2nd Edition

Springer

Springer Handbook of Electronic and Photonic Materials

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Foreword

Prof. Arthur Willoughby
University of Southampton

The editors and authors of the *Springer Handbook of Electronic and Photonic Materials* are to be congratulated on the second edition of this distinguished volume, which will be an invaluable source of information for all students, scientists, professionals, and other interested people working in these areas. Having made contributions to earlier handbooks, I am well aware of the considerable and sustained work that is necessary to produce a volume of this kind. This particular Handbook, however, is distinguished by its breadth of coverage in the field and the way in which it discusses the very latest developments. In such a rapidly moving field, this is a considerable challenge, which has been met admirably.

Previous handbooks and encyclopedias have tended to concentrate on semiconducting materials, for the understandable reason of their dominance in the electronics field, and the wide range of semiconducting materials and phenomena that must be covered. Few have been courageous enough to predict future trends, but in 1992 *Mahajan* and *Kimerling* attempted this in the Introduction to their *Concise Encyclopaedia of Semiconducting Materials and Related Technologies* (Pergamon) and foresaw future challenges in the areas of nanoelectronics, low dislocation-density III–V substrates, semi-insulating III–V substrates, patterned epitaxy of II–Vs, alternative dielectrics and contacts for silicon technology, and developments in ion-implantation and diffusion. To a greater or lesser extent, all of these have been proved to be true, but it illustrates how difficult it is to make such a prediction.

Not many people would have thought, two decades ago, that the III–nitrides would occupy an important position in this book. As high melting point materials, with the associated growth problems, they were not high on the list of favorites for light emitters at the blue end of the spectrum! The story is a fascinating one – at least as interesting as the solution to the problem of the short working life of early solid-state lasers at the red end of the spectrum. Likewise, more recently, the advances in white-light emitting diodes (WLEDs) have impacted us all, in replacement of traditional incandescent bulbs for applications such as car headlights, torches, and other lighting, and are making a huge impact in saving energy. Optoelectronics and photonics, in general, have seen one of the most spectacular advances over the last decade, and this is fully reflected in the book, ranging from visible-light emitters and phosphors to infrared materials. Part D of this book covers a wide range of work in this area, including III–V and II–VI optoelectronic materials and bandgap engineering, as well as photonic glasses, liquid crystals, organic photoconductors, and the new area of photonic crystals. The entire part reflects materials for light generation, processing, transmission and detection – all the essential elements for using light instead of electrons.

New materials have emerged since the first edition of this book was published in 2006 and they are also fully reflected in the book. One of these is graphene, which is under active research in order to discover its most effective applications, and a whole chapter is deservedly devoted to this. Other 2D materials have followed this discovery, and offer similarly exciting possibilities.

Another strong feature of this book is its coverage of fundamental properties in Part A, including optical, magnetic, electronic and dielectric properties, which lays the groundwork for the rest of the book. Likewise, in Part B, we learn about single-crystal growth, epitaxy, semiconductor compounds' growth and related characterization, all of which will be extremely instructive to those new to the field.

In the *Materials for Electronics* section (Part C), the book charts the progress in silicon – overwhelmingly the dominant material for a whole range of electronic functions and circuitry – including new dielectrics and other issues associated with shrinking geometry of circuits and devices to produce ever higher packing densities. It also includes areas rarely covered in other books: thick films, high-temperature electronic materials, and amorphous and microcrystalline materials. The existing developments that extend the life of silicon technology, including silicon/germanium alloys, appear too, and raise the question again as to whether the predicted timetable for the demise of silicon has again been declared too early! Ferroelectrics – a class of materials used so effectively in conjunction with silicon – certainly deserve to be here.

The chapters in Part E (*Novel Materials and Selected Applications*), break new ground in a number of admirable ways. Most of us are familiar with informa-

tion recording devices such as CDs, DVDs, etc., but few are aware of the materials, or principles, involved. This book describes magnetic information storage materials, as well as phase-change optical recording, keeping us fully up to date with respect to recent developments. The chapters in this section cover a diverse range of materials with applications such as solar cells, sensors, photoconductors, carbon nanotubes, graphene, thermoelectric materials, and metamaterials on which such a huge volume of work is presently being pursued worldwide. Both ends of the spectrum, from research to applications, are represented in chapters on organic electronics and packaging materials, as well as flexible substrates, perovskites, and materials for terahertz engineering.

So, a particular strength of this book is that it ranges from the fundamental science (Part A) through growth and characterization of the materials (Part B) to applications (Parts C–E). Virtually all the materials covered here have a wide range of applications, which is one of the reasons why this book is going to be so useful. As I indicated before, few of us will be successful in predicting the future direction and trends that occupy the high-ground in this field in the coming decade, but this book teaches us the basic principles of materials and leaves it to us to adapt these to the needs of tomorrow. I commend it to you most warmly.

Arthur Willoughby

Preface

After several years in use, this second edition of the *Springer Handbook of Electronic and Photonic Materials* is brought out to update the coverage and include new topics. Like the first edition, it represents a comprehensive treatise on electronic and photonic materials, with each chapter written by experts in the field. It is aimed at senior undergraduate and graduate students, researchers, and practicing professionals working in the area of electronic, optoelectronic, and photonic materials.

The idea for the first edition of this volume grew out of the need for a reference work that covers the wide spectrum of topics in materials that today's electrical engineers, material scientists, and physicists need. Electronic and photonic materials is a truly interdisciplinary subject that encompasses a number of traditional disciplines such as materials science, electrical engineering, chemical engineering, mechanical engineering, physics, and chemistry. It is not unusual to find a mechanical engineering faculty carrying out research on electronic packaging, and electrical engineers carrying out characterization measurements on semiconductors. There are only a few established university departments specializing in electronic or photonic materials. In general, electronic materials as a *discipline* appears as a research group or as an interdisciplinary activity within a college or faculty. One could argue that, because of the very fact that it is such an interdisciplinary field, there is a greater need to have a handbook that covers not only fundamental topics but also advanced topics; hence the present Handbook.

The chapters in this second edition of the *Springer Handbook of Electronic and Photonic Materials* provide the necessary background and up-to-date knowledge in a wide range of topics. Each chapter has an introduction to the topic, many clear illustrations, and numerous references. Clear explanations and illustrations make the handbook useful for all levels of research. All chapters are as self-contained as possible. There are both fundamental and advanced chapters that will appeal to readers with different backgrounds. This is particularly important for this Handbook since the subject matter is highly interdisciplinary. For example, there will be readers with a background (first degree) in chemical engineering working on semiconductor processing and who need to learn the fundamentals of semiconductor physics. Someone with a first degree in physics would need to quickly update himself on materials science concepts such as liquid phase epitaxy and so on. Difficult mathematics has been avoided and, whenever possible, the explanations have been given semiquantitatively. There is a Glossary of Defining Terms at the end of the Handbook, which is a particularly useful feature in an interdisciplinary handbook.

As indicated before, the second edition is a major revision of the first one. Some chapters of the first edition have been left out and many chapters have gone through major revisions. Quite a few new chapters have been added: Photoconductivity in Materials Research; Temperature-Insensitive Band-Gap III-V Semiconductors: Tl-III-V and III-V-Bi; Graphene; Organic Solar Cells; Materials for Terahertz Engineering; Metamaterials; Thermoelectric Materials; Transparent Conductive Oxides; and Inorganic Perovskite Oxides.

The editors are very grateful to all the authors for their excellent contributions and for their cooperation in delivering their manuscripts in the various stages of the production of this Handbook. Sincere thanks go to Judith Hinterberg for all her support and help throughout the long period of commissioning the contributions and for getting them ready for production. Ursula Barth and Constanze Ober have very skilfully handled the myriad issues involved in getting the Handbook ready for production, copy-editing, figure redrawing, proof preparation and correction, and our sincere thanks go to them also for all their dedicated work in making the Handbook attractive to read.

It is a pleasure to thank Professor Arthur Willoughby for his many helpful suggestions that have made this a better Handbook. His wealth of experience as the Editor-in-Chief of the *Journal of Materials Science: Materials in Electronics* played an important role not only in selecting chapters but also in finding the right authors.

Finally, the Editors wish to thank all the members of their families (Nicolette (SK) and Marian, Samuel and Thomas (PC)) for their support and particularly for their endurance during the entire project.

Safa Kasap — Saskatoon, Canada
Peter Capper — Southampton, UK

About the Editors

Safa Kasap is currently a Distinguished Professor of Electronic and Optoelectronic Materials and Devices in the Electrical Engineering Department at the University of Saskatchewan, Canada. He obtained his BSc (1976), MSc (1978), and PhD (1983) degrees from the Imperial College of Science, Technology and Medicine, University of London, UK, specializing in amorphous semiconductors and chalcogenide glasses. In 1996 he was awarded the DSc (Engineering) from London University for his research contributions to materials science in electrical engineering. He is a Fellow of the American Physical Society and the Royal Society of Canada. He is the author of Optoelectronics and Photonics: Principles and Practices (2nd Edition) and Principles of Electronic Materials and Devices (4th Edition). Both textbooks are widely used by many major universities and professionals. He is the Deputy Editor-in-Chief for the Journal of Materials Science: Materials in Electronics.

Peter Capper was formerly Materials Team Leader at SELEX ES, which is now part of Leonardo MW Ltd. Dr Capper obtained his BA (1968) and PhD (1971) in Chemical Physics and Physics from Essex University and Portsmouth Polytechnic, UK, respectively. He has spent some 40 years in the infrared industry, growing and characterizing cadmium mercury telluride (CMT) and other tellurium-based materials. He holds patents in the bulk growth of CMT, has authored/co-authored over 100 papers and given several invited talks at international crystal growth/infrared (IR) conferences. He is a Fellow of the Institute of Physics and an Editor for the Journal of Materials Science: Materials in Electronics. He has edited/co-edited ten books in IR materials and devices and crystal growth.

Part B Growth and Characterization

12 **Bulk Crystal Growth: Methods and Materials**
Peter Capper 269
12.1 Background 269
12.2 History 270
12.3 Techniques 271
12.4 Materials Grown 278
12.5 Conclusions 289
References 289

13 **Single-Crystal Silicon: Growth and Properties**
Fumio Shimura 293
13.1 Overview 294
13.2 Starting Materials 295
13.3 Single-Crystal Growth 296
13.4 New Crystal Growth Methods 304
References 306

14 **Epitaxial Crystal Growth: Methods and Materials**
Peter Capper, Stuart Irvine, Tim Joyce 309
14.1 Liquid-Phase Epitaxy (LPE) 309
14.2 Metal Organic Chemical Vapor Deposition 319

14.3 Molecular Beam Epitaxy (MBE) 329
References 337

15 **Narrow Bandgap II–VI Semiconductors: Growth**
Peter Capper 343
15.1 Bulk Growth Techniques 344
15.2 Liquid Phase Epitaxy (LPE) 349
15.3 Metal–Organic Vapor Phase Epitaxy (MOVPE) 353
15.4 Molecular Beam Epitaxy (MBE) 358
15.5 Alternatives to MCT 361
References 362

Minoru Isshiki, Jifeng Wang 365
16.1 Crystal Properties 367
16.2 Epitaxial Growth 371
16.3 Bulk Crystal Growth 375
16.4 Conclusions 381
References 381

17 **Structural Characterization**
Paul D. Brown 385
17.1 Radiation–Material Interactions 386
17.2 Particle–Material Interactions 387
17.3 X-ray Diffraction 390
17.4 Optics, Imaging and Electron Diffraction 393
17.5 Characterizing Functional Activity 403
17.6 Sample Preparation 404
17.7 Case Studies – Complementary Characterization of Electronic and Optoelectronic Materials 406
17.8 Concluding Remarks 411
References 412

18 **Surface Chemical Analysis**
David Sykes 413
18.1 Electron Spectroscopy 414
18.2 Glow-Discharge Spectroscopies (GDOES and GDMS) 416
18.3 Secondary Ion Mass Spectrometry (SIMS) 417
18.4 Conclusion 423

19 **Thermal Properties and Thermal Analysis: Fundamentals, Experimental Techniques and Applications**
Safa Kasap, Jiří Málek, Roman Svoboda 425
19.1 Heat Capacity 426
19.2 Thermal Conductivity 431
19.3 Thermal Expansion 436
19.4 Enthalpic Thermal Properties 438
19.5 Temperature-Modulated DSC (TMDSC) 446

20 **Electrical Characterization of Semiconductor Materials and Devices**
M. Jamal Deen, Fabien Pascal 453
20.1 Resistivity 454
20.2 Hall Effect 462
20.3 Capacitance–Voltage Measurements 464
20.4 Current–Voltage Measurements 470
20.5 Charge Pumping 472
20.6 Low-Frequency Noise 473
20.7 Deep-Level Transient Spectroscopy 477
References 479

Part C Materials for Electronics

21 **Single-Crystal Silicon: Electrical and Optical Properties**
Mark Auslender, Shlomo Hava 485
21.1 Silicon Basics 485
21.2 Electrical Properties 495
21.3 Optical Properties 515
References 520

22 **Silicon-Germanium: Properties, Growth and Applications**
Yaser M. Haddara, Peter Ashburn, Darren M. Bagnall 523
22.1 Physical Properties of Silicon-Germanium 524
22.2 Optical Properties of SiGe 530
22.3 Growth of Silicon-Germanium 534
22.4 Polycrystalline Silicon-Germanium 537
References 539

23 **Temperature-Insensitive Band-Gap III-V Semiconductors: TI-III-V and III-V-Bi**
Hajime Asahi 543
23.1 TI-III-V Alloy Semiconductors 544
23.2 III-V-Bi Alloy Semiconductors 550
23.3 Summary 554
References 554

24 **Amorphous Semiconductors: Structure, Optical, and Electrical Properties**
Kazuo Morigaki, Chisato Ogihara 557
24.1 Electronic States 557
24.2 Structural Properties 560
24.3 Optical Properties 561
24.4 Electrical Properties 565
24.5 Light-Induced Phenomena 567
24.6 Nanosized Amorphous Structure 569
References 570

25 **Amorphous and Microcrystalline Silicon**
Akihisa Matsuda 573
25.1 Reactions in SiH_4 and SiH_4/H_2 Plasmas 574
25.2 Film Growth on a Surface 575

25.3 Defect Density Determination for a-Si:H and μc-Si:H 580
25.4 Device Applications 582
25.5 Recent Progress in Material Issues Related to Thin-Film Silicon Solar Cells 583
25.6 Summary 586
References 586

26 **Ferroelectric Materials**
Roger Whatmore 589
26.1 Definitions and Background 589
26.2 Ferroelectric Materials 593
26.3 Ferroelectric Materials Fabrication Technology 600
26.4 Ferroelectric Applications 607
References 613

27 **Dielectric Materials for Microelectronics**
Robert M. Wallace 615
27.1 Overview 615
27.2 Gate Dielectrics 620
27.3 Isolation Dielectrics 635
27.4 Capacitor Dielectrics 636
27.5 Interconnect Dielectrics 639
27.6 Summary 641
References 641

28 **Thin Films**
Robert D. Gould†, Safa Kasap, Asim K. Ray 645
28.1 Deposition Methods 647
28.2 Structure 669
28.3 Properties 680
28.4 Concluding Remarks 699
References 702

29 **Thick Films**
Neil White 707
29.1 Thick Film Processing 708
29.2 Substrates 710
29.3 Thick Film Materials 711
29.4 Components and Assembly 714
29.5 Sensors 717
References 720

Part D Materials for Optoelectronics and Photonics

30 **III–V Ternary and Quaternary Compounds**
Sadao Adachi 725
30.1 Introduction to III–V Ternary and Quaternary Compounds 726
30.2 Interpolation Scheme 726
30.3 Structural Parameters 727
30.4 Mechanical, Elastic and Lattice Vibronic Properties 729
30.5 Thermal Properties 731

30.6 Energy Band Parameters 733
30.7 Optical Properties 737
30.8 Carrier Transport Properties 739
References 741

31 **Group III Nitrides**
Romualdo A. Ferreyra, Congyong Zhu, Ali Teke, Hadis Morkoç 743
31.1 Crystal Structures of Nitrides 745
31.2 Lattice Parameters of Nitrides 746
31.3 Mechanical Properties of Nitrides 748
31.4 Thermal Properties of Nitrides 752
31.5 Electrical Properties of Nitrides 757
31.6 Optical Properties of Nitrides 769
31.7 Properties of Nitride Alloys 782
31.8 Doped GaN 786
31.9 Defects in GaN 789
31.10 GaN-Based Nanostructures 794
31.11 Summary and Conclusions 801
References 802

32 **Electron Transport Within III-V Nitride Semiconductors**
Stephen K. O'Leary, Poppy Siddiqua, Walid A. Hadi, Brian E. Foutz, Michael S. Shur, Lester F. Eastman† 829
32.1 Electron Transport Within Semiconductors and the Monte Carlo Simulation Approach 830
32.2 Steady-State and Transient Electron Transport Within Bulk Wurtzite GaN, AlN, and InN 834
32.3 Electron Transport Within III–V Nitride Semiconductors: A Review 845
32.4 Conclusions 850
References 850

33 **II-IV Semiconductors for Optoelectronics: CdS, CdSe, CdTe**
Minoru Isshiki, Jifeng Wang 853
33.1 Background 853
33.2 Solar Cells 853
33.3 Radiation Detectors 858
33.4 Conclusions 863
References 863

34 **II-VI Narrow Bandgap Semiconductors: Optoelectronics**
Ian M. Baker 867
34.1 Overview 867
34.2 Applications and Sensor Design 870
34.3 Photoconductive Detectors in HgCdTe 871
34.4 Sprite Detectors 872
34.5 Introduction to Photovoltaic Devices in HgCdTe 873
34.6 Manufacturing Technology for Photodiode Arrays 879
34.7 Advanced HgCdTe Technologies 886
34.8 Emission Devices in II–VI Semiconductors 892
34.9 Potential for Reduced Dimensionality in HgTe–CdTe 893
References 893

35 **Optoelectronic Devices and Materials**
Stephen J. Sweeney, Jayanta Mukherjee 897
35.1 Introduction to Optoelectronic Devices 898
35.2 Light-Emitting Diodes and Semiconductor Lasers 900
35.3 Single- and Multimode Lasers 913
35.4 Optical Amplifiers 922
35.5 Modulators 923
35.6 Photodetectors 927
35.7 Conclusions 929
References 930

36 **Liquid Crystals**
Geoffrey Luckhurst, David Dunmur 933
36.1 Introduction to Liquid Crystals 933
36.2 The Basic Physics of Liquid Crystals 940
36.3 Liquid-Crystal Devices 947
36.4 Materials for Displays 956

Harry E. Ruda, Naomi Matsuura 1013
39.1 PC Overview 1014
39.2 Traditional Fabrication Methodologies for Static PCs 1017
39.3 Tunable PCs 1027
39.4 Summary and Conclusions 1030
References 1031

40 **Quantum Wells, Superlattices, and Band-Gap Engineering**
Mark Fox, Radu Ispasoiu 1037
40.1 Principles of Bandgap Engineering and Quantum Confinement 1038
40.2 Optoelectronic Properties of Quantum-Confined Structures 1040
40.3 Emitters 1047

40.4 Detectors 1050
40.5 Modulators 1052
40.6 Quantum Dots and Nanowires 1053
40.7 Conclusions 1055
References 1055

41 **Glasses for Photonic Integration**
Ray DeCorby, Mehrdad Irannejad 1059
41.1 Main Attributes of Glasses as Photonic Materials 1061
41.2 Glasses for Integrated Optics 1068
41.3 Laser Glasses for Integrated Light Sources 1071
41.4 Summary 1077
References 1077

42 **Optical Nonlinearity in Photonic Glasses**
Keiji Tanaka 1081
42.1 Third-Order Nonlinearity in Homogeneous Glass 1083
42.2 Second-Order Nonlinearity in Poled Glass 1088
42.3 Particle-Embedded Systems 1089
42.4 Photoinduced Phenomena 1090
42.5 Summary 1091
References 1092

Part E Novel Materials and Selected Applications

43 **Solar Cells and Photovoltaics**
Stuart Irvine 1097
43.1 Figures of Merit for Solar Cells 1098
43.2 Crystalline Silicon 1100
43.3 Amorphous Silicon 1102
43.4 GaAs Solar Cells 1102
43.5 CdTe Thin-Film Solar Cells 1104
43.6 $CuInGaSe_2$ ($CIGS_2$) Thin-Film Solar Cells 1105
43.7 Excitonic PV 1107
43.8 Conclusions 1107
References 1108

44 **Disordered Semiconductors on Mechanically Flexible Substrates for Large-Area Electronics**
Peyman Servati, Arokia Nathan 1111
44.1 a-Si:H TFTs on Flexible Substrates 1112
44.2 Field-Effect Transport in Amorphous Films 1112
44.3 Electronic Transport Under Mechanical Stress 1118
References 1123

45 **Photoconductors for X-Ray Image Detectors**
M. Zahangir Kabir, Safa Kasap 1125
45.1 X-Ray Photoconductors 1127
45.2 Dark Current Limitations 1136
45.3 Metrics of Detector Performance 1139
45.4 Summary 1145
References 1145

46 **Phase-Change Memory Materials**
Alexander V. Kolobov, Junji Tominaga, Paul Fons 1149
46.1 Structure of Ge-Sb-Te Phase-Change Alloys 1150
46.2 Mechanism of the Phase-Change Process 1156
46.3 Present Applications and Future Trends 1158
References 1160

47 **Carbon Nanotubes and Bucky Materials**
Mark Baxendale 1163
47.1 Carbon Nanotubes 1163
47.2 Bucky Materials 1170
References 1170

48 **Graphene**
Henry H. Radamson 1173
48.1 Graphene Synthesis 1174
48.2 Band Structure and Electronic Applications 1176
48.3 Characterization of Graphene Material 1178
48.4 Photonic Applications 1180
References 1182

49 **Magnetic Information-Storage Materials**
Charbel Tannous, R. Lawrence Comstock† 1185
49.1 Magnetic Recording Technology 1186
49.2 Magnetic Random-Access Memory 1215
49.3 Extraordinary Magnetoresistance (EMR) 1220
49.4 Summary 1220
References 1220

50 **High-Temperature Superconductors**
Rainer Wesche 1225
50.1 The Superconducting State 1228
50.2 Cuprate High-T_c Superconductors: An Overview 1234
50.3 Physical Properties of Cuprate Superconductors 1239
50.4 Superconducting Films 1244
50.5 The Special Case of MgB_2 1245
50.6 Iron-Based Superconductors 1248
50.7 Summary 1250
References 1252

51 **Molecular Electronics**
Michael C. Petty, Takashi Nagase, Hitoshi Suzuki, Hiroyoshi Naito 1257
51.1 Electrically Conductive Organic Compounds 1258
51.2 Materials 1261
51.3 Plastic Electronics 1263
51.4 Molecular-Scale Electronics 1266
51.5 DNA Electronics 1274
51.6 Conclusions 1276
References 1276

52 **Organic Materials for Chemical Sensing**
Asim K. Ray 1281
52.1 Analyte Requirements 1282
52.2 Brief Review of Inorganic Materials 1283
52.3 Macrocylic Compounds for Sensing 1286
52.4 Sensing with Phthalocyanine and Porphyrin 1291
52.5 Polymeric Materials 1297
52.6 Cavitand Molecules 1303
52.7 Concluding Remarks 1305
References 1305

53 **Packaging Materials**
Darrel Frear 1311
53.1 Package Applications 1312
53.2 The Materials Challenge of Electronic Packaging 1313
53.3 Materials Coefficient of Thermal Expansion 1315
53.4 Wirebond Materials 1315
53.5 Solder Interconnects 1317
53.6 Substrates 1322
53.7 Underfill and Encapsulants 1323
53.8 Electrically Conductive Adhesives (ECAs) 1324
53.9 Thermal Issues 1326
53.10 Summary 1327
References 1327

54 **Organic Solar Cells**
Masahiro Hiramoto, Yusuke Shinmura 1329
54.1 History 1330
54.2 Excitons 1331
54.3 Donor–Acceptor Sensitization 1332
54.4 Exciton Diffusion 1332
54.5 Blended Junctions 1333
54.6 Route Formation 1334
54.7 π–π Stacking 1335
54.8 HOMO–LUMO Gap 1335
54.9 Tandem Cells 1336
54.10 Conclusions 1337
References 1337

55 **Materials for Terahertz Engineering**
Roger Lewis 1339
55.1 Overview 1339
55.2 Terahertz Sources 1343
55.3 Terahertz Detectors 1345
55.4 Terahertz Components 1346
55.5 Conclusion 1347
References 1347

56 **Metamaterials**
Vassili Fedotov 1351
56.1 Bulk Metamaterials 1351
56.2 Planar Metamaterials 1365
References 1375

57 **Thermoelectric Materials**
Donald T. Morelli 1379
57.1 Overview of the Field 1380
57.2 Semiconductors as Thermoelectric Materials 1381
57.3 New Concepts in Thermoelectric Materials Design 1385
57.4 Summary and Future Outlook 1389
References 1390

58 **Transparent Conductive Oxides**
Hideo Hosono, Kazushige Ueda 1391
58.1 Overview 1391
58.2 Materials Design for TCOs 1395
58.3 New Approach to Explore Candidate Materials: Materials Genome Approach 1402
References 1403

59 **Inorganic Perovskite Oxides**
Tatsumi Ishihara 1405
59.1 Typical Properties of Perovskite Oxides 1409
59.2 Photocatalytic Activity 1411
59.3 Application for Solid Oxide Fuel Cells (SOFCs) 1413
59.4 Oxygen Separating Membrane 1418
59.5 Summary 1419
References 1420

About the Authors 1421
Detailed Contents 1435
Glossary of Defining Terms 1461
Subject Index 1495

List of Abbreviations

2DEG	two-dimensional electron gas
2DHG	two-dimensional hole gas
3DAP	three-dimensional atom probe microscopy

A

ABE	acceptor-bound exciton
AC	alternating current
ACPM	absolute constant photocurrent method
ACRT	accelerated crucible rotation technique
ACT	advanced Compton telescope
ADX	angular dispersive x-ray diffraction
AECA	anisotropic electrically conductive adhesives
AEM	analytical electron microscope
AES	Auger electron spectroscopy
AFC	antiferromagnetically coupled
AFM	atomic force microscopy
AG	Adam-Gibbs
AHE	anomalous Hall effect
ALD	atomic layer deposition
ALE	atomic layer epitaxy
AMA	active matrix array
AMFPI	active matrix flat-panel imager
AMOLED	active matrix organic light-emitting diode
AMR	anisotropic magnetoresistance
APD	avalanche photodiode
ASTC	Advanced Storage Technology Consortium
AuNp	hybrid graphene-gold nanoparticles
AWG	arrayed-waveguide grating

B

BAR	bit aspect ratio
BE	bound exciton
BEEM	ballistic-electron-emission microscopy
BEOL	back end of line
BER	bit error rate
BET	Brunauer, Emmett and Teller
BIL	burst-illumination LIDAR
BJT	bipolar junction transistor
BLG	bilayer graphene
BLIP	background limited detectors
BPSG	boro-phosphosilicate glass
BSA	bovine serum albumin
BSE	backscattered electron
BSF	basal stacking fault
BZ	Brillouin zone

C

CAIBE	chemically assisted ion beam etching
CARR	compound annual reduction rate
CB	conduction band
CBD	chemical bath deposition
CBE	chemical beam epitaxy
CBED	convergent beam electron diffraction
CC	constant current
CCD	charge-coupled device
CCSS	coclose-spaced sublimation
CCZ	continuous Czochralski method
CDD	charge density difference
CFL	compact fluorescent lamps
CFLPE	container-free LPE
CGC	coupled granular continuous
CGL	charge-generation layer
CHCC	conduction–hole–conduction–conduction
CHSH	conduction–hole–spin–hole
CID	compositional interdiffusion
CIP	current-in-plane
CKR	cross Kelvin resistor
CL	cathodoluminescence
CMOS	complementary metal-oxide-semiconductor
CMP	chemical mechanical polishing
CMS	core multishell
CO	carbon monoxide
COD	catastrophic optical damage
COP	crystal originated particle
CP	charge pumping
CPM	constant photocurrent method
CPP	current-perpendicular-to-plane
CPU	central processing unit
CRA	cast recrystallize anneal
CSD	chemical solution deposition
CSO	chip scale optic
CSP	chip scale packaging
CSS	close-space sublimation
CTE	coefficient of thermal expansion
CTEM	conventional TEM
CTL	charge transport layer
CVD	chemical vapor deposition
CVT	chemical vapor transport
CW	continuous wave
CZ	Czochralski

