to 75 μm by Optical Microscopy (E20) and a paper by Loveland [63] are good references. Dark field illumination can use the detecting power of the microscope rather than the resolving power for sizes below the resolving power of the optical microscope.

Green [64] was the first investigator to systematize the use of the microscope for direct measurement. He dispersed the pigment in a medium on a microscope slide, photographed the dispersion at a known magnification, and projected the image on a screen to increase the magnification for measurement. Dunn [65] bypassed the photomicrograph by projecting the image of the particles directly from the slide on the screen.

Ideally, the pigment should be dispersed in the medium in which it is used, but this is rarely done. Green used turpentine, Allen [66] recommended a viscous vehicle, and Eide [67] used fused resins. Gehman and Morris [68] milled the pigment in rubber, dissolved the mix in a solvent, and applied the suspension to the slide.

Microscopes equipped with view-through linear scales, circles or ellipses in graduated sizes, may be used as a direct measurement method [69]. The comparison scale may be a micrometer eyepiece, an eyepiece reticule, or a scale engraved on the microscope side.

The use of the electron microscope for particle characterization is now a routine practice. The resolving power is many times that of the light microscope and may be used in scanning as well as transmission mode. With state-of-the-art surface analysis tools such as energy dispersive x-ray (EDX) built into the scanning electron microscope (SEM) equipment, elemental analysis of a single-pigment particle within the coating matrix can be done conveniently while the coating sample is in the instrument.

ARRAY METHOD USING OPTICAL MICROSCOPE

The array method of particle sizing lends itself to systems of monodispersed spheres, as in Fig. 18 (from Duke [69]). These are highly uniform with respect to diameter. When placed on a flat plate, the spheres tend to align themselves into hexagonal arrays. These are characterized by straight rows of the particles. Because of this, the rows can be measured, and the diameter of the particles may be derived by dividing by the number in the row.

TRANSMISSION ELECTRON MICROSCOPY

Transmission electron microscopy (TEM) is useful for the measurement of latex microspheres of 200 nm and larger [70,71]. The procedure usually utilizes the magnification factor of the microscope in the size determination from photomicrographs. Because this factor is not always dependable, photographs are sometimes made against a replica diffraction grating of known spacing. Fig. 19 shows 100-nm latex microspheres on a 2160-line/mm grating. Sources of error include uncertainty in the accuracy of the line spacing, the roughness of the lines, and the line thickness relative to the size of the particles. Duke [72] has used an internal standard of NIST traceable materials, as shown in Fig. 20, and reports accurate sizing to as small as 50 nm.

Chromatography: Angstrom Particle Sizing

The separation of angstrom-sized particles may be affected by the use of hydrodynamic chromatography. In this

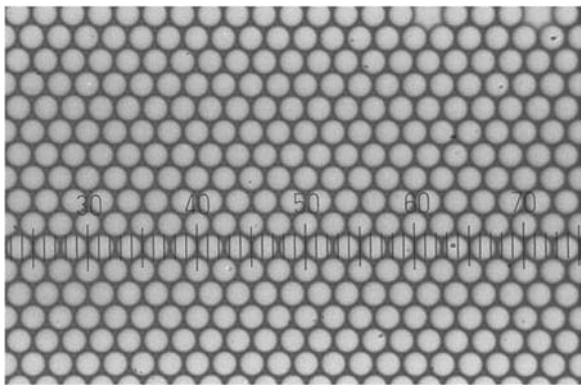

Fig. 18—Microphotograph of 10 micron particles in array. (Photo compliments of Thermo Fisher Scientific Inc.)

technique, the mixture of very small particles is allowed to transgress a long capillary tube in which the liquid medium is flowing in laminar flow. It is well known that fluids, both gasses and liquids, will experience a pressure drop as a function of distance traveled and of the diameter of the tubing that occurs because the fluid in actual contact with the wall of the tube does not flow and is stationary. For noncompressible fluids (i.e., liquids), this variation in flow velocity from wall to center of tube may be used to separate particles of differing size.

For laminar flow, the velocity of flow through the cross section of the tube increases from the wall to the center, essentially in concentric "layers" [73]. This may be represented by the vectorial diagram in Fig. 21 of the flow velocity profile. The actual velocity of flow of one of the "concentric circular layers" will be a function of its distance from the wall of the tube. The flow velocity gradient is given by

$$V_r = \frac{(P_0 - P_L)R^2}{4\eta L}[1-(r/R)^2] \tag{14}$$

where:

V_r = liquid velocity at radius, r,
$(P_0 - P_L)$ = pressure drop for the distance, L,

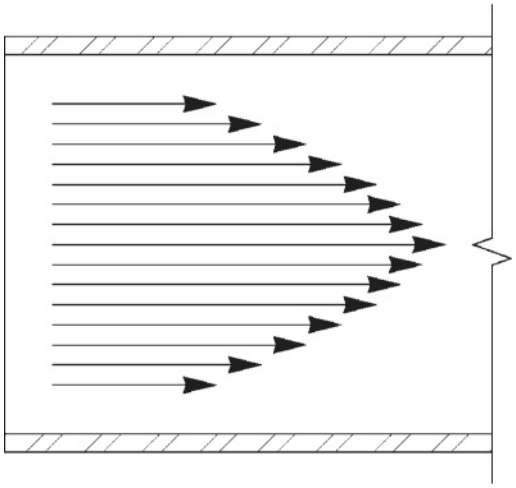

Fig. 21—Vectorial representation of the velocity of a fluid (gasses and liquids) in laminar flow. The velocity at the wall of a pipe is zero and a maximum at the center in the absence of turbulent flow. The rate of increase in velocity toward the center is a function of the fluid viscosity in the absence of turbulent flow. (Drawing compliments of George Mills, Jr. Building Design Solutions, LLC.)

R = inside radius of capillary,
R = effective radius of liquid at V_r,
η = viscosity of fluid in flow, and
L = length of capillary.

Because the larger particles tend to have statistically more volume in the fluid away from the wall, the larger particles are under a greater influence of the faster-moving fluid away from the wall more so than the smaller particles, which can physically fit in the slower-moving layer nearer the wall. Thus, the larger particles advance faster than the smaller ones affecting the separation.

Light Attenuation and Scattering Techniques

Spectrophotometric Techniques. Gamble and Barnett [74] developed a method for measuring particle-size distribution by the scattering of light in the near infrared. The pigment is dispersed in low concentration and placed in a transmission cell for spectrophotometric measurement. From the shape of the spectrophotometric curve, the relative size and size distribution characteristics of an unknown pigment are obtained in terms of calibrated samples (Fig. 22).

Bailey [75] also developed a spectral transmission method using infrared wavelengths from 0.4 to 2 μm. The spectrophotometric curve was related to size by graphic comparison with specimens of known sizes.

Atherton and Peters [76] measured light scattering by polydispersed system of spherical particles. The size distribution curves for the materials compared favorably with direct measurement with the electron microscope.

Leobel [77] used a spectrophotometer to obtain the effect of wavelength on turbidity in the determination of the size of latex particles. The sizes of particles used for calibration were determined from electron micrographs.

LIGHT-SCATTERING TECHNIQUES

When solid particles pass through a light beam, the light will interact with the particles in one or more ways. It can

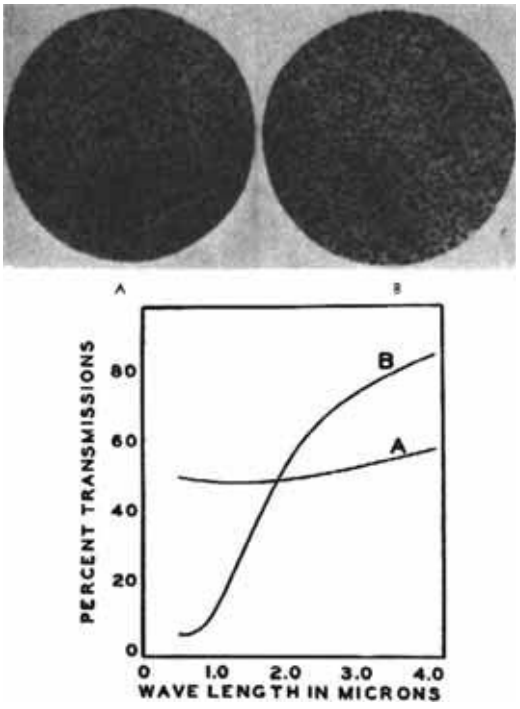

Fig. 22—Particle size may be determined from the scattering of radiation in the near infrared region of the spectrum.

either be reflected, refracted, diffracted, or adsorbed and reradiated. This is shown schematically in Fig. 23. The scattered radiation will present a pattern that is dependent on the shape and size distribution of the particles. By evaluating the scattered radiation detected at different locations relative to the beam direction and in different positions, much can be learned about the scattering media. Fig. 24 depicts some of the angular intensities of scattered light produced by particles of various sizes. With low-cost computers and stable detectors, instruments have been developed that can monitor this scattered radiation, giving fast and reliable data.

Angular-dependence techniques, which include detection and manipulation of signals from front (reflection) as well as side and rear (diffraction), have been integrated into a single instrument. Angular-dependence, light-scattering techniques have been widely studied for information concerning the sizes of both pigmentary and nonpigmentary particles. In the latter class, polymeric organic materials from molecular to latex sizes have been included. Debye and Bueche [78] described how to characterize the optical inhomogeneities related to size from information concerning the way a system scatters light.

Angular-dependence techniques include the work of Brice et al. [79], who designed a photoelectric photometer for measurement of molecular weight by applying the Debye theory.

Aughey and Baum [80] note that particles in the size range of large molecules produce variations in the intensity of light scattered at large angles to the illuminating beam. Progressively larger particles produce significant variation in the light scattered at small angles. The light source is a well-defined monochromatic beam. The cell containing the dispersion is stationary, and the photoelectric tube travels around the cell in an arc that covered a useful range from 0.05° to 140°. Scattered light reaches the tube

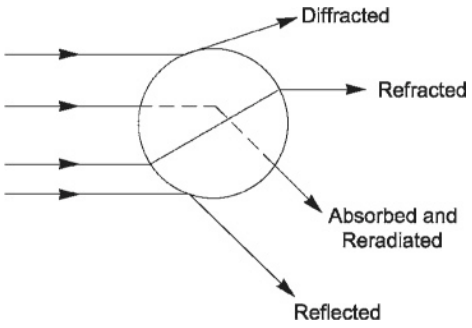

Fig. 23—Possible interactions when light strikes a particle. (Drawing compliments of George Mills, Jr. Building DesignSolutions, LLC.)

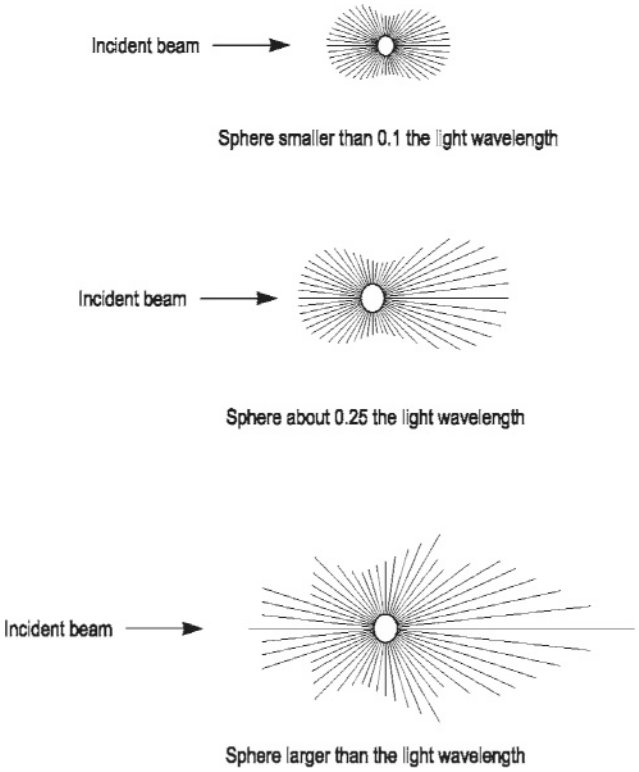
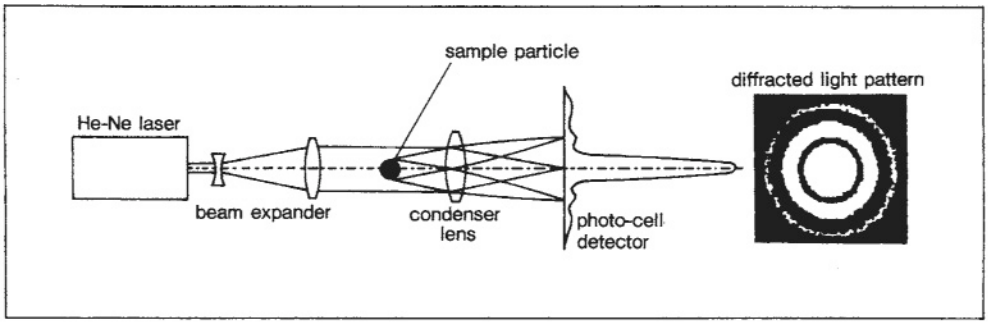
through a small aperture in the housing for the tube. The radii of the optical inhomogeneities range from 0.1 to 100 μm. Modern diode array detectors are now available to do similar tasks without the movement.