D

DA	Drude approximation
DAG	direct alloy growth
DAP	donor–acceptor pair

DBE	donor-bound exciton
DBP	dual beam photoconductivity
DBR	distributed Bragg reflector
DC	direct current
DCA	direct chip attach
DCPBH	double-channel planar buried heterostructure
DCXRD	double crystal x-ray diffraction
DEZ	diethylzinc
DFB	distributed feedback
DFT	density functional theory
DH	double heterostructure
DIL	dual-in-line
DiP	dual-in-line-package
DLHJ	double-layer heterojunction
DLPH	double-layer planar heterostructure
DLTS	deep-level transient spectroscopy
DME	detector materials engineering
DMFT	dynamical mean field theory
DMS	dilute magnetic semiconductor
DOS	density of states
DP	Dulong–Petit rule
DPI	dual polarization interferometric
DPN	dip-pen nanolithography
DQE	detective quantum efficiency
DQW	double quantum well
DRAM	dynamic random-access memory
DSC	differential scanning calorimeter
DSIMS	dynamic SIMS
DSP	digital signal processor
DSSR	double split-ring resonator
DTGS	deuterated triglycerine sulfate
DUT	device under test
DVD	digital versatile disk
DW	domain wall
DWB	dual-waveband detector
DWDM	dense wavelength-division multiplexing

E

e-APD	electron avalanche photodiode
EAM	electroabsorption modulator
EBIC	electron beam-induced current
EBL	electron beam lithography
ECA	electrically conductive adhesives
ECB	electrically controlled birefringence
ECC	exchange-coupled-composite
ECR	electron cyclotron resonance
ECRPECVD	electron cyclotron PECVD
EDFA	erbium-doped fiber amplifier
EDMR	electrically detected magnetic resonance
EDS	energy dispersive x-ray spectroscopy
EDX	energy dispersive x-ray
EELS	electron energy loss spectroscopy
EEPROM	electrically erasable programmable read-only memory
EFG	edge-defined film-fed growth
EHP	electron–hole pair
EIA	Electronic Industries Alliance
EL	electroluminescence
ELISA	enzyme-linked immunosorbent assay
ELO	epitaxial lateral overgrowth
ELOG	epitaxial layer overgrowth
EMA	effective media approximation
EMR	extraordinary magnetoresistance
ENDOR	electron–nuclear double resonance
EOT	equivalent oxide thickness
EP	exciton polariton
EPD	etch pit density
EPR	electron paramagnetic resonance
ESA	excited state absorption
ESCA	electron spectroscopy for chemical analysis
ESR	electron spin resonance
ETB	empirical tight-binding approximation
EXAFS	extended x-ray absorption fine structure

F

FAB	fabrication facility
FBG	fiber Bragg grating
FBZ	first Brillouin zone
FCA	free-carrier absorption
fcc	face-centered cubic
FeRAM	ferroelectric random access memory
FET	field-effect transistor
FF	fill factor
FFT	fast Fourier transformation
FHD	flame hydrolysis deposition
FIB	focused ion beam
FIC	fast ion conductor
FinFET	fin field effect transistor
FM	ferromagnetic
FMR	ferromagnetic resonance
FOD	flame oxidation deposition
FOM	figure of merit
FPA	focal plane array
FPD	flow pattern defect
FRAM	ferroelectric random-access memory
FSG	fluorinated silicate glass
FSS	frequency selective surface
FT	Fourier transform
FTIR	Fourier-transform infrared
FTO	fluorine-doped tin oxide
FTPS	Fourier-transform photocurrent spectroscopy
FWHM	full width at half maximum
FX	free exciton
FZ	floating-zone

G

GC	glassy carbon
GDA	generalized Drude approximation
GDMS	glow discharge mass spectrometry
GDOES	glow discharge optical emission spectroscopy
GM	grid method
GMR	giant magnetoresistance

GNR	graphene nanoribbon
GOI	gate oxide integrity
GRL	granular recording layer
GSMBE	gas-source molecular beam epitaxy

H

HAADF	high-angle annular dark field
HAMR	heat assisted magnetic recording
HARP	high-gain avalanche rushing photoconductor
HAZ	heat affected zone
HBT	heterojunction bipolar transistor
hcp	hexagonal close-packed
HDC	horizontal directional solidification crystallization
HDMR	heated dot magnetic recording
HEMT	high electron mobility transistor
HFET	heterojunction field effect transistor
HIP	hot isostatic pressing
HIS	high impedance surface
HMS	head-media separation
HNP	high nitrogen pressure
HOLZ	high-order Laue zone
HOMO	highest occupied molecular orbital
HOT	higher operating temperature
HPB	high-pressure Bridgman
HPD	high-pressure depletion
HREM	high-resolution electron microscopy
HRTEM	high-resolution transmission electron microscopy
HRXRD	high-resolution x-ray diffraction
HSG	hemispherical-grain
HSRS	higher silane-related species
HV	high vacuum
HVPE	hydride vapor phase epitaxy
HWE	hot-wall epitaxy

I

I/O	input/outputs
IBI	isobutyl iodide
IC	integrated circuit
ICSD	inorganic crystal structure database
ICTS	isothermal capacitance transient spectroscopy
IDCA	integrated detector – cooler assembly
IDE	interdigitated electrode
IFIGS	interface-induced gap states
IFTOF	interrupted field time-of-flight
IgG	immunogamma globulin
IMC	integrated magnetic concentrator
IMM	inverted metamorphic structure
IMP	interdiffused multilayer process
IMPATT	impact avalanche transit time
iOLEDS	inverted OLED
iPCM	interfacial phase-change memory
IPEYS	internal photoemission yield spectroscopy
IPS	in-plane switching
IQE	internal quantum efficiency
IR	infrared
ISB	intersubband
ISE	ion-selective electrode
ISHE	inverse spin-Hall effect
ITO	indium tin oxide
IZO	indium zinc oxide

J

JFET	junction field-effect transistor

K

KCR	Kelvin contact resistance
KKR	Kramers–Kronig relation
KWW	Kohlrausch–Williams–Watts

L

LA	longitudinal acoustical
LAST	lead–antimony–silver–telluride
LC	liquid crystal
LCD	liquid crystal display
LD	laser diode
LDA	local density approximation
LDD	lightly doped drain
LEC	liquid encapsulated Czochralski
LED	light-emitting diode
LEEBI	low-energy electron beam irradiation
LEIS	low-energy ion scattering
LEL	lower explosive limit
LEO	lateral epitaxial overgrowth
LF	low frequency
LFN	low-frequency noise
LL	Luttinger liquid
LLS	laser light scattering
LMA	law of mass action
LMR	longitudinal magnetic recording
LMTO	linearized muffin-tin orbitals
LO	longitudinal optical
LOCOS	local oxidation of silicon
LPCVD	low pressure chemical vapor deposition
LPD	light point defect
LPE	liquid phase epitaxy
LPEE	liquid phase electroepitaxy
LSDA	local spin density approximation
LSTD	laser light scattering tomography defect
LTCC	low-temperature co-fired ceramic
LUMO	lowest unoccupied molecular orbital
LWIR	long-wavelength infrared

M

MAA	monomer methacrylic acid
MBE	molecular beam epitaxy
MC	Monte Carlo
MCCZ	magnetic field applied continuous CZ

MCL	magnetic cap layer
MCT	mercury cadmium telluride
MCZ	Czochralski growth with an applied magnetic field
MDF	model dielectric function
MDP	molecularly doped polymer
MDSC	temperature-modulated differential scanning calorimetry
MEED	medium-energy electron diffraction
MEM	micro-electromechanical
MEMS	micro-electromechanical system
MESFET	metal–semiconductor field-effect-transistor
MF	meeting front
MFCs	mass flow controllers
MHJ	mesa heterojunction
MI-M-I-M	metal-insulator-metal-insulator-metal
MIGS	metal-induced gap state
MIM	metal–insulator–metal
MIP	molecularly imprinted polymer
MIPS	millions of instructions per second
MIS	metal–insulator–semiconductor
ML	monolayer
MLC	multilayer ceramic
MLHJ	multilayer heterojunction
MO	metal-organic
MOCVD	metal-organic chemical vapor deposition
MOD	metal-organic deposition
MODFET	modulation-doped FET
MOMBE	metal-organic molecular beam epitaxy
MOPA	master oscillator power amplifier
MOS	metal–oxide–semiconductor
MOSFET	metal–oxide–semiconductor field-effect transistor
MOSS	multi-beam optical stress sensor
MOVPE	metal-organic vapor phase epitaxy
MPB	morphotropic phase boundary
MPC	modulated photoconductivity
MPU	microprocessor unit
MQD	multiple quantum disk
MQW	multiple quantum well
MR	magnetoresistance
MRAM	magnetic random-access memory
MRI	magnetic resonance imaging
MS	metal-semiconductor
MSG	microstructure glass
MTC	minimal thermal conductivity
MTF	modulation transfer function
MTJ	magnetic tunneling junction
MUTIS	metal-ultrathin insulator–semiconductor
MWIR	medium-wavelength infrared
MWNT	multiwall nanotube

N

NBTI	negative-bias temperature instability
NCA	nanochannel alumina
NCG	nanochannel glass
NDM	negative differential mobility
NDR	negative differential resistance
near-IR	near-infrared
NEPh	noise equivalent photons
NETD	noise equivalent temperature difference
NeXT	nonthermal energy exploration telescope
NHE	normal hydrogen electrode
NHF	nonreversing heat flow
NMOS	n-type-channel metal-oxide-semiconductor
NMR	nuclear magnetic resonance
NNH	nearest-neighbor hopping
NREL	National Renewable Energy Laboratory
NTC	negative temperature coefficient
NTCR	negative temperature coefficient of resistance
NTD	neutron transmutation doping
NW	nanowire
NW LED	nanowire light-emitting diode
NWQD	nanowire quantum dot

O

OCV	open circuit potential
ODMR	optically detected magnetic resonance
OLED	organic light-emitting diode
OMVPE	organometallic vapor phase epitaxy
OPSEL	optically pumped surface-emitting laser
OPV	organic photovoltaic device
OSF	oxidation-induced stacking fault
OSG	organo-silicate glass
OSL	optically stimulated luminescence
OZM	overlap zone-melting

P

PA	photoinduced absorption
PACE-I	producible alternative to CdTe epitaxy
PAMBE	plasma-assisted molecular beam epitaxy
PAni	polyaniline
PAS	positron annihilation spectroscopy
PBG	photonic band gap
PCA	principal component analysis
PCB	printed circuit board
PCM	phase-change memory
PDP	plasma display panel
PDS	photothermal deflection spectroscopy
PE BJT	polysilicon emitter bipolar junction transistor
PECVD	plasma-enhanced chemical vapor deposition
PEM	polymer electrolyte membrane
PES	photoemission spectroscopy
PET	positron emission tomography
PGEC	phonon-glass-electron crystal
PICTS	photoinduced current transient spectroscopy
PIDC	photoinduced discharge

PL	photoluminescence
PLC	planar lightwave circuit
PLD	pulsed laser deposition
PM	particulate matter
PMOS	p-type MOS
PMR	perpendicular magnetic recording
POF	plastic optical fiber
ppm	parts per million
PR	photoreflectance
PRAM	phase-change random access memory
PRML	partial response maximum likelihood
PRT	platinum resistance thermometer
PSL	photo-stimulated luminescence
PTC	positive temperature coefficient
PTCR	positive temperature coefficient of resistance
PTS	photon-trapping structure
PV	photovoltaic
PVD	physical vapor deposition
PVT	physical vapor transport
PZC	point of zero charge
PZT	lead zirconate titanate

Q

QA	quench anneal
QC	quantum cascade
QCL	quantum cascade laser
QCM	quartz crystal microbalance
QCSE	quantum-confined Stark effect
QD	quantum dot
QDIP	quantum dot infrared photodetector
QE	quantum efficiency
QFL	quasi-Fermi level
QHE	quantum Hall effect
QW	quantum well
QWIP	quantum well intersubband photodetector

R

RA	resistance × area
RAIRS	reflection adsorption infrared spectroscopy
RBS	Rutherford backscattering spectrometry
RCLED	resonant cavity light emitting diode
RDF	radial distribution function
RDS	reflection difference spectroscopy
RE	rare earth
RED	reflection electron diffraction
RF	radio frequency
RGO	reduced graphene oxide
RH	relative humidity
RHEED	reflection high-energy electron diffraction
RHF	reversing heat flow
RIBE	reactive ion beam etching
RIE	etching reactive ion etching
RIL	resistive interface layer
RIU	refractive index units
RKKY	Ruderman–Kittel–Kasuya–Yoshida
RMS	root mean square
ROIC	readout integrated circuit
RRR	residual resistivity ratio
RTA	rapid thermal annealing
RTD	resistance temperature device
RTS	random telegraph signal

S

S-R-H	Shockley–Read–Hall
SA	self-assembly
SA-VPE	selective-area vapor-phase epitaxy
SAF	synthetic antiferromagnet
SAM	self-assembled monolayer
SAW	surface acoustic wave
SAXS	small-angle x-ray scattering
SCE	saturated calomel electrode
SCH	separate confinement heterostructure
SCLC	space-charge-limited current
SCM	step-coverage method
SCVT	seeded chemical vapor transport
SD	sputtering deposition
SDW	spin density wave
SE	spectroscopic ellipsometry
SEM	scanning electron microscopy
SF	staking fault
SFM	synthetic ferrimagnetic media
SG	selenide glass
SGE	spin-Gunn effect
SHE	spin-Hall effect
SiC	silicon carbide
SIMS	secondary ion mass spectrometry
SiON	silicon oxynitride
SIPBH	semi-insulating planar buried heterostructure
SK	Stranski–Krastanov
SL	superlattice
SL-APD	superlattice avalanche photodiode
SMD	shifted-modulation-doped
SMR	spin-Hall magnetoresistance
SNR	signal-to-noise ratio
SO	small outline
SOA	semiconductor optical amplifier
SOC	system-on-a-chip
SOFC	solid oxide fuel cell
SOI	silicon-on-insulator
SPAD	single-photon avalanche diode
SPC	spin-polarized current
SPE	spin-Peltier effect
SPECT	single-photon emission computed tomography
SPGE	spin photo-galvanic effect
SPR	surface plasmon resonance
SPRI	surface plasmon resonance imaging
SPV	surface photovoltage
SPVT	seeded physical vapor transport
SQW	single quantum well

SRAM	static random-access memory
SRR	split-ring resonator
SSE	spin-Seebeck effect
SSG	superstructure grating
SSIMS	static secondary ion mass spectrometry
SSMBE	solid source molecular beam epitaxy
SSPC	steady-state photoconductivity
SSPG	steady-state photocarrier grating
SSR	solid-state recrystallization
SSRM	scanning spreading resistance microscopy
STEBIC	scanning transmission electron beam induced conductivity
STHM	sublimation traveling heater method
STI	shallow trench isolation
STM	scanning–tunnelling microscopy
STN	super-twisted nematic
STT	spin-transfer torque
SUL	soft underlayer
SUMIT	simultaneous unipolar multispectral integrated technology
SVP	saturated vapor pressure
SWC	spin-wave current
SWCN	single-wall carbon nanotube
SWIR	short-wavelength infrared
SWNT	single-wall nanotube

T

TA	transverse acoustical
TAB	tab automated bonding
TADF	thermally activated delayed fluorescence
TAT	trap-assisted tunneling
TCE	thermal coefficient of expansion
TCO	transparent conducting oxide
TCR	temperature coefficient of resistivity
TCRI	temperature coefficient of the refractive index
TD	threading dislocation
TDD	threading dislocation density
TDDB	time-dependent dielectric breakdown
TDI	time-delay and integration
TE	transverse electric
TEC	thermal expansion coefficient
TED	transmission electron diffraction
TEM	transmission electron microscopy
TEM-CL	TEM-cathodoluminescence
TET	two-electron transition
TFSCLC	trap-free space-charge-limited current density
TFT	thin film transistor
THM	traveling heater method
TL	thermoluminescence
TLC	trap-limited conduction
TLM	transmission line measurement
TM	transverse magnetic
TMR	tunnel magnetoresistance
TN	twisted nematic
TNM	Tool–Narayanaswamy–Moynihan
TO	transverse optical
TOF	time-of-flight
ToFSIMS	time-of-flight SIMS
TOS	transparent oxide semiconductor
TPB	triple phase boundary
TPC	transient photoconductivity
TPV	thermo-photovoltaic
TRAPATT	trapped plasma avalanche-triggered transit
TRMC	time-resolved microwave conductivity
TSL	thermally stimulated luminescence
TVAN	twisted vertically aligned

U

UAPD	unipolar avalanche photodiode
UBM	under bump metallurgy
UD	uniformly doped
UHV	ultrahigh vacuum
UHV-ECR-RMS	ultrahigh vacuum-electron cyclotron resonance-radio-frequency magnetron sputtering
ULSI	ultra-large-scale integration
UMS	ultrasonic micro-spectroscopy

V

VAN	vertically aligned nematic
VAP	valence-alternation pairs
VB	valence band
VCSEL	vertical cavity surface emitting laser
VCZ	vapor-pressure-controlled Czochralski
VD	vacuum distillation
VE	vacuum evaporation
VECSEL	vertical external cavity surface emitting laser
VGA	visual graphics array
VGF	vertical gradient freezing
ViGS	virtual gap states
VIS	visible
VLS	vapor-liquid-solid
VLSI	very-large-scale integration circuit
VOC	volatile organic compound
VOx	vanadium oxide
VPE	vapor phase epitaxy
VRH	variable-range hopping
VS	vapor-solid
VTD	vapor transport deposition
VUV	vacuum ultraviolet
VUVG	vertical unseeded vapor growth
VW	Volmer–Weber

W

WAT	weak absorption tail
WDM	wavelength division multiplexing
WDX	wavelength dispersive x-ray

WEEE	waste in electrical and electronic equipment
WKB	Wentzel–Kramers–Brillouin
WSP	wafer scale packaging
WXI	wide-band x-ray imager

X

XANES	x-ray absorption near-edge structure
XAS	x-ray absorption spectroscopy
XEBIT	x-ray-sensitive electron beam image tube
XGA	extended graphics array
XPS	x-ray photoelectron spectrometry
XRD	x-ray diffraction
XRF	x-ray fluorescence
XRSP	x-ray storage phosphor

Y

YL	yellow luminescence

Z

ZTCR	zero temperature coefficient of resistance

1. Perspectives on Electronic and Photonic Materials

Tim Smeeton, Colin Humphreys

Electronic and photonic materials have a tremendous impact on the modern world. They include a wide range of material classes and are developed through a deeply interdisciplinary combination of physics, chemistry, materials science, and engineering. In this introductory chapter, we give some perspectives on this exciting and ever-changing field. We give an example of the tremendous integration of different materials used in today's consumer products, and then take a historical look at the development of some key semiconductor materials and devices from inception to today. Focusing in particular on the development of the transistor and integrated circuit and some of the key electronic and photonic applications of compound semiconductors, we take advantage of the long-distance view to point out some unifying themes across the wide portfolio of materials while appreciating their unique features.

It can be easy to forget how remarkable electronic and photonic materials are. Take the light emitting diode (LED) as an example: An electric current is passed through a tiny stack of layers of slightly different materials and brilliant colored light is emitted. Of course, the LED is carefully designed, and there are powerful theories to explain the behavior, but that should not detract from the initial moment of wonderment that it works at all. Or that a room can be lit by photons generated in the active region of an LED which includes just a few thousand cubic micrometers of material – about the same volume as a grain of flour.

We all literally *see* the output from LEDs every day, from television screens, vehicle lights, or lighting luminaires. Most other electronic and photonic materials and devices are less conspicuous to our senses but together they have played an indisputable role in defining the way people live, work, and communicate in the twenty-first century: from microprocessors containing billions of transistors which provide immense computational power to laser diodes and radiofrequency transceivers which enable trans-global and wireless communication. These complex devices are only available today thanks to the work of countless researchers over the past century who have identified, designed and understood a vast array of materials, produced them with extraordinary purity, quality and economy, and deployed them in device designs which harness their power.

The detailed chapters in this handbook provide comprehensive introductions to the huge range of technical fields which electronic and photonic materials now occupy, written by world experts. In this introductory chapter, we have the luxury of stepping back from the details of these complex fields and reviewing the whole, in search of some perspective. First, we take a look at the complex mixture of electronic and photonic materials which are in use today and reflect on some common themes. Next, the majority of the chapter is dedicated to a review of the development of a handful of the most important semiconductor materials and devices since the early breakthroughs of the 1940s: the birth of electronics in germanium and silicon; the integrated circuit (IC); some of the key electronic and optoelectronic uses of III–V semiconductors; and the recent rise of III-nitride materials. These reviews serve as a tribute to breakthroughs of the last 75 years, hopefully providing some perspective of how the science and technology of these materials has come to its current state and perhaps providing some encouragement and inspiration to those who are striving to develop materials today.

1.1 Tremendous Integration

A starting point for perspective is to appreciate the complex mixture of materials and devices that are routinely integrated together. For a case study, we need look no further than something which is probably within touching distance as you read this sentence: a smartphone. One of the defining technologies of the twenty-first century, it has been enabled by an astonishing convergence of electronic and photonic materials and devices. No two models are quite the same, but let us teardown a hypothetical handset and its supporting infrastructure, laying forward references to the detailed chapters in this book as we go. As a user, we see text, images and video from a high-resolution liquid crystal display (LCD) in which blue light emitted from indium gallium nitride (InGaN) LEDs (Chaps. 31, 35, and 40) excites a rare-earth-doped yttrium aluminum garnet (YAG) phosphor (Chap. 38) to produce white light which, in turn, is color-filtered into red, green, and blue components and modulated at the pixel level by liquid crystal cells (Chap. 36) controlled by silicon or indium gallium zinc oxide (IGZO) thin film transistors (TFTs) (Chap. 44). We have touch control thanks to capacitive sensors which use an optically transparent and electrically conducting oxide such as indium tin oxide (ITO) (Chap. 58). Low power consumption multicore processors, RAM, and flash memories – all silicon – provide the computing power and storage (Chap. 21). The device is powered by a high energy-density lithium ion battery (Chap. 11). Wireless connectivity is provided between gallium arsenide (GaAs) based transistor radio transceivers on the handset and base stations equipped with silicon, silicon carbide (SiC), or aluminum gallium nitride (AlGaN) transistor amplifiers. Beyond that, data communication – which gives the smartphone its purpose – is via silica (SiO_2) optical fibers (Chap. 41) using indium phosphide (InP)-based laser diodes, optical receivers, switches and amplifiers (Chap. 35) to data centers based on high-performance silicon processors. And we can go further still: The data centers consume electrical power distributed through more power transistors (silicon, SiC and AlGaN) and perhaps originally generated by crystalline silicon, amorphous silicon, copper indium gallium selenide (CIGS) or cadmium telluride (CdTe) photovoltaic cells (Chap. 43).

The list of core materials is already well into double figures, but we have still only scratched the surface. If we consider just the families of semiconductor components in a little more detail, these include multiple alloy compositions (Chap. 30) with optimized combinations of impurity doping (Chap. 2). Not even to mention dozens – probably hundreds – of different electrode, interconnect, dielectric and packaging (Chaps. 27, 29, and 53) materials.

We could go on, but surely the point is made: A remarkably complex combination of materials and devices is involved. It is a phenomenal achievement of technology and business – we could argue a wonder of the modern world – that this dense concentration of different materials and technologies can be brought together with such synergy in a reliable, mass-produced product weighing less than 150 g that can be sold at a price accessible to billions of people. It is often the product design or the software of these devices which steal the limelight in marketing, but it is the electronic and photonic materials which are the unassuming heroes!

Electronic and photonic materials include almost all types and forms of material:

- Inorganic compounds (semiconductors, dielectrics)
- Organic molecules (liquid crystals, semiconductors)
- Ionic crystals (batteries), polymers (packaging, lithography masks)
- Metals/alloys (electrodes, interconnect wiring)
- Single crystal
- Polycrystalline
- Amorphous
- Thin film
- Nanostructured
- Two-dimensional.

Despite this breadth, there is at least one strong unifying theme across all: the need for extraordinary precision in the design and fabrication of the materials. These materials demand combinations of high purities, low defect densities, and precise chemical composition that probably exceed the requirements of any other area of technology. These requirements have been met by a unique convergence of physics, chemistry, materials science and engineering which brings together the core theoretical understanding with the means for fabrication.

Two aspects, in particular, are vital for delivering the necessary precision: exact material fabrication methods and detailed understanding of material structure and properties. In many cases, the ultimate device performance is determined by how far we fall short of fabricating the *perfect* material. If the number of crystalline defects is too high, or if there are too many impurities, or if an interface is too rough, or if ..., a device may fail. Minute deviations from a target specification can have catastrophic effects. Taking LED or laser diode fabrication as an example, a change

in composition of material or doping accounting to much less than 1% of a layer just a few nanometers thick can be the difference between a viable device and a costly failure. In nearly all device fabrication steps, from bulk growth methods for fabrication of substrates with near-perfect quality, to thin film growth methods to deposit precise material compositions with atomic-scale precision, to processing technology to pattern device features at the nanometer scale, and through to packaging and integration methods, material production techniques are the lifeblood of the field. The precision of fabrication techniques needs to be at least matched by the precision with which we can determine the structure of the resulting materials. This means that the structural and chemical characterization tools and techniques are an inseparable aspect of the story of all electronic and photonic materials. Accurate understanding of the quality (or otherwise) of the materials that we make – obtained from microscopy or other tools – has been a continuous driver or enabler for progress in material and device development.

When the material fabrication expertise and understanding of structure and properties are combined with deep understanding of the physics of device design, the result is the remarkable devices that can enrich our lives.

So, today's electronic and photonic materials span a tremendous range of fields and disciplines. How did this myriad of technologies successfully emerge and grow? Why have the materials that are in use today become dominant over others? In the next sections, we will give some very selective answers to these questions, hoping to provide a perspective of how some technologies have reached the current state. In particular, we have chosen to focus on a few sectors of semiconductor development to explain some of the early development of what became mainstream technologies. Often the key messages are learnt in these early years – before a technical field fragments into highly specialized sectors – and may provide the most valuable perspective.

1.2 The Silicon Age

1.2.1 The Transistor and Early Semiconductor Materials Development

Electronics is the control of electrons to produce useful properties; electronic materials are the media in which this manipulation takes place. The foundations for today's electronics were laid in 1947 – 50 years after J.J. Thompson had discovered the electron – with the first demonstration of the semiconductor transistor effect. Building on quantum theories to explain semiconductor behavior from the 1930s [1.1, 2] and improvements in purity of candidate semiconductor materials, John Bardeen and Walter Brattain used germanium to build and demonstrate the first *semiconductor triode*. Later, to be named the point contact transistor to reflect its transresistive properties, this success at Bell Laboratories was obtained just a few years after a research group led by William Shockley was established to focus on understanding semiconducting materials. It was to earn Brattain, Bardeen, and Shockley the 1956 Nobel Prize for Physics.

The first point-contact transistor was based around three contacts onto an n-doped germanium block: When a small current passed between the *base* and *emitter*, an amplified current would flow between the *collector* and *emitter* [1.3]. The emitter and collector contacts needed to be located very close to one another (50–250 μm), and this was achieved by evaporating gold onto the corner of a plastic triangle, cutting the film with a razor blade, and touching this onto the germanium – the two isolated strips of gold serving as the two contacts [1.4]. At about 1 cm in height, based on relatively impure polycrystalline germanium and adopting a different principle of operation, the device bears barely any resemblance to today's IC electronics components. Nonetheless, it was the first implementation of a solid-state device capable of modulating (necessary for signal amplification in communications) and switching (needed for logic operations in computing) an electric current. In a world whose electronics were delivered by the thermionic vacuum tube, the transistor was immediately identified as a component which could be *employed as an amplifier, oscillator, and for other purposes for which vacuum tubes are ordinarily used* [1.3].

In spite of this, after the public announcement of the invention at the end of June 1948, the response of both the popular and technical press was somewhat muted. It was after all still *little more than a laboratory curiosity* [1.5] and ultimately point-contact transistors were never suited to mass production. The individual devices differed significantly in characteristics, the noise levels in amplification were high and they were rapidly to be superseded by improved transistor types.

A huge range of transistor designs have been introduced from the late 1940s to now. These successive generations either drew upon or served as a catalyst

for a range of innovations in semiconductor materials processing and understanding. There are many fascinating differences in device design but from a materials science point of view the three most striking differences between the first point-contact transistor and the majority of electronics in use today are the choice of semiconductor, the purity of this material, and its crystalline quality. Many of the key electronic materials technologies of today derive from the developments in these fields in the very early years of the semiconductor industry.

Both germanium and silicon had been produced with increasing purity throughout the 1940s [1.6]. Principally because of germanium's lower melting temperature (937 °C compared with 1415 °C) and lower chemical reactivity, its preparation had always proved easier and was therefore favored for the early device manufacture such as the first transistor. However, the properties of silicon make it a much more attractive choice for solid-state devices. Although germanium is expensive and rare, silicon is, after oxygen, the second most abundant element. Silicon has a higher breakdown field and a greater power handling ability; its semiconductor band gap (1.1 eV at 300 K) is substantially higher than that of germanium (0.7 eV), so silicon devices are able to operate over a greater range of temperatures without intrinsic conductivity interfering with performance.

These two materials competed with one another in device applications until the introduction of novel doping techniques in the mid-1950s. Previously, p- and n-doping had been achieved by the addition of dopant impurities to the semiconductor melt during solidification. A far more flexible technique involved the diffusion of dopants from the vapor phase into the solid semiconductor surface [1.7]. It became possible to dope with a degree of two-dimensional precision when it was discovered that silicon's oxide served as an effective mask to dopant atoms and that a photoresist could be used to control the etching away of the oxide [1.8, 9]. Successful diffusion masks could not be found for germanium and it was soon abandoned for mainstream device manufacturing. Dopant diffusion of this sort has since been superseded by the implantation of high-energy ions which affords greater control and versatility.

Shockley was always aware that the material of the late 1940s was nothing like pure enough to make reliable high performance commercial devices. Quantum mechanics suggested that to make a high quality transistor out of the materials, it was necessary to reduce the impurity level to about one part in 10^{10}. This was a far higher degree of purity than existed in any known material. However, William Pfann, who worked at Bell Laboratories, came up with the solution. He invented a technique called zone-refining to solve this problem, and showed that repeated zone refining of germanium and silicon reduced the impurities to the level required. The work of *Pfann* is not widely known but was a critical piece of materials science that enabled the practical development of the transistor [1.10, 11].

At a similar time, great progress was being made in reducing the crystalline defect density of semiconducting materials. Following initial hostility by some of the major researchers in the field, it was rapidly accepted that transistor devices should adopt single crystalline material [1.12]. Extended single crystals of germanium several centimeters long and up to 2 cm in diameter [1.12, 13] and later similar silicon crystals [1.14] were produced using the *Czochralski* technique of pulling a seed crystal from a high purity melt [1.15]. The majority of material in use today is still derived from this route. To produce silicon with the very lowest impurity concentration, an alternative method called float zoning was developed where a polycrystalline rod was converted to a single crystal by the passage of a surface tension confined molten zone along its length [1.16–18]. No crucible is required in the process, so there are fewer sources of impurity contamination. Float zoning is used to manufacture some of the purest material in current use [1.19]. The early Czochralski material contained dislocation densities of $10^5 - 10^6\,\mathrm{cm}^{-2}$ but by the start of the 1960s dislocation free material was obtained [1.20–23]. Initially, most wafers were on the silicon (111) plane, which was easiest to grow, cut, and polish [1.24]. For field-effect devices, which are discussed below, use of the (100) plane was found to offer preferable properties, so this was introduced in the same decade. The impurity concentration in dislocation-free silicon has been continually reduced up to the present day and wafer diameters have increased almost linearly (though accelerating somewhat in recent years) from about 10 mm in the early 1960s to the *dinner plate* 300 mm which dominates today [1.19] and with 450 mm tentatively in the pipeline within the next decade. These improvements represent one of the major achievements in the growth and processing of semiconductor materials.

A series of generations of transistors followed in rapid succession after Brattain and Bardeen's first triumph. Here, we only mention a few of the major designs whose production has traits in common with technology today. Early in 1948, *Shockley* developed a detailed formulation of the theory of p–n junctions that concluded with the conception of the junction transistor [1.25, 26]. This involved a thin n-doped base layer sandwiched between p-doped emitter and collector layers (or vice versa). This p–n–p (n–p–n) structure is the

simplest form of the bipolar transistor (so-called because of its use of both positive and negative charge carriers), a technology that remains important in analogue and high-speed digital ICs today. In April 1950, by successively adding arsenic and gallium (n- and p-type dopants, respectively) impurities to the melt, n–p–n junction structures with the required p-layer thickness ($\approx 25\,\mu m$) were formed from single crystal germanium. When contacts were applied to the three regions, the devices behaved much as expected from *Shockley's theory* [1.25, 27]. Growth of junction transistors in silicon occurred shortly afterwards and they entered production by Texas Instruments in 1954 [1.12].

By the later years of the 1950s, the diffusion doping technique was used to improve the transistor's speed response by reducing the thickness of the base layer in the diffused base transistor [1.28]. This began the trend of manufacturing a device in situ on a substrate material, so, in a sense, it was the foundation for all subsequent microelectronic structures. Soon afterwards, epitaxial growth techniques were introduced (what would today be described as vapor phase epitaxy (VPE)) which have since become central to both silicon and compound semiconductor technology. Gas phase precursors were reacted to produce very high quality and lightly doped crystalline silicon on heavily doped substrate wafers to form epitaxial diffused transistors. Even though the collector contact was made through the thickness of the wafer, the use of highly doped (low resistance) wafers reduced the series resistance and therefore increased the frequency response [1.29].

For some years, the highest performance devices were manufactured using the so-called *mesa* process where the emitter and diffused base were raised above the collector using selective etching of the silicon [1.25]. The planar process (which was at the heart of nearly all device production until the last few years) was subsequently developed, in which the p–n junctions were all formed inside the substrate using oxide masking and diffusion from the surface. This resulted in a flat surface to which contacts could be made using a patterned evaporated film [1.30]. This processing technique was combined with some exciting thoughts at the end of the 1950s and led to the application of transistor devices and other components in a way which was to transform the world, that is, the IC.

1.2.2 The Integrated Circuit

With the benefit of hindsight, the IC concept is quite simple. The problem faced by the electronics industry in the 1950s was the increasing difficulty of physically fitting into a small device all of the discrete electronic components (transistors, diodes, resistors, and capacitors), and then connecting them together. It was clear that this problem would eventually limit the complexity, reliability, and speed of circuits which could be created. Transistors and diodes were manufactured from semiconductors but resistors and capacitors were best formed from alternative materials. Even though they would not deliver the levels of performance achievable from the traditional materials, functioning capacitors and resistors *could* be manufactured from semiconductors, so, in principle, all of the components of a circuit could be prepared on a single block of the semiconducting material. This reasoning had been proposed by Englishman G.W.A. Dummer at a conference in 1952 [1.31], but small-scale attempts to realize circuits had failed, largely because they were based on connecting together layers in grown-junction transistors [1.32]. In 1958, however, Jack Kilby successfully built a simple oscillator and *flip–flop* logic circuits from components formed in situ on a germanium block and interconnected to produce circuits. He received the Nobel Prize in 2000 for *his part in the invention of the IC*.

Kilby's circuits were the first built on a single semiconductor block, but by far the majority of the circuit's size was taken up by the wires connecting together the components. Robert Noyce developed a truly IC in the form that it was later to be manufactured. While Kilby had used the mesa technique with external wiring, Noyce applied the planar technique to form transistors on silicon and photolithographically defined gold or aluminum interconnects. This was more suited to batch processing in production and was necessary for circuits with large numbers of components.

In the 1960s, a new transistor design – the metal oxide semiconductor field effect transistor (MOSFET) – was introduced that replaced the bipolar device used in the first chips [1.33]. In this device, a *gate* was deposited onto a thin insulating silicon oxide layer on the silicon. The application of a voltage to the gate resulted in an inversion layer in the silicon below the oxide, thereby, modifying the conducting channel between *source* and *drain* contacts. This structure was a p-MOS device (current transfer between the collector and emitter was by hole conduction) grown on (111) silicon using an aluminum gate. Earlier attempts at such a device had failed because of trapped impurities and charges in the gate oxide – this new structure had reduced the density of these to below tolerable levels but the device still could not compete with the bipolar transistors of its time [1.24]. By 1967, however, (100) silicon (which offered lower densities of states at the Si/SiO_2 interface) was used together with a polycrystalline silicon gate to construct a more effective and more easily processed device with advantages over the bipolar transistor. In the early 1970s, the n-MOS device,

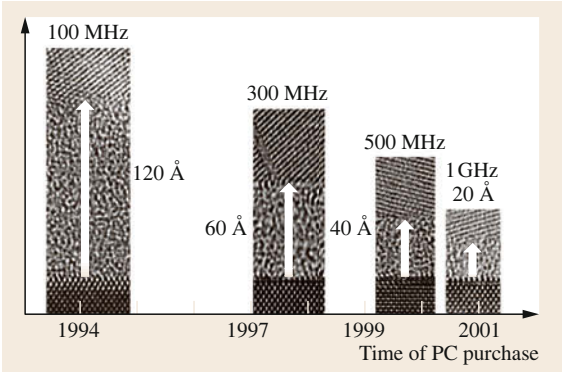

Fig. 1.1 The relentless march to zero thickness. HRTEM images of SiO_2 gate oxide thickness used in personal computers before high-k gate oxides were introduced. (After [1.34], with permission from Cambridge University Press)

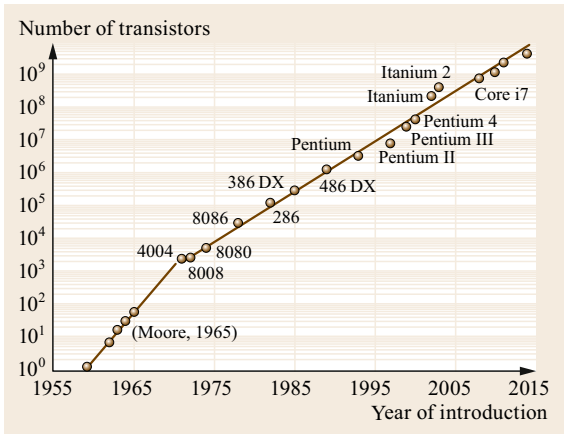

Fig. 1.2 The realization of Moore's law by commercial Intel processors: the logarithmic increase in the number of transistors in each processor chip

which was even less tolerant of the positive gate oxide charges, was realized thanks to much improved cleanliness in the production environment. With conduction occurring by the transfer of electrons rather than holes, these were capable of faster operation than similar p-MOS structures (the mobility of electrons in silicon is about three times that of holes). By the 1980s, these two devices, were combined in the complementary MOS (CMOS) device which afforded much lower power consumption and simplified circuit design [1.35].

The MOSFET is still a common structure in microelectronics today. Of course, now it can be much smaller, with transistor dimensions well below 100 nm, enabling more transistors within a single chip. The smaller dimensions are achieved through improvements in optical lithographic patterning methods. The minimum dimension of components which can be lithographically patterned on an IC is ultimately limited by the wavelength of radiation used in the process and this has continually been decreased over the past few decades. In the late 1980s, wavelengths of 365 nm were employed; by the late 1990s, 248 nm were common; and today, 193 nm is being used; sometimes coupled with *double-patterning* processes to extend to the smallest dimensions. Research into extreme ultraviolet lithography (e.g., at 13.5 nm wavelength) continues for potential use in future generation processes.

Providing good performance from transistors with smaller dimensions required significant advances in materials. For example: better control of doping; use of copper interconnects instead of aluminum; and *low-k* dielectric insulating layers between interconnects instead of silicon dioxide. Perhaps, the most disruptive modification was the replacement of the *native* silicon oxide as the gate insulator by *high-k* dielectric material such as hafnium oxide (Chap. 27). Smaller MOSFET dimensions had required ever thinner silicon gate oxide thicknesses – as shown clearly in Fig. 1.1 – eventually culminating in gate insulator layers just a few atoms thick; sufficiently thin that electron quantum mechanical tunneling through it became a significant power drain. Use of *high-k* material such as hafnium oxide, which has a significantly higher dielectric constant than silicon oxide ($k \approx 22$, compared with $k \approx 3.9$), enabled a return to thicker, tunneling-resistant, gate insulators for devices launched in the early 2000s. This improvement required huge commitment in research and development, including development and production scale-up of new methods to deposit sufficiently perfect *high-k* material (e.g., atomic layer deposition, ALD).

A most recent development in transistor technology has seen the abandonment of the traditional planar geometry and the first widespread use of three-dimensional (3-D) transistor geometries to further reduce leakage problems associated with the extreme proximity of source and drain. For example, the fin field effect transistor (FinFET), where the transistor channel is formed in a several nanometers wide ridge that protrudes above the planar substrate surface and is covered on its three exposed edges by gate material.

The development in complexity and performance of silicon devices, significantly due to materials science progress, is unparalleled in the history of technology. Never before could improvements be measured in terms of a logarithmic scale for such a sustained period. This is often seen as the embodiment of *Moore's law*. Noting a doubling of the number of components fitted onto ICs each year between 1959 and 1965, *Moore* predicted that this rate of progress would continue until at least

10 years later [1.36]. From the early 1970s, a modified prediction of doubling the number of components every couple of years has been sustained to the current day. Since the goals for innovation have often been defined assuming the continuation of the trend, it should perhaps be viewed more as a self-fulfiling prophecy. A huge variety of statistics relating to the silicon microelectronics industry follow a logarithmically scaled improvement from the late 1960s to the current day: the number of transistors shipped per year (increasing); average transistor price (decreasing); and number of transistors on a single chip (increasing) are examples [1.37]. The final member of this list is plotted in Fig. 1.2.

1.3 The Compound Semiconductors

It has been said that silicon is to electronics what steel is to mechanical engineering [1.38]. Steel is very effectively used for most of the world's construction but there are some tasks which it is incapable of performing and others for which alternative structural materials are better suited. In the same way, there are some crucial applications – such as optoelectronics and very high speed electronics – that silicon cannot usually deliver but which a wide range of compound semiconductors are better equipped to perform.

Silicon's band gap is indirect (an electron–hole recombination across the band gap must be accompanied by an interaction with a phonon in the lattice) that severely limits the potential efficiency of light emission from the material. Many of the important compound semiconductors, such as the alloys $Al_xGa_{1-x}As$, $In_xGa_{1-x}N$, $Al_yGa_{1-y}N$, and $Al_xIn_yGa_{1-x-y}P$, exhibit direct band gaps (no phonon interaction is required), so they can efficiently emit brilliant light in LEDs and laser diodes. Furthermore, in these alloy systems, where the band gap can be adjusted by changing the composition, there is a means of selecting the energy released when an electron and hole recombine across the gap and therefore controlling the wavelength of the photons emitted. From the $Al_xIn_yGa_{1-x-y}As$ and $Al_yIn_xGa_{1-x-y}N$ alloy systems, there is, in principle, a continuous range of direct band gaps from deep in the infrared (InAs; $\lambda = 3.5\,\mu m$) to far into the ultraviolet (AlN; $\lambda = 200\,nm$). The semiconductor band gaps of these materials and the corresponding photon wavelengths are put into context with the visible spectrum in Fig. 1.3.

Compounds are also very useful in high speed electronics applications. One of the determining factors in the speed of a transistor is the velocity of the charge carriers in the semiconductor. In GaAs, the electron drift velocity is much higher than in silicon, so its transistors are able to operate at significantly higher frequencies. The electron velocity in InAs is higher still. Furthermore, in the same way that silicon was preferred to germanium, devices manufactured using semiconductors such as GaN, which have much wider band gaps than silicon (3.4 eV compared with 1.1 eV), are capable of operating in much higher temperature environments.

Apart from these advantageous properties of compound semiconductors, the use of different alloy compositions, or totally different semiconductors, in a single device introduces entirely new possibilities. In silicon, most device action is achieved by little more than careful control of dopant impurity concentrations. In structures containing thin layers of semiconductors with different band gaps (heterostructures), there is the potential to control more fundamental parameters such as the band gap width, mobilities, and effective masses of the carriers [1.38]. In these structures, important new features become available which can be used by the device designer to tailor specific desired proper-

ties. Hebert Kroemer and Zhores Alferov shared the Nobel prize in 2000 *for developing semiconductor heterostructures used in high-speed- and optoelectronics*.

We will mainly consider the compounds formed between elements in group III of the periodic table and those in group V (the III–V semiconductors); principally those based around GaAs and InP which were developed over much of the last 40 years, and GaN and its related alloys which have been most heavily studied only during the last two decades. Other families are given less attention here, though they also have important applications (e.g., the II–VI materials in optoelectronic applications). It can be hazardous to try and consider the *compound semiconductors* as a single subject. Though lessons can be learnt from the materials science of one of the compounds and transferred to another, each material is unique and must be considered on its own (i. e., of course, the purpose of the specialized chapters which follow in this handbook).

It is worth repeating that the power of the compound semiconductors lies in their use as the constituent layers in heterostructures. The principal contribution from chemistry and materials science to enable successful devices has been in the manufacture of high-quality bulk single crystal substrates and the development of techniques to reliably and accurately produce real layered structures on these substrates from the plans drawn up by a device theorist. In contrast to silicon, the compound semiconductors include volatile components, so encapsulation has been required for the synthesis of low-defect InP and GaAs substrates such as in the liquid encapsulated Czochralski technique [1.39, 40]. The size and crystalline quality of these substrates lag some way behind those available in silicon. Crucial to the commercialization of electronic and optoelectronic heterostructures were the improvements over the last few decades in the control of epitaxial growth available to the crystal grower. The first successful heterostructures were manufactured using deposition onto a substrate from the liquid phase (liquid phase epitaxy (LPE)) – *a beautifully simple technology but with severe limitations* [1.38]. However, the real heterostructure revolution had to wait for the 1970s and the introduction of molecular beam epitaxy (MBE) and metallorganic chemical vapor deposition (MOCVD) – also known as metallorganic vapor phase epitaxy (MOVPE) provided that the deposition is epitaxial.

MBE growth occurs in an ultrahigh vacuum with the atoms emitted from effusion cells forming *beams* which impinge upon and form compounds at the substrate surface. It derives from pioneering work at the start of the 1970s [1.41]. MOCVD relies on chemical reactions occurring on the substrate involving metallorganic vapor phase precursors and also stems from initial work at this time [1.42]. In contrast to LPE, these two techniques permit the combination of a wide range of different semiconductors in a single structure and offer a high degree of control over the local composition, in some cases on an atomic layer scale. The successful heterostructure devices of the late 1970s and 1980s would not have been achievable without these two tools and they still dominate III–V device production and research today.

1.3.1 High-Speed Electronics

The advantages of the III–V materials over silicon for use in transistors capable of operating at high frequencies were identified early in the semiconductor revolution [1.43]. Shockley's first patent for p–n junction transistors had included the proposal to use a wide-gap emitter layer to improve performance, and in the 1950s, *Kroemer* presented a theoretical design for a heterostructure transistor [1.44]. Some years later, the structure of a GaAs metal semiconductor FET (MESFET) was proposed and realized soon afterwards [1.45, 46]. In these devices, a Schottky barrier surface potential was used to modulate the conductivity of the GaAs channel. One of the earliest applications of the III–Vs was the low-noise amplifiers in microwave receivers that offered substantial improvements relative to the silicon bipolar transistors of the time. The devices were later used to demonstrate subnanosecond switching in monolithic digital ICs [1.47]. Today, they form the core of the highest speed digital circuits and are used in high speed electronics in microwave radar systems and wireless communications which incorporate monolithic ICs.

For at least 30 years, there have been repeated attempts to replicate the MOSFET, the dominant transistor form in silicon ICs, on GaAs material. These attempts have been frustrated by the difficulty of reproducibly forming a high quality stoichiometric oxide on GaAs. In direct analogy with the initial failure of constructing working n-MOSFETs on silicon, the GaAs devices have consistently been inoperable because of poor quality gate oxides with a high density of surface states at the GaAs–insulator interface [1.40]. One of the research efforts focused on realizing this device was, however, to be diverted and resulted in the discovery of probably the most important III–V electronic device, that is, the high electron mobility transistor (HEMT).

The background to this invention lies in the beautiful concept of modulation doping of semiconductors which was first demonstrated in 1978 [1.48]. One of the tenets of undergraduate semiconductor courses is the demonstration that as the dopant density in a semiconductor increases, the mobility of the carriers is reduced,

because the carriers are scattered more by the ionized dopants. It was found that in a multilayer of repeating n-AlGaAs layers and undoped GaAs layers, the electrons supplied by donor atoms in the AlGaAs, moved into the adjacent potential wells of the lower-band gap GaAs layers. In the GaAs these suffered from substantially less ionized impurity scattering and therefore demonstrated enhanced mobility.

While working in a group attempting to create GaAs MOSFETs (and seemingly despairing at the task [1.49]), *Takashi Mimura* heard of these results and conceived of a field effect transistor where the conducting channel exploited the high mobility associated with a modulation doped structure. In essence, a doped AlGaAs layer was formed above the undoped GaAs channel of the transistor. Donated carriers gathered in the GaAs immediately below the interface where they did not suffer from as much ionized impurity scattering and so their mobility would approach that of an ultrapure bulk semiconductor. The current was conducted from the source to the drain by these high mobility carriers and so the devices were able to operate in higher frequency applications [1.49]. Realization of the structure required a very abrupt interface between the GaAs and AlGaAs and was considered beyond the capability of MOCVD of the time [1.49]. However, following the advances made in MBE procedures during the 1970s, the structure was achieved by that technique within a few months of the original conception [1.49, 50]. The first operational HEMT chips were produced on December 24, 1980: By pleasing coincidence this was the anniversary of Brattain and Bardeen's demonstration of their point-contact resistor to the management of Bell Labs in 1947. Structures based on the same principle as Mimura's device were realized in France very shortly afterwards [1.51].

The commercialization of the HEMT became significant in the late 1980s, thanks to broadcasting satellite receivers. The improved performance of the devices compared with the existing technology allowed the satellite parabolic dish size to be reduced by at least a factor of two. Structures similar to these have since played a crucial role in the massive expansion in mobile telephones.

The evolution in HEMT structures since the early 1980s is a fine example of how fundamental compound semiconductor properties have been exploited as the technology has become available to realize new device designs. The electron mobility in InAs is much higher than that in GaAs and rises as the indium content in $In_xGa_{1-x}As$ is increased [1.52]. The introduction of an InGaAs (as opposed to GaAs) channel to the HEMT structure, to create the so-called pseudomorphic HEMT (pHEMT), resulted both in increased electron mobility and a higher density of carriers gathering from the doped AlGaAs layer (because of the larger difference in energy between the conduction band minima of InGaAs and AlGaAs than that between GaAs and AlGaAs) [1.39]. The indium content and thickness of the channel are limited by the lattice mismatch with the GaAs (Fig. 1.3). If either is increased too much, then misfit dislocations are formed within the channel. The restriction is reduced by growing lattice matched structures on InP, rather than GaAs, substrates. $Al_{0.48}In_{0.52}As$ and $In_{0.53}Ga_{0.47}As$ are both lattice matched to the InP (Fig. 1.3) and their conduction band minimum energies are well separated, so that in the InGaAs below the interface between the two compounds a high density of electrons with a very high mobility is formed. Compared to the pHEMTs, these InP-based HEMTs exhibited significant improvements, were shown to exhibit gain at over 200 GHz, and became established as the leading transistor for millimeter-wave low noise applications such as radar [1.39].

1.3.2 Light Emitting Devices

LEDs and laser diodes exploit the direct band gap semiconductors to efficiently convert an electric current into photons of light. Work on light emission from semiconductor diodes was carried out in the early decades of the twentieth century [1.53], but the start of the modern era of semiconductor optoelectronics traces from the demonstration of lasing and LED behavior from p–n junctions in GaAs [1.54, 55] and $GaAs_{1-x}P_x$ [1.56]. The efficiency of these LEDs was low and the lasers had large threshold currents and only operated at low temperatures. A year later, in 1963, *Kroemer* and *Alferov* independently proposed the concept of the double heterostructure (DH) laser [1.57, 58]. In the DH device, a narrow band gap material was to be sandwiched between layers with a wider gap so that there would be some degree of confinement of carriers in the *active layer*. By the end of the decade, DH devices had been constructed that exhibited continuous lasing at room temperature [1.59, 60]. Alferov's laser was grown by LPE on a GaAs substrate with a 0.5 μm GaAs active layer confined between 3 μm of $Al_{0.25}Ga_{0.75}A$ on either side. The launch of the compact disk in 1982 saw this type of device, or at least its offspring, becoming taken for granted in the households of the world.

One of the major challenges in materials selection for heterostructure manufacture has always been avoiding the formation of misfit dislocations to relieve the strain associated with lattice parameter mismatch between the layers. $Al_xGa_{1-x}As$ exhibits a direct band gap for $x < 0.45$ and the early success and sustained

dominance of the AlGaAs/GaAs system derive significantly from the very close coincidence of the AlAs and GaAs lattice parameters (5.661 Å and 5.653 Å; Fig. 1.3). This allows relatively thick layers of AlGaAs with reasonably high aluminum content to be grown lattice matched onto GaAs substrates with no misfit dislocation formation. The use of the quaternary alloy solid solution $In_xGa_{1-x}As_yP_{1-y}$ was also suggested in 1970 [1.59] to offer the independent control of lattice parameters and band gaps. Quaternaries based on three group III elements have since proved very powerful tools for lattice matching within heterostructures. $(Al_xGa_{1-x})_{0.5}In_{0.5}P$ was found to be almost perfectly lattice matched to GaAs and additionally have a very similar thermal expansion coefficient (which is important to avoid strain evolution when cooling after growth of heteroepitaxial layers at high temperatures). By varying x in this compound, direct band gaps corresponding to light between red and green could be created [1.61]. Lasers based on this alloy grown by MOCVD are a common choice for the red wavelengths (650 nm) used in DVD reading (Fig. 1.3).

Obtaining lattice matching is not so crucial for layers thinner than the critical thickness for dislocation production and can be less of an issue these days because of probably the most important development in the history of optoelectronic devices, that is, the introduction of the quantum well. In some way a quantum well structure is an evolution of the double heterostructure but with a very much thinner active layer. It is the chosen design for most solid-state light emitting devices today. With the accurate control available from MBE or MOCVD, and following from some early work on superlattices [1.62], very thin layers of carefully controlled composition could be deposited within heterostructure superlattice stacks. It became possible to grow GaAs layers much less than 10 nm thick within AlGaAs–GaAs heterostructures. The carriers in the GaAs were found to exhibit quantum mechanical confinement within the one-dimensional potential well [1.63, 64]. Lasing from $GaAs/Al_{0.2}Ga_{0.8}As$ quantum wells was reported the following year [1.65], but it was a few years before the emission matched that achievable from DH lasers of the time [1.66] and the quantum well laser was further advanced to significantly outperform the competition by researchers in the 1980s [1.67].

The introduction of heterostructures with layer thicknesses on the nanometer or atomic scale represents the final stage in scaling down of these devices. Similarly, Brattain and Bardeen's centimeter-sized transistor has evolved into today's microprocessors with far submicron FETs whose gate oxide thicknesses are measured in Angstroms. Throughout this evolution, materials characterization techniques (Chaps. 17–20) have contributed heavily to the progress in our understanding of electronic materials and these techniques deserve a brief detour here. As the dimensions have been reduced over the decades, the cross-sectional images of device structures published in the literature have progressed from optical microscopy [1.28], to scanning electron microscopy (SEM) images [1.66], to today's high- or atomic-resolution transmission electron microscopy (TEM) analysis of ultrathin layers. The challenge of obtaining relevant and representative data from the smaller volume of material, which is available in higher magnification analysis, has been met during the past decade or so by widespread adoption of highly site specific specimen preparation techniques based around focused ion beam (FIB) milling. For each new material family, understanding of defects and measurement of their densities (e.g., by TEM and x-ray topography) have contributed to improvements in quality. Huge improvements in x-ray optics have seen high-resolution x-ray diffraction techniques develop to become a cornerstone of heterostructure research and production quality control [1.68]. Scanning-probe techniques such as scanning tunneling and atomic force microscopy have become crucial to the understanding of MBE and MOCVD growth. Chemically sensitive techniques such as secondary ion mass spectroscopy and Rutherford backscattering have improved to provide information on doping concentrations and compositions in layered structures with excellent depth resolution. Chemically sensitive measurements have truly reached the atomic scale in the past decade through the exploitation of new generations of aberration-corrected and monochromated transmission electron microscopes and three-dimensional atom probe microscopy (3DAP). The disruptive improvement of spatial resolution enabled by the new generation TEMs continues to yield invaluable insight into atomic-scale material, interface, and device structures, especially when combined with chemically sensitive techniques such as electron energy loss spectroscopy (EELS). Meanwhile, the application of 3DAP to semiconducting and insulating materials and devices provides, for the first time, the *holy grail* of 3-D, atom-by-atom chemically resolved maps. By way of example, we show an atomic-scale chemical map of the critical layers in a III-nitride laser diode structure in Fig. 1.4, revealing crucial information on the distribution of alloy and dopant atoms. The materials characterization process remains a critical element of electronic and photonic materials research.

A primary commercial driver for semiconductor laser diode research has been to produce more effective emitters of infrared wavelengths for transmission of data along optic fibers. Devices based on InP sub-

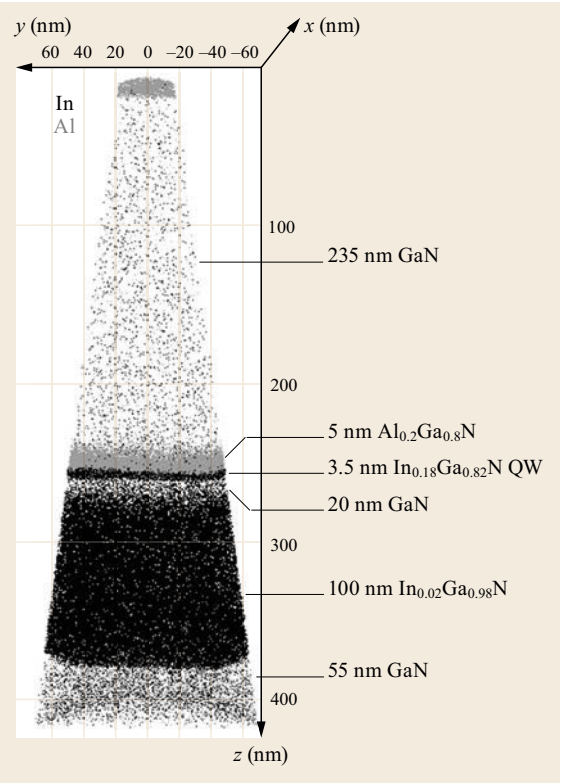

Fig. 1.4 Reconstructed atom map of the active region of a III-nitride laser diode structure determined by 3-D atom probe microscopy (3DAP). Indium atoms are displayed as *black* (25% displayed); aluminum atoms are displayed as *gray* (25% displayed); other atoms are not displayed. (After [1.69], with permission from AIP Publishing)

strates have proven to be extremely effective because of its fortuitous lattice parameter match with other III–V alloys which have band gaps corresponding to the low-absorption *windows* in optic fibers. While remaining lattice matched to InP, the $In_xGa_{1-x}As_yP_{1-y}$ quaternary can exhibit band gaps corresponding to infrared wavelengths of 1.3 and 1.55 μm at which conventional optic fibers absorb the least of the radiation (the absolute minimum is for 1.55 μm). Room temperature continuous lasing of 1.1 μm radiation was demonstrated from the material in 1976 [1.70], and InP-based lasers and photodiodes have played a key role in the optical communications industry since the 1980s [1.39].