Diffraction of Laser Light. Instruments using diffraction of single-wave-length laser light have been made possible by the development of low-cost, highly stable lasers and diode array detector technology. By fluidizing the particles in a stream of air, they are directed through a cell being illuminated by a laser source. The He–Ne laser, emitting a coherent beam of 632.8 nm wavelength, is often used. To increase the cross-sectional area of the beam, expanders are often employed (Fig. 25).

The diffraction pattern that is seen by the detector is a pattern of rings varying in darkness depending on the size distribution of the passing particles. On-board computers use both the Fraunhofer diffraction and Mie scattering theories to calculate the particle-size distribution





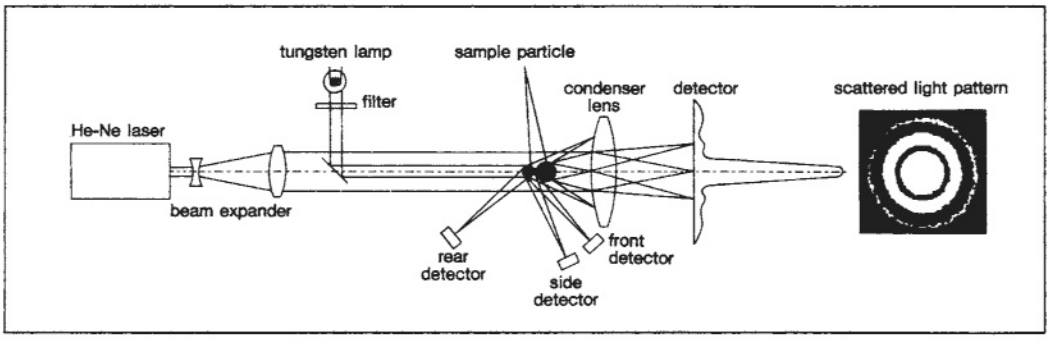


Fig. 24—Angular intensity of scattered light after striking a particle. (Drawing compliments of George Mills, Jr. Building Design Solutions, LLC.)

Principle of Operation

The He-Ne laser emits a beam of 632.8 nm whose flux is enlarged by a beam expander and radiated upon the particles suspended in the liquid. After it has been diffracted and dispersed by the particles, the laser beam passes through the condenser lens and its image is formed at the photo-cell detector located at the focal point of the lens.

The diffraction pattern that appears at the detector is a pattern of light and dark concentric rings that corresponds to the particle size distribution of the sample. Now, using both of the Fraunhofer diffraction and Mie scattering theories, the intensity values are used to calculate the particle size distribution of the sample.

Here is how the LA-900 works.

Light irradiating the particles is scattered at various angles. If the particles are comparatively large, this scattering tends to be concentrated in a forward direction. As the size of the particles decreases, the light is scattered in all directions. Therefore, to measure larger particles, data from a small angle of scatter is required; to measure smaller particles, a larger angle of scatter is required.

On the LA-900, to measure the distribution of low angle scattered light, a condenser lens is used with an array detector at the focal point of the lens. To measure large angle scattered light, detectors are used at the front and rear of the sample chamber. From angular measurement of the scattered light by all of these detectors, the particle distribution is calculated from Mie theory.

It is also true that as the wavelength of the light becomes shorter, so does the measurement size of the particles. Therefore the LA-900 uses a He-Ne laser beam and a red light beam and a blue light beam obtained by filtering a tungsten lamp to expand the measurable range.

Fig. 25—Schematic layout for the large-particle system. (Courtesy of Horbia Instruments, Inc.)

of the sample. These methods allow the determination of size distribution based on the intensity distribution of the diffracted laser beam. Since the intensity pattern is a function of the actual particle size, mixtures of particles having different densities may be measured together, unlike those relying on Stokes' law. The instrument is reported to address 0.1 to 200 μm particles.

Total Light Scattering. Instruments capable of monitoring light from all sides can effectively measure particles even smaller than the usual limit of 0.1 μm. This limit is imposed because of the physics relating the wavelength of the incident radiation and the interacting particles. By taking advantage of a set of detectors located strategically around the scattering cell, data relating to even very small particles less than 0.1 μm are determined. As the size of the particle decreases, the intensity of the scattered light obscures critical differences in the angular distribution. In practice, this difficulty in treatment of data leads to the so-called laser-diffraction measurement barrier.

Since there is an increase in both the side and rear scattering with very small particles, it is possible to take advantage of the phenomenon. Fig. 26 is an instrument diagram with an arrangement of detectors that allow a single instrument to measure a broad range of sizes. Light irradiating the particles is scattered at various angles. For relatively large particles, light is scattered in the forward direction, while, for smaller particles, the light tends to be scattered in all directions. By arranging a lens system and manipulating data from the detectors, the particle-size distribution is calculated from the Mie theory. Since the size of the particles measured is a function of the wavelength of the impinging radiation, the instrument uses a beam of filtered blue light to expand the range.

X-RAY SCATTERING

The Debye-Scherrer small angle x-ray scattering technique for observing interference effects related to particle size is well known [81]. Some generalizations on the use of the technique were addressed by Debye [82].

Yudowitch [83] and Danielson et al. [84] both employed the "diffraction peak" procedure for the determination of latex particle size. For control they used a latex whose size had been determined under the electron microscope.

Particles that are perfect spheres can be described by a single value representing the sphere's diameter. Calibrated microscopes are useful in reading such values directly from the reticule. They have some utility with spherical resin particles and with visual measurement of standardized test materials. Classification of most powders, on the other hand, must address particles of various shapes and sizes together as a collection.

A particle-size determination utilizes some size-dependent property that can be measured and then relates

TABLE 2—Definitions of particle size

Symbol	Name	Definition	Formula
d_v	Volume diameter	Diameter of a sphere having the same volume as the particle	$V = \frac{\pi}{6} d_v^3$
d_s	Surface diameter	Diameter of a sphere having the same surface as the particle	$S = \pi d_s^2$
d_sV	Surface volume diameter	Diameter of a sphere having the same external surface-to-volume ratio as a sphere	$d_{sv} = \frac{d_v^3}{d_s^2}$
d_d	Drag diameter	Diameter of a sphere having the same resistance to motion as the particle in a fluid of the same viscosity and at the same velocity (d_d approximates to d_s when Re is small)	$F_D = C_D A_{pf} \frac{V^2}{2}$ where $C_0A = f(d_d)$ $F_d = 3\pi d_d \eta v$ $Re < 0.2$
d_f	Free-falling diameter	Diameter of a sphere having the same density and the same free-falling speed as the the particle in a fluid of the same density and viscosity	
dst	Stokes' diameter	The free-falling diameter of a particle in the laminar flow region (Re <0.2)	$d_{st}^2 = \frac{d_v^3}{d_d}$
d_a	Projected area diameter	Diameter of a circle having the same area as the particle resting in a stable position	$A = \frac{\pi}{4} d_a^2$
d_P	Projected area diameter	Diameter of a circle having the same area as the projected area of the particle in random orientation	Mean value for all possible orientations $d_P = d_s$ for convex particles
d_c	Perimeter diameter	Diameter of a circle having the same perimeter as the projected outline of the particle	
d_A	Sieve diameter	The width of the minimum square aperture through which the particle will pass	
d_F	Ferer's diameter	The mean value of the distance between pairs of parallel tangents to the projected outline of the particle	
d_M	Martin's diameter	The mean chord length of the projected outline of the particle	
d_R	Unrolled diameter	The mean chord length through the center of gravity of the particle	$E(d_R) = \frac{1}{\pi} \int_0^{2\pi} d_R d\theta_R$

this property to a linear dimension. The measurement derives either from individual particles or as a property of the collection of particles that is often expressed as a diameter of sorts. Measurement of a single individual particle may have its size expressed in different "diameters" depending on the direction and method of view. Particle characterization may involve determining the rate of a particle's travel through a fluid (either under the influence of gravity or while being subjected to angular acceleration due to rotation), its actual surface area, its ability to pass through a screen of square or round holes of differing size, or its ability to scatter light of various wavelengths in various directions. For the new technology employing ultrasonics, the interference of sound transmission through a liquid is used to correlate a size distribution.

It is convenient to use the term "equivalent diameters" when comparing sizes. The value so determined for a given collection of irregular particles will vary somewhat depending on the technique used (i.e., the size-dependent variable being measured). The definition of some of these "diameters" is presented in Table 2 along with their mathematical representation. Table 3 lists some of the methods, the nominal particle-size range, and the size measured. The methods available for determining particle size take advantage of many different characteristics of the powder particle.

Definitions of Particle Size and Shape

Particle shapes are everything but spherical for pigments and fillers that are produced, essentially, by crushing and shattering. As the sizes get smaller, the actual particle shape plays an increasingly important role in its use in a coating as well as on the physical laws employed for its characterization. From the diagram in Fig. 5, the same particle may be defined in a number of ways [85]. Some of these include the following:

Martin's Diameter. The distance between opposite sides of a particle measured on a line bisecting the projected area. To ensure statistical significance, all measurements are made in the same direction regardless of particle orientation.

Feret's Diameter. The distance between parallel tangents on opposite sides of the particle profile. Again, to ensure statistical significance, all measurements are made in the same direction regardless of particle orientation. Note:

TABLE 3—Comparison of particle-sizing methods

	Nominal Range, μm	Size Determined
Gas Permeability	**0.1–40**	**Mean**
Gas Adsorption	**0.005–50**	**Mean**
Brownian Motion	**0.01–3**	**Mean**
Sieving		
Dry	>10	Passing through
Wet	2–74	minimum opening
Microscope		
Optical	0.5–500	Martin's, Feret's, or equivalent circle diameter
Electron	0.002–15	
Zone sensing		
Resistivity	0.05–500	Volume or area
Optical	1–500	
Elutriation		
Laminar flow	3–75	Equivalent spherical diameter (E.S.D.)
Cyclone	8–50	
Centrifugal classification	0.5–50	E.S.D.
Mercury intrusion	0.01–200	E.S.D.
Centrifugal sedimentation		E.S.D.
Mass accumulation	0.05–25	
Photo extinction	0.5–100	
X-ray	0.01–5	
Gravity sedimentation		E.S.D.
Pipettes and hydrometers	1–100	
Photo extinction	0.05–100	
X-ray	0.1–60	
Hydrodynamic chromatography		
Packed column	0.03–2	E.S.D.
Capillary column	0.1–60	
Cascade impactor	0.05–30	Aerodynamic diameter

Both Martin's and Feret's diameters are generally used for particle-size analysis by optical and electron microscopy.

Equivalent Circle Diameter. The diameter of the circle having an area equal to the projected area of the particle in random orientation. This diameter is usually determined subjectively and measured by ocular micrometers called graticules.

Equivalent Spherical Diameter (E.S.D.). This often affords a more useful measure, particularly where industrial processing is involved. This diameter is determined, in effect, by measuring the behavior of the irregular particle in a certain circumstance and relating that to the behavior of a sphere of otherwise identical properties.

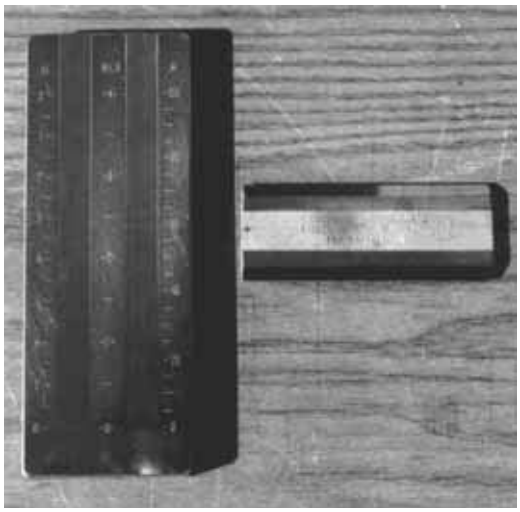

Fig. 27—Hegman fineness-of-dispersion gage. (Compliments of Lynn Shirey.)