A second major driver for laser diode research since the 1970s was to produce laser components for reading or writing optical storage media. We have already mentioned the AlGaAs infrared ($\lambda = 780$ nm) emitters used to read compact discs (CD) and the AlGaInP red ($\lambda = 650$ nm) lasers in DVD devices (Fig. 1.3). As lasers emitting the shorter wavelength became available, the optical disc's surface pits (through which bits of data are stored) could be made smaller and the storage density increased. The pursuit of shorter wavelength laser diodes for higher density optical storage supported extensive development of wide band gap II–VI compounds, principally ZnSe, for their potential in green ($\lambda \approx 520$ nm) and blue ($\lambda \approx 440$ nm) wavelengths. Laser operation in this part of the visible spectrum proved difficult to realize [1.71] and, although a blue/green laser was demonstrated in the early 1990s following improvements in the p-doping of ZnSe [1.72], the devices were prone to rapid deterioration during operation and were never commercialized. Ultimately, the winning laser diode technology for the third generation of optical storage laser was based on III-nitride materials following breakthroughs in the 1990s that are introduced in the next section. Blue/violet ($\lambda = 405$ nm) emitting $In_xGa_{1-x}N$-based laser diodes enabled Blu-ray (BD), the third and current generation of optical storage. CD, DVD, and BD technologies were introduced in 1982, 1995, and 2006, respectively, providing data storage per layer of approximately 0.7 GB, 4.7 GB, and 25 GB; a growth of data capacity five times per decade.

It is likely that BD also marks the final phase of the consumer optical disk era as network-based data distribution and storage replace the widespread use of optical discs. This is a good time, therefore, to note that for over 30 years the rapid advances in home entertainment (music, films, and console games) and computing (software distribution and data storage) were enabled in part by laser diode materials and device technology. The technology race for optical storage laser diodes leaves a legacy of extraordinary laser component technologies that inevitably evolve to bring value to new sectors, for example, the imminent growth of laser diode-based image projectors and automotive headlights. Of course, the growth in network data distribution which has caused the consumer optical disk era to peak is enabled by the laser diodes used in network data communication, a wonderful example of the ebb and flow of technology dominance.

1.3.3 The III-Nitrides

In the final section of this chapter, we focus on the III-nitride materials, such as GaN, $In_xGa_{1-x}N$, and $Al_yGa_{1-y}N$ and their devices, which have been subject to some of the most widespread research and development among all electronic and photonic materials since the mid-1990s. III-nitride LEDs and laser diodes have revolutionized the lighting, display, and optical storage industries during the past decade. Electronic devices based on these materials are expected to have a strong

impact on electrical power distribution and electric vehicles in the next.

The relevance of the $In_xGa_{1-x}N$ alloy for visible light emitting devices is clear from Fig. 1.3. The InN and GaN direct band gaps correspond to wavelengths straddling the visible spectrum, and the alloy potentially offers access to all points in-between. The early commercially successful InGaN light emitters were marketed by Nichia Chemical Industries following the research work of *Shuji Nakamura* who demonstrated the first blue InGaN DH LEDs [1.73], blue InGaN quantum well LEDs, and laser diodes soon after [1.74]. Nakamura, together with other pioneers in III-nitride growth, Isamu Akasaki, and Hiroshi Amano received the 2014 Nobel Prize for Physics for their contributions to blue LED technology. Meanwhile, the wide band gap and other advantageous properties of GaN and $Al_yGa_{1-y}N$ alloys provide new opportunities for high-frequency and power transistors for high voltage switching and deep ultraviolet light emitters.

The development of III-nitride materials and devices has much in common with the early research of other III–V systems. For example, MOCVD and MBE growth technologies were both successfully used for III-nitride device growth (MOCVD has become the preferred technology for mass manufacturing of light emitting devices); both electronic and optoelectronic device applications were explored from an early stage; and one of the obstacles limiting early device development was achieving sufficiently high p-type carrier densities. However, in some ways III-nitrides presented new challenges: Although *conventional* III–Vs all share the same cubic crystallographic structure, the nitrides most readily form in a hexagonal allotrope that has strong polar and piezoelectric properties; the vast majority of III-nitride device development and manufacturing has used heteroepitaxial growth on highly lattice-mismatched substrates leading to devices with very high defect densities, in contrast to a reliance on homoepitaxy or closely lattice matched substrates in previously successful III–V systems where much lower defect densities are standard; and many III-nitride devices have been found to be astonishingly more tolerant to the presence of these crystalline defects than other III–Vs. We will focus briefly on two fascinating aspects of the story of the III-nitrides today: the variety of substrate materials in mainstream use, and the remarkable – and still not fully understood – properties of the $In_xGa_{1-x}N$ alloy.

First, the plurality of substrate materials in use for LEDs. Synthesis of large bulk GaN crystals – the obvious substrate choice from a technical perspective – is much more difficult than for other III–Vs such as GaAs or InP. Methods including ammonothermal growth and hydride VPE are technically viable routes to produce high quality GaN substrates today. However, in the early stages of III-nitride development, there were no large area GaN substrates available and heteroepitaxial growth of GaN on foreign substrates was the only option for commercial LED production. Even today, GaN substrate costs are very high owing to combinations of high temperature, high pressures, slow growth rates, and expensive precursor materials in the manufacturing process.

A consequence of the initial necessity of heteroepitaxy, and ongoing commercial barriers to the use of GaN substrates, is that a total of four substrate materials are in use for commercial production of InGaN-based blue LEDs: sapphire (α-Al_2O_3), silicon carbide, silicon, and GaN. Substrate choice is not purely based on technical factors – commercial considerations are strong drivers – but in the context of conventional compound semiconductors, it is extraordinary that four completely different substrates can be used to produce LEDs with approximately competitive device performance (say, competitive within a factor of two).

Current LED production is dominated by use of sapphire substrates, with silicon carbide substrates a distant second and silicon and GaN substrates just entering the market in recent years. Sapphire is by no means an ideal choice. First, it is electrically insulating which means that electrical contacts cannot be made to the device through the substrate material, thus, requiring LED designs with both n- and p-contacts on the same surface. Second, the refractive indices of sapphire and GaN are significantly different, which lead to low efficiency of extraction of light from the LED chip unless special measures are applied, such as the removal of the substrate or 3-D patterning of the sapphire surface prior to GaN growth. Third, and perhaps most importantly, sapphire has a large lattice mismatch of approximately 16% with GaN [1.75]. This large lattice mismatch is relieved by the formation of misfit dislocations at the GaN/Al_2O_3 interface which lead to threading dislocations propagating through the GaN into the active layers of the devices. The key discovery for reducing the defect densities to tolerable levels was the use of *buffer* layers at the interface with the sapphire [1.75]. Dislocation densities of approximately $10^9\,cm^{-2}$ were adequate for the first commercial LEDs and countless refinements to buffer layer growth have led to typical threading dislocation densities of approximately 10^7–$10^8\,cm^{-2}$ in devices today. In principle, silicon carbide has advantages over sapphire: it can be electrically conducting, the substrate can be readily etched to form chip shapes that improve light extraction efficiency, and it has a smaller lattice mismatch with GaN. However, despite these significant differences,

devices grown on sapphire and silicon carbide have remained broadly competitive with one another. Cost and availability considerations led to sapphire becoming the mainstream substrate choice for LEDs during the early 2000s.

More recently, silicon and GaN have emerged as alternative substrate choices, for quite distinct reasons. Silicon substrates are pursued as a route to reduce LED manufacturing costs compared with incumbent production on sapphire. A key driver is the lower cost of silicon wafers, especially in large wafer formats (at least 150 mm diameter) which can be processed by otherwise unused and fully depreciated wafer processing lines previously established for silicon electronics processing. In addition to the lower substrate cost, GaN-on-silicon enables cost reductions to be made in processing, packaging, and phosphors. For example, GaN-on-silicon facilitates chip scale packaging (CSP), chip scale optics (CSO), and die level integration. CSP has been used for silicon electronics for many years and this technology can now be used for GaN-on-silicon. CSP also reduces the phosphor usage, gives improved thermal performance and is a route to wafer scale packaging (WSP). The main technical challenges to delivering viable device performance and yield are large lattice mismatch (again) and large difference in thermal expansion coefficient compared with GaN, which leads to cracking and bowing during cool down after growth unless careful strain engineering is used during growth [1.76]. In contrast, GaN substrates are substantially more expensive than sapphire, and only viable in smaller formats (typically 50–75 mm diameter). However, LEDs grown on GaN substrates benefit from much lower threading dislocation densities and consequently deliver some of the best device efficiencies, especially for small chips operated at high drive currents [1.77]. The next few years will reveal if silicon substrates or GaN substrates can substantially displace the incumbent sapphire and silicon carbide-based production.

Throughout the history of InGaN LED research, there has been ongoing fascination and controversy regarding the precise mechanism of light emission from InGaN quantum wells. The original driver behind this was the extraordinarily high light emission efficiency of InGaN quantum wells, despite the presence of dislocation densities as high as $10^9\,\mathrm{cm}^{-2}$. Obtaining similar light emission efficiencies in other III–V materials typically required dislocation densities to be several orders of magnitude lower.

For a few years, a popular explanation for the high efficiency of light emission from InGaN quantum wells was that strong fluctuations in the indium concentration in the quantum wells created low-energy quantum-dot like sites that localized electrons and holes and reduced the deleterious impact of dislocations on the light emission process. This explanation was based primarily on TEM analysis of InGaN quantum wells which indicated nanometer-scale regions with greatly higher indium fraction than the remainder of the quantum well – so called *indium clusters*. Many attempts were made to control and optimize this clustering process to increase light emission efficiency. However, since we demonstrated that the apparent indium concentration fluctuations could be a misleading artifact of TEM analysis [1.78, 79], and that high light emission efficiency could be obtained from InGaN quantum wells with random indium distribution [1.80], this theory is no longer widely supported. The origin of localization is now supposed to be due to much subtler features of the InGaN quantum wells.

Recently, the controversy concerning InGaN light emission has evolved to also explaining the phenomenon of *efficiency droop* in InGaN LEDs. *Droop* refers to the observed reduction in efficiency of state-of-the-art LEDs when they are operated at high current densities. There is great pressure to understand and reduce droop because of the potential cost benefit from using smaller LED chips with higher operating currents (i. e., high current densities). The subject of dozens of high profile publications and review articles over the last 10 years, many theories have been vigorously proposed for lower efficiencies at high current densities: increased Auger recombination of electrons and holes; overflow of electrons from the LED active region; the delocalization of carriers; and a complex role of large-scale crystalline defects.

Although these important technical debates are still largely unresolved, the global impact of InGaN LEDs cannot be disputed. This is a good example of how commercial success of electronic and photonic devices can easily occur before full technical understanding of the materials is established. Twelve years ago, in the introduction to the 1st Edition of this handbook, we wrote of the potential for III-nitride LEDs to replace traditional light sources such as incandescent light bulbs, but noted the need to reduce costs and increase the output power from individual LEDs to reach this goal. These commercial and technical barriers were emphatically overcome and the potential is now being realized. Production costs have been driven down by massive economies of scale during epitaxial growth, improvements in yield, cheaper device processing, and improved device performance which mean fewer, smaller LEDs are required for a given application. Tremendous improvements in LED performance – in particular, higher efficiency and high power light output – have been delivered through countless improvements in all aspects of the LED technology, including the core semiconductor material

fabrication. As a consequence, InGaN blue- or violet-emitting LEDs, combined with phosphors that produce white light emission, are now cornerstone technologies in domestic, retail, industrial and outdoor lighting, vehicle headlights, and LCD backlighting. These solid-state technologies provide large energy savings compared with conventional light sources. Every day for the foreseeable future, we will directly sense – through our eyes – the light generated by these devices. Next generation LED lighting may be even more efficient, by omitting phosphors and generating white light by mixing red, yellow, green, and blue LEDs. Such lighting would be color tunable and could mimic sunlight indoors. There is increasing evidence that such optimized lighting would be good for our health, increase productivity at work, and even improve examination results in schools.

In this introductory chapter, we have glimpsed just one sector of the electronic and photonic materials landscape, focusing on just a few semiconductor families. We have given examples of the complex interdependence and balance of power between different materials and technologies: the astonishing integration of materials which we take for granted in a budget smartphone; the switch from germanium to silicon in the early years of the transistor; the dominance and relentless performance improvements in silicon ICs over several decades; the laser-diode enabled growth of consumer optical storage to its peak; and the co-existence of dramatically different approaches to make LEDs which are revolutionizing the way we light the world. There is a complex fusion of science and engineering excellence, ingenious breakthroughs, serendipity, and commercial considerations. But underpinning it all is the need to fundamentally understand and precisely control these fascinating materials. And this is all the more exciting because the pace of progress is so high, and the influence of the materials is so great, thanks to the electronic and photonic materials being the enabling technology in so many aspects of modern life. The detailed chapters in the rest of this book are a valuable resource to support further advances in this vital field.

2. Electrical Conduction in Metals and Semiconductors

Safa Kasap, Cyril Koughia, Harry E. Ruda

Electrical transport through materials is a large and complex field, and in this chapter we cover only a few aspects that are relevant to practical applications. We start with a review of the semi-classical approach that leads to the concepts of drift velocity, mobility and conductivity, from which Matthiessen's Rule is derived. A more general approach based on the Boltzmann transport equation is also discussed. We review the conductivity of metals and include a useful collection of experimental data. The conductivity of nonuniform materials such as alloys, polycrystalline materials, composites and thin films is discussed in the context of Nordheim's rule for alloys, effective medium theories for inhomogeneous materials, and theories of scattering for thin films. We also discuss some interesting aspects of conduction in the presence of a magnetic field (the Hall effect). We present a simplified analysis of charge transport in semiconductors in a high electric field, including a modern avalanche theory (the theory of *lucky* drift). The properties of low-dimensional systems are briefly reviewed, including the quantum Hall effect.

A good understanding of charge carrier transport and electrical conduction is essential for selecting or developing electronic materials for device applications. Of particular importance are the drift mobility of charge carriers in semiconductors and the conductivity of conductors and insulators. Carrier transport is a broad field that encompasses both traditional *bulk* processes and, increasingly, transport in low dimensional or quantized structures. In other chapters of this handbook, Baranovskii describes hopping transport in low mobility solids such as insulators, Morigaki deals with the electrical properties of amorphous semiconductors and Gould discusses in detail conduction in thin films. In this chapter, we outline a semi-quantitative theory of charge transport suitable for a wide range of solids of use to materials researchers and engineers. We introduce theories of *bulk* transport followed by processes pertinent to ultra-fast transport and quantized transport in lower dimensional systems. The latter covers such phenomena as the Quantum Hall Effect, and Quantized Conductance and Ballistic Transport in Quantum Wires that has potential use in new kinds of devices. There are many more rigorous treatments of charge transport; those by *Rossiter* [2.1] and *Dugdale* [2.2] on metals, and *Nag* [2.3] and *Blatt* [2.4] on semiconductors are highly recommended.

2.1 Fundamentals: Drift Velocity, Mobility and Conductivity

Basic to the theory of the electronic structure of solids are the solutions to the quantum mechanical problem of an electron in a periodic potential known as Bloch waves. These wavefunctions are traveling waves and provide the physical basis for conduction. In the semi-classical approach to conduction in materials, an electron wavepacket made up of a superposition of Bloch waves can in principle travel unheaded in an ideal crystal. No crystal is ideal, however, and the imperfections cause scattering of the wavepacket. Since the interaction of the electron with the potential of the ions is incorporated in the Bloch waves, one can concentrate on the relatively rare scattering events which greatly simplifies the theory. The motion of the electrons between scattering events is essentially free (with certain provisos such as no interband transitions) subject only to external forces, usually applied electric or magnetic fields. A theory can then be developed that relates macroscopic and measurable quantities such as conductivity or mobility to the microscopic scattering processes. Principle in such a theory is the concept of *mean free time* τ which is the average time between scattering events. τ is also known as the *conductivity relaxation time* because it represents the time scale for the momentum gained from an external field to relax. Equivalently, $1/\tau$ is the average probability per unit time that an electron is scattered.

There are two important velocity quantities that must be distinguished. The first is the *mean speed* u or *thermal velocity* v_{th} which, as the name implies, is the average speed of the electrons. u is quite large being on the order of $\sqrt{3k_{\mathrm{B}}T/m_{\mathrm{e}}^*} \approx 10^5\,\mathrm{m/s}$ for electrons in a nondegenerate semiconductor and $\sqrt{2E_{\mathrm{F}}/m_{\mathrm{e}}^*} \approx 10^6\,\mathrm{m/s}$ for electrons in a metal, where k_{B} is Boltzmann's constant, T is the temperature, E_{F} is the Fermi energy of the metal, and m_{e}^* is the electron effective mass. The distance an electron travels between scattering events is called the free path. It is straightforward to show that the average or *mean free path* for an electron is simply $\ell = u\tau$. The second velocity is the mean or *drift velocity* $\boldsymbol{v}_{\mathrm{d}}$ (variables in boldface are vectors) which is simply the vector average over the velocities of all N electrons,

$$\boldsymbol{v}_{\mathrm{d}} = \frac{1}{N}\sum_{i=1}^{N} \boldsymbol{v}_i \,. \tag{2.1}$$

With no external forces applied to the solid, the electron motion is random and thus the drift velocity is zero. When subject to external forces like an electric field, the electrons acquire a net drift velocity. Normally, the magnitude of the drift velocity is much smaller than u so that the mean speed of the electron is not affected to any practical extent by the external forces. An exception is charge transport in semiconductors in high electric fields, where $|\boldsymbol{v}_{\mathrm{d}}|$ becomes comparable to u.

The drift velocity gives rise to an electric current. If the density of electrons is n then the current density $\boldsymbol{J}_{\mathrm{e}}$ is

$$\boldsymbol{J}_{\mathrm{e}} = -en\boldsymbol{v}_{\mathrm{d}} \tag{2.2}$$

where e is the fundamental unit of electric charge. For the important case of an applied electric field $\boldsymbol{E}$, the solutions of the semi-classical equations give a drift velocity that is proportional to $\boldsymbol{E}$. The proportionality constant is the *drift mobility* μ_{e}

$$\boldsymbol{v}_{\mathrm{d}} = -\mu_{\mathrm{e}}\boldsymbol{E} \,. \tag{2.3}$$

The drift mobility might be a constant or it might depend on the applied field (usually only if the field is large). Ohm's Law defines the conductivity σ of a material $\boldsymbol{J} = \sigma\boldsymbol{E}$ resulting in a simple relation to the drift mobility

$$\sigma = en\mu_{\mathrm{e}} \,. \tag{2.4}$$

Any further progress requires some physical theory of scattering. A useful model results from the simple assumption that the scattering randomizes the electron's velocity (taking into proper account the distribution of electrons and the Pauli Exclusion Principle). The equation of motion for the drift velocity then reduces to a simple form

$$\frac{\mathrm{d}\boldsymbol{v}_{\mathrm{d}}}{\mathrm{d}t} = \frac{\boldsymbol{F}(t)}{m_{\mathrm{e}}^*} - \frac{\boldsymbol{v}_{\mathrm{d}}}{\tau} \,, \tag{2.5}$$

where $\boldsymbol{F}(t)$ is the sum of all external forces acting on the electrons. The effect of the scattering is to introduce a frictional term into what otherwise would be just Newton's Law. Solutions of (2.5) depend on $\boldsymbol{F}(t)$. In the simplest case of a constant applied electric field, the steady-state solution is trivial,

$$\boldsymbol{v}_{\mathrm{d}} = \frac{-e\boldsymbol{E}\tau}{m_{\mathrm{e}}^*} \,. \tag{2.6}$$

The conductivity and drift mobility can now be related to the scattering time [2.5],

$$\mu_{\mathrm{e}} = \frac{e\tau}{m_{\mathrm{e}}^*} \quad \text{and} \quad \sigma = \frac{ne^2\tau}{m_{\mathrm{e}}^*} \,. \tag{2.7}$$

More sophisticated scattering models lead to more accurate but more complicated solutions.

The simple expression (2.7) can be used to explain qualitative features of conduction in materials once a physical origin for the scattering is supplied. For any scattering site, the effective area is the *scattering cross-section* S as depicted in Fig. 2.1. The scattering cross section is related to the mean free path since the volume $S\ell$ must contain one scattering center. If there are N_S scattering centers per unit volume then

$$\ell = \frac{1}{SN_S} , \tag{2.8}$$

or, rewriting in terms of τ,

$$\tau = \frac{1}{SN_S u} . \tag{2.9}$$

Once the cross-section for each physically relevant scattering mechanism is known then the effect on the scattering time and conductivity is readily calculated.

An overly restrictive assumption in the above analysis is that the electron's velocity is completely randomized every time it is scattered. On the other hand, suppose that ν collisions are required to completely destroy the directional velocity information. That is only after an average of ν collisions do all traces of correlation between the initial and the final velocities disappear. The *effective* mean free path ℓ_{eff} traversed by the electron until its velocity is randomized will now be larger than ℓ; to first order $\ell_{\text{eff}} = \nu\ell$. ℓ_{eff} is termed the *effective* or the *conduction mean free path*. The corresponding *effective scattering cross* section is

$$S_{\text{eff}} = \frac{1}{N_S \ell_{\text{eff}}} . \tag{2.10}$$

The expressions for mobility and conductivity become

$$\mu = \frac{e\nu\tau}{m_e^*} = \frac{e\nu\ell}{m_e^* u} = \frac{e\ell_{\text{eff}}}{m_e^* u} = \frac{e}{m_e^* u N_S S_{\text{eff}}} \tag{2.11}$$

and

$$\sigma = \frac{e^2\nu\tau}{m_e^*} = \frac{e^2 n\nu\ell}{m_e^* u} = \frac{e^2 n\ell_{\text{eff}}}{m_e^* u} = \frac{e^2 n}{m_e^* u N_S S_{\text{eff}}} . \tag{2.12}$$

Suppose that in a collision the electron is scattered at an angle θ to its original direction of travel as shown in Fig. 2.2. It is convenient to introduce a quantity $S_\theta(\theta)$, called the *differential scattering cross section*, defined so that $2\pi \sin\theta S_\theta \mathrm{d}\theta$ represents the probability of scattering at an angle between θ and $\theta + \mathrm{d}\theta$ with respect to the original direction. If the magnitude of the velocity is not changed then the fractional change in component of the velocity along the original direction is $1 - \cos\theta$. The average number of collisions ν required to randomize the velocity is then

$$\nu = \frac{1}{\langle 1 - \cos\theta \rangle} , \tag{2.13}$$

where the average is given by

$$\langle 1 - \cos\theta \rangle = \frac{\int_0^\pi (1 - \cos\theta)\, S_\theta\,(\theta) \sin\theta \mathrm{d}\theta}{\int_0^\pi S_\theta\,(\theta) \sin\theta \mathrm{d}\theta} . \tag{2.14}$$

The effective cross sectional area S_{eff} is then

$$S_{\text{eff}} = 2\pi \int_{\theta_m}^{\pi} (1 - \cos\theta)\, S_\theta\,(\theta) \sin\theta \mathrm{d}\theta . \tag{2.15}$$

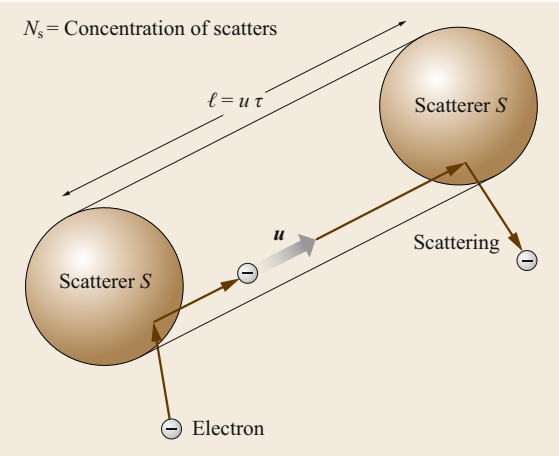

Fig. 2.1 Scattering of an electron from a scattering center. The electron travels a mean distance $\ell = u\tau$ between collisions

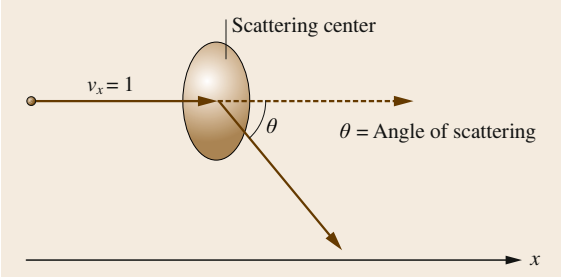

Fig. 2.2 An electron moving in the x-direction becomes scattered though an angle θ with respect to the original direction

As an example, consider conduction electrons scattering from charged impurities in a nondegenerate semiconductor where small angle deviations predominate. The differential cross section for coulombic scattering from a charged impurity center with charge $+Ze$ is

$$S_\theta(\theta) = \frac{16k^2}{u^4} \times \frac{1}{\theta^4}\,; \quad k = \frac{Ze^2}{4\pi\varepsilon_0\varepsilon_r m_e^*}\,, \tag{2.16}$$

where $k = Ze^2/4\pi\varepsilon_0\varepsilon_r m_e^*$ and ε_r is the relative permittivity of the semiconductor. Let r_m be the maximum effective radius of action for the impurity at which the minimum scattering angle θ_m occurs. Then the integral in (2.15) evaluates to

$$S_{\text{eff}} = \frac{2\pi k^2}{u^4} \ln\left(1 + \frac{r_m^2 u^4}{k^2}\right). \tag{2.17}$$

In a nondegenerate semiconductor, the equipartition theorem links velocity to temperature, $m_e^* u^2/2 = 3kT/2$, so that $u \propto T^{1/2}$. Thus,

$$S_{\text{eff}} = \frac{A}{T^2} \ln\left(1 + BT^2\right), \tag{2.18}$$

where A and B are constants. The drift mobility due to scattering from ionized impurities becomes

$$\mu_I = \frac{e}{m_e^* u S_{\text{eff}} N_I} \propto \frac{1}{T^{1/2}} \frac{T^2}{A\ln(1+BT^2)} \frac{1}{N_I} \approx \frac{CT^{3/2}}{N_I}\,, \tag{2.19}$$

where N_I is the density of ionized impurities (it represents N_S), and C is a new constant. At low temperatures where lattice scattering is insignificant, we expect $\mu_I \propto T^{3/2}/N_I$ for nondegenerate semiconductors.

The above semiquatitative description is sufficient to understand the basic principles of conduction. A more rigorous approach involves solving the Boltzmann charge transport equation and is addressed in Sect. 2.6.

2.2 Matthiessen's Rule

In general, the conduction electron whether in a metal or in a semiconductor can be scattered by a number of mechanisms, such as lattice vibrations, impurities, lattice defects such as dislocations, grain boundaries, vacancies, surfaces, or any other deviation from a perfectly periodic lattice. All these scattering processes increase the overall resistivity of the substance by reducing the mean scattering time. The relation between the types of scattering and the total scattering time can be obtained by considering scattering from lattice vibrations and impurities as shown in Fig. 2.3. We define two mean free times τ_L and τ_I:τ_L is the mean free time considering only scattering from lattice vibrations (phonons) and τ_I is the mean free time considering only collisions with impurities. In a small unit of time dt, the total probability of scattering (dt/τ) is simply the sum of the probability for phonon scattering (dt/τ_L) and the probability for impurity scattering (dt/τ_I), and thus

$$\frac{1}{\tau} = \frac{1}{\tau_L} + \frac{1}{\tau_I}\,. \tag{2.20}$$

We have assumed that neither τ_L nor τ_I is affected by the presence of the other scattering mechanism, that is each type of scattering is independent. The above expression can be generalized to include all types of independent scattering mechanisms yielding

$$\frac{1}{\tau} = \sum_i \frac{1}{\tau_i}\,, \tag{2.21}$$

where τ_i is the mean scattering time considering the ith scattering process alone. Since the drift mobility μ_d

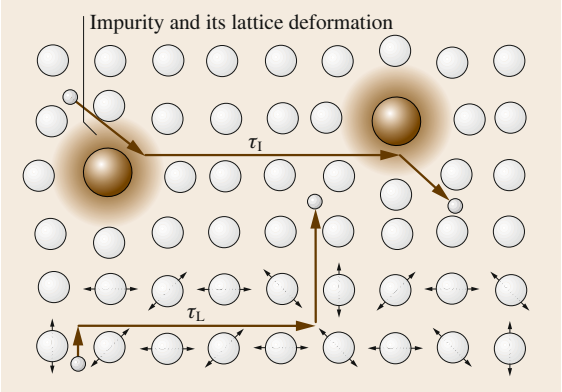

Fig. 2.3 Scattering from lattice vibrations alone with a mean scattering time τ_L, and from impurities alone with a mean scattering time τ_I

is proportional to τ, (2.21) can be written in terms of the drift mobilities determined by the various scattering mechanisms. In other words,

$$\frac{1}{\mu_d} = \sum_i \frac{1}{\mu_i} , \tag{2.22}$$

where μ_i is the drift mobility limited just by the ith scattering process. Finally, since the resistivity is inversely proportional to the drift mobility, the relation for resistivity is

$$\rho = \sum \rho_i , \tag{2.23}$$

where ρ_i is the resistivity of the material if only the ith scattering process were active. Equation (2.23) is known as Matthiessen's rule. For nearly perfect, pure crystals the resistivity is dominated by phonon scattering ρ_T. If impurities or defects are present, however, there are an additional resistivities ρ_I from the scattering off the impurities and ρ_D from defect scattering, and $\rho = \rho_T + \rho_I + \rho_D$.

Matthiessen's rule is indispensable for predicting the resistivities of many types of conductors. In some cases like thin films, the rule is obeyed only approximately, but it is nonetheless still useful for an initial (often quite good) estimate.

2.3 Resistivity of Metals

2.3.1 General Characteristics

The effective resistivity of a metal, by virtue of Matthiessen's rule, is normally written as

$$\rho = \rho_T + \rho_R , \tag{2.24}$$

where ρ_R is called the *residual resistivity* and is due to the scattering of electrons by impurities, dislocations, interstitial atoms, vacancies, grain boundaries and so on. The residual resistivity shows very little temperature dependence whereas ρ_T is nearly linear in absolute temperature. ρ_T will be the main resistivity term for many high-quality, nonmagnetic pure, crystalline metals. In classical terms, we can take the thermal vibrations of a lattice atom with mass M as having a mean kinetic energy KE of $(1/2)Ma^2\omega^2$, where a and ω are the amplitude and frequency of the vibrations. This mean KE must be of the order of kT so that the amplitude $a \propto T^{1/2}$. Thus the electron scattering cross section $S = \pi a^2 \propto T$. Since the mean speed of conduction electron in a metal is the Fermi speed and is temperature insensitive, $\mu \propto \tau \propto 1/S \propto T^{-1}$, and hence the resistivity $\rho \propto T$. Most nonmagnetic pure metals obey this relationship except at very low temperatures. Figure 2.4 shows the resistivity of Cu as a function of temperature where above ≈ 100 K, $\rho \propto T$.

The $\rho \propto T$ behavior can also be derived more rigorously by noting that at high temperatures, the phonon concentration n_{ph} increases as T. The mean scattering time τ is inversely proportional to n_{ph} so that $\rho \propto T$. Frequently, the resistivity versus temperature behavior of pure metals can be empirically represented by a power law of the form,

$$\rho = \rho_0 \left(\frac{T}{T_0}\right)^n , \tag{2.25}$$

where ρ_0 is the resistivity at the reference temperature, T_0, and n is a characteristic index that best fits the data. For the nonmagnetic pure metals, n is close to unity whereas it is close to 2 for the magnetic metals Fe and Ni [2.5]. Figure 2.5 shows ρ versus T for various metals. Table 2.1 summarizes the values ρ_0 and n for various metals.

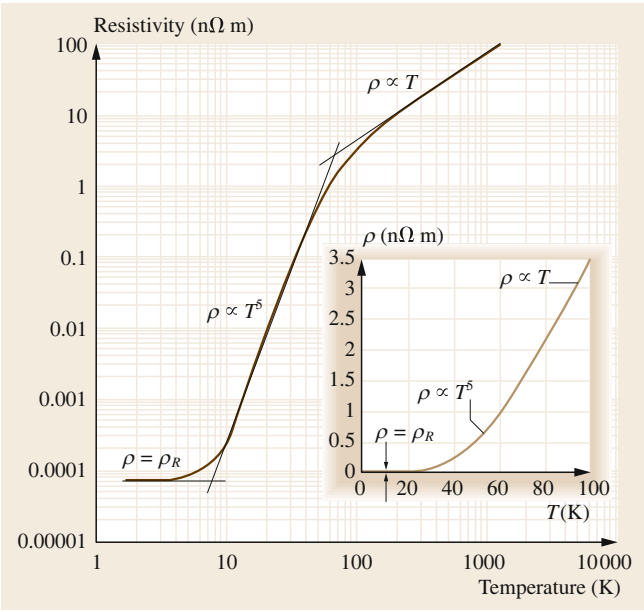

Fig. 2.4 The resistivity of copper from low to high temperatures (near its melting temperature, 1358 K) on a log–log plot. Above about 100 K, $\rho \propto T$, whereas at low temperatures, $\rho \propto T^5$, and at the lowest temperatures ρ approaches the residual resistivity ρ_R. The inset shows the ρ versus T behavior below 100 K on a linear plot. (ρ_R is too small to see on this scale.) (After [2.5])

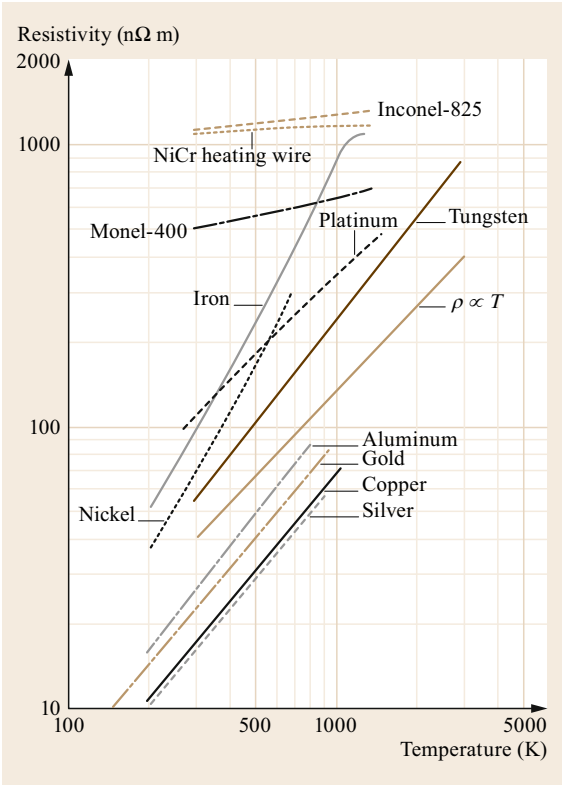

Fig. 2.5 The resistivities of various metals as a function of temperature above 0 °C. Tin melts at 505 K, whereas nickel and iron go through a magnetic-to-nonmagnetic (Curie) transformation at about 627 K and 1043 K, respectively. The theoretical behavior ($\rho \propto T$) is shown for reference. (After [2.5])

As apparent from Fig. 2.4, below ≈ 100 K, the $\rho \propto T$ behavior fails, and $\rho \propto T^5$. The reason is that, as the temperature is lowered, the scattering by phonons becomes less efficient, and it takes many more collisions to fully randomize the initial velocity of the electron. The mean number of collisions ν required to randomize the velocity scales with T^{-2} [2.5], and at low temperatures, the concentration n_{phonon} of phonons increases as T^3. Thus,

$$\sigma \propto \nu\tau \propto \frac{\nu}{n_{\text{phonon}}} \propto \frac{T^{-2}}{T^3} \propto T^{-5} \qquad (2.26)$$

which explains the low-temperature $\rho - T$ behavior in Fig. 2.4. The low temperature $\rho \propto T^5$ and high temperature $\rho \propto T$ regimes are roughly separated by the *Debye temperature* T_{D}. For $T > T_{\text{D}}$ we expect $\rho \propto T$, and for $T < T_{\text{D}}$ we expect $\rho \propto T^5$.

In the case of metals with impurities and for alloys, we need to include the ρ_{R} contribution to the overall resistivity. For $T > T_{\text{D}}$, the overall resistivity is

$$\rho \approx AT + \rho_{\text{R}} \,, \qquad (2.27)$$

where A is a constant, and the AT term in (2.27) arises from scattering from lattice vibrations. Normally, ρ_{R} has very little temperature dependence, and hence very roughly ρ versus T curves shift to higher values as ρ_{R} is increases due to the addition of impurities, alloying or cold working the sample (mechanical deformation that generates dislocations) as illustrated for Cu–Ni alloys in Fig. 2.6.

Table 2.1 Typical resistivities at 273 K (0 °C) ρ_0 and thermal coefficients of resistivity α_0 at 0 °C for various metals above 0 °C and below melting temperature. The resistivity index n in $\rho = \rho_0(T/T_0)^n$ is also shown. Note that n is fitted to resistivity data above 273 K but below the melting temperature of the metal. Data selectively combined from various sources, including [2.6, 7]

Resistivity versus temperature behavior of nearly all metals is characterized by the *temperature coefficient of resistivity* (TCR) α_0 which is defined as the fractional change in the resistivity per unit temperature increase at the reference temperature T_0, i. e.,

$$\alpha_0 = \frac{1}{\rho_0}\left(\frac{\mathrm{d}\rho}{\mathrm{d}T}\right)_{T=T_0}, \tag{2.28}$$

where ρ_0 is the resistivity at the reference temperature T_0, usually at 273 K (0 °C) or 293 K (20 °C), $\mathrm{d}\rho = \rho - \rho_0$ is the change in the resistivity due to a small increase, $\mathrm{d}T = T - T_0$, in temperature. Assuming that α_0 is temperature independent over a small range from T_0 to T, we can integrate (2.28), which leads to the well known equation,

$$\rho = \rho_0[1 + \alpha_0(T - T_0)]\,. \tag{2.29}$$

Equation (2.29) is actually only valid when α_0 is *constant* over the temperature range of interest which requires (2.27) to hold. Over a limited temperature range this will usually be the case. Although it is not obvious from (2.28), we should, nonetheless, note that α_0 depends on the reference temperature, T_0 by virtue of ρ_0 depending on T_0.

It is instructive to mention that if $\rho \approx AT$ as we expect for an ideal pure metal, then $\alpha_0 = T_0^{-1}$. If we take the reference temperature T_0 as 273 K (0 °C), then α_0 should ideally be 1/(273 K) or $3.66 \times 10^{-3}\,\mathrm{K}^{-1}$. Examination of a_0 for various metals shows that $\rho \propto T$ is not a bad approximation for some of the familiar pure metals used as conductors, e.g., Cu, Al, Au, but fails badly for others, such as indium, antimony and, in particular, the magnetic metals, e.g., iron and nickel.

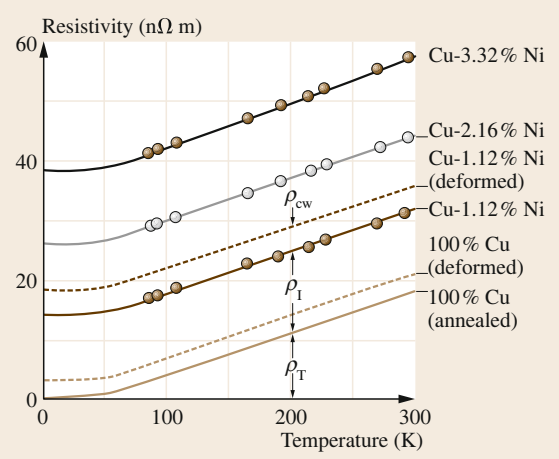

Fig. 2.6 Resistivities of annealed and cold-worked (deformed) copper containing various amounts of Ni (given in atomic percentages) versus temperature

Frequently we are given α_0 at a temperature T_0, and we wish to use some other reference temperature, say T_0', that is, we wish to use ρ_0' and α_0' for ρ_0 and α_0 respectively in (2.29) by changing the reference from T_0 to T_0'. Then we can find α_1 from α_0,

$$\alpha_0' = \frac{\alpha_0}{1 + \alpha_0(T_0' - T_0)}$$
$$\text{and} \quad \rho = \rho_0'\left[1 + \alpha_0'\left(T - T_0'\right)\right]. \tag{2.30}$$

For example, for Cu $\alpha_0 = 4.31 \times 10^{-3}\,\mathrm{K}^{-1}$ at $T_0 = 0\,°\mathrm{C}$, but it is $\alpha_0 = 3.96 \times 10^{-3}\,\mathrm{K}^{-1}$ at $T_0 = 20\,°\mathrm{C}$. Table 2.1 summarizes α_0 for various metals. Note that α_0 in Table 2.1 is at 0 °C and can be converted to α_0' at 20 °C using (2.30).

2.3.2 Fermi Electrons

The electrical properties of metals depend on the behavior of the electrons at the Fermi surface. The electron states at energies more than a few kT below E_F are almost fully occupied. The Pauli exclusion principle requires that an electron can only be scattered into an empty state, and thus scattering of deep electrons is highly suppressed by the scarcity of empty states (scattering where the energy changes by more than a few kT is unlikely). Only the electrons near E_F undergo scattering. Likewise, under the action of an external field, only the electron occupation near E_F is altered. As a result, the density of states (DOS) near the Fermi level is most important for the metal electrical properties, and only those electrons in a small range ΔE around E_F actually contribute to electrical conduction. The density of these electrons is approximately $\mathrm{g}(E_\mathrm{F})\Delta E$ where $\mathrm{g}(E_\mathrm{F})$ is the DOS at the Fermi energy. From simple arguments, the overall conductivity can be shown to be [2.5]

$$\sigma = \frac{1}{3}e^2 v_\mathrm{F}^2 \tau\, \mathrm{g}(E_\mathrm{F})\,, \tag{2.31}$$

where v_F is the Fermi speed and τ is the scattering time of these Fermi electrons. According to (2.31), what is important is the density of states at the Fermi energy, $\mathrm{g}(E_\mathrm{F})$. For example, Cu and Mg are metals with valencies I and II. Classically, Cu and Mg atoms each contribute 1 and 2 conduction electrons respectively into the crystal. Thus, we would expect Mg to have higher conductivity. However, the Fermi level in Mg is where the top tail of the 3p-band overlaps the bottom tail of the 3s band where the density of states is small.

In Cu, on the other hand, E_F is nearly in the middle of the 4 s band where the density of states is high. Thus, Mg has a lower conductivity than Cu.

The scattering time τ in (2.31) assumes that the scattered electrons at E_F remain in the same energy band as, for example, in Cu, whose simplified energy band diagram around E_F is shown in Fig. 2.7a. In certain metals, there are two different energy bands that overlap at E_F. For example, in Ni, 3d and 4s bands overlap at E_F as shown in Fig. 2.7b. An electron can be scattered from the 4s to the 3d band and vice versa. Electrons in the 3d band have very low drift mobilities and effectively do not contribute to conduction so that only $g(E_F)$ of the 4s band operates in (2.31). Since 4s to 3d band is an additional scattering mechanism, by virtue of Matthiessen's rule, the effective scattering time τ for the 4s band electrons is shortened and hence σ from (2.31) is smaller. Thus, Ni has poorer conductivity than Cu.

Equation (2.31) does not assume a particular density of states model. If we now apply the *free electron model* for $g(E_F)$, and also relate E_F to the total number of conduction electrons per unit volume n, we would find that the conductivity is the same as that in the Drude model,

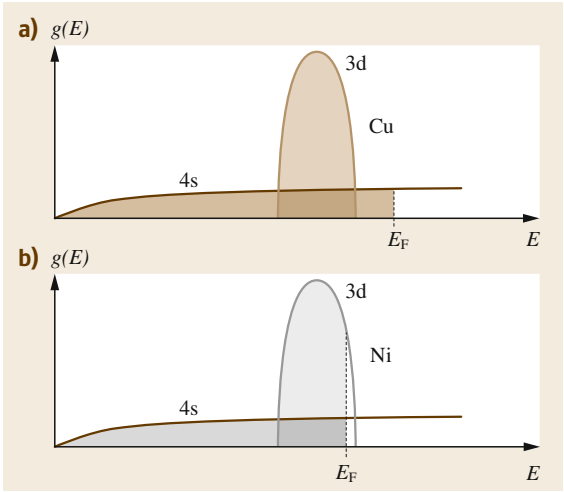

Fig. 2.7 Simplified energy band diagrams around E_F for **(a)** copper and **(b)** nickel

that is

$$\sigma = \frac{e^2 n \tau}{m_e} \,. \tag{2.32}$$

2.4 Solid Solutions and Nordheim's Rule

In an *isomorphous alloy* of two metals, i. e., a binary alloy which forms a binary *substitutional solid solution*, an additional mechanism of scattering appears, the *scattering off solute phase atoms*. This scattering contributes to lattice scattering, and therefore increases the overall resistivity. An important semi-empirical equation which can be used to predict the resistivity of an alloy is Nordheim's rule. It relates the impurity part of the resistivity ρ_I to the atomic fraction X of solute atoms in a solid solution via

$$\rho_I = CX(1-X) \,, \tag{2.33}$$

where the constant C is termed the Nordheim coefficient and represents the effectiveness of the solute atom in increasing the resistivity. Nordheim's rule was originally derived for crystals. Combining Nordheim's rule with Matthiessen's rule (2.23), the resistivity of an alloy of composition X should follow

$$\rho = \rho_{matrix} + CX(1-X) \,, \tag{2.34}$$

where ρ_{matrix} is the resistivity of the matrix due to scattering from thermal vibrations and from other defects, in the absence of alloying elements.

Nordheim's rule assumes that the solid solution has the solute atoms randomly distributed in the lattice. For sufficiently small amounts of impurity, experiments show that the increase in the resistivity ρ_I is nearly always simply proportional to the impurity concentration X, that is, $\rho_I \propto X$. For dilute solutions, Nordheim's rule predicts the same linear behavior, that is, $\rho_I = CX$ for $X \ll 1$.

Originally the theoretical model for ρ_I was developed by *Nordheim* [2.8] by assuming that the solute atoms simply perturb the periodic potential and thereby increase the probability of scattering. Quantum mechanical calculations for electron scattering within a single band, such as the s-band, at E_F show that

$$\rho_I \propto g(E_F) V^2_{scatter} X(1-X) \,, \tag{2.35}$$

where $g(E_F)$ is the DOS at E_F, and $V_{scatter}$ is matrix element for scattering from one wavefunction to another at the Fermi surface in the same band, which for an s-band is

$$V_{scatter} = \left\langle \psi_s^* \left| \Delta V \right| \psi_s \right\rangle , \tag{2.36}$$

where ΔV is the difference between the potentials associated with solvent and solute atoms, and ψ_s is the

Table 2.2 Nordheim coefficients (at 20 °C) for dilute alloys obtained from $\rho_i = CX$ and $X < 1$ at.%. Note: For many isomorphous alloys, C may be different at higher concentrations; that is, it may depend on the composition of the alloy [2.7, 9]. Maximum solubility data from [2.10]

Solute in solvent (element in matrix)	Nordheim coefficient (nΩ m)	Maximum solubility at 25 °C (at.%)
Au in Cu matrix	5500	100
Mn in Cu matrix	2900	24

Zn in Au matrix	950	15

wavefunction of an electron in the s-band at E_F. It is clear that C is only independent of X if $g(E_F)$ and $V_{scatter}$ remain the same for various X which may not be true. For example, if the effective number of free electrons increases with X, E_F will be shifted higher, and C will not be constant.

Table 2.2 lists some typical Nordheim coefficients for various additions to copper and gold. The value of the Nordheim coefficient depends on the type of solute and the solvent. A solute atom that is drastically different in size to the solvent atom will result in a bigger increase in ρ_I and will therefore lead to a larger C. An important assumption in Nordheim's rule in (2.33) is that the alloying does not significantly vary the number of conduction electrons per atom in the alloy. Although this will be true for alloys with the same valency, that is, from the same column in the Periodic Table (e.g., Cu–Au, Ag–Au), it will not be true for alloys of different valency, such as Cu and Zn. In pure copper, there is just one conduction electron per atom, whereas each Zn atom can donate two conduction electrons. As the Zn content in brass is increased, more conduction electrons become available per atom. Consequently, the resistivity predicted by (2.34) at high Zn contents is greater than the actual value because C refers to dilute alloys. To get the correct resistivity from (2.34) we have to lower C, which is equivalent to using an *effective* Nordheim coefficient C_{eff} that decreases as the Zn content increases. In other cases, for example, in Cu–Ni alloys, we have to increase C at high Ni concentrations to account for additional electron scattering mechanisms that develop with Ni addition. Nonetheless, the Nordheim rule is still useful for predicting the resistivities of dilute alloys, particularly in the low-concentration region.

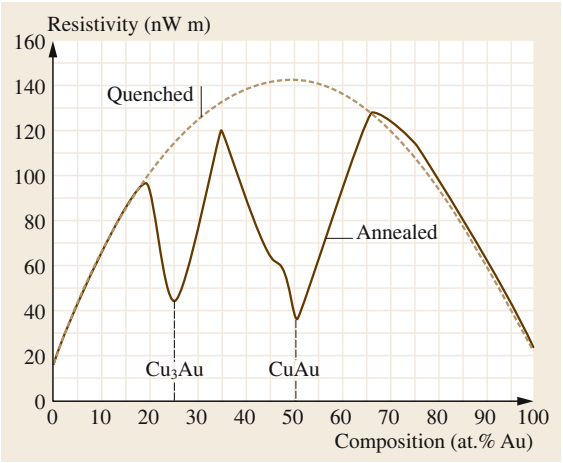

Fig. 2.8 Electrical resistivity versus composition at room temperature in Cu–Au alloys. The quenched sample (*dashed curve*) is obtained by quenching the liquid, and it has the Cu and Au atoms randomly mixed. The resistivity obeys the Nordheim rule. On the other hand, when the quenched sample is annealed or the liquid slowly cooled (*solid curve*), certain compositions (Cu_3Au and CuAu) result in an ordered crystalline structure in which Cu and Au atoms are positioned in an ordered fashion in the crystal and the scattering effect is reduced

In some solid solutions, at some concentrations of certain binary alloys, such as 75% Cu–25% Au and 50% Cu–50% Au, the annealed solid has an orderly structure; that is, the Cu and Au atoms are not randomly mixed, but occupy regular sites. In fact, these compositions can be viewed as a pure compound – like the solids Cu_3Au and CuAu. The resistivities of Cu_3Au and CuAu will therefore be less than the same composition random alloy that has been quenched from the melt. As a consequence, the resistivity ρ versus composition X curve does not follow the dashed parabolic curve throughout; rather, it exhibits sharp falls at these special compositions, as illustrated in Fig. 2.8. The *effective media approximation* may be used as an effective tool to estimate the resistivities of inhomogeneous media.

2.5 Carrier Scattering in Semiconductors

At low electric fields, ionized impurity scattering and phonon scattering predominate. Other types of scattering include carrier-carrier scattering, inter-valley scattering, and neutral impurity scattering; these may generally be ignored to a first approximation.

For phonon scattering, both *polar* and *non-polar phonon scattering* should be considered. In polar scattering, short wavelength oscillations of atoms on different sub-lattices vibrating out of phase produce an effective dipole moment proportional to the bond polarity. Since such vibrational modes are optically active (since this dipole moment can interact with an incident electromagnetic field), this type of lattice scattering is usually referred to as *polar optical phonon scattering*. Since a sub-lattice is necessary for optical modes, this scattering mechanism is not present in elemental semiconductors such as Si, Ge, or diamond.

Non-polar phonon scattering comes from long wavelength oscillations in the crystal, involving small displacements of tens to thousands of atoms. The wavelength depends on the material and its elastic properties. Such modes are very similar to sound vibrations and are thus referred to as acoustic modes. The associated atomic displacements correspond to an effective built-in strain, with local change in the lattice potential, causing carrier scattering known as *deformation potential acoustic phonon scattering*. Since the change in potential is relatively small, the scattering efficiency is relatively low as compared with polar optical phonon scattering.

Each scattering process contributes to the drift mobility according to *Matthiessen's rule*

$$\frac{1}{\mu_e} = \sum_i \frac{1}{\mu_i} \qquad (2.37)$$

as discussed in Sect. 2.3 above. Figure 2.9 shows the contributions of each scattering process for n-type ZnSe – a material that has applications in optoelectronics. At room temperature, polar optical phonon scattering and ionized impurity scattering dominate. These processes depend on the carrier concentration. The curve for ionized impurity scattering decreases markedly with increasing carrier concentration owing to the increasing concentration of ionized donors that supply these carriers. The ionized impurity scattering mobility is roughly inversely proportional to the concentration of ionized impurities. However, as the carrier concentration increases, as in a degenerate semiconductor, the average energy per carrier also increases (i. e., carriers move faster on average) and thus carriers are less susceptible to being scattered from the ionized impurity centers. In contrast, the polar phonon scattering rate is determined by the number of participating phonons which depends on the thermal energy available to create a given quantized vibrational mode.

The temperature dependence of the mobility may be estimated by considering the effect of temperature on ionized impurity and phonon scattering and combining these mechanisms using Matthiessen's rule. Phonon

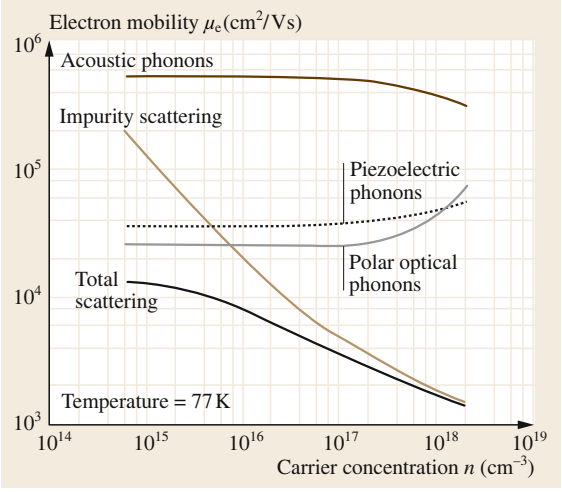

Fig. 2.9 Dependence of electron mobility on carrier concentration for ZnSe at 77 K. (After [2.11])

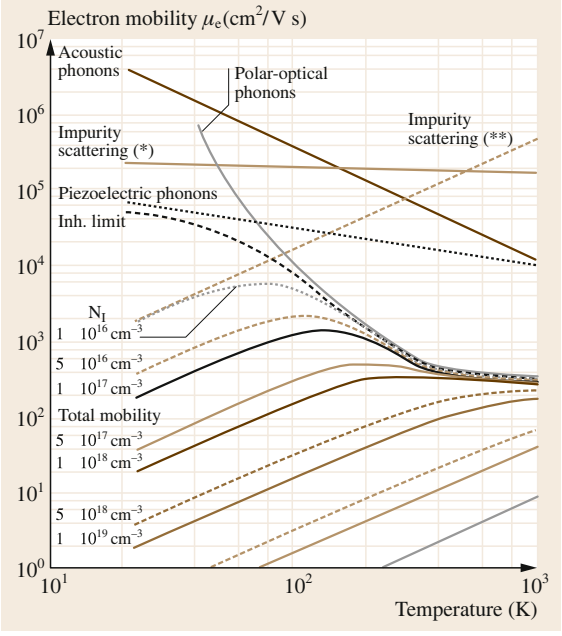

Fig. 2.10 Dependence of electron mobility on temperature and doping for ZnSe. (After [2.11])

scattering increases strongly with increasing temperature T due to the increase in the number of phonons resulting in a $T^{-3/2}$ dependence for the polar phonon mobility. For ionized impurity scattering, increasing the temperature increases the average carrier velocity and hence increases the carrier mobility for a set concentration of ionized impurities. Once a temperature is reached such that impurity ionization is complete, the ionized impurity based carrier mobility can be shown to increase with temperature T as approximately, $T^{+3/2}$. At low temperatures, the mobility is basically determined by ionized impurity scattering and at high temperatures by phonon scattering leading to a peaked curve. Invoking the previous discussions for the dependence of the total mobility on carrier concentration, it is clear that the peak mobility will depend on the doping level, and the peak location will shift to higher temperatures with increased doping as shown in Fig. 2.10.