Sedimentation (Stokes') E.S.D. The diameter of a sphere of the same density as the particle and having the identical free-fall velocity of the particle.

Volume E.S.D. The diameter of a sphere having the same volume as the particle.

Drawdown Techniques for Texture and Oversize

During the manufacturing of paints and coatings, there is a need for rapid, "on-the-floor" testing to determine whether a dispersion has reached its maximum grind. The "grind" gages were developed to provide quick, on-the-spot answers. Some of the tests could be done in the factory at the disperser during the grinding stage of production. Actually, during the production of paints and pigmented coatings, the pigments are not ground but are only wet out and dispersed to their "primary" size. This primary size is the smallest possible size supplied from the producer.

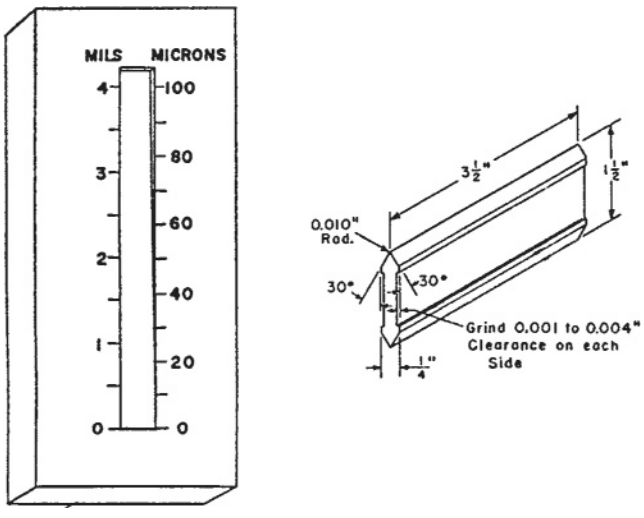

Fig. 28—ASTM dispersion gage and scraper.

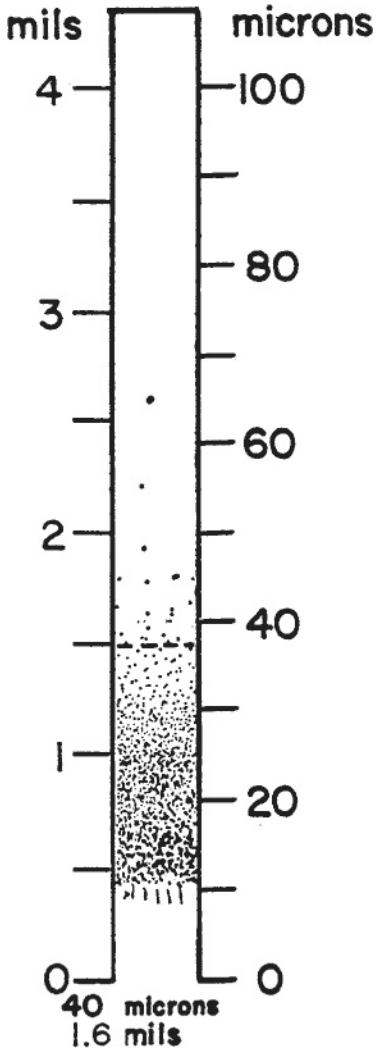

Fig. 29—Typical pattern produced by a dispersion gage.

THIN-FILM DRAWDOWN FOR OVERSIZE PARTICLES

This test [86] is suited particularly for detecting oversize particles that adversely affect the gloss of high-gloss industrial enamels. A 2-mL wet film of the enamel is spread on a glass plate with a Bird applicator blade. Inspection of the film is best made in a dimly lit room with the operator facing a light source such as a window or under a fluorescent light with a grid that can be reflected from the wet paint sample. With the eye focused on the silhouetted image of the window sash or the reflected pattern from the light or ceiling, extremely fine particles may be detected and compared with a visual standard. They appear as a roughness to the wet surface.

A variation of this approach is to illuminate the specimen at grazing incidence with a spotlight and view the film through a magnifier parallel to the specimen. Still another version is the use of wedge-shape or step-wise multithickness films.

FINENESS-OF-DISPERSION GAGES

Drawdown tests for the detection of oversize particles led to development of fineness-of-dispersion gages, or, as first called, fineness-of-grind gages. The gage is a steel block in which is cut a wedge-shape channel, tapering usually from 4 mils at the deep end to zero at the other end, though other depths and different widths and lengths of the channel are available. Some gages have twin channels. An excess of the sample is placed in the deep end of the channel, and the excess is drawn to the shallow end with a scraper. At some point along the channel, coarse particles or agglomerates become visible. The results are interpreted by reference to standard reference patterns. The addition of slow-evaporating solvents may be required to thin down the system to allow more time for reading the gage without experiencing volume loss by evaporation.

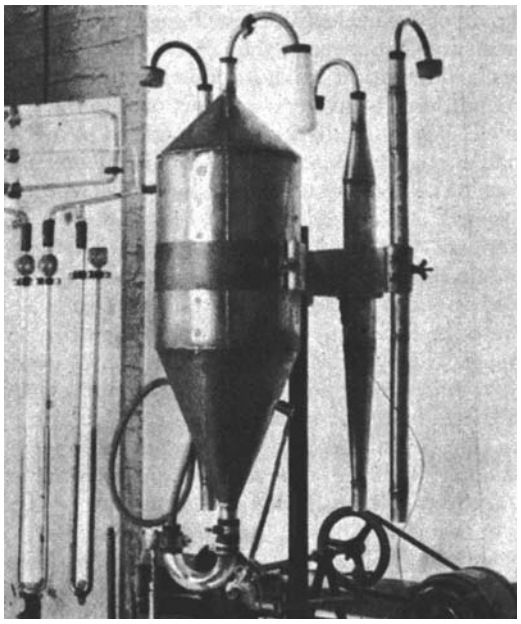

Fig. 30—The roller particle-size analyzer.

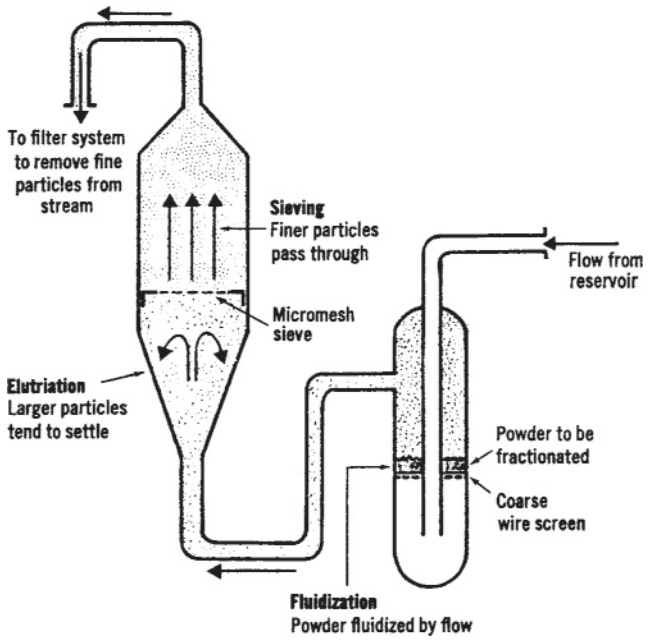

Fig. 31—Felvation. Fractionating powders into different sizes by a combination of fluidization, elutriation, and sieving. (Courtesy of *Chemical and Engineering News.*)

St. Louis Gage. This [87], the first of the dispersion gages, was designed to facilitate the use of the North Standards. The channel is 2 in. (51 cm) long and 0.005 in. (0.13 mm) deep at the deep end. The sample and the selected North Standard are placed side by side in the deep end, drawn by a scraper toward the shallow end, and compared.

Hegman Gage. The Hegman gage [88,89] (Fig. 27) made the North standards and the St. Louis gage obsolete. It is essentially a St. Louis gage with the addition of a scale to show the depth of the channel or the distance from the deep end. Instead of evaluating the dispersion in terms of the North standards, the distance from the deep end is reported. The finer the dispersion, the greater the distance. This is the reverse of the North standards, where the finer the dispersion, the lower is the number of the standard.

ASTM Gage. The gage specified in ASTM Test Method for Fineness of Dispersion of Pigment-Vehicle Systems (D1210) is almost identical to the Hegman. The steel block (Fig. 28) is about 180 mm long, 63.35 mm wide, and 12.7 mm thick. The channel is 100 μm deep at the heel. The gage is calibrated according to depth in steps of 10 μm along one edge and to the corresponding nearest 0.1 mil along the other. The dimensions of the scraper are shown in the diagram.

Experience has shown that the speed of drawdowns and the angle at which the scraper is held have no important effect on the results. However, the time lapse between the drawdown and reading, as well as operator technique, are important [87]. Readings should be made within 10 s after completion of the drawdown, especially for dispersions with a rating of seven or better due to the volume loss from solvent evaporation. Good practice suggests three drawdowns using fresh material each time. The first drawdown allows accommodation to the light source and a rough estimate of the dispersion pattern and the end point. Subsequent readings may then be made within 3 or 4 s. ASTM directs viewing the drawdown with the line of vision at a right angle to the long dimension of the channel and at an angle between 20° and 30° with the face of the gage in a light that renders the pattern readily visible. Diffuse subdued light is preferred.

Elimination of operator variance is aided by the use of six standard patterns. Fig. 29 illustrates reading of the end points, and the scales show the depth of the channel. This scale appears to have some advantage over both the North and the Hegman scales as it is related directly to the dimensions of the oversize particles. Other scales in use include the FSCT (Federation of Societies for Coatings Technology) scale, which divides the distance into ten parts.

Constant Depth Gage. The channels in this gage are of constant depth rather than tapered as in the gages previously described. The gage most often used has four channels, 1/2 in. (1.3 cm) wide and 6 in. (15 cm) long, having depths of 0.002 (0.005 cm), 0.0015 (0.0038 cm), 0.0010 (0.0025 cm), and 0.0005 in. (0.004 cm), equivalent to Hegman values of 4, 5, 6, and 7, respectively. Other depths can be supplied. The advantage of this type of gage is the long path available for inspection, a condition that should minimize the influence of bubbles and foreign matter on the ratings.

NPIRI Grindometer. Printing ink films are much thinner than those of paints or coatings. Relatively fine particles in the latter would be considered relatively coarse in the ink. Because of this, the printing ink range is addressed with a gage designed by the National Printing Ink Research Institute (NPIRI) called the Grindometer [90,91]. The channel of this gage is only 0.001 in. deep at the deep end, is 1 in. (2.54 cm) wide, and the scale is graduated in steps of 0.0001 in. (0.000 25 cm) [92].

X-RAY MICRORADIOGRAPHY TECHNIQUE

This technique detects undispersed clumps of pigment (inorganic types only) in paint. It uses low-energy x-rays [93] to resolve oversize material in the range of 1 μm or less, which is below the range detectable with fineness-of-dispersion gages.

A thin film of paint is spread over the surface of photographic-sensitized, fine-grain film. The specimen is exposed to x-rays and the film developed after removal of the paint. The film is enlarged optically to reveal silhouettes of the oversize materials on a photographic negative. Determination of size may be made following the methods used for light and electron microscopy.

Separation and Collection: Particle Size by Elutriation

This approach is primarily a means for separating or fractionating a quantity of pigment into portions according to particle size rather than providing a value of the sizes separated. Size determinations may then be made on the separated fractions. The technique has utility in evaluating the influence of pigment and filler particle size on the properties of the formulated product. After standardizing operating conditions for a material and measuring sizes by an independent method, approximate size distribution may be estimated for additional material.

Roller Particle-Size Analyzer. This device [94] uses elutriation by air to separate pigments into sizes. The glass U-tube at the bottom of Fig. 30 is charged with the specimen of pigment. Air under pressure is admitted through a nozzle that extends to the bottom of the tube. The other arm of the tube is connected to the metal settling tube. By proper selection of size of nozzle, size of settling tube, and velocity of the air, separation into desired fractions is obtained. The fractions are collected in paper extraction thimbles connected with a gooseneck to the settling tube. During the separating, the U-tube and the settling tube are vibrated vigorously. Using 25-g charges, the average time required for separations ranges from 62 min for particles up to 5 μm in diameter to 11 min for particles from 40 to 80 μm in diameter.

Felvation. This method [95] combines elutriating and sieving for fractionating fine powders. The basic apparatus (Fig. 31) consists of a column about 4 in. (10 cm) in diameter and 24 in. (61 cm) in height. The specimen is placed in the narrow tube at the right. Fluid is introduced and allowed to pass through at a relatively low rate. The powder soon becomes fluidized in the conical base of the column. The flow of the liquid is increased gradually. The smaller particles reach the sieve and pass through it. The throttling action of the sieve increases the flow through it. Hence, particles that have passed through do not fall back and clog the screen. Eventually, particles just larger than the sieve openings reach the sieve, but they do not block the screen as they reduce the flow around them and then tend to fall from the sieve.

The sieve functions only as a gage. It does not support the powder. Highly accurate electroformed sieves are used, but, because of their small size [1 in. (2.5 cm) in diameter], their cost is reasonable. Besides being economical, the method is rapid. Complete fractionations can be run in a period as short as 10 min.

THE ROLE OF PARTICLE-SIZE REFERENCE TEST MATERIAL

Carefully prepared particles of known size and composition have become an important part of testing for emulsions, powders, film, and processes. When properly used, reference particles are an important factor in demonstrating compliance with standards such as ISO-9000, U.S. Food and Drug Administration (FDA) Good Manufacturing Practices, and various military specifications [96]. In the past two decades, the need for instrument calibration has prompted the establishment of several businesses specializing in the production and supply of reference particles, which are available in assortment of materials of various sizes, densities, and grades.

A brief discussion of some typical applications will illustrate the usefulness of these test reference particles. They are used for instrument calibration, filter checking, flow tracing, and evaluation of processes such as blending, cleaning, and spraying, to name a few.

Instrument calibration and checking covers two broad classes: (1) particle-size analyzers and (2) particle contamination analyzers. Both types of instruments are calibrated or controlled by spherical particle-size standards, primarily polystyrene microspheres, which are normally measured and calibrated by methods traceable to the National Institute of Standards and Technology (NIST). The spherical calibration particles have fairly predictable instrument responses and are available as aqueous suspensions of highly uniform particles in discrete sizes (diameters) from 0.02 to 2000 μm. In addition to polystyrene spheres, which may be nonfluorescent or may contain various fluorescent dyes, calibration spheres are composed of silica and glass. Nonspherical materials such as alumina, quartz, and various milled powders are available as experimental materials or controls.

Particle-size spectrometers are used to measure the particle-size distribution of powders, suspensions, emulsions, and aerosols. Other than composition, particle-size distribution is probably the most important variable in product quality and performance. The major class of instruments, particle counters, is used to measure trace amounts of particle contamination in air, water, chemicals, beverages, and medicines. A recent variation of the particle counter can measure particle contamination on flat surfaces, such as silicon wafers, and a variety of optical and electronic parts. These instruments, as well as optical and electron microscopes, require calibration and reference particles to assure both the quality and traceability of measurements.

In addition to instrument evaluation and calibration, reference particles are used to verify retention ratings and pore-size distribution of air and liquid filter media. Using aerosol particle generators and precision particle counters up and down stream, high-efficiency particulate air (HEPA) filters can be certified for use in ultraclean manufacturing operations for rigorous contamination control. Polystyrene spheres with approximately a 0.25-μm diameter are frequently used for this purpose.

Another broad class of reference particle application is their use in validating processes, such as for cleaning, blending, dispersing, separation, and spraying. Fluorescent particles, which have bright and distinctive colors that can be contrasted with other background materials, are frequently used to follow the flow or direction of a process. Other materials such as pollens, ground walnut shells, refractory powders, or other materials of the desired particle size and specific gravity are available as model systems for evaluating processes.

In conclusion, reference particles are a key ingredient of modern testing methods, and their use should be considered at an early stage in any QA/QC program as quality management programs require the regular and timely evaluation and standardization of particle-sizing equipment.

Rheology and Viscometry[1]

Richard R. Eley[2]

NOMENCLATURE

Φ = Fluidity integral
α = Rate of decay of roughness amplitude, s^{-1}
β = Time constant characteristic of a critical shear rate, s
γ = Dimensionless shear strain
γ = Shear strain rate, s^{-1}
γ_w = Wall shear rate in tube flow, s^{-1}
δ = Phase shift; thickness of adsorbed polymer layer
ε = Extensional (Hencky) strain, dimensionless
ε = Extensional (Hencky) strain rate, s^{-1}
η = Coefficient of viscosity
η_0 = Zero-shear viscosity
η_∞ = High-shear limiting Newtonian viscosity
η_d = Dispersion viscosity
η_e = Extensional viscosity
η_l = Liquid-phase viscosity
η_r = Relative viscosity η_d/η_l
η' = Dynamic viscosity
$[\eta]$ = Intrinsic viscosity (limiting viscosity number)
θ = Angle of inclination with respect to the vertical
λ = Wavelength of coating surface striations; elastic stress relaxation time constant
ν = Kinematic viscosity
π = Ratio of circumference of a circle to its diameter
ρ = Density
γ = Surface tension
σ = Shear stress; generalized stress
σ_0 = Stress imposed at zero time; Yield stress
σ_e = Tensile stress
σ_s = Tangential surface shear stress
σ_w = Wall shear stress
τ = Viscosity-kinetic time constant for drying, wicking, or thixotropy
ϕ = Volume fraction of internal (dispersed) phase of a dispersion
ϕ_e = Effective volume fraction for a dispersion
ϕ_m = Maximum packing fraction of a dispersion, where $\eta_r \rightarrow \infty$
ω = Angular frequency ($= 2\pi f$)(rad·s^{-1})
A = Area of shear face
De = Deborah number (λ/t)
F = Force
F_g = Force of gravity
G = Shear modulus
G_∞ = Plateau modulus
G^* = Complex shear modulus
G' = Storage modulus
G'' = Loss modulus
K = Consistency in power law model; constant in viscosity-molecular weight equation
L = Capillary tube length
M_w = Weight-average polymer molecular weight
M_c = Critical (entanglement) polymer molecular weight
P = Pressure
Q = Volumetric flow rate
R = Capillary tube radius; particle radius; air bubble radius
T = Absolute temperature
T_g = Glass transition temperature
a = Curvature parameter in Eq (15); amplitude of coating surface striations
a_0 = Time-zero amplitude of coating surface striations
e = Base of the natural logarithmic scale = 2.71828
f = Frequency, hertz
g = Gravitational acceleration
h = Film thickness
k = Boltzmann's constant; general rate constant
l = Length
m = Kinetic energy correction term for capillary tube flow, Eqs (74) and (75)
n = Power law exponent
t = Time
v = Velocity
x = Coordinate parallel to substrate
y = Coordinate normal to substrate

INTRODUCTION

THIS ARTICLE PRESENTS A BRIEF REVIEW OF principles and methods of rheological analysis for the coatings industry. However, the information and methodology discussed applies equally well to the characterization of coatings, adhesives, inks, and sealants. These products share a common task, in that they are applied to a sub-

strate—and must function—as a thin film. The process of application and film formation obviously requires not only a large total deformation, but also a high degree of control of flow, in order to achieve success. Flow cannot be controlled unless it is properly measured. Typical industrial viscosity test methods have several faults: (1) the methods do not closely relate to actual industrial processes, (2) the test devices are unsuitable for non-Newtonian fluids, (3) the result is usually a single point, and (4) in general, such measurements do not correlate well to performance. The objective for the applied rheologist, therefore, is to develop methods of rheological characterization that

1. yield accurate data for complex fluids and
2. can be specifically related to the critical processes that paints must undergo. To meet the latter goal requires characterization methods that cover a wide range of stresses and time scales.

Though all other properties be acceptable, a coating will usually not meet with success if the rheology is not. Experienced formulators say that more than half the cost of new product development is consumed in "getting the rheology right." Furthermore, "minor" changes in a raw material or process can create significant and unexpected variability in product rheology, and such problems naturally require urgent solution. For these reasons and others, rheological analysis is a vital and cost-effective tool for the coatings industry.

The performance of coatings is governed by viscosity variations over a span of several orders of magnitude in shear rate or shear stress (at least four to as many as eight), if processes ranging from coating application, to leveling and sagging, to pigment settling are considered. To characterize fluid rheology over such a broad range of stress and deformation requires a "research-quality" rheometer. In order to take advantage of the capabilities built into the sophisticated rheological instrumentation now available, more than a passing knowledge of the subject of rheology is required. This chapter is therefore tutorial in style, aiming to provide the novice an entry point to the discipline. Certain concepts are discussed at some length because of their importance or complexity. One of these is viscoelasticity. It is worth the time because (a) a number of commercial instruments are capable of viscoelastic characterization of materials and (b) it is established that viscoelasticity exerts control over coating processes when present.

Finally, in the words of Professor Ken Walters, "rheology is a difficult subject." This is certainly true, as it combines several disciplines under one banner: mathematics, physics, physical chemistry, colloid and polymer science, fluid mechanics, etc. In addition, the experimental methods used are often complex and highly specialized. Furthermore, rheology requires mastery of concepts peculiar to the science, with which most persons have had limited opportunity to become familiar in the normal course of a technical education. Nevertheless, it is quite possible for the nonspecialist to acquire a useful working knowledge of the principles and practice of rheology, which may be used profitably to understand the link between formulation and performance of coatings.

DEFINITIONS OF BASIC TERMS

Rheology

The term "rheology" derives from the Greek *ρειν*, which means "to flow." Rheology is defined classically as "the study of the deformation and flow of matter," and may be defined operationally as "the study of the response of certain materials to stress." In order to quantify the deformation and flow behavior of materials, three basic terms must be defined. The first two of these relate to the measurement of the deformation (strain and strain rate) and the third to the measurement of the force required to deform a material (stress).

Deformation (Strain)

A *deformation* (or *strain)* is a change in shape and/or volume of a material in response to an applied stress. There are two principal types of deformation: *reversible* (elastic, rubber-band-like), and *irreversible* (inelastic or viscous). Irreversible deformation is the definition of flow. Rheologically interesting materials display a third type, in which either or both viscous and elastic response to stress can be seen, depending on the rate or the duration of stress applied.

During the lifetime of a coating the deformation history may be complex (see Table 1), the most important deformation types being simple shear and extension. For purposes of definition, we will limit our discussion to simple shear. Simple shear deformation is analogous to the spreading of a deck of playing cards, each card representing a thin volume element (or shear plane) displaced relative to its neighbor (Fig. 1). If a force F is applied to the uppermost volume element (thickness dy), the material will deform by the displacement of adjacent volume elements by a distance dx. The total thickness is Δy, and the total displacement is Δx. The shear strain γ is the ratio of the net displacement Δx to the distance of separation of the confining surfaces Δy,

$$\gamma = \frac{\Delta x}{\Delta y} \tag{1}$$

Strain Rate

Unlike solids (e.g., rubber band), liquids cannot support a constant deformation or strain. Thus, in order to measure the viscosity or resistance to flow of a fluid, we do not measure the deformation (strain), but, instead, the rate of deformation (strain rate). The strain rate is the change in strain per unit time, or the time derivative of the strain, symbolized $\dot{\gamma}$ (where the "dot" signifies "time derivative of"). Therefore, from Fig. 1,

$$\dot{\gamma} = \frac{\Delta x}{\Delta t} = \frac{\Delta(\Delta x/\Delta y)}{\Delta t} = \frac{\Delta(\Delta x/\Delta t)}{\Delta y} = \frac{\Delta v}{\Delta y} \tag{2}$$

For the case of simple shear deformation the strain rate is termed the shear rate. The dimensionality of γ is $LT^{-1}L^{-1}$ (e.g., cm · s^{-1} · cm^{-1}). Unit cancellation leaves reciprocal time (s^{-1}) as the unit of shear rate. It is conceptually helpful, however, to remember that, as shown by Eq (2), the shear rate is actually a velocity gradient ($\Delta v/\Delta y$, change in velocity per unit gap between shearing surfaces).