2.6 The Boltzmann Transport Equation

A more rigorous treatment of charge transport requires a discussion of the *Boltzmann Transport Equation*. The electronic system is described by a distribution function $f(\boldsymbol{k}, \boldsymbol{r}, t)$ defined in such a way that the number of electrons in a six-dimensional volume element $\mathrm{d}^3\boldsymbol{k}\mathrm{d}^3\boldsymbol{r}$ at time t is given by $\frac{1}{4}\pi^{-3}f(\boldsymbol{k}, \boldsymbol{r}, t)\mathrm{d}^3\boldsymbol{k}\mathrm{d}^3\boldsymbol{r}$. In equilibrium, $f(\boldsymbol{k}, \boldsymbol{r}, t)$ depends only on energy and reduces to the Fermi distribution f_0 where the probability of occupation of states with momenta $+\boldsymbol{k}$ equals that for states with $-\boldsymbol{k}$, and $f_0(\boldsymbol{k})$ is symmetrical about $\boldsymbol{k} = 0$, giving no net charge transport. If an external field acts on the system (i. e., non-equilibrium), the occupation function $f(\boldsymbol{k})$ will become asymmetric in $\boldsymbol{k}$-space. If this non-equilibrium distribution function $f(\boldsymbol{k})$ is completely specified and appropriate boundary conditions supplied, the electronic transport properties can be completely determined by solving the *steady state Boltzmann transport equation* [2.12]

$$\boldsymbol{v}\cdot\nabla_{\boldsymbol{r}}f + \dot{\boldsymbol{k}}\cdot\nabla_{\boldsymbol{k}}f = \left(\frac{\partial f}{\partial t}\right)_{\mathrm{c}} , \tag{2.38}$$

where:

1. $\boldsymbol{v}\cdot\nabla_{\boldsymbol{r}}f$ represents diffusion through a volume element $\mathrm{d}^3\boldsymbol{r}$ about the point $\boldsymbol{r}$ in phase space due to a gradient $\nabla_{\boldsymbol{r}}f$
2. $\dot{\boldsymbol{k}}\cdot\nabla_{\boldsymbol{k}}f$ represents drift through a volume element $\mathrm{d}^3\boldsymbol{k}$ about the point $\boldsymbol{k}$ in phase space due to a gradient $\nabla_{\boldsymbol{k}}f$ (for example, $\hbar\dot{\boldsymbol{k}} = e\left(\boldsymbol{E} + \frac{1}{c}\boldsymbol{v}\times\boldsymbol{B}\right)$ in the presence of electric and magnetic fields)
3. $(\partial f/\partial t)_{\mathrm{c}}$ is the collision term and accounts for the scattering of electrons from a point $\boldsymbol{k}$ (for example, this may be due to lattice or ionized impurity scattering).

Equation (2.38) may be simplified by using the *relaxation time approximation*

$$\left(\frac{\partial f}{\partial t}\right)_{\mathrm{c}} = \frac{\Delta f}{\tau} = -\frac{f - f_0}{\tau} \tag{2.39}$$

which is based on the assumption that for small changes in f carriers return to equilibrium in a characteristic time τ, dependent on the dominant scattering mechanisms. Further simplifications of (2.38) using (2.39) applicable for low electric fields lead to a simple equation connecting the mobility μ to the *average scattering time* $\langle\tau\rangle$

$$\mu \cong \frac{e\langle\tau\rangle}{m^*} . \tag{2.40}$$

The details of calculations may be found in various advanced textbooks, for example *Bube* [2.13], *Blatt* [2.4]. The average scattering time may be calculated assuming a *Maxwell–Boltzmann* distribution function and a parabolic band

$$\langle\tau\rangle = \frac{2}{3k_{\mathrm{B}}T}\frac{\int_0^\infty \tau(E)E^{3/2}e^{-E/k_{\mathrm{B}}T}\mathrm{d}E}{\int_0^\infty E^{3/2}e^{-E/k_{\mathrm{B}}T}\mathrm{d}E} . \tag{2.41}$$

Quantum mechanical perturbation theory can be used to calculate the carrier scattering rate for different processes i, giving,

$$\tau_i(E) = aE^{-\alpha} , \tag{2.42}$$

where a and α are constants and E is the electron energy. Substituting (2.42) into (2.41) gives

$$< \tau_i >= \frac{4a\Gamma\,(5/2-\alpha)}{3\pi^{1/2}(k_{\mathrm{B}}T)^{\alpha}} \tag{2.43}$$

in terms of the *gamma function* Γ. Using this approach, the expressions for the mobility for the case of lattice and impurity scattering may be easily found

$$\mu_{\mathrm{L}} \propto \frac{4e}{m^*\sqrt{9\pi k_{\mathrm{B}}}}T^{-\frac{3}{2}} , \tag{2.44}$$

$$\mu_{\mathrm{I}} \propto \frac{8ek_{\mathrm{B}}^{3/2}}{N_{\mathrm{I}}m^*\sqrt{\pi}}T^{+\frac{3}{2}} , \tag{2.45}$$

where N_{I} is the concentration of ionized impurities.

2.7 Resistivity of Thin Polycrystalline Films

Two new dominant scattering mechanisms must be considered in polycrystalline thin films – *scattering by grain boundaries* and *scattering at the surface*. The scattering by grain boundaries is schematically shown in Fig. 2.11. As a first approximation, the conduction electron may be considered free within a grain, but becomes scattered at the grain boundary. Its mean free path ℓ_{grains} is therefore roughly equal to the average grain size d. If $\lambda = \ell_{\text{crystal}}$ is the mean free path of the conduction electrons in the single crystal, then according to Matthiessen's rule

$$\frac{1}{\ell} = \frac{1}{\ell_{\text{crystal}}} + \frac{1}{\ell_{\text{grains}}} = \frac{1}{\lambda} + \frac{1}{d} \,. \tag{2.46}$$

The resistivity is inversely proportional to the mean free path which means the resistivity of the single crystal $\rho_{\text{crystal}} \propto 1/\lambda$ and resistivity of the polycrystalline sample $\rho \propto 1/\ell$. Thus,

$$\frac{\rho}{\rho_{\text{crystal}}} = 1 + \left(\frac{\lambda}{d}\right). \tag{2.47}$$

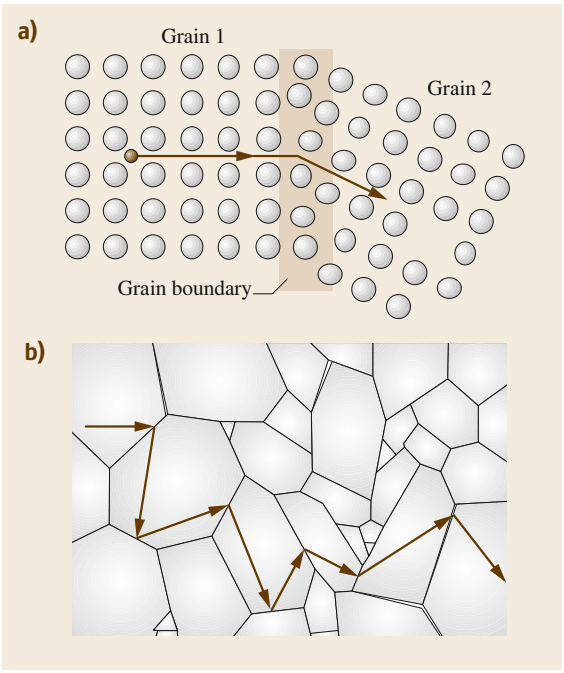

Fig. 2.11 **(a)** Grain boundaries cause electron scattering and therefore add to the resistivity according to Matthiessen's rule. **(b)** For a very grainy solid, the electron is scattered from grain boundary to grain boundary, and the mean free path is approximately equal to the mean grain diameter

Figure 2.12 clearly demonstrates that even simple considerations agree well with experimental data. However, in a more rigorous theory we have to consider a number of effects. It may take more than one scattering at a grain boundary to totally randomize the velocity so that we need to calculate the effective mean free path that accounts for how many collisions are needed to randomize the velocity. There is a possibility that the electron may be totally reflected back at a grain boundary (bounce back). Let σ be the conductivity of the polycrystalline (grainy) material and σ_{crystal} be the conductivity of the bulk single crystal. Suppose that the probability of reflection at a grain boundary is R. If d is the average grain size (diameter) then the two conductivities may be related using the *Mayadas* and *Shatzkes* formula [2.15]

$$\frac{\sigma}{\sigma_{\text{crystal}}} = 1 - \frac{3}{2}\beta + 3\beta^2 - 3\beta^3 \ln\left(1 + \frac{1}{\beta}\right)$$
$$\text{where} \quad \beta = \frac{\lambda}{d}\left(\frac{R}{1-R}\right), \tag{2.48}$$

The β in (2.48) represents the λ/d ratio adjusted for the reflection to transmission ratio of the electron at the grain boundary. When the grain size is large, β is small

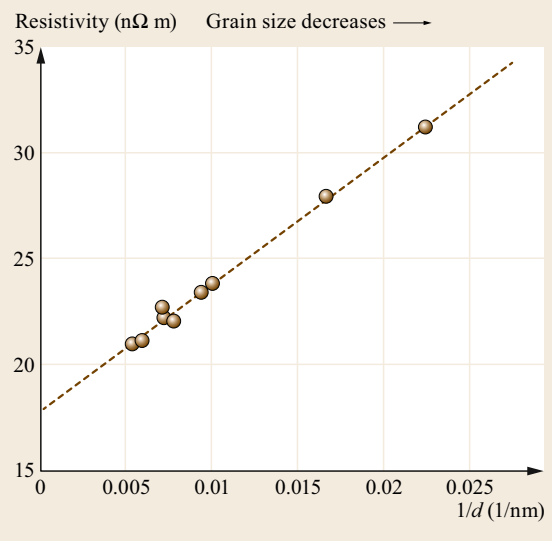

Fig. 2.12 Resistivity of Cu polycrystalline film versus reciprocal mean grain size (diameter), $1/d$. Film thickness $D = 250–900\,\text{nm}$ does not affect the resistivity. The *straight line* $\rho = 17.8\,\text{n}\Omega\,\text{m} + (595\,\text{n}\Omega\,\text{nm})(1/d)$. (After [2.14])

and (2.48) simples to

$$\frac{\rho}{\rho_{\text{crystal}}} \approx 1 + \frac{3}{2}\beta \,. \tag{2.49}$$

For highly polycrystalline films, the grain size would be small and $\beta \gg 1$

$$\frac{\rho}{\rho_{\text{crystal}}} \approx \frac{4}{3}\beta \,. \tag{2.50}$$

Equation (2.49) implies that the Matthiessen's rule is reasonably well obeyed when the grains are larger than the mean free path. For copper, typically R values are 0.24–0.40, and R is somewhat smaller for Al. Equation (2.48) for a Cu film with $R \approx 0.3$ predicts $\rho/\rho_{\text{crystal}} \approx 1.21$ for roughly $d \approx 3\lambda$ or a grain size $d \approx 120\,\text{nm}$ since in the bulk crystal $\lambda \approx 40\,\text{nm}$. *Tellier* et al. [2.16] have given extensive discussions of grain boundary scattering limited resistivity of thin films.

Scattering from the film surfaces must also be included in any resistivity calculation. It is generally assumed that the scattering from a surface is partially *inelastic*, that is the electron loses some of the velocity gained from the field. The inelastic scattering is also called *nonspecular*. (If the electron is elastically reflected from the surface just like a rubber ball bouncing from a wall, then there is no increase in the resistivity.) If the parameter p is the fraction of surface collisions which are specular (elastic) and if the thickness of film D is greater than λ, and $\sigma_{\text{bulk}} = 1/\rho_{\text{bulk}}$, than in accordance with Fuchs-Sondheimer equation [2.17, 18] the conductivity σ of the film is

$$\frac{\sigma}{\sigma_{\text{bulk}}} = 1 - \frac{3\lambda}{8D}(1-p) \,, \quad (\lambda/D > 1) \,. \tag{2.51}$$

If D is much shorter than ℓ,

$$\frac{\sigma}{\sigma_{\text{bulk}}} = \frac{3D}{4\lambda}\left[\ln\left(\frac{\lambda}{D}\right) + 0.423\right] \times (1+2p) \,, \quad (\lambda/D \ll 1) \,. \tag{2.52}$$

For purely nonspecular (inelastic) scattering, an approximate estimate can be obtained from

$$\frac{\rho}{\rho_{\text{bulk}}} \approx 1 + \frac{3}{8}\left(\frac{\lambda}{D}\right) . \tag{2.53}$$

Figure 2.13 shows the resistivity of Cu films as a function of film thickness D. The Cu thin films in this case are single crystal layers grown on the (001) surface of a single crystal of MgO (which is the substrate). As

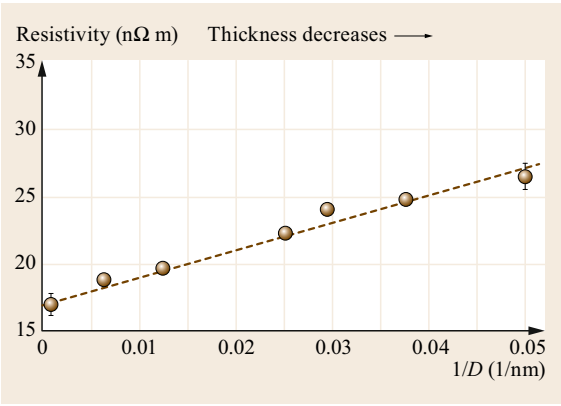

Fig. 2.13 The resistivity ρ_{film} of single crystal thin films of Cu against reciprocal film thickness $1/D$ at 25 °C. The films are grown on the surface of a single crystal of MgO and the best straight line is $\rho_{\text{film}} = 17.0\,\text{n}\Omega\,\text{m} + (200\,\text{n}\Omega\,\text{m}\,\text{nm})(1/D)$. (Data extracted from [2.19])

the film is a single crystal, there is no grain boundary scattering, and the observed increase in the resistivity with decreasing film thickness is due to the scattering of the electrons from the film surfaces. The experiments in Fig. 2.13 can be explained by the simplified Fuchs–Sondheimer equation with an average $p = 0.20$.

For elastic or specular scattering $p = 1$ and there is no change in the conductivity. The value of p depends on the film preparation method (e.g., sputtering, epitaxial growth etc.) and the substrate on which the film has been deposited. Table 2.3 summarizes the resistivities of thin Cu and Au gold films deposited by various preparation techniques. Notice the large difference between the Au films deposited on a noncrystalline glass substrate and on a crystalline mica substrate. Such differences between films are typically attributed to different values of p. The p-value can also change (increase) when the film is annealed. Obviously, the polycrystallinity of the film will also affect the resistivity as discussed above. Typically, most epitaxial thin films, unless very thin ($D \ll \ell$), deposited onto heated crystalline substrates exhibit highly specular scattering with $p = 0.8 - 1$.

It is generally very difficult to separate the effects of surface and grain boundary scattering in thin polycrystalline films; the contribution from grain boundary scattering is likely to exceed that from the surfaces. In any event, both contributions, by Matthiessen's general rule, increase the overall resistivity. Figure 2.12 shows an example in which the resistivity ρ_{film} of thin Cu polycrystalline films is due to grain boundary scattering, and thickness has no effect (D was 250–900 nm and much greater than λ). The resistivity ρ_{film} is plotted against the reciprocal mean grain size $1/d$, which then follows the

Table 2.3 Resistivities of some thin Cu and Au films at room temperature. PC: Polycrystalline film; RT is room temperature; D = film thickness; d = average grain size. FS and MS refer to Fuchs–Sondheimer and Mayadas–Shatzkes descriptions of thin film resistivity. At RT for Cu, $\lambda = 38-40$ nm, and for Au $\lambda = 36-38$ nm. Data selectively combined from various sources [2.14, 19–22, 24–27]

Film	D (nm)	d (nm)	ρ (nΩ m)	Comment
Cu films				
Cu encapsulated in SiO_2/Cu/SiO_2 [2.20]	45.3 31.7	101 41	28.0 35.5	DC sputtering. Cu film sandwiched in SiO_2/Cu/SiO_2, annealed at 150 °C. MS with $R = 0.50$
Cu encapsulated in SiO_2/Ta/Cu/Ta/SiO_2 [2.21]	34.2	39.4	37.3	DC sputtering. Cu film sandwiched in SiO_2/Ta/Cu/Ta/SiO_2,annealed at 600 °C. MS with $R = 0.47$
Cu on Ta/SiO_2/Si(001) [2.21]	35	40	31	Sputtering and then annealing at 350 °C
Cu (single crystal) on TiN/MgO (001) [2.22]	40 13	∞ ∞	21 29.7	Cu single crystal epitaxial layer on TiN(100) on MgO surface (001). Ultra-high vacuum, DC sputtering. FS with $p \approx 0.6$ in vacuum, $p = 0$ in air.
Cu on TiN, W and TiW [2.14]	> 250	186 44	21 31	CVD (chemical vapor deposition). Substrate temperature 200 °C, ρ depends on d not $D = 250-900$ nm. MS.
Cu on crystalline Si (100) surface [2.23]	51.2 17.2 8.6	$D/2.3$	32.2 70.5 126	Ion beam deposition with negative substrate bias. Resistivity follows FS and MS equations combined; surface and grain boundary scattering. FS and MS, $p = 0$, $R = 0.24$, $d = D/2.3$
Au films				
Au epitaxial film on mica	30		25	Single crystal on mica. $p \approx 0.8$, highly specular scattering
Au PC film on mica	30		54	PC. Sputtered on mica. p is small
Au film on glass	30		70	PC. Evaporated onto glass. p is small, nonspecular scattering
Au on glass [2.24]	40 40	8.5 3.8	92 189	PC. Sputtered films. $R = 0.27-0.33$

expected linear behavior in (2.49). On the other hand, Fig. 2.13 shows the resistivity of Cu films as a function of film thickness D. In this case, the thin films are grown epitaxially (as a single crystal) on MgO single crystal surfaces and the grain boundary scattering is absent, which is a clear cut case for surface scattering; the transport is described by (2.51). Chapter 28 provides a more advanced treatment of conduction in thin films.

2.8 Inhomogeneous Media: Effective Media Approximation

The *effective media approximation* (EMA) attempts to estimate the properties of inhomogeneous mixture of two or more components using the known physical properties of each component. The general idea of any EMA is to substitute for the original inhomogeneous mixture some imaginary homogeneous substance – the *effective medium* (EM) – whose response to an external excitation is the same as that of the original mixture. The EMA is widely used for investigations of non-uniform objects in a variety of applications such as composite materials [2.28, 29], microcrystalline and amorphous semiconductors [2.30–33], light scattering [2.34], conductivity of dispersed ionic semiconductors [2.35] and many others.

Calculations of the conductivity and dielectric constant of two component mixtures are reviewed by *Reynolds* and *Hough* [2.36] and summarized by *Rossiter* [2.1]. For such a mixture we assume that the two components α and β are randomly distributed in space with volume fractions of χ_α and $\chi_\beta = 1 - \chi_\alpha$. The dielectric properties are described by an *effective permittivity* ε_{eff} given by the ratio

$$\varepsilon_{\text{eff}} = \frac{\langle D \rangle}{\langle E \rangle} , \tag{2.54}$$

where $\langle E \rangle$ is the average electric field and $\langle D \rangle$ is the average displacement field. The displacement field averaged over a large volume may be calculated from

$$\begin{aligned} \langle D \rangle &= \frac{1}{V} \int_V D \mathrm{d}v = \frac{1}{V} \left(\int_{V_\alpha} D \mathrm{d}v + \int_{V_\beta} D \mathrm{d}v \right) \\ &= \chi_\alpha \langle D_\alpha \rangle + \chi_\beta \langle D_\beta \rangle , \end{aligned} \tag{2.55}$$

where $\langle D_\alpha \rangle$ and $\langle D_\beta \rangle$ are the average displacement fields inside regions of the respective components and V_α and V_β are their volumes. Likewise the electric field

is given by

$$\langle E\rangle = \chi_\alpha \langle E_\alpha\rangle + \chi_\beta \langle E_\beta\rangle . \tag{2.56}$$

From (2.54) one gets

$$\varepsilon_{\text{eff}} = \varepsilon_\beta + \left(\varepsilon_\alpha - \varepsilon_\beta\right) \chi_\alpha f_\alpha \tag{2.57}$$

or

$$\left(\varepsilon_{\text{eff}} - \varepsilon_\alpha\right) \chi_\alpha f_\alpha + \left(\varepsilon_{\text{eff}} - \varepsilon_\beta\right) \chi_\beta f_\beta = 0 \tag{2.58}$$

where ε_α and ε_β are the permittivities of the components and $f_\alpha = \langle E_\alpha\rangle / \langle E\rangle$ and $f_\beta = \langle E_\beta\rangle / \langle E\rangle$ are so-called *field factors*. The choice between (2.57) and (2.58) depends on particle geometry. Equation (2.57) is better when the particles of component are dispersed in a continuous medium β. Equation (2.58) is preferred when the particle size of the two components is of the same order of magnitude.

The field factors can be calculated analytically only for phase regions with special specific geometries. The field factor for ellipsoids is given by (*Stratton* [2.48])

$$f_\alpha = \sum_{i=1}^{3} \frac{\cos^2 \alpha_i}{1 + A_i \left(\frac{\varepsilon_\alpha}{\varepsilon^*} - 1\right)} , \tag{2.59}$$

where α_i are the angles between the ellipsoid axes and the applied field and the constants A_i depend on the axial ratios of the ellipsoids; they must satisfy

$$\sum_{i=1}^{3} A_i = 1 .$$

For a spheroid, $A_2 = A_3 = A$ and $A_1 = 1 - 2A$. For a random orientation of spheroids, $\cos^2\alpha_1 = \cos^2\alpha_2 = \cos^2\alpha_3 = \frac{1}{3}$. In the case of long particles with aligned axes, $\cos^2\alpha_1 = \cos^2\alpha_2 = \frac{1}{2}$ and $\cos^2\alpha_3 = 0$. The values of parameters entering (2.59) can be found in Table 2.4 which shows a set of *mixture rules*, i. e., a set of formulae allowing one to calculate ε_{eff} for some specific cases (such as spheres, rods, lamellae, etc.). The presence of some degree of orientation somewhat simplifies the calculations as shown in the Table 2.5.

The same formulae can be used to calculate the conductivity of mixtures by substituting the appropriate conductivity σ for ε. For some special cases, the mixture rules of Table 2.5 lead to very simple formulae which allows one to calculate the conductivity of inhomogeneous alloys with those specific geometries. These *mixture rules* are summarized in Table 2.6.

The most general approach to calculating the effective dielectric permittivity comes from

$$\varepsilon_{\text{eff}} = \varepsilon_\beta \left(1 - \chi_\alpha \int_0^1 \frac{G(L)}{t - L} \mathrm{d}L\right) , \tag{2.60}$$

Table 2.7 Mixture rules and corresponding spectral functions $G(L)$

Mixture rule by *Bruggemann* [2.43]: $\chi_\alpha \frac{\varepsilon_\alpha-\varepsilon_{\text{eff}}}{\varepsilon_\alpha+2\varepsilon_{\text{eff}}} + \chi_\beta \frac{\varepsilon_\beta-\varepsilon_{\text{eff}}}{\varepsilon_\beta+2\varepsilon_{\text{eff}}} = 0$

$$G(L) = \frac{3\chi_\alpha-1}{2\chi_\alpha}\delta(L)\Theta(3\chi_\alpha-1) + \frac{3}{4\pi\chi_\alpha L}\sqrt{(L-L^-)(L^+-L)}\Theta(L-L^-)\Theta(L^+-L)$$

where $L^{+/-} = \frac{1}{3}\left(1+\chi_\alpha \pm 2\sqrt{2\chi_\alpha-2\chi_\alpha^2}\right)$

Mixture rule by *Maxwell-Garnett* [2.53]: $\frac{\varepsilon_{\text{eff}}-\varepsilon_\beta}{\varepsilon_{\text{eff}}+2\varepsilon_\beta} = \chi_\alpha \frac{\varepsilon_\alpha-\varepsilon_\beta}{\varepsilon_\alpha+2\varepsilon_\beta}$

$$G(L) = \delta\left(L-\frac{1-\chi_\alpha}{3}\right)$$

Table 2.7 (continued)

Mixture rule by *Looyenga* [2.54]: $\varepsilon_{\text{eff}}^{1/3} = \chi_\alpha \varepsilon_\alpha^{1/3} + \chi_\beta \varepsilon_\beta^{1/3}$

$$G(L) = \chi_\alpha^2 \delta(L) + \frac{3\sqrt{3}}{2\pi}\left(\chi_\beta^2 \left|\frac{L-1}{L}\right|^{1/3} + \chi_\alpha \chi_\beta \left|\frac{L-1}{L}\right|^{2/3}\right)$$

Mixture rule by *Monecke* [2.55]: $\varepsilon_{\text{eff}} = \dfrac{2\left(\chi_\alpha \varepsilon_\alpha + \chi_\beta \varepsilon_\beta\right)^2 + \varepsilon_\alpha \varepsilon_\beta}{(1+\chi_\alpha)\varepsilon_\alpha + (2-\chi_\alpha)\varepsilon_\beta}$

$$G(L) = \frac{2\chi_\alpha}{1+\chi_\alpha}\delta(L) + \frac{1-\chi_\alpha}{1+\chi_\alpha}\delta\left(L - \frac{1+\chi_\alpha}{3}\right)$$

Mixture rule for hollow sphere equivalent by *Bohren* and *Huffman* [2.56]:

$$\varepsilon_{\text{eff}} = \varepsilon_\alpha \frac{(3-2f)\varepsilon_\beta + 2f\varepsilon_\alpha}{f\varepsilon_\beta + (3-f)\varepsilon_\alpha}$$

$$G(L) = \frac{2}{3-f}\delta(L) + \frac{1-f}{3-f}\delta\left(L - \frac{3-f}{3}\right)$$

where $f = 1 - \dfrac{r_{\text{i}}^3}{r_{\text{o}}^3}$ and $r_{\text{i/o}}$ is the inner/outer radius of the sphere

where $t = \varepsilon_\beta/(\varepsilon_\beta - \varepsilon_\alpha)$ and $G(L)$ is the *spectral function* which describes the geometry of particles in terms of the *depolarization factor* L. Equation (2.60) is commonly known as the *Bergman* representation [2.57] and represents a general approach to modeling a heterogeneous mixture in terms of effective properties [2.58]. The advantage of the spectral representation is that it distinguishes between the influence of geometrical quantities and that of the dielectric properties of the components on the effective behavior of the system. Although the spectral function $G(L)$ is generally unknown for an arbitrary two-phase composite, it's analytically known or can be numerically derived for any existing mixture rule. Examples of spectral functions and corresponding solutions are shown in Table 2.7.

2.9 The Hall Effect

The Hall effect is closely related to the phenomenon of conductivity and is observed as the occurrence of a voltage appearing across a conductor carrying an electric current in a magnetic field. The schematic of the experiment is shown in the Fig. 2.14. The effect is often characterized by the *Hall coefficient*

$$R_{\text{H}} = \frac{E_y}{J_x B_z}\,, \tag{2.61}$$

where E_y is the Hall effect electric field in the y-direction, J_x is the current density in the x-direction and B_z is magnetic field in the z-direction.

The *Hall effect for ambipolar conduction* in a sample where there are both negative and positive charge carriers, e.g., electrons and holes in a semiconductor, involves not only the concentrations of electrons and holes, n and p respectively, but also the electron and hole drift mobilities, μ_{e} and μ_{h}. In the first approximation, the Hall coefficient can be calculated in the following way. Both charge carriers experience a Lorentz force in the same direction since they are drifting in the opposite directions but of course have opposite signs as illustrated in Fig. 2.14. Thus, both

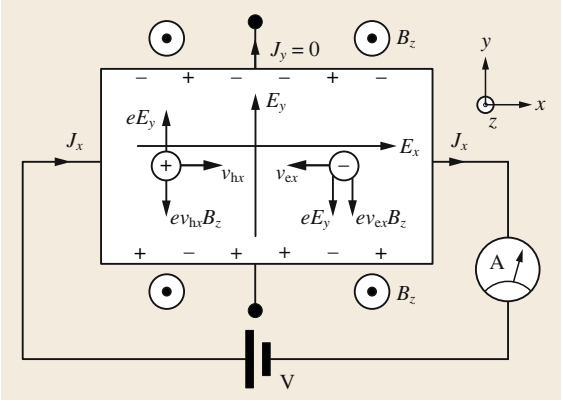

Fig. 2.14 Hall effect for ambipolar conduction. The magnetic field B_z is out of the plane of the paper. Both electrons and holes are deflected toward the bottom surface of the conductor and so the Hall voltage depends on the relative mobilities and concentrations of electrons and holes

holes and electrons accumulate near the bottom surface. The magnitude of the Lorentz force, however, will be different since the drift mobilities and hence drift velocities will be different. Once equilibrium is reached, there should be no current flowing in the y-direction as we have an open circuit. The latter physical arguments lead to the following Hall coefficient [2.5],

$$R_{\mathrm{H}} = \frac{p\mu_{\mathrm{h}}^2 - n\mu_{\mathrm{e}}^2}{e\,(p\mu_{\mathrm{h}} + n\mu_{\mathrm{e}})^2}$$

$$\text{or} \quad R_{\mathrm{H}} = \frac{p - nb^2}{e\,(p + nb)^2}, \tag{2.62}$$

where $b = \mu_{\mathrm{e}}/\mu_{\mathrm{h}}$.

It is clear that the Hall coefficient depends on both the drift mobility ratio and the concentrations of holes and electrons. For $p > nb^2$, R_{H} will be positive and for $p < nb^2$, it will be negative. Note that the carrier concentration is not zero when the Hall coefficient is zero but rather $n/p = (\mu_{\mathrm{h}}/\mu_{\mathrm{e}})^2$. As an example, Fig. 2.15 shows the dependence of Hall coefficient versus electron concentration for a single crystal silicon. The calculations are based on (2.62) and the law of mass action

$$np = n_{\mathrm{i}}^2\,, \tag{2.63}$$

where n_{i} is the electron concentration in the intrinsic semiconductor.