Stress

Force applied to a material creates a state of stress within the material. Stress can be expressed in units of force per unit area (e.g., dyn · cm^{-2}), or, equivalently, energy per unit volume (e.g., erg · cm^{-3}). In terms of Fig. 1, the shear stress σ is the force F necessary to maintain steady shearing

TABLE 1—Rheological components of coating processes

Process	Deformation Type or Attribute	Rheological Property
Roll coating	Squeezing flow	Biaxial extensional viscosity
	Stretching flow	Uniaxial extensional viscosity
	Shearing flow	Shear viscosity
	High strain rates	High-shear viscosity
	Large accelerations	Elasticity (G')
	Large decelerations	G' recovery
	Surface area transients	Dynamic surface tension
Spray	High shear rate	High-shear viscosity
	Large accelerations	Elasticity (G')
	High-strain-rate extensional deformation	Extensional viscosity/elasticity
	Surface area transients	Dynamic surface tension
Brushing/rolling	Medium shear rate	Shear viscosity
	Stretching flow	Extensional viscosity/elasticity
	Surface area transients	Dynamic surface tension
Leveling/sagging	Slow shear flow	Low shear stress viscosity
	Surface-stress driven	Dynamic surface tension
	Transient (nonequilibrium process)	Structure recovery kinetics
Curtain coating	Stretching flow	Extensional viscosity/elasticity
	Surface area transients	Dynamic surface tension
	Shear (pumping, extrusion)	Shear viscosity

motion against the resistance of the confined fluid, divided by the area of the shear face A,

$$\sigma = \frac{F}{A} \tag{3}$$

The stress is determined both by the magnitude of the applied force and by the area over which it is applied. Stress can therefore be thought of as a kind of "force intensity" or the "concentratedness" of the force. Consider the analogy of a bowling ball placed on a mattress. It sinks deep into the mattress because the area over which its weight is applied is relatively small. However, if a two-foot square board were placed under the ball first it would barely sink at all. The depth to which the ball sinks into the mattress depends on the area over which the force is applied. The smaller the area of contact of the weight with the mattress, the higher the stress, and the greater the resulting strain—the deeper the weight sinks.

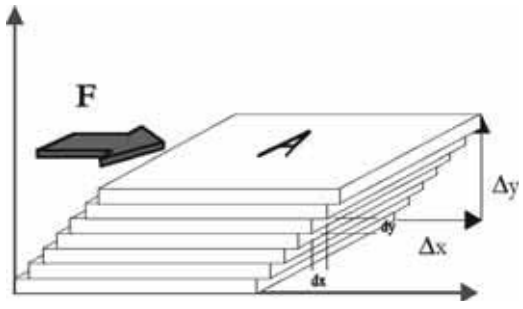

Fig. 1—Diagram for term definitions for simple shear.

Viscosity

The viscosity of a fluid characterizes its resistance to flow. The resistance to flow is, in turn, a measure of the friction between the flow units of the fluid (e.g., molecules), and may also be a measure of the forces of interaction between the flow units. Thus, a "viscous" fluid (one reluctant to flow) may be so because of high molecular weight (as in motor oil) or be of relatively low molecular weight, but having strong inter-molecular interactions (e.g., hydrogen bonds, as between sugar molecules in honey).

The interaction of molecules in flow dissipates energy, chiefly as frictional heat. Flow, therefore, is a process that costs energy, of which the viscosity is a measure. For the case of shear deformation, the viscosity η is calculated as the ratio of shear stress to shear rate. The viscosity, following from the discussion above, is therefore the energy per unit volume dissipated to attain a unit velocity gradient,

$$\eta = \frac{\sigma}{\dot{\gamma}} \tag{4}$$

Modulus

Materials comply with an applied stress by deforming or undergoing strain. For ideal Hookean materials, the strain will be proportional to the applied stress. The modulus is

TABLE 2—Units in various systems			
Variable	**cgs**	**MKS**	**SI**
Strain	Dimensionless	Dimensionless	Dimensionless
Strain rate	s^{-1}	s^{-1}	s^{-1}
Stress	dyne · cm^{-2}	Newton(N) · m^{-2}	Pascal (Pa) (=1 N·m^{-2})
Viscosity	Poise (P)	. . .	Pa·s (=10 P)
	Centipoise (cP) (= 0.01 P)		mPa·s (=10^{-3} Pa·s=1 cP)
Modulus	dyne · cm^{-2}	N·m^{-2}	Pa

the proportionality constant between the stress and strain, as in

$$G = \frac{\sigma}{\gamma} \tag{5}$$

where the shear modulus G is equal to the ratio of the shear stress to the shear strain. Most polymeric materials and coatings systems, in the solid state, are non-Hookean, i.e., the modulus is not a material constant, but will depend on both rate and extent of deformation.

Units

Various systems of units for rheological variables may be encountered in the literature. Until recently, the most common system of units for rheological terms was the cgs (centimeter-gram-second), or "small metric" system. However, international convention now specifies *Système Internationale* (SI) units as the standard. The SI system is based on the "large metric," or MKS (meter-kilogram-second) units, with some additional named units. The units associated with the above defined variables according to the various units systems are given in Table 2.

GENERAL CLASSIFICATION OF FLUID BEHAVIOR

Newtonian Fluids

Isaac Newton postulated that the force resisting motion of liquids is proportional to the rate at which one attempts to "separate the parts" of the liquid. In terms of our defined quantities, this would be expressed as a proportionality of stress to rate of strain:

$$\sigma \propto \dot{\gamma} \tag{6}$$

or

$$\sigma = \eta\dot{\gamma} \tag{7}$$

where η is the constant of proportionality, and is termed the coefficient of viscosity or simply the viscosity.

Equation (7) is the simplest example of a constitutive equation, an expression that allows one to predict the flow properties of a material in response to an applied stress. Fluids that obey Eq (7) over a range of shear rate are said to be Newtonian over that range. The viscosity of Newtonian fluids is a material constant (like the density or heat capacity) and depends only on the thermodynamic variables of temperature, pressure, and concentration. If the viscosity of a Newtonian fluid is measured at any arbitrary shear rate or shear stress, the viscosity under all deformation conditions is known.

Non-Newtonian Fluids

Fluids of commerce comprise a wide variety of materials, with a wide range of consistencies. In general, polymer solutions, emulsions, colloidal dispersions, and other suspensions of particulate solids will be *non-Newtonian*. For non-Newtonian materials, the viscosity is no longer a material constant, but is now a *material function*—in this case, a "function" of the shear rate (or shear stress). For non-Newtonian fluids, a viscosity measured at a single shear rate is not an adequate representation of the rheology of the system.

TYPES OF NON-NEWTONIAN BEHAVIOR

In the following sections, the various types of non-Newtonian behavior will be outlined. At the same time, some mathematical expressions that are commonly used to describe non-Newtonian flow will be introduced. Mathematical models are useful for summarizing flow behavior quantitatively. To be sure, materials can be evaluated merely by qualitative comparison of flow curves (e.g., by visual inspection), but the mathematical analysis of flow has value. For one thing, the model constants may have physical significance. For example, some models contain a yield stress term as a fitted parameter (see "Plastic (Yield) Behavior"). The magnitude of this parameter may be coupled to sag or leveling performance [1]. A later section of this chapter, "Leveling," gives examples of how leveling can be predicted for non-Newtonian fluids using constants from models discussed below. Furthermore, the values of model parameters may be related to formulation variables, allowing one, in principle, to optimize rheology by adjusting composition in a rational way.

It should be understood that the models about to be discussed are idealizations, and therefore are limited in their ability to represent the behavior of real materials. The models are able to describe real behavior at least over a limited range of stress or strain rate. Thus, a second use of mathematical models of flow is to make predictions of flow behavior, bearing in mind that it is risky to extrapolate the models beyond their range of validity.

As mentioned above, the simplest flow model is the Newtonian expression, which has only one constant, the coefficient of viscosity η. To describe more complicated behavior we will have to add additional coefficients and terms, the physical significance of which will be given when possible.

Shear-Dependent Viscosity

Materials for which the viscosity falls with increasing shear rate[3] are designated *shear thinning*. Simple shear thinning without either time dependence (see "Time-Dependent Fluids") or a yield stress (see "Plastic (Yield) Behavior") is termed *pseudoplastic* behavior. An increase of viscosity with increasing rate of shear is called *shear thickening*. The term *dilatancy* (see under "Shear Thickening Fluids") is often applied to shear thickening behavior, although this strictly refers to shear thickening accompanied by a volume

[3] Any definitions or descriptions of shear rate-dependent behavior may likewise be stated in terms of shear stress dependence.

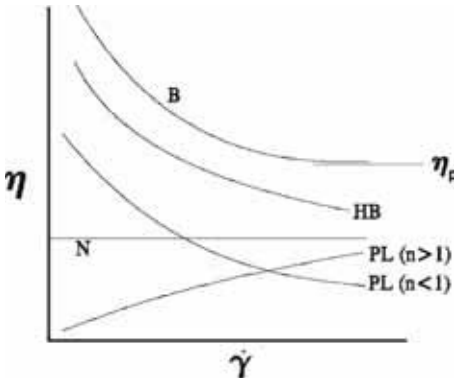

Fig. 2—Viscosity-shear rate curves for simple flow models. Symbols represent the following fluid models: N = Newtonian; B = Bingham (η_p = plastic viscosity); HB = Herschel-Bulkley; PL = power law (n = exponent).

increase, as the term implies. Fig. 2 shows curves illustrating viscosity-shear rate relationships for Newtonian and some non-Newtonian fluids.

Equation (4) describes Newtonian behavior, for which the viscosity η is a material constant and independent of shear rate (contour *N,* Fig. 2). More complicated viscosity-shear rate behavior requires a more complex expression to model it. The first level of complexity is to add a yield stress term σ_0 (see "Plastic (Yield) Behavior") to the Newtonian model, resulting in the Bingham equation [2]

$$\sigma = \sigma_0 = \eta_p \dot{\gamma} \tag{8}$$

Equation (8) says that above the yield stress the shear stress (minus the yield stress) is directly proportional to shear rate.[4] It is a common misconception that this corresponds to Newtonian behavior above the yield stress. Fig. 2, curve B shows that the Bingham model displays power-law-like behavior, but deviates from the power law (curve PL) at higher shear rate, approaching the so-called "plastic viscosity" η_p as a limit. Casson [3] obtained an equation similar to Bingham's except each term appears as the square root,

$$\sigma^{1/2} - \sigma_0^{1/2} = \eta_\infty^{1/2} \dot{\gamma}^{1/2} \tag{9}$$

The Casson model is not empirical, but was theoretically derived, specifically for systems whose primary flow units are rigid rods. Casson's equation is reputed to hold for a variety of paint systems, particularly as modified by Asbeck [4]

$$\eta^{1/2} - \eta_\infty^{1/2} = \sigma_0^{1/2} \dot{\gamma}^{-1/2} \tag{10}$$

which is somewhat surprising since few paints utilize rod-shaped particles as fillers or pigments. In fact, this author's experience is that the Casson model does not represent paint flow as well as certain other models (see below). Cohu and Magnin [5] showed that if the exponent 1/2 is replaced by 1/*n* the Casson form is able to describe paint rheology over several decades of shear rate. In Eqs (9) and (10), η_∞ (sometimes called the *Casson viscosity*) is not actually an "infinite-shear viscosity," but represents a limiting viscosity that is approached at high shear rate. The value obtained for the Casson viscosity will vary with the maximum experimental shear rate. As with all such models, the user must be aware that the constants resulting from a Casson analysis do not necessarily represent true physical properties because the analysis is merely a process of curve-fitting. For example, a finite yield value will usually be obtained by Casson analysis even when the material clearly does not exhibit yield behavior.

The next complication we will introduce is to let the exponent of the shear rate in the Newtonian law take values other than unity. In other words, the shear stress now will depend on some power of the shear rate

$$\sigma = K\dot{\gamma}^n \tag{11}$$

Eq (11) is known as the power law or Ostwald–deWaele model. Here, K is a constant sometimes called the "consistency,"[5], which has replaced the coefficient of viscosity η. This substitution of K for η is necessary because the exponent n can be other than unity, in which case K will not have proper viscosity units associated with it. The power law exponent n has been termed the "flow index." Its value characterizes the dependence of viscosity on shear rate, i.e., whether the viscosity rises or falls with increasing shear. A value of $n < 1$ corresponds to shear thinning behavior and $n > 1$ to shear thickening (Fig. 2 curves PL). Dividing Eq (11) through by $\dot{\gamma}$ yields a form of the power law that relates the viscosity to the shear rate

$$\eta = K\dot{\gamma}^{n-1} \tag{12}$$

If $n = 1$ in Eqs (11) and (12), the power law reduces to the Newtonian law.

The next complication consists in adding a yield stress term to the power law expression

$$\sigma - \sigma_0 = K\dot{\gamma}^n \tag{13}$$

giving an expression known as the Herschel–Bulkley equation. This model describes power law behavior above the yield point (curve HB, Fig. 2).