In the case of *monopolar conduction*, e.g., conduction in metals or in doped semiconductors, (2.62) reduces to

$$R_{\mathrm{H}} = -\frac{1}{en}\,, \quad (\text{for } n \gg p) \tag{2.64}$$

or

$$R_{\mathrm{H}} = \frac{1}{ep}\,, \quad (\text{for } p \gg n)\,. \tag{2.65}$$

Therefore, (considering as an example a n-type semiconductor where $\sigma = ne\mu_{\mathrm{n}}$) one can write

$$\mu_{\mathrm{H}} = \frac{\sigma}{ne} = -\sigma R_{\mathrm{H}} \tag{2.66}$$

which provides a simple expression for determining the electron mobility known as the *Hall mobility*. Note, however, that the Hall mobility may differ from the drift mobility discussed in the previous sections. The difference arises from the carriers in a semiconductor having

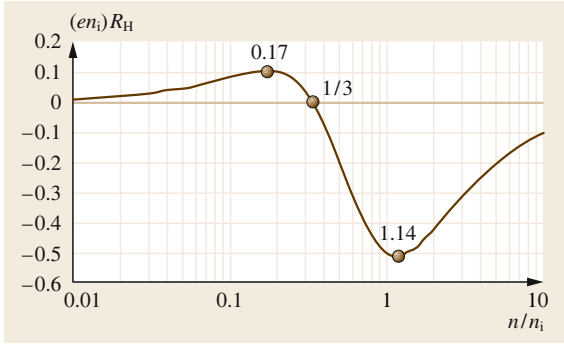

Fig. 2.15 Normalized Hall coefficient versus normalized electron concentration plot for single-crystal silicon. The values 0.17, 1.14 and 0.33 shown are the n/n_{i} values when the magnitude R reaches maxima and zero respectively. In single-crystal silicon, $n_{\mathrm{i}} = 1.5\times10^{10}\,\mathrm{cm}^{-3}$, $\mu_{\mathrm{e}} = 1350\,\mathrm{cm}^2\mathrm{V}^{-1}\mathrm{s}^{-1}$ and $\mu_{\mathrm{h}} = 450\,\mathrm{cm}^2\mathrm{V}^{-1}\mathrm{s}^{-1}$

a distribution of energies. An average is used to describe the effect of carriers occupying different allowed states. (This is distinct from the earlier discussions of mobility where it was assumed that all the carriers have the same mean free time between collisions.) To include this, it is necessary to use a formal analysis based on the Boltzmann transport equation, as discussed in Sect. 2.6. If we express the averaging of the carriers with energy E and distribution function $f(E)$, we can write the energy-averaged $\tau(E)$ (i. e., $\langle\tau\rangle$) as

$$\langle\tau\rangle = \frac{\int \tau(E) f(E)\mathrm{d}E}{\int f(E)\mathrm{d}E} \tag{2.67}$$

and the energy-averaged τ^2 (i. e., $\langle\tau^2\rangle$) as

$$\langle\tau\rangle = \frac{\int \tau^2(E) f(E)\mathrm{d}E}{\int f(E)\mathrm{d}E}\,. \tag{2.68}$$

The rigorous analysis [2.12] shows that the Hall mobility μ_{H} in terms of the drift mobility μ_{d} is

$$\mu_{\mathrm{H}} = r_{\mathrm{H}} \times \mu_{\mathrm{d}}\,, \tag{2.69}$$

where r_{H} is the *Hall factor* given by the ratio

$$r_{\mathrm{H}} = \frac{\langle\tau^2\rangle}{\langle\tau\rangle^2}\,. \tag{2.70}$$

The magnitude of the *Hall factor* will depend on the magnitude of the scattering mechanisms that contribute to τ, but usually at low magnetic fields, $r_{\mathrm{H}} \approx 1$ and the two mobilities are identical.

2.10 High Electric Field Transport

The previous sections focused on carrier transport in weak electric fields where the energy gained by carriers from the field is lost to the lattice through collisions with phonons or ionized impurities. However at higher fields, the efficiency of collision mechanisms diminishes and the carrier system contains more energy than the lattice. The carriers are then called *hot* with effective temperatures T_e for electrons and T_h for holes. In this case, the drift velocity no longer obeys Ohm's law, and becomes non-linear in the applied field with a clear tendency to saturation due to the appearance of a new dissipation mechanism involving optical phonon generation. Figure 2.16 shows the drift velocity saturation for both electrons and holes in Si and electrons in GaAs; GaAs shows a region of electron velocity overshoot and then negative differential resistivity due to inter-valley scattering, i. e., the transfer of electrons from the Γ minimum to the L conduction band minimum.

Solving the Boltzmann transport equation by analogy with (2.6) and (2.7) the electron (or hole) mobility may be defined as

$$\mu = \frac{e\,\langle\tau(T_e)\rangle}{m^*}\,, \tag{2.71}$$

where e is elementary charge and m^* is the electron (or hole) effective mass and $\langle\tau(T_e)\rangle$ is the mean free time

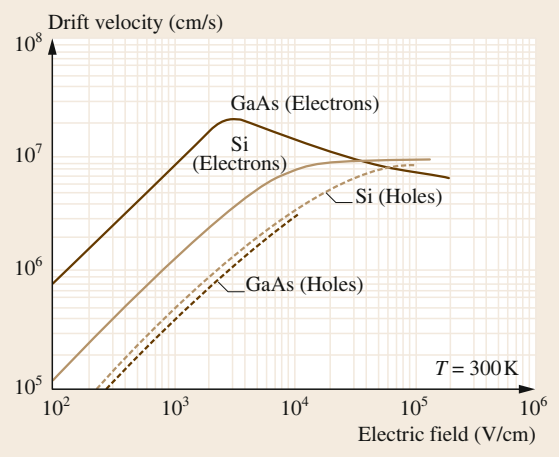

Fig. 2.16 Dependence of carrier drift velocity on electric field for GaAs and Si. (After [2.59])

which now strongly depends on T_e. Therefore, the high-field mobility is related to the low field mobility μ_0 by

$$\mu = \mu_0\left(\frac{T_e}{T}\right)^{\beta}\,, \tag{2.72}$$

where β depends on electric field and scattering mechanisms. Thus, in order to determine the dependence of the mobility on electric field, the dependence of the effective carrier temperature on field is required. This may be found by using the time-dependent Boltzmann transport equation. Suppose that F is the field, then for non-degenerate conditions with $T_e \gg T$

$$\frac{T_e}{T} \propto F^{-\frac{2}{2\beta-1}} \tag{2.73}$$

and hence

$$\mu(E) \propto \mu_0 F^{-\frac{2}{2\beta-1}}\,. \tag{2.74}$$

For acoustic phonon scattering, $\beta = -3/2$ and the drift mobility shows no saturation, increasing with field as $F^{1/4}$. Saturation in the drift velocity may be achieved only when $\beta \to \infty$ due to optical phonon scattering where large energy changes are involved. The saturation velocity v_s (related to the saturation mobility by $v_s = F\mu_s$) may be calculated using the energy and momentum rate equations for optical phonon scattering

$$\frac{\mathrm{d}\,\langle E\rangle}{\mathrm{d}t} = eFv_s - \frac{E_{op}}{\tau_e} \tag{2.75}$$

$$\frac{\mathrm{d}\,\langle m^* v_s\rangle}{\mathrm{d}t} = eF - \frac{m^* v_s}{\tau_m} \tag{2.76}$$

where E_{op} is the optical phonon energy, τ_e and τ_m are the energy and momentum relaxation times, respectively. At steady state and for not extremely high fields, one may assume that $\tau_e \approx \tau_m$. (It is worth noting that at the highest electric fields $\tau_e > \tau_m$ and may lead to the appearance of avalanche, as discussed in Sect. 2.11). Therefore, the solution of (2.75) and (2.76) is

$$v_s = \left(\frac{E_{op}}{m^*}\right)^{1/2}\,. \tag{2.77}$$

in agreement with the experimental values shown in Fig. 2.16.

2.11 Impact Ionization

At very high electric field (in the range 2×10^5 V/cm or larger) a new possibility appears: a carrier may have kinetic energy in excess of the binding energy of a valence electron to its parent atom. In colliding with an atom, such a carrier can rupture the covalent bond and produce an electron-hole pair. This process is called *impact ionization* and is characterized by the *impact ionization coefficient* α (α_e for electrons and α_h for holes). The released electrons and holes may, in turn, impact ionize more atoms producing new electron-hole pairs. This process is called *avalanche* and is characterized by the *multiplication factor*, M, which is the ratio of number of collected carriers to the number of initially injected carriers.

The field dependence of the impact ionization coefficient, at least over the limited fields where avalanche is observed, is usually modeled by experimentalists by using

$$\alpha = A\exp\left[-\left(\frac{B}{F}\right)^n\right], \tag{2.78}$$

where F is the field A, B, n are constants that depend on the semiconductor material properties such as the E-$\boldsymbol{k}$ electronic structure, phonon energies and spectra, scattering mechanisms and so on. The constant B has been semiquantitatively argued to depend on E_g/τ where E_g is the bandgap and $1/\tau$ is the phonon scattering rate; higher bandgap semiconductors tend to have steeper slopes on log α versus $1/F$ plots and the log α versus $1/F$ curve tends to shift to higher fields. Typically, it has been found that $n\approx1$ at low fields and $n\approx2$ for high fields. Figure 2.17 shows experimental data for a variety of materials over a wide range of electric fields.

Avalanche multiplication in crystalline semiconductors has been well studied over several decades and is now well developed and used in various commercial applications, such as avalanche photodiodes in optical communications, high sensitivity radiation detectors, and x-ray and nuclear detectors [2.69, 70]. In the case of amorphous semiconductors, the present work points to only a-Se exhibiting avalanche multiplication in the bulk for reasons explained in reference [2.71], with reports dating back to the 1980s [2.61, 62, 72]. Avalanche in a-Se has also been commercialized in ultrasensitive video tubes [2.73], with potential application in medical imaging [2.74].

The origin of (2.78) in its simple $n=1$ form lies in *Shockley*'s [2.75] *lucky electron* model. When a carrier moves a distance z down-stream (along the field) without being scattered, it gains an energy eFz. An unlucky carrier is scattered so frequently that its eFz never reaches the threshold ionization energy E_I for impact ionization. On the other hand, a *lucky electron* is a ballistic electron that avoids scattering for a substantial distance, and hence is able to build its eFz to reach E_I and thereby cause impact ionization. If λ is the mean free path of collisions, then Shockley's model gives

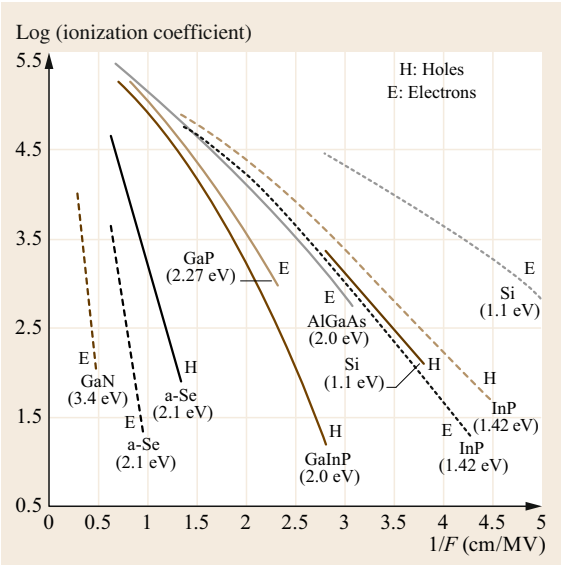

Fig. 2.17 Semilogarithmic plot of the dependence of the impact ionization coefficient on the reciprocal field for various crystalline and amorphous semiconductors for comparison; H indicates holes and E electrons. The y-axis is a base-10 logarithm of α in which α is in 1/cm. Data for a-Se electrons and holes from [2.60–62]; Data for crystalline semiconductors are for GaP [2.63]; GaInP ($Ga_{0.52}In_{0.48}P$) [2.64]; $Al_{0.60}Ga_{0.40}As$ [2.65]; InP [2.66]; Si, [2.67]; GaN (calculation only) [2.68]

$$\alpha = \frac{eF}{E_I}\exp\left(-\frac{E_I}{e\lambda F}\right). \tag{2.79}$$

The main problem with the Shockley model is that there are just not enough ballistic electrons to cause sufficient impact ionizations to explain the experiments. A better model was developed by *Baraff* [2.76] who numerically solved the Boltzmann transport equation for a simple parabolic band and energy independent mean free path to provide a relationship between α and F in terms of four parameters, that is, threshold energy for impact ionization, mean free path associated with ionizations, optical phonon energy, and mean free path for optical phonon scattering. Baraff's theory served experimental-

ists quite well in terms of comparing their results even though the model was not intuitive and was limited in terms of its assumptions and applicability to real semiconductors.

Impact ionization theory in crystalline solids only reached an acceptable level of confidence and understanding in the 1980s and 1990s with the development of the lucky-drift model by *Ridley* [2.77] and its extension by *Burt* [2.78], and *Mackenzie* and *Burt* [2.79]. The latter major advancement in the theory appeared as the *lucky drift* (LD) *model*, and it was based on the realization that at high fields, hot electrons do not relax momentum and energy at the same rates. Momentum relaxation rate is much faster than the energy relaxation rate. An electron can drift, being scattered by phonons, and have its momentum relaxed, which controls the drift velocity, but it can still gain energy during this drift. Stated differently, the mean free path λ_E for energy relaxation is much longer than the mean free path λ for momentum relaxation.

In the *Mackenzie* and *Burt* [2.79] version of the LD model, the probability $P(E)$ that a carrier attains an energy E is given by,

$$P(E) = \exp\left(-\int_0^E \frac{dE'}{eF\lambda(E')}\right) + \int_0^E \frac{dE_1}{eF\lambda(E_1)} \times \exp\left(-\int_0^{E_1} \frac{dE'}{eF\lambda(E')}\right) \times \exp\left(-\int_{E_1}^{E} \frac{dE'}{eF\lambda_E(E')}\right), \tag{2.80}$$

where as mentioned above λ is the mean free path associated with momentum relaxing collisions and λ_E is the mean energy relaxation length associated with the energy relaxing collisions. The first term is the Shockley lucky electron probability, i. e., the electron moves ballistically to energy E. The second term is the lucky drift probability term which is composed of the following: the electron first moves ballistically to some intermediate energy E_1 $(0 < E_1 < E)$ from where it begins its lucky drift to energy E_I; hence the integration over all possible E_1. The impact ionization coefficient can then readily be evaluated from

$$\alpha = \frac{eFP(E_I)}{\int_0^{E_I} P(E)dE}\,. \tag{2.81}$$

The model above is based on a hard threshold ionization energy E_I, that is, when a carrier attains the energy E_I, ionization ensues. The model has been further refined by the inclusion of soft threshold energies which represent the fact the ionization does not occur immediately when the carrier attains the energy E_I, and the carrier drifts further to gain more energy than E_I before impact ionization [2.80–84].

Assuming λ and λ_E are energy independent, which would be the case for a single parabolic band in the crystalline state, (2.80) and (2.81) can be solved analytically to obtain

$$\alpha = \frac{1}{\lambda} \times \frac{\frac{\lambda}{\lambda_E}\exp\left(\frac{-E_I}{eF\lambda_E}\right) + \left(\frac{\lambda}{\lambda_E}\right)^2 \exp\left(\frac{-E_I}{eF\lambda}\right)}{1 - \exp\left(\frac{-E_I}{eF\lambda_E}\right) - \left(\frac{\lambda}{\lambda_E}\right)^2 \left[1 - \exp\left(\frac{-E_I}{eF\lambda}\right)\right]}\,. \tag{2.82}$$

For $\lambda_E > \lambda$, and in the *low field region*, where typically $(\alpha\lambda) < 10^{-1}$, or $x = E_I/eF\lambda > 10$, (2.82) leads to a simple expression for α,

$$\alpha = \left(\frac{1}{\lambda_E}\right)\exp\left(-\frac{E_I}{eF\lambda_E}\right). \tag{2.83}$$

For crystalline semiconductors, one typically also assumes that λ_E depends on the field F, λ and the optical phonon energy $\hbar\omega$ as

$$\lambda_E = \frac{eF\lambda^2}{2\hbar\omega}\coth\left(\frac{\hbar\omega}{2kT}\right). \tag{2.84}$$

As the field increases, λ_E eventually exceeds λ, and allows lucky drift to operate and the LD carriers to reach the ionization energy.

It is worth noting that the model of lucky drift is successfully used not only for crystalline semiconductors but to amorphous semiconductors [2.83].

2.12 Two-Dimensional Electron Gas

Heterostructures offer the ability to spatially engineer the potential in which carriers move. In such structures having layers deposited in the z-direction, when the width of a region with confining potential $t_z < \lambda_{dB}$, the de Broglie electron wavelength, electron states become stationary states in that direction, retaining Bloch wave character in the other two directions (i. e., x- and y-directions), and is hence termed a *2-D electron gas* (2DEG). These structures are notable for their extremely high carrier mobility.

High mobility structures are formed by selectively doping the wide bandgap material behind an initially undoped spacer region of width d as shown in Fig. 2.18a. Ionization and charge transfer leads to carrier build-up in the low potential region of narrow bandgap material adjacent to the hetero-interface. The equilibrium band bending (i. e., through Poisson's equation) in the well region, as shown in Fig. 2.18b, results from the equalization of ionized donor concentration in the wide bandgap material and 2DEG concentration adjacent to the heterointerface. When the associated interfacial field is sufficiently strong, carriers are confined within λ_{dB} and electron states are quantized into subbands (i. e., E_0 and E_1), as shown in Fig. 2.18b.

Figure 2.19 shows the contributions of component scattering mechanisms to the low temperature mobility of a 2DEG formed at a $Ga_{0.70}Al_{0.3}As$-GaAs heterointerface, as a function of the electron gas density. As for bulk samples, the most important mechanism limiting the low temperature mobility is ionized impurity scat-

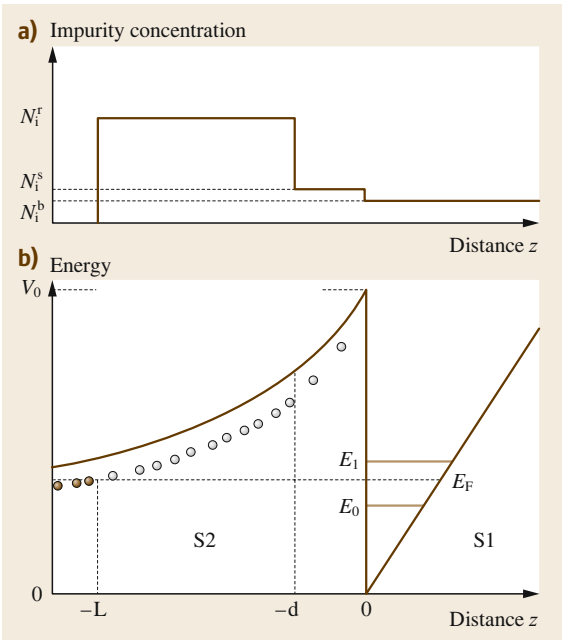

Fig. 2.18 **(a)** Doping profile for a selectively doped 2DEG heterostructure. The S1 is a narrow bandgap material adjacent to the heterointerface. The S2 is selectively doped wide-bandgap material including an initially undoped spacer region of width d. **(b)** Conduction energy band structure for a selectively doped 2DEG heterostructure. The equilibrium band bending (through Poisson's equation) in the well region results from the equalization of the ionized donor concentration in the wide-bandgap material and the 2DEG concentration adjacent to the heterointerface. When the associated interfacial field is sufficiently strong, carriers are confined within λ_{dB} and electron states are quantized into the sub-bands E_0 and E_1. (After [2.84])

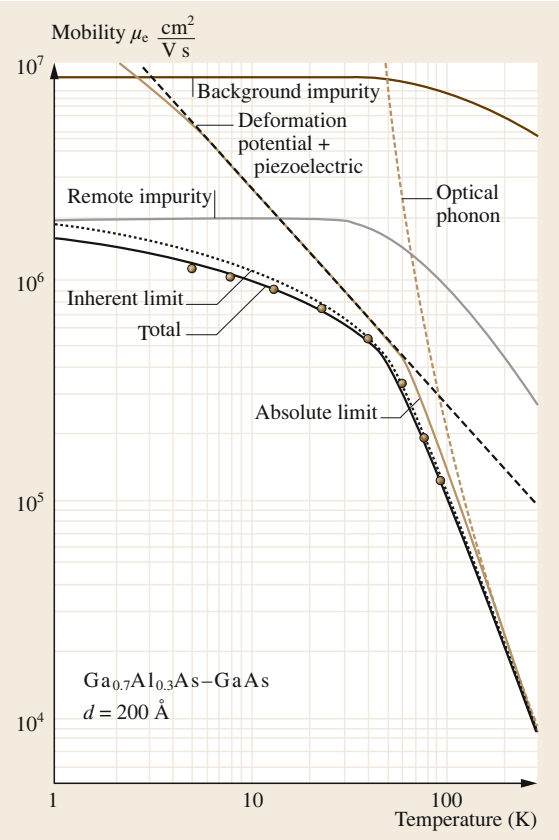

Fig. 2.20 Dependence of 2DEG electron mobility on temperature for a $Ga_{0.70}Al_{0.3}As$-GaAs heterostructure. (After [2.84])

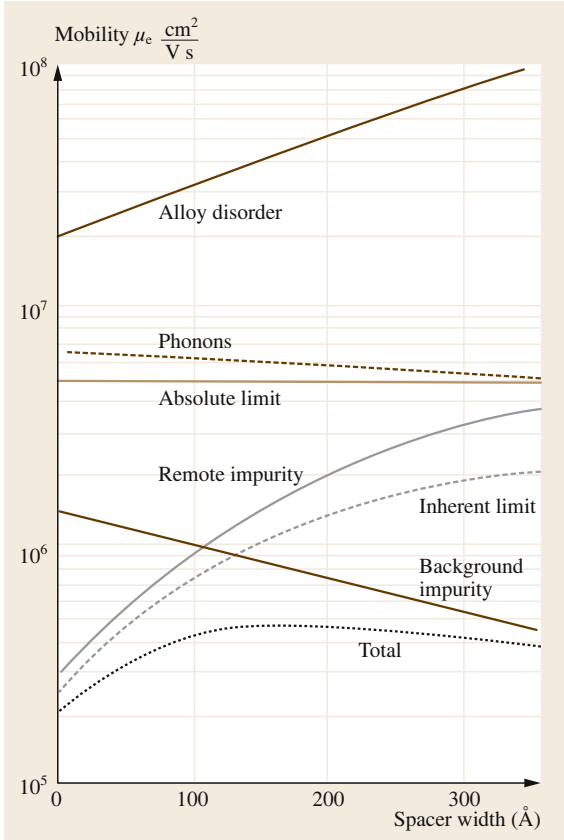

Fig. 2.21 Dependence of 2DEG electron mobility on spacer width for a $Ga_{0.70}Al_{0.3}As$-GaAs heterostructure. (After [2.84])

tering, except at high electron densities, where so-called *alloy disorder scattering* is significant. Ionized impurity scattering may be further broken down into scattering from ionized impurities that are with the GaAs quantum well, known as *background impurities*, those beyond the spacer region, termed *remote impurity scattering*. For high purity growth, the unintentional background impurity concentration can be kept to very low limits and impurity scattering based mobility values are then dictated by remote impurity scattering. Since carriers in the well are only weakly scattered by the tail field of these remote Coulomb centers, the mobility of such 2DEG systems can be orders of magnitude higher than bulk samples. The temperature dependence of the electron mobility for such a system is shown in Fig. 2.20. Notice how, similar to bulk sample, increasing temperature increases the phonon population such that for the example shown, above about 100 K, polar optical phonon scattering controls the mobility.

Figure 2.21 shows the dependence of the 2DEG mobility on the spacer width. Two competing factors are active – for narrow spacer widths, the transfer efficiency of carriers to the GaAs well is high and so a lower remote doping concentration is sufficient to provide for a given constant 2DEG concentration, but since the Coulomb scatters are so close to the 2DEG, they scatter very efficiently and limit the mobility. On the other hand, for large spacer widths, carrier transfer efficiency is quite poor requiring higher remote doping to supply the given 2DEG concentration; however, being relatively far away each of the scattering centers are less effective at lowering the mobility, but given their high concentration, the net effect is still a decrease in the mobility at large spacer widths as seen in the figure.

2.13 One-Dimensional Conductance

In the case where carriers are confined within regions of width L_x, $L_y < \lambda_{dB}$ in two directions x and y, respectively, the electron energy in those two directions become quantized with quantum numbers n_x and n_y, respectively. In the third direction z, electrons travel as Bloch waves with energy that may be approximated by $\hbar^2 k_z^2/2m^*$ giving an expression for the total energy E of the so-called *1-D electron system* or *quantum wire* as

$$E(n_x, n_y, n_z) = \frac{\hbar^2 \pi^2}{2m^*}\left(\frac{n_x^2}{L_x^2} + \frac{n_y^2}{L_y^2}\right) + \frac{\hbar^2 k_z^2}{2m^*} . \quad (2.85)$$

The associated electron wavefunctions are

$$\Psi(x, y, z) = \frac{1}{2\sqrt{L_x L_y L_z}} \sin\left(\frac{n_x \pi x}{L_x}\right) \times \sin\left(\frac{n_y \pi y}{L_y}\right) e^{ik_z z} . \quad (2.86)$$

Using these equations, one can readily derive an expression for the density of states per unit energy range

$$\mathrm{DOS} = 2 \times 2\left(\frac{L_z}{2\pi}\right)\left(\nabla_{k_z} E\right)^{-1} = \frac{2L_z}{h}\sqrt{\frac{m^*}{2(E - E_{n_x,n_y})}} . \quad (2.87)$$

In order to evaluate the conductance of this quantum wire, consider the influence of a weak applied potential V. Similar to the case for bulk transport the applied field displaces the *Fermi surface* and results in a change in the electron wave-vector from $\boldsymbol{k}_0$ (i. e., with no applied potential) to $\boldsymbol{k}_V$ (i. e., when the potential is applied). When V is small compared with the electron energy

$$k_0 = \sqrt{\frac{2m^*(E - E_{n_x,n_y})}{\hbar^2}} , \quad (2.88)$$

$$k_V = k_0\sqrt{1 + \frac{eV}{E - E_{n_x,n_y}}} \approx k_0\left(1 + \frac{1}{2}\frac{eV}{E - E_{n_x,n_y}}\right) . \quad (2.89)$$

This leads to establishing a current density J in the wire

$$J = \frac{2e^2\,(\mathrm{DOS})\sqrt{(E_F - E_{n_x,n_y})}}{\sqrt{2m^*}} . \quad (2.90)$$

Which may be simplified to the following expressions for J and the current flowing in the wire for a given quantum state $E\{n_x, n_y\}$, I

$$J_{n_x,n_y} = \frac{2e^2 V L_z}{h} \quad \text{and} \quad I_{n_x,n_y} = \frac{2e^2 V}{h} . \quad (2.91)$$

The expression for the conductance through one channel corresponding to a given quantum state $\{n_x, n_y\}$ is then given by

$$G_{n_x,n_y} = \frac{I_{n_x,n_y}}{V} = \frac{2e^2}{h} . \quad (2.92)$$

Notice how the conductance is quantized in units of e^2/h with each populated channel contributing equally to the conductance – moreover, this is a fundamental result, being independent of the material considered. In practice, deviations from this equation can occur (although generally less than 1%) owing to the finiteness of real nanowires and impurities in or near the channel, influencing the conductivity and even resulting in weak localization. Generally, unlike both bulk and 2DEG systems, ionized impurity scattering is suppressed in nanowires. The main reason for this is that an incident electron in a quantum state $\{n_x, n_y\}$ traveling along the wire with wave-vector $\boldsymbol{k}_z\{n_x, n_y\}$, can not be elastically scattered into any states except those in a small region of $\boldsymbol{k}$-space in the vicinity of $-\boldsymbol{k}_z\{n_x, n_y\}$. Such a scattering event involves a large change in momentum of $\approx 2\boldsymbol{k}_z\{n_x, n_y\}$ and thus, the probability of such events is very small. As a result, the mean free path and mobility of carriers in such quantum wires are substantially increased.

The nature of carrier transport in quantum wires depends on the wire dimensions (i. e., length L_{Wire} and diameter d_{Wire}) as compared with the carrier mean free path, l_{Carrier}. When $l_{\mathrm{Carrier}} \gg L_{\mathrm{Wire}}$, d_{Wire} the only potential seen by the carriers is that associated with the wire walls, and carriers exhibit wavelike behavior, being guided through the wire as if it were a waveguide without any internal scattering. Conversely, if $d_{\mathrm{Wire}} \ll \lambda_{\mathrm{DeBroglie}}$, only a few energy states in the wire are active, and in the limit of an extremely small waveguide, only one state or channel is active, analogous to a single mode waveguide cavity – this case is termed *quantum ballistic transport*. In the limit, $l_{\mathrm{Carrier}} \ll L_{\mathrm{Wire}}$, d_{Wire}, scattering dominates transport throughout the wire – with numerous scattering events occurring before a carrier can traverse the wire or move far along its length. In such a case the transport is said to be *diffusive*.