Fig. 3 shows a generalized equilibrium flow curve [6,7]. This figure represents the general features of the shear rate dependence of viscosity for non-Newtonian fluids (log-log axes). The term "equilibrium" means that time-dependence has been removed experimentally by measuring the equilibrium viscosity. Fig. 3 consists of four main segments: a low shear rate Newtonian regime, region I; a "power-law" shear thinning regime, region II; a high-shear Newtonian regime, region III; and a possible shear-thickening regime, region IV. The figure is explained in detail below (see *Shear Thinning Fluids).* The chief limitation of the power law models is that they are valid only over a limited range, namely, the linear portion of region II in Fig. 3. Power law models cannot account for the upper or lower Newtonian regions and, in fact, predict infinite viscosity at zero shear rate and zero viscosity at infinite shear rate, both unrealistic limiting behaviors. Nevertheless, the power law models are found to be useful within their limitations, particularly

[4] In the Bingham expression and in other models incorporating a yield stress term, it is important to note that the equations describe flow behavior only when $\sigma > \sigma_0$. When $\sigma \le \sigma_0$, $\gamma = 0$ (i.e., $\eta = \infty$), and there is no flow.

[5] Mathematically, K corresponds (in numerical magnitude but not dimensionally) to the viscosity at unit shear rate (1 reciprocal second).

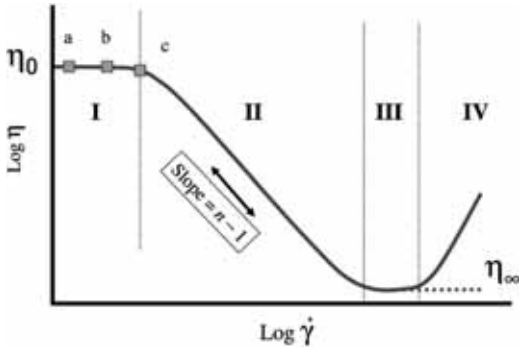

Fig. 3—Generalized equilibrium flow curve: η_0 = zero-shear viscosity (random structure, maximum disorder); η_∞ = high-shear limiting viscosity (maximum order). Region I is the first Newtonian plateau. Region II is the power law regime. Region III is the second Newtonian plateau. Region IV the shear-thickening regime (adapted from Ref. [6]).

for engineering-type calculations. The Herschel-Bulkley equation has been found to be superior to a number of other models in describing the flow behavior of a wide variety of coatings materials over a useful range of deformation conditions [8].

In order to account for the behavior outside region II in Fig. 3, more elaborate models are required. A simple extension of the power law model is to add an upper Newtonian limiting viscosity, η_∞

$$\eta = \eta_\infty + K'\dot{\gamma}^{n-1} \tag{14}$$

This expression is known as the Sisko model [9] and includes regions II and III of Fig. 3.

Of several proposed models encompassing regions I, II, and III inclusively, two in particular have found wide acceptance and utility in the literature. These are the Cross and Carreau models. Hieber et al. [10] wrote a general form of which the Cross and Carreau models are special cases (here modified to include Region III):

$$\eta = \eta_\infty + \frac{\eta_0 - \eta_\infty}{(1-[\beta\dot{\gamma}]^a)^{(1-n)/a}} \tag{15}$$

Here, η_0 is the first Newtonian plateau viscosity and a is a constant that determines the curvature of the transition region between the lower Newtonian regime and the power law regime. The value of a can be a measure of the molecular weight distribution of a polymer [10] or the particle-size distribution of a colloidal dispersion. Setting $a = 1 - n$ in the above expression yields the Cross equation, while setting $a = 2$ gives the Carreau-B model. The parameter n has the identical meaning as in the simple power law model [Eqs (11) and (12)], i.e., it is the slope of the power law regime in a log-log plot of shear stress versus shear rate. The constant β has the dimension of time and is actually a time constant representing a characteristic time of the system. This time constant may be related to, for example, the diffusional or rotational relaxation time of the flow units (be they colloidal particles or polymer chains) or to the time for rupture of particle flocs or aggregates under shear. The transition from the initial Newtonian plateau (region I) to the shear thinning regime (region II) in Fig. 3 is governed by the value of β, in an inverse sense: increasing β decreases the shear rate of the onset of shear thinning and vice versa. In other words, β defines a characteristic shear rate of transition, $\dot{\gamma}_{tr}$ [11–13]

$$\dot{\gamma}_{tr} = \frac{1}{\beta} \tag{16}$$

The constant β will be related to the time constant for Brownian diffusion of the primary flow units of a fluid. Stokes–Smoluchowski–Einstein theory gives the value of β for a dilute particulate dispersion as

$$\beta = \frac{6\pi\eta d^3}{k_B T} \tag{17}$$

where η is the viscosity of the continuous phase, d is the particle diameter, k_B the Boltzmann constant, and T absolute temperature. For a typical aqueous latex dispersion, d = 250 nm, η = 0.05 P, for which (at 25°C) β=0.36 s, corresponding to $\dot{\gamma}_{tr}$ =2.8 s^{-1}.

When the experimental shear rate equals $1/\beta$, the shear-ordering effect begins to dominate the randomizing effects of Brownian motion, and onset of shear thinning is seen [14] (see "Shear-Thinning Fluids"). This event corresponds approximately to point c in Fig. 3. Equations (16) and (17) tell how to control the transition from Newtonian to shear thinning behavior. Any change that increases the value of β (such as increasing the effective particle size or the continuous-phase viscosity, or lowering the temperature) will move the shear thinning transition to lower shear rates. Decreasing β extends Newtonian behavior to higher shear rates. While Eq (17) is strictly valid only for very dilute dispersions, it still provides qualitative guidelines for manipulating the rheology of dispersions. For concentrated dispersions, η should be taken as the viscosity of the dispersion [15–17].

It follows from the above discussion that the broader the size distribution of the flow units, the wider the

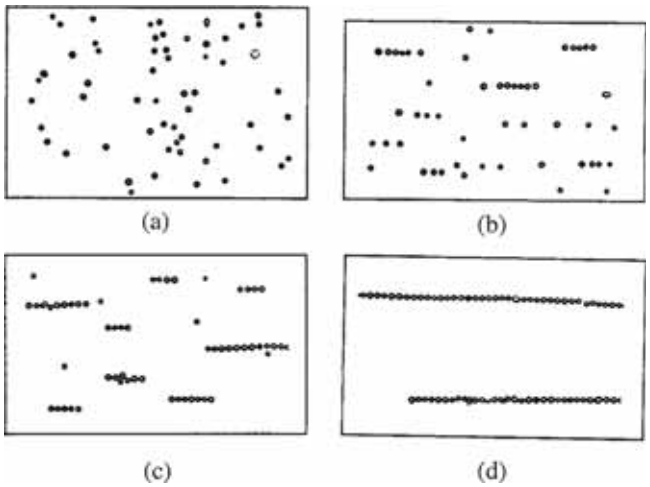

Fig. 4—Dilute suspension of glass microspheres in a polymer solution confined between glass plates with small plate separation: (a) just after loading, particles are randomly distributed; [(b)–(d)] after being sheared in a side-to-side direction at both increasing duration and shear rate. (By permission from J. Michel, R. Patzold, and R. Donis, *Rheologica Acta,* Vol. 16, 1977, p. 317. Cited in Ref. [20].)

spectrum of relaxation times and the more gradual the transition from region I to II (corresponding to a smaller value of *a)*. The shear rate of transition is fixed by β (a *mean* relaxation time), while *a* represents the *distribution* of relaxation times.

Shear-Thinning Fluids

The term *pseudoplastic* has been applied to fluids that decrease in viscosity with increasing shear rate (or shear stress) and implies shear-thinning behavior without yield stress. However, the term is passing out of use in favor of the more general description *shear thinning.* Particulate dispersions, polymer colloids, and polymer solutions can display this behavior above a certain concentration threshold.

Viscosity is a measure of the dissipation of energy or the "energy cost" to flow. Shear thinning behavior, therefore, implies that an increase of shear rate causes a structural change in the fluid that allows it to flow more efficiently and consequently with less energy dissipation. The mechanism[6] involves a shear-induced increase in order, or anisotropy, within the system. Thermal (Brownian) motion tends to keep systems disordered (of random order). Shear forces work against this, tending to impose orderliness. If shear rates are low, the randomizing forces win out and the micro-structure and hence the viscosity do not change for small increases of shear rate (point *a* to *b* in Fig. 3). Because of Brownian motion, the microstructure is no less random anywhere in region I than at zero shear rate, and therefore the viscosity is equal to η_0, the zero-shear value. As the shear rate approaches a critical magnitude (see "Shear-Dependent Viscosity"), the competition of thermal randomizing and shear ordering starts to favor ordering (point *c* in Fig. 3). In the case of polymers in solution, randomly coiled polymer chains tend to stretch in the direction of shear, partially uncoil, and align in more or less parallel fashion, at 45° to the shear gradient. In the case of a dispersion, the particles tend to line up like "strings of pearls" (Fig. 4) and eventually in ordered planes perpendicular to the shear gradient, according to Hoffman [18–20]. The result is a steadily decreasing viscosity with increasing shear rate as the degree of order increases. Ultimately, if the shear rate is high enough, the maximum amount of shear ordering possible is attained and the viscosity once again becomes independent of shear rate (Newtonian region III).

Fig. 3 shows the overall way in which viscosity varies with shear rate for systems such as those described above. Region I is the low-shear Newtonian regime (where Brownian motion controls structure). Region II is the shear-thinning segment of the flow curve (where shear forces control the structure). Here, the viscosity decreases exponentially with shear rate, hence, it is often referred to as the "power law" regime. Region III is the high-shear Newtonian regime. Here, the maximum degree of shear ordering has been attained—thus, the viscosity is once again independent of shear rate. The high-shear limiting Newtonian viscosity is usually given the symbol η_∞. Fig. 5 superposes the micrographs of Fig. 4 on the non-Newtonian flow curve

[6] The following discussion applies strictly to "stable" systems, i.e., those in which the net force between flow units is repulsive and which therefore do not flocculate. The shear-thinning mechanism for unstable systems (net interparticle force attractive) is discussed in the subsection entitled *Mechanism of Thixotropy*.

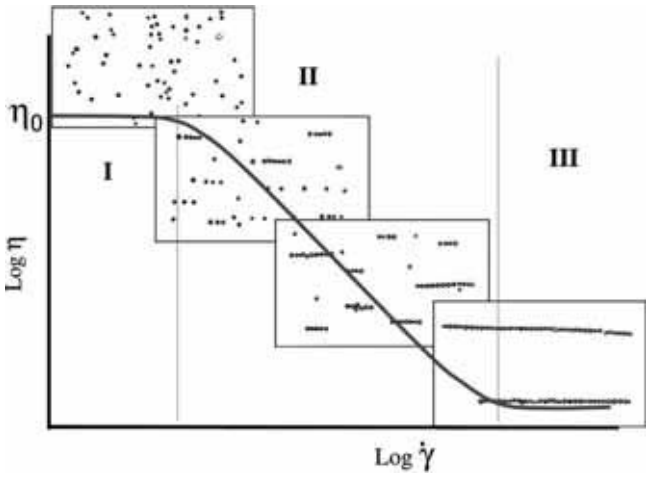

Fig. 5—Figs. 4(a)–4(d) superimposed on the equilibrium flow curve (Fig. 3) to illustrate the progression from random microstructure in region I through increasing degree of order in region II, to completely ordered microstructure in region III.

of Fig. 3, illustrating the microstructural state associated with each of the regions I, II, and III. Thus, in region I, the particles are isotropically (randomly) distributed due to Brownian motion. In region II there is a progressively increasing degree of order, culminating in a completely ordered micro-structure in region III.

Region IV is a shear-thickening region that is occasionally seen, especially with concentrated dispersions. In actuality, shear thickening in dispersions may occur at virtually any shear rate, depending on dispersion concentration [21], so that one or more of the other regimes are obliterated. That is, the equilibrium flow curve may consist of regions I to IV; I, II, and IV only; I and IV only; or IV only.

Note, once again, that structural order and viscous dissipation are inversely related. An increase in order means decreasing viscosity (Region II), while a decrease in order results in an increase in viscosity (Region IV) [22]. It follows that, for Newtonian behavior, no change must occur in structural ordering with shear. If the disperse system is unstable, i.e., tending to flocculate, the dotted curve may be followed (Fig. 6) instead of displaying a low-shear Newtonian regime [7]. Some systems may possess an apparent yield stress (see "Plastic (Yield) Behavior"). (See

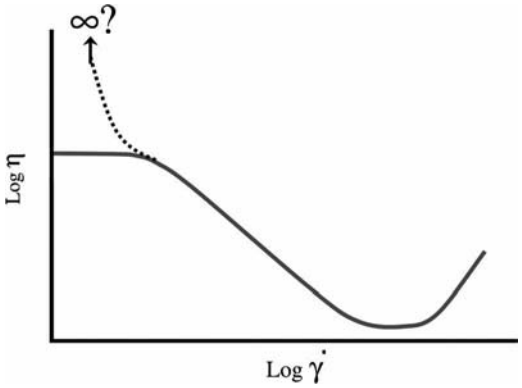

Fig. 6—Flow curve seen for unstable (flocculating) dispersions is indicated by the ascending curve going toward infinite viscosity at low shear rate.

"Dispersion Rheology" for additional discussion of particulate system rheology.)

As a general statement, the range of accurate measurement of most laboratory viscometers (for typical coatings fluids) is in the power law region. It may require extraordinary methods or special instrumentation to characterize fluid behavior in regions I or III.

SHEAR-THICKENING FLUIDS

We have seen above that shear thinning involves a shear-induced increase in order of a system. This allows the elements of a fluid to move or flow with minimum expenditure of energy. Conversely, shear thickening implies that shear has caused a decrease in order of a system. The resulting disordered system dissipates more energy during flow and hence is more viscous. An example of this is provided by the catastrophic increase in viscosity observed by Hoffman [19], which he attributed to the "buckling" or "log-jamming" of ordered, layered arrays of particles. Hoffman has recently reviewed the differing viewpoints on the mechanism of shear thickening [23].

A frequently encountered type of shear thickening behavior is dilatancy. Properly, dilatant behavior is shear thickening accompanied by an increase in volume of the fluid. It is most commonly observed in relatively concentrated disperse systems. In a dilatant system, the disperse phase particles are minimally lubricated by the liquid continuous phase. Furthermore, at rest, the particles of the disperse phase are in a random close-packed structure for which the interstitial volume is relatively minimal as well (Fig. 7). If the dispersion moves only slowly, adequate time exists for the meager liquid phase to flow sufficiently to maintain the dispersed phase in a "wetted" or lubricated state, and the system is able to maintain its close-packed structure. Faster or more forceful motion causes a liquid-starved condition because the interstitial volume increases as the system is deformed or made to flow (Fig. 7). Consequently, there is no longer enough liquid to lubricate the system. The particles are, therefore, incompletely wetted and forced flow would ultimately create microscopic voids, leading to fracture of the material. The surface of a dilatant material may appear dry when stressed due to the withdrawal of surface liquid into the increased interstitial volume. This can be seen when walking on wet sand on the beach. The resistance to deformation of the material can increase tremendously with increased deformation rate due to these effects.

During the course of a pigment grind operation, a fairly sudden maximum in viscosity is often seen and is an indication that a good grind (i.e., to primary particles) has been achieved. In fact, the surge in viscosity and power draw result from the grind having become dilatant. Dilatancy is desirable here because it facilitates energy transfer throughout the grind. Thus, dilatancy is frequently an indicator of the achievement of a stable dispersion of primary particles. In general, dilatant systems are not also thixotropic, and therefore will flow under even very low stresses. For this reason, coating systems in a dilatant state may suffer from rapid settling and be difficult to redisperse. For most coating operations, dilatancy is undesirable. Pumping of dilatant dispersions may result in high back-pressure in lines, excessive wear of system components, high power consumption, and loss of metering. In industrial rollcoating, dilatancy shortens coating lifetime on the roll, causing "dry edges" and loss of film thickness control.

Dilatancy is very sensitive to dilution and can be dramatically reduced or eliminated by a small reduction in solids. Also, addition of polymeric flocculants or electrolyte, or of a particulate phase of different particle size, or warming can alleviate undesirable dilatancy. Flow curve measurement is an excellent way to quantify the degree of reduction of dilatancy achieved by these measures.

Time-Dependent Fluids

Time-dependent fluids are those whose viscosity is a function of time, as well as shear rate (or shear stress). The most common such behavior encountered in coatings is time-dependent shear thinning or *thixotropy* [24]. Barnes has written a comprehensive review of the subject of thixotropy [25]. At constant shear rate and temperature, the viscosity of thixotropic fluids will fall, eventually reaching a constant value representing equilibrium between structure breakdown and restructuring processes. If the shear rate is changed, the viscosity will approach a new equilibrium value at a characteristic rate. This behavior is illustrated in Fig. 8, showing the way viscosity changes for a time-dependent system when the imposed shear rate (or shear stress) is changed in steps. Initially, the shear

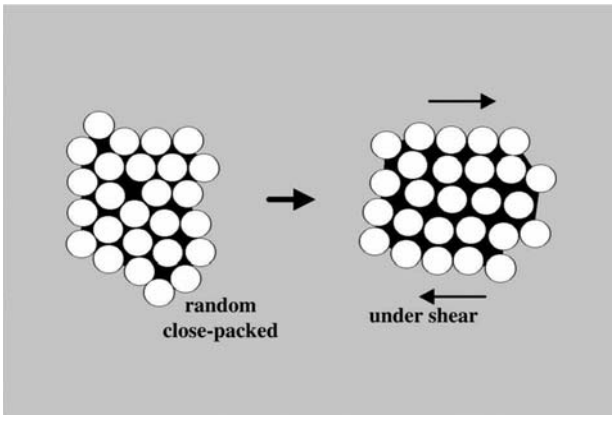

Fig. 7—Dilatant behavior is volume expansion under shear. Random close-packed structure gives way to less-efficient packing with necessary volume dilation.

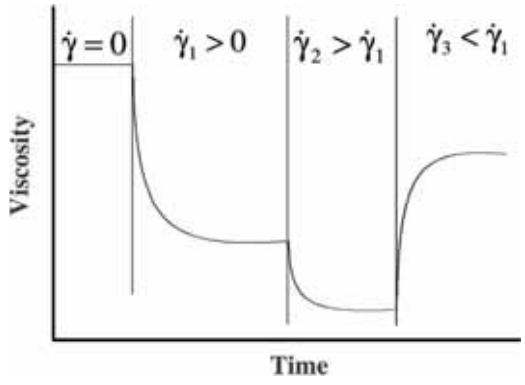

Fig. 8—Time-dependent fluid behavior. At $\dot{\gamma}$ = 0, viscosity is high (or infinite). Imposing $\dot{\gamma} > 0$ causes viscosity to fall exponentially, reaching new equilibrium value. Subsequent changes in $\dot{\gamma}$ result in re-equilibration of structure, hence viscosity.

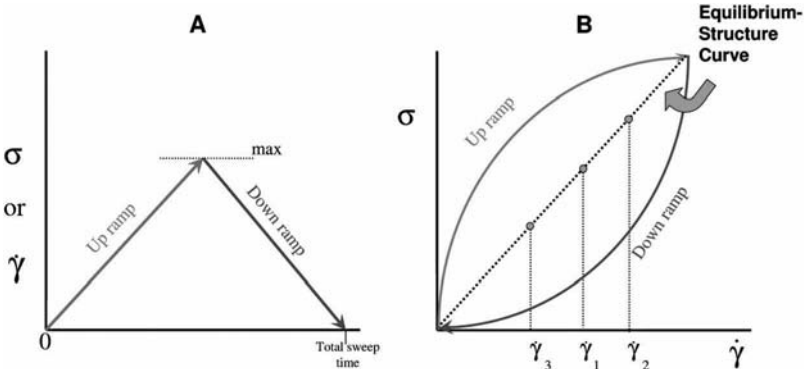

Fig. 9—(A) Shear rate or shear stress ramp experiment. Shear rate or stress increases linearly (or logarithmically) to pre-selected maximum over a selected sweep time period, resulting in a given acceleration gradient ($\dot{\gamma}$) or stress rate ($\dot{\sigma}$); (B) Thixotropic loop. Equilibrium structure curve (approximately bisecting loop) corresponds to data from experiment as in Fig. 8.

rate is zero, and the viscosity is very high or infinite for a thixotropic system. If a shear rate greater than zero is imposed ($\dot{\gamma}_1$), the viscosity drops exponentially, ultimately reaching a constant value. Increasing the shear rate to $\dot{\gamma}_2$ decreases the viscosity further to a new equilibrium value. A decrease of the shear rate to $\dot{\gamma}_3$ results in an exponential rise of viscosity to a higher equilibrium value. If, instead of a multiple steady-shear experiment, just described, we were to carry out a shear rate (or shear stress) ramp experiment [Fig. 9A], the time dependence would result in a loop [Fig. 9B]. The explanation of the loop is given below, but has to do with the fact that in a ramp experiment the equilibrium structure is never attained. The circuit in Fig. 9(*b*) is called a *thixotropic loop*. Roughly bisecting the loop is the equilibrium-structure curve generated from the equilibrium viscosity data of Fig. 8. The analogous time-dependent behavior for shear thickening materials has been called *rheopexy* (a rather rare phenomenon). The preferred term now for the latter is *antithixotropy*.

"Thixotropic Index" Test

We emphasize that the most important characteristic of thixotropic behavior is not shear thinning alone, but time dependence. The relatively slow change of viscosity provides a means of control of flow behavior and is the reason thixotropy is formulated into coatings. Hence, it is important to correctly characterize the time-dependent aspect of the behavior. For this reason, the so-called "thixotropic index" test is of limited benefit for characterization of such systems.

We will digress for a moment to discuss the thixotropic index test since it is very widespread in practice. This misnamed test determines the ratio of viscosities measured at arbitrary high- and low-shear conditions. ASTM Test Method D2196 specifies taking the ratio of viscosities measured on the Brookfield Synchro-Lectric viscometer at two speeds, representing a tenfold speed ratio. Since only equilibrium viscosities are measured, the test yields no information about time dependence and should be called the "shear-thinning index" instead (it is so termed in ASTM D2196). Its value, like many quality-control tests, is in its simplicity and "quick-and-easy" character, requiring no interpretation. As long as a given coating formulation changes little, so that the hidden kinetic factor would be expected to change little, the "thix index" can reveal when something has gone awry (i.e., can be useful as a gross indicator whether a formulation error has occurred). However, it is always possible that the recovery kinetics of the system might change, and this would go completely unnoticed if the thix index were the only test used to evaluate the rheology. Below, we will present test methods which can be almost as simple as the thix index, but which give more useful, relevant, and complete information about thixotropic systems.

Mechanism of Thixotropy

Thixotropy is formally defined as an isothermal, reversible sol-gel (fluid-solid) transformation [26]. As stated, it is experienced as a viscosity which is both time- and shear-dependent. Its origin is the breakdown under shear of internal fluid structure to smaller flow units, or the reassembly of structure from smaller units when shear is relaxed.

The mechanism of shear thinning in thixotropic (time-dependent) systems is different from that in pseudoplastic (time-independent) systems. In pseudoplastic systems, shear thinning is the consequence of order externally imposed by shear [14]. In thixotropic systems, an internally imposed, viscosifying structure exists at rest, and the viscosity falls because of the collapse of that structure under shear. (Flocculated systems possess extra mechanisms of energy dissipation [27]; therefore, their viscosity will be higher than that of a deflocculated dispersion of the same composition.) A further important difference between the two is in the amount of time the structure requires to respond to changes in shear rate. In the case of time-independent systems, rapid structural equilibration quickly accommodates to changes in shear rate. The accommodation process essentially is particle diffusion, which is rapid for submicron particles (see "Shear-Dependent Viscosity"). The viscosity (a measure of structure) thus always "keeps up" with changes in shear rate for such systems. For thixotropic systems, the rate of structural reorganization is slower than the experimental rate of change of shear rate ($\dot{\gamma}$) or slow with respect to the time of observation at constant shear rate. In a "shear rate ramp" experiment (see below), the structural breakdown always lags behind the ever-increasing shear rate, so that the viscosity on the "up" ramp will be higher than the equilibrium viscosity at a given shear rate. On the "down" side of the ramp, the rebuilding of structure lags behind the rate of reduction of

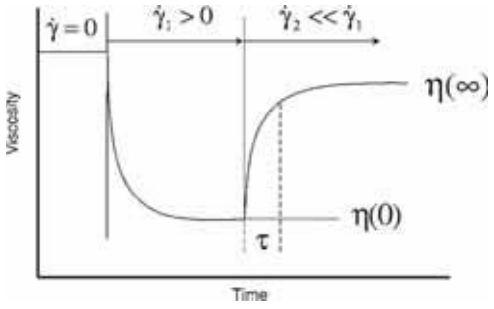

Fig. 10—Step-shear method for thixotropic recovery. High shear rate $\dot{\gamma}_1$ simulates application process, followed by low shear rate $\dot{\gamma}_2$, emulating film after application. Viscosity recovers from zero-time value $\eta(0)$ with a characteristic time constant τ, eventually reaching final level $\eta(\infty)$.

shear rate, so that the measured viscosity is always lower than the equilibrium value. Thus, a thixotropic loop is seen, the size of which should be proportional to the structural time constant for a given ramp time. Holding the shear rate constant, as in the description above, allows the structure breakdown process to "catch up." The viscosity then continues to change until equilibrium between structural breakdown and recovery rates is achieved.

Thixotropy Test Methods

Two common test methods for experimental characterization of thixotropy are the thixotropy index test, and the thixotropic loop test, described above. In the latter, a programmed increase and decrease of shear rate (or shear stress) is applied to a material [Fig. 9A], resulting in the generation of a loop [Fig. 9B]. The size of the loop can be obtained by numerical integration and is taken as an indicator of the rate of structural breakdown and recovery for a given ramp time (the larger the loop, the slower the breakdown-recovery rates). This method is a difficult one to do correctly, however, and is more complex than first appears. The result (loop size) depends on the shear history of the sample—the time interval since its last shear experience—and the magnitude of the shear undergone. It also depends on the shear rate (or shear stress) maximum in the loop experiment and the ramp rate ($\ddot{\gamma}$ or $\dot{\sigma}$).

A better method is one which puts the thixotropic material into a known state, i.e., having had a controlled shear experience, followed by the test itself. Such a method is the step-shear test (Fig. 10). In it, a high shear rate (order of 10^4 s^{-1} desirable) is applied to the material, allowing time for the viscosity (hence, structure) to reach equilibrium; then the shear rate is suddenly reduced to a very low value (e.g., order of 1 s^{-1}). The equilibrium amount of structure, which can exist at the lower shear rate, is greater than at the previous high shear rate, so reassembly of fluid structure occurs, accompanied by an approximately exponential rise of viscosity. Meaningful physical constants can be extracted from the data by fitting the following equation to the recovery curve

$$\eta(t) = \eta(0) + [\eta(\infty) - \eta(0)][1 - e^{-t/\tau}] \quad (18)$$

where $\eta(t)$ is the viscosity as a function of time, t, $\eta(0)$ the sheared-out viscosity (at time zero), $\eta(\infty)$ the infinite-time recovered viscosity level, and τ the time constant describing the recovery rate. The ratio $\eta(\infty)/\tau$, which may be termed the *Recovery Parameter,* has been found in our laboratories to correlate well to thixotropy-related properties such as sag resistance and air entrainment [28]. Table 3 shows data for two gel coat formulas, one sagging and one nonsagging. The conventional thix index results do not predict the sag behavior and, in fact, are opposite what would be expected from the observed behavior. The step-shear experimental parameters τ and $\eta(\infty)$ are given, along with their ratio. The nonsagging formula ("with additive") has both a shorter recovery time and a higher final recovered viscosity, and the recovery parameter takes both of these into account to predict significantly better sag resistance than for the "without additive" material.

The step-shear test puts useful thixotropy characterization within reach of any formulation laboratory, for it can be performed on an inexpensive viscometer (such as the Brookfield Synchro-Lectric or Wells–Brookfield Cone/Plate Viscometer) as well as on more sophisticated instrumentation. The latter offer advantages, of course, particularly with viscoelastic characterization capability. The ideal way to characterize thixotropic recovery is to break down the structure under high, steady shear (as in the step-shear method), then step down to a small-amplitude (small strain) oscillatory-shear test, as described by Dodge [29] (Fig. 11). The rebuilding of structure can then be followed by means of the viscoelastic parameters, which are sensitive probes of the fluid structure responsible for thixotropy. This method more faithfully mimics processes occurring in the relatively quiescent film after application. Fig. 12 shows the recovery curves of the viscoelastic moduli G' and G'' (see *The Viscoelastic Parameters and Their Measurement)* obtained from such a step-shear experiment. Note

TABLE 3—Gel coat thixotropy test data comparison: τ is the recovery time constant and $\eta(\infty)$ the recovered viscosity level from a step-shear experiment; $\eta(\infty)/\tau$ is the recovery parameter.

Composition	τ, s	$\eta(\infty)$, P	$\eta(\infty)/\tau$, P/s	Thix Index	Sag?
With additive	8.9	116	13	4.04	No
Without additive	18.2	97.3	5.4	4.24	Yes

the transition from fluid to solid as the elastic modulus G' crosses over and exceeds the viscous modulus G''.

Plastic (Yield) Behavior

An ideal plastic material behaves as an elastic solid until a critical stress is applied, whereupon it will "yield" and become fluid. This critical stress is the yield stress, the minimum stress necessary to initiate flow. Ideally, the properties of a material exhibiting yield behavior would be those of an elastic, or "Hookean," solid, below the yield stress. For such materials, the steady-shear viscosity would be infinite (or undefined), the deformation linear with stress, and the yield value a material constant. For most real materials, however, deformation below the yield point is a combination of elastic strain and viscous flow. This is because interparticle forces ("secondary bonds") are comprised of a range of types, having a corresponding range of relaxation times [30]. As a consequence, the measured yield value will depend on the rate at which the stress is increased up to the point where flow occurs (the faster the rate of stress increase, the higher the measured yield value).[7]

Barnes and Walters [31] have suggested that many if not most materials with an apparent yield stress will be found, in reality, to have a high but finite viscosity if measured at sufficiently low stresses. In practical terms, yield stress behavior can have important consequences for the processing, stability, and application of coatings. There is quite clearly some sort of flow discontinuity that occurs at low stresses, the magnitude of which is apparently related to the number and strength of interparticle attractive forces [30,32]. The yield stress is therefore an "engineering reality" [33] that must be taken into account when formulating paints or dispersions. A yield stress may be desirable or undesirable depending on the process in question. Materials with a yield stress will often exhibit thixotropy and viscoelasticity as well [34].

[7] For this reason, yield stress values cited in the literature are meaningless unless the exact experimental methodology is provided.

Static Versus Dynamic Yield

There are two types of yield stress that may be measured. The first is the static yield stress, measured by the startup of flow from nonflowing conditions. The second is the dynamic yield stress, which is the shear stress at which a presently fluid material suddenly turns solid (or exhibits a sharp flow discontinuity). Experimental methods exist for measuring both types of yield values [35], and one should measure the type that is relevant to the process in question. For example, for long-term suspension of solids or for start-up flow in pumps, the static yield stress is important. Postapplication leveling and sag behavior on the other hand would be governed by the dynamic yield stress, but the kinetics of structural recovery (rate of approach to the yield point) must also be taken into account (see thixotropy in "Time-Dependent Fluids"). Some have used curve-fitting techniques to obtain a value for the yield stress by fitting flow curve data to a rheological model. The Bingham, Herschel-Bulkley, and Casson models contain a yield stress term and have been commonly used to obtain a yield stress from measured flow behavior. Such methods are questionable, however, since one is attempting to infer a property of the solid state from behavior of a fluid [27,36].

Yield Stress Test Methods

Startup-of-flow methods include the use of penetrometer-type instruments such as a thermomechanical analyzer, where increasing force is applied to a standard probe. The yield stress is determined as the break point of a force-penetration curve [37].

An instrument known as a "controlled-stress" rheometer is well-suited to measurement of yield stress and other properties of structured materials. For this type of instrument, the shear stress is the independent (or controlled) variable, while the dependent (or measured) variable is the shear rate. This allows the applied stress to be gradually increased from a low value as the instrument registers zero shear rate (i.e., infinite viscosity) until the applied stress reaches the yield value, whereupon the viscosity becomes finite. This value is recorded as the measured yield stress.

Another fairly novel method employs a special vaned rotor to remedy problems of wall slip with filled materials [38–40]. The vaned rotor consists of rectangular blades or vanes fixed to a rotating shaft. Advantages of this geometry are as follows: (1) There is little disturbance of the sample when this type of probe is inserted, and (2) when the rotor turns, the material moves as if a "solid cylinder." Thus, the yield surface is within the material itself, avoiding problems of wall slip.

With the vaned rotor attached to a "controlled-strain-rate" type rheometer, the yield stress is measured by monitoring the torque as the geometry is rotated at a constant low rate. The torque will go through a maximum, corresponding to concerted yielding along the "virtual" cylindrical surface defined by the vane radii. The yield stress is related to the maximum torque T_m according to [39]

$$\sigma_0 = \frac{T_m}{K} \tag{19}$$

where K is the vane geometric constant given by

$$K = \frac{\pi D^3}{2}\left(\frac{H}{D} + \frac{1}{3}\right) \tag{20}$$

where D is the rotor diameter and H the vane height.

Using a controlled-stress rheometer, measurement of the yield stress using the vaned rotor is straightforward. The torque is ramped slowly and the stress at which a finite displacement is detected is reported as the yield stress.

Practical Aspects of Yield Behavior

Some of the practical consequences of yield behavior occur in the processing of pigment dispersions, for example. Dispersions with high yield stresses may be difficult to dispense accurately or reproducibly via automatic metering systems. Pumps may actually refuse to move or such materials may cavitate while being pumped; solenoid valves may "freeze." Coatings with significant yield stresses may exhibit poor leveling [1] since, as the shear stress decreases during the course of the leveling process, the material effectively becomes immobile when the dynamic yield stress is reached.

On the other hand, a small yield stress can be of great value in inhibiting settling of particulate suspensions. The shear stress exerted on the surrounding medium by a spherical particle falling under the influence of gravity may be calculated using the following relationships:

$$\sigma = \frac{F_g}{A} = \frac{\text{Force of gravity on particle}}{\text{Surface area of particle}}$$

$$F_g = \frac{4}{3}\pi R^3(\rho_p - \rho_l)g; \quad A = 4\pi R^2$$

$$\sigma_g = \frac{R}{3}(\rho_p - \rho_l)g$$

where R is the particle radius, ρ_p is the particle density, ρ_l is the liquid density, and g is gravitational acceleration. For a titanium dioxide particle of radius 0.2 mm and density 4 g·cm^{-3}, the shear stress acting on the particle due to gravity is about 0.2 dyne/cm^2. To prevent settling of such a particle, the surrounding medium need only resist with an opposing stress of greater than 0.2 dyne/cm^2. Even this, alas, is impossible for a Newtonian liquid, be it water or honey since it will flow under all stresses no matter how small (it is only a question of how slowly). A pigment particle will inevitably settle out of such a fluid, especially for viscosities of practical magnitudes. However, if the suspending medium possesses a yield stress equal to or greater than the particle shear stress, the particle "thinks" it is suspended in a solid and will remain suspended indefinitely. This argument assumes more or less ideal yield behavior, which, as described above, may rarely be encountered. A medium with a measured yield stress of apparently sufficient magnitude may or may not permit the particle to settle over long periods of time due to the possibility of viscous flow below the apparent yield point. In addition, ambient vibration can break the structure locally around a particle, leading to settling even where the measured yield stress appears adequate. Therefore, to ensure practical stability, one should build in a higher yield value than that calculated from the above.

Elastic Liquids (Viscoelasticity)

In ideal viscous flow, all input energy is converted either to heat or energy of motion. None is stored (i.e., none is converted into potential energy). Therefore, viscous flow results in irreversible deformation. Newtonian liquids show essentially ideal viscous (also called "inelastic") behavior over a wide range of deformation rate. For ideal elastic ("Hookean") substances, all the energy of deformation is stored, similar to a stretched rubber band. Consequently, elastic deformation is not permanent, but is in fact completely reversible. Real materials can display a mixture of elastic and viscous character, in varying degrees. Hence, the term *viscoelastic* is applied to such materials. Not all non-Newtonian fluids have significant elastic properties, but many do. Significant elasticity in fluids generally indicates the presence of some association network or microstructure. That is, elementary flow units are linked together in some fashion such that the structural relaxation time (see below) is measurably long. This structure, and particularly the destruction and rebuilding process that occurs during and after coating application, can have great consequences for application and film formation processes. An example of this is the influence of elasticity on leveling of an applied coating [41] (see also Massouda [42], Glass [43], and Cohu and Magnin [44]).