As discussed previously, ionized impurity and lattice scattering contribute to l_{Carrier}, with l_{Carrier} decreasing with increasing temperature due to phonon scattering. For strong impurity scattering, this may not occur until relatively high temperatures. In the intermediate case of $L_{\text{Wire}} \gg l_{\text{Carrier}} \gg d_{\text{Wire}}$ and where $d_{\text{Wire}} \ll \lambda_{\text{DeBroglie}}$ scattering is termed *mixed mode* and is often called *quasi-ballistic*.

2.14 The Quantum Hall Effect

The observation of, and first explanation for the Hall Effect in a 2DEG by von *Klitzing* et al. [2.85], won them a Nobel Prize. As shown in Fig. 2.22 the Hall resistivity exhibits plateaus for integer values of h/e^2, independent of any material dependent parameters. This discovery was later shown to be correct to a precision of at least one part in 10^7, enabling extremely accurate determinations of the fine structure constant (i. e., $\alpha = (\mu_0 c e^2/2h) \approx 1/137$) and a fundamental resistance standard to be established.

For the six point Hall geometry used (as shown in the insert to Fig. 2.18), one can define the *Hall resistivity* $\rho_{xy} = g_1 V_{\text{H},y}/I_x$ and *longitudinal resistivity* $\rho_{xx} = g_2 V_{\text{L},x}/I_x$ where g_1 and g_2 are geometric constants related to the sample geometry. These resistivities are related to corresponding conductivities through the conductivity and resistivity tensors

$$\begin{aligned}
\rho_{xy} &= \frac{\sigma_{xy}}{\sigma_{xx}^2 + \sigma_{xy}^2} \,, \\
\rho_{xx} &= \frac{\sigma_{xx}}{\sigma_{xx}^2 + \sigma_{xy}^2} \,, \\
\rho_{yx} &= -\rho_{xy} \,, \\
\rho_{yy} &= \rho_{xx} \,.
\end{aligned} \tag{2.93}$$

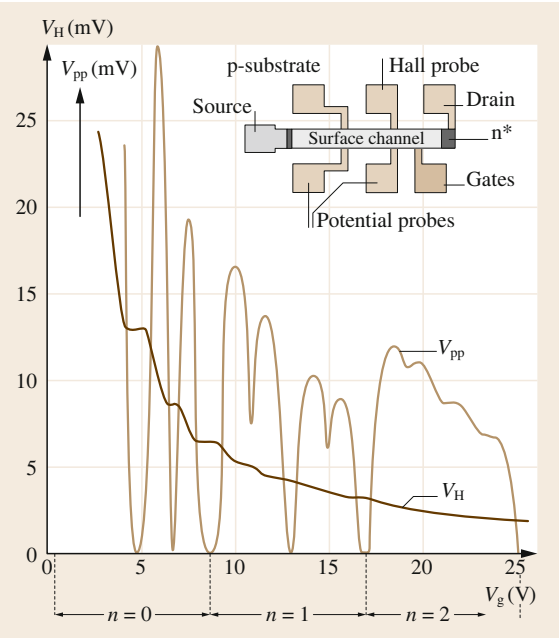

Fig. 2.22 Hall voltage V_{H} and voltage drop across electrodes V_{PP} as a function of gate voltage V_{g} at 1.5 K, when $B = 18$ T. Source-drain current is 1 μA. *Insert* shows plan view of a device with length 400 μm, width 50 μm and an interprobe separation of 130 μm. (After [2.85])

Starting from a classical equation of motion for electrons in an electric field E_x, magnetic field B_z, and defining the *cyclotron frequency* $\omega_{\text{c}} = eB_z/m^*$, the velocities perpendicular to the applied magnetic field can be deduced as

$$v_x = \frac{E_x}{B_x} \sin \omega_{\text{c}} t \quad \text{and} \quad v_y = \frac{E_x}{B_x} (\cos \omega_{\text{c}} t - 1) \tag{2.94}$$

with the time averaged velocities

$$\langle v_x \rangle = \frac{E_x}{B_x} \quad \text{and} \quad \langle v_y \rangle = \frac{E_x}{B_x} \tag{2.95}$$

leading to Hall and longitudinal resistivities of

$$\sigma_{xx} = \sigma_{yy} = 0 \quad \text{and} \quad \sigma_{xy} = -\sigma_{yx} = \frac{n_{\text{s}} e}{B_z} \,, \tag{2.96}$$

where n_{s} is the areal electron concentration. Below, a quantum approach is used to establish a relationship for the electron concentration n_{s}. Note that the motion of the electrons in the crossed fields are quantized with allowed levels termed *Landau levels* E_n

$$E_n = \left(n + \frac{1}{2}\right) \hbar \omega_{\text{c}} + g^* \mu_{\text{B}} B_z + \varepsilon_z \,, \tag{2.97}$$

where n is the quantum number describing the particular Landau Level, g^* is the *Landé factor*, μ_{B} is the Bohr magneton and $g^* \mu_{\text{B}} B_z$ is *the spin magnetic energy*, and E_z is the energy associated with the z-motion

of the carriers. xy-plane carrier motion is characterized by the cyclotron energy term E_{xy},

$$E_{xy} = \frac{\hbar^2 k_{xy}^2}{2m_e^*} = \left(n + \frac{1}{2}\right)\hbar\omega_c \,. \tag{2.98}$$

Following this description and noting that the motion of electrons in the xy-plane may be expressed in terms of wavefunctions of the *harmonic oscillator* using the *Landau gauge* of the *vector potential* $[0, xB_z, 0]$, we may write the density of states per unit area, $\mathrm{DOS_A}$ as

$$\mathrm{DOS_A} = \frac{m_e^* \omega_c L_x L_y}{2\pi\hbar} \,. \tag{2.99}$$

Since the degeneracy of each Landau level is one (i. e., since they are single spin states), this enables one to find n_s assuming Landau state filling up to the pth level (for integer p)

$$n_s = \frac{m_e^* \omega_c p}{2\pi\hbar} \,. \tag{2.100}$$

Using the definition of the cyclotron frequency gives the final form

$$n_s = \frac{peB_z}{\hbar} \tag{2.101}$$

which may be used to rewrite the previous expressions for Hall and longitudinal resistivity

$$\rho_{xx} = \rho_{yy} = 0 \quad \text{and} \quad \rho_{xy} = -\rho_{yx} = \frac{h}{pe^2} \,. \tag{2.102}$$

Equation (2.102) shows that Hall resistivity is quantized in units of h/pe^2 whenever the Fermi energy lies between filled Landau levels. Consistent with observation, the result is independent of the semiconductor being studied. Although this model provides an excellent basis for understanding experiments, understanding the details of the results (i. e., in particular the existence of a finite width for the Hall effect plateaus and zero longitudinal resistance dips) requires a more complete treatment involving so-called localized states.

Acknowledgments. The authors thank Dr. Robert Johanson for helpful discussions on the subject.

3. Optical Properties of Electronic Materials: Fundamentals and Characterization

Jan Mistrik, Safa Kasap, Harry E. Ruda, Cyril Koughia, Jai Singh

Light interacts with materials in a variety of ways; this chapter focuses on refraction and absorption. Refraction is characterized by a material's refractive index. We discuss some of the most useful models for the frequency dependence of the refractive index, such as those due to Cauchy, Sellmeier, Gladstone–Dale, and Wemple–DiDominico. Examples are given of the applicability of the models to actual materials. We present various mechanisms of light absorption, including absorption by free carriers, phonons, excitons and impurities. Special attention is paid to fundamental and excitonic absorption in disordered semiconductors and to absorption by rare earth, trivalent ions due to their importance in modern photonics. We also discuss the effect of an external electric field on absorption, and the Faraday effect. Practical techniques for determining the optical parameters of thin films are outlined. Finally, we present a short technical classification of optical glasses and materials.

3.1 Optical Constants

The changes that light undergoes upon interacting with a particular substance are known as the optical properties of that substance. These optical properties are influenced by the macroscopic and microscopic properties of the substance, such as the nature of its surface and its electronic structure. Since it is usually far easier to detect the way a substance modifies light than to investigate its macroscopic and microscopic properties directly, the optical properties of a substance are often used to probe other properties of the material. There are many optical properties, including the most well known: reflection, refraction, transmission and absorption. Many of these optical properties are associated with important optical constants, such as the refractive index and the extinction coefficient. In this section we review these optical constants, such as the refractive index and the extinction coefficient. Books by *Adachi* [3.1], *Fox* [3.2] and *Simmons* and *Potter* [3.3] are highly recommended. In addition, *Adachi* also discusses the optical properties of III–V compounds in this handbook in Chap. 30.

3.1.1 Refractive Index and Extinction Coefficient

The refractive index n of an optical or dielectric medium is the ratio of the velocity of light c in a vacuum to its velocity v in the medium; $n = c/v$. Using this and Maxwell's equations, one obtains the well-known formula for the refractive index of a substance as $n = \sqrt{\varepsilon_r \mu_r}$, where ε_r is the relative permittivity (dielectric constant) and μ_r is the relative magnetic permeability. As $\mu_r = 1$ for nonmagnetic substances, one gets $n = \sqrt{\varepsilon_r}$, which is very useful for relating the dielectric properties of a material to its optical properties at any particular frequency of interest. Since ε_r depends on the wavelength of the light, the refractive index depends on it too, which is called dispersion. In addition to dispersion, an electromagnetic wave propagating through a lossy medium (one that absorbs or scatters radiation passing through it) experiences attenuation, which means that it loses its energy due to various loss mechanisms such as the generation of phonons (lattice waves), photogeneration, free-carrier absorption and scattering. In such materials, the refractive index is a complex function of the frequency of the light wave.

The complex refractive index N, with real part n and imaginary part K (called the extinction coefficient), is related to the complex relative permittivity, $\varepsilon_r = \varepsilon_r' - i\varepsilon_r''$ by

$$N = n - iK = \sqrt{\varepsilon_r} = \sqrt{\varepsilon_r' - i\varepsilon_r''} \tag{3.1}$$

where ε_r' and ε_r'' are, respectively, the real and imaginary parts of ε_r. Equation (3.1) gives

$$n^2 - K^2 = \varepsilon_r' \quad \text{and} \quad 2nK = \varepsilon_r'' \,. \tag{3.2}$$

The optical constants n and K can be determined by measuring the reflectance from the surface of a material as a function of polarization and the angle of incidence. For normal incidence, the reflection coefficient r is obtained as

$$r = \frac{1-N}{1+N} = \frac{1-n+iK}{1+n-iK} \,. \tag{3.3}$$

The reflectance R is then defined by

$$R = |r|^2 = \left|\frac{1-n+iK}{1+n-iK}\right|^2 = \frac{(1-n)^2+K^2}{(1+n)^2+K^2} \,. \tag{3.4}$$

Notice that whenever K is large, for example over a range of wavelengths, the absorption is strong, and the reflectance is almost unity. The light is then reflected, and any light in the medium is highly attenuated.

Optical properties of materials are typically presented by showing either the frequency dependence (dispersion relation) of n and K or ε_r' and ε_r''. An intuitive guide to explaining dispersion in insulators is based on a single oscillator model in which the electric field in the light induces forced dipole oscillations in the material (displaces the electron shells to oscillate about the nucleus) with a single resonant frequency ω_0 [3.1]. The frequency dependences of ε_r' and ε_r'' are then obtained as

$$\varepsilon_r' = 1 + \frac{N_{at}}{\varepsilon_0}\alpha_e' \quad \text{and} \quad \varepsilon_r'' = 1 + \frac{N_{at}}{\varepsilon_0}\alpha_e'' \,, \tag{3.5}$$

where N_{at} is the number of atoms per unit volume, ε_0 is the vacuum permittivity, and α_e' and α_e'' are the real and imaginary parts of the electronic polarizability, given respectively by

$$\alpha_e' = \alpha_{e0}\frac{1-(\omega/\omega_0)^2}{[1-(\omega/\omega_0)^2]^2 + (\gamma/\omega_0)^2(\omega/\omega_0)^2} \,, \tag{3.6a}$$

and

$$\alpha_e'' = \alpha_{e0}\frac{(\gamma/\omega_0)(\omega/\omega_0)}{[1-(\omega/\omega_0)^2]^2 + (\gamma/\omega_0)^2(\omega/\omega_0)^2} \,, \tag{3.6b}$$

where α_{e0} is the direct current (DC) polarizability corresponding to $\omega = 0$ and γ is the loss coefficient. Using (3.1), (3.2) and (3.5) with (3.6), it is then possible to study the frequency dependence of n and K. Figure 3.1a shows the dependence of n and K on the normalized frequency ω/ω_0 for a simple single electronic dipole oscillator of resonance frequency ω_0. It is seen that n and K peak close to $\omega = \omega_0$. If a material has a $\varepsilon_r'' \gg \varepsilon_r'$, then $\varepsilon_r \approx -i\varepsilon_r''$ and $n = K \approx \sqrt{\varepsilon_r''/2}$ is obtained from (3.2). Figure 3.1b shows the dependence of the reflectance R on the frequency. It is observed that R reaches its maximum value at a frequency slightly above $\omega = \omega_0$, and then remains high until ω reaches nearly $3\omega_0$; so the reflectance is substantial while absorption is strong. The normal dispersion region is the frequency range below ω_0 where n falls as the frequency decreases; that is, n decreases as the wavelength λ increases. The anomalous dispersion region is the frequency range above ω_0, where n decreases as ω increases. Below ω_0, K is small and if ε_{DC} is $\varepsilon_r(0)$, the refractive index becomes (approximately)

$$n^2 \approx 1 + (\varepsilon_{DC} - 1)\frac{\omega_0^2}{\omega_0^2 - \omega^2} \,; \quad \omega < \omega_0 \,. \tag{3.7}$$

Since $\lambda = 2\pi c/\omega$, defining $\lambda_0 = 2\pi c/\omega_0$ as the resonance wavelength, one gets

$$n^2 \approx 1 + (\varepsilon_{DC} - 1)\frac{\lambda^2}{\lambda^2 - \lambda_0^2} \,; \quad \lambda > \lambda_0 \,. \tag{3.8}$$

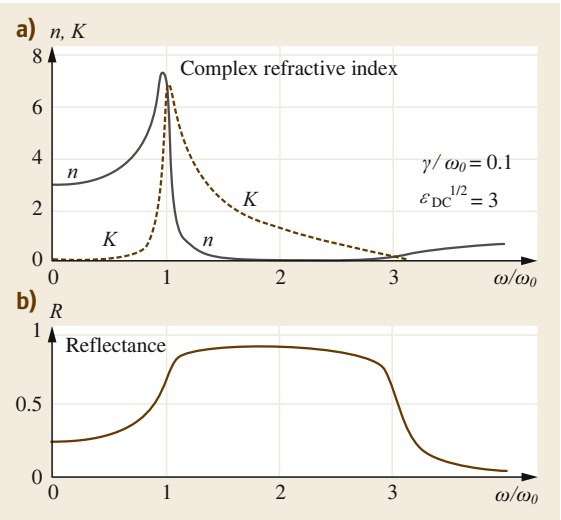

Fig. 3.1a,b The dipole oscillator model. **(a)** Refractive index and extinction coefficient versus normalized frequency. **(b)** Reflectance versus normalized frequency

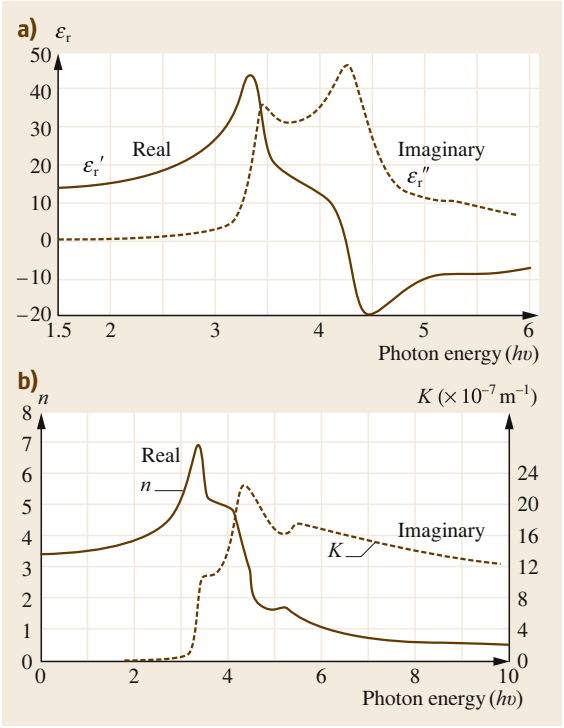

Fig. 3.2 **(a)** Complex relative permittivity of a silicon crystal as a function of photon energy plotted in terms of real (ε_r') and imaginary (ε_r'') parts. **(b)** Optical properties of a silicon crystal versus photon energy in terms of real (n) and imaginary (K) parts of the complex refractive index. (After [3.4])

While intuitively useful, the dispersion relation in (3.8) is far too simple. More rigorously, we have to consider the dipole oscillator quantum-mechanically, which means that a photon excites the oscillator to a higher energy level; see, for example, [3.2, 3]. The result is that we have a series of $\lambda^2/(\lambda^2-\lambda_i^2)$ terms with various weighting factors A_i that add to unity, where the λ_i represent different resonance wavelengths. The weighting factors A_i involve quantum-mechanical matrix elements.

Figure 3.2 shows the complex relative permittivity and the complex refractive index of crystalline silicon in terms of photon energy $h\nu$. For photon energies below the bandgap energy (1.1 eV), both ε_r'' and K are negligible and n is close to 3.7. Both ε_r'' and K increase and change strongly as the photon energy becomes greater than 3 eV, far beyond the bandgap energy. Notice that both ε_r' and n peak at $h\nu \approx 3.5$ eV, which corresponds to a direct photoexcitation process – the excitation of electrons from the valence band to the conduction band – as discussed later.

3.1.2 Kramers–Kronig Relations

If we know the frequency dependence of the real part, ε_r', of the relative permittivity of a material, then we can use the Kramers–Kronig relations to determine the frequency dependence of the imaginary part ε_r'', and vice versa. The transform requires that we know the frequency dependence of either the real or imaginary part over a frequency range that is as wide as possible, ideally from DC to infinity, and that the material is linear; in other words it has a relative permittivity that is independent of the applied field. The Kramers–Kronig relations for $\varepsilon_r = \varepsilon_r' + i\varepsilon_r''$ are given by [3.4]

$$\varepsilon_r'(\omega) = 1 + \frac{2}{\pi} P \int_0^\infty \frac{\omega' \varepsilon_r''(\omega')}{\omega'^2 - \omega^2} \, d\omega' \,, \tag{3.9a}$$

and

$$\varepsilon_r''(\omega) = -\frac{2\omega}{\pi} P \int_0^\infty \frac{\varepsilon_r'(\omega')}{\omega'^2 - \omega^2} \, d\omega' \,, \tag{3.9b}$$

where ω' is the integration variable, P represents the Cauchy principal value of the integral and the singularity at $\omega = \omega'$ is avoided.

Similarly, one can relate the real and imaginary parts of the polarizability, $\alpha'(\omega)$ and $\alpha''(\omega)$, and those of the complex refractive index, $n(\omega)$ and $K(\omega)$ as well.

For $\alpha'(\omega)$ and $\alpha''(\omega)$, one can analogously write

$$\alpha'(\omega) = \frac{2}{\pi} P \int_0^\infty \frac{\omega' \alpha''(\omega')}{\omega'^2 - \omega^2} \, \mathrm{d}\omega' \tag{3.10a}$$

and

$$\alpha''(\omega') = -\frac{2\omega}{\pi} P \int_0^\infty \frac{\alpha'(\omega')}{\omega'^2 - \omega^2} \, \mathrm{d}\omega' \,. \tag{3.10b}$$

3.2 Refractive Index

There are several simplified models describing the spectral dependence of the refractive index n.

3.2.1 Cauchy Dispersion Equation

The dispersion relationship for the refractive index (n) versus the wavelength of light (λ) is stated in the following form

$$n = A + \frac{B}{\lambda^2} + \frac{C}{\lambda^4} \,, \tag{3.11}$$

where A, B and C are material-dependent specific constants. The Cauchy equation (3.11) is typically used in the visible region of the spectrum for various optical glasses, and is applied to normal dispersion. The third term is sometimes dropped for a simpler representation of n versus λ behavior. The original expression was a series in terms of the wavelength, λ, or frequency, ω, of light as

$$n = a_0 + a_2\lambda^{-2} + a_4\lambda^{-4} + a_6\lambda^{-6} + \ldots \lambda > \lambda_\mathrm{h} \,, \tag{3.12a}$$

or

$$n = n_0 + n_2\omega^2 + n_4\omega^4 + n_6\omega^6 + \ldots \omega < \omega_\mathrm{h} \,, \tag{3.12b}$$

where $\hbar\omega$ is the photon energy, $\hbar\omega_\mathrm{h} = hc/\lambda_\mathrm{h}$ is the optical excitation threshold (the bandgap energy), while a_0, a_2 ... , and n_0, n_2, ... are constants. A Cauchy relation of the following form

$$n = n_{-2}(\hbar\omega)^{-2} + n_0 + n_2(\hbar\omega)^2 + n_4(\hbar\omega)^4 \,, \tag{3.13}$$

can be used satisfactorily over a wide range of photon energies. The dispersion parameters, calculated from (3.13), of a few materials are listed in Table 3.1.

Cauchy's dispersion relation, given in (3.13), was originally called the elastic-ether theory of the refractive index [3.5–7]. It has been widely used for many materials, although in recent years it has been largely replaced by the Sellmeier equation, which we consider next.

3.2.2 Sellmeier Dispersion Equation

The dispersion relationship can be quite complicated in practice. An example of this is the Sellmeier equation, which is an empirical relation between the refractive index n of a substance and the wavelength λ of light in the form of a series of $\lambda^2/(\lambda^2 - \lambda_i^2)$ terms, given by

$$n^2 = 1 + \frac{A_1\lambda^2}{\lambda^2 - \lambda_1^2} + \frac{A_2\lambda^2}{\lambda^2 - \lambda_2^2} + \frac{A_3\lambda^2}{\lambda^2 - \lambda_3^2} + \cdots \,, \tag{3.14}$$

where λ_i is a constant and A_1, A_2, A_3, λ_1, λ_2 and λ_3 are called Sellmeier coefficients, which are determined by fitting this expression to the experimental data. The full Sellmeier formula has more terms of similar form, such as $A_i\lambda^2/(\lambda^2 - \lambda_i^2)$, where $i = 4, 5, \ldots$ but these can generally be neglected when considering n versus λ behavior over typical wavelengths of interest and by ensuring that the three terms included in the Sellmeier equation correspond to the most important or relevant terms in the summation. Examples of Sellmeier coefficients for some materials, including pure silica (SiO_2) and 86.5 mol% SiO_2-13.5 mol% GeO_2, are given in Table 3.2. Two methods are used to find the refractive index of silica-germania glass $(SiO_2)_{1-x}(GeO_2)_x$: (a) a simple, but approximate, linear interpolation of the refractive index between known compositions, for example $n(x) - n(0.135) = (x - 0.135)[n(0.135) - n(0)]/0.135$ for $(SiO_2)_{1-x}(GeO_2)_x$, so $n(0.135)$ is used

for 86.5 mol% SiO_2-13.5 mol% GeO_2 and $n(0)$ is used for SiO_2; (b) an interpolation for the coefficients A_i and λ_i between SiO_2 and GeO_2

$$n^2 - 1 = \frac{\{A_1(S) + X[A_1(G) - A_1(S)]\}\lambda^2}{\lambda^2 - \{\lambda_1(S) + X[\lambda_1(G) - \lambda_1(S)]\}^2} + \cdots , \tag{3.15}$$

where X is the atomic fraction of germania, S and G in parentheses refer to silica and germania [3.8]. The theoretical basis of the Sellmeier equation is that the solid is represented as a sum of N lossless (frictionless) Lorentz oscillators such that each takes the form of $\lambda^2/(\lambda^2 - \lambda_i^2)$ with different λ_i, and each has different strengths, with weighting factors (A_i, $i = 1, 2, \ldots N$) [3.9, 10]. Knowledge of appropriate dispersion relationships is essential when designing photonic devices, such as waveguides.

There are other dispersion relationships that inherently take account of various contributions to optical properties, such as the electronic and ionic polarization and the interactions of photons with free electrons. For example, for many semiconductors and ionic crystals, two useful dispersion relations are

$$n^2 = A + \frac{B\lambda^2}{\lambda^2 - C} + \frac{D\lambda^2}{\lambda^2 - E} , \tag{3.16}$$

and

$$n^2 = A + \frac{B}{\lambda^2 - \lambda_0^2} + \frac{C}{\left(\lambda^2 - \lambda_0^2\right)^2} + D\lambda^2 + E\lambda^4 , \tag{3.17}$$

where A, B, C, D, E and λ_0 are constants particular to a given material. Table 3.3 provides a few examples.

The refractive index of a semiconductor material typically decreases with increasing bandgap energy E_g. There are various empirical and semi-empirical rules and expressions that relate n to E_g. In Moss' rule, n and E_g are related by $n^4 E_g = K =$ constant (≈ 100 eV). In the *Hervé–Vandamme* relationship [3.11],

$$n^2 = 1 + \left(\frac{A}{E_g + B}\right)^2 , \tag{3.18}$$

where A and B are constants ($A \approx 13.6$ eV and $B \approx 3.4$ eV and $dB/dT \approx 2.5 \times 10^{-5}$ eV/K). The refractive index typically increases with increasing temperature. The temperature coefficient of the refractive index (TCRI) of a semiconductor can be found from the *Hervé–Vandamme* relationship [3.11]

$$\mathrm{TCRI} = \frac{1}{n}\frac{dn}{dT} = \frac{(n^2 - 1)^{3/2}}{13.6n^2}\left(\frac{dE_g}{dT} + \frac{dB}{dT}\right) . \tag{3.19}$$

TCRI is typically in the range 10^{-6}–10^{-4}.

3.2.3 Gladstone–Dale Formula

The *Gladstone–Dale formula* is an empirical equation that allows the average refractive index n of an oxide glass to be calculated from its density ρ and its constituents as

$$\frac{n-1}{\rho} = p_1 k_1 + p_2 k_2 + \cdots = \sum_{i=1}^{N} p_i k_i = C_{GD} , \tag{3.20}$$

where the summation is for various oxide components (each a simple oxide), p_i is the weight fraction of the i-th oxide in the compound, and k_i is the refraction coefficient that represents the polarizability of the i-th oxide. The right-hand side of (3.20) is called the Gladstone–Dale coefficient C_{GD}. In more general terms, as a mixture rule for the overall refractive index, the Gladstone–Dale formula is frequently written as

$$\frac{n-1}{\rho} = \frac{n_1 - 1}{\rho_1} w_1 + \frac{n_2 - 1}{\rho_2} w_2 + \cdots , \tag{3.21}$$

Table 3.3 Parameters from (3.16) and (3.17) for some selected materials (Si data from [3.12]; others from [3.13])

where n and ρ are the effective refractive index and effective density of the whole mixture respectively, n_1, n_2, ... are the refractive indices of the constituents, and ρ_1, ρ_2, ... represent the densities of each constituent. Gladstone–Dale equations for the polymorphs of SiO_2 and TiO_2 give the average n values as [3.14]

$$n(SiO_2) = 1+0.21\rho \quad \text{and} \quad n(TiO_2) = 1+0.40\rho\,. \tag{3.22}$$

3.2.4 Wemple–DiDominico Dispersion Relation

The *Wemple–DiDominico dispersion relation* is a semi-empirical relationship used to find the refractive indices of a variety of materials for photon energies below the interband absorption edge, given by [3.15]

$$n^2 = 1+\frac{E_0E_d}{E_0^2-(h\nu)^2}\,, \tag{3.23}$$

where ν is the frequency, h is the Planck constant, E_0 is the single oscillator energy, E_d is the dispersion energy, which is a measure of the average strength of interband optical transitions; $E_d = \beta N_c Z_a N_e$ (eV), where N_c is the effective coordination number of the cation nearest-neighbor to the anion ($N_c = 6$ in NaCl, $N_c = 4$ in Ge), Z_a is the formal chemical valency of the anion ($Z_a = 1$ in NaCl; 2 in Te; 3 in GaP), N_e is the effective number of valence electrons per anion excluding the cores ($N_e = 8$ in NaCl, Ge; 10 in TlCl; 12 in Te; $9\frac{1}{3}$ in As_2Se_3), and β is a constant that depends on whether the interatomic bond is ionic (β_i) or covalent (β_c): $\beta_i = 0.26\pm0.04$ eV (this applies to halides such as NaCl and ThBr and most oxides, including Al_2O_3, for example), while $\beta_c = 0.37\pm0.05$ eV (applies to tetrahedrally bonded A^NB^{8-N} zinc blende- and diamond-type structures such as GaP, ZnS, for instance). (Note that wurtzite crystals have a β that is intermediate between β_i and β_c.) Also, empirically,

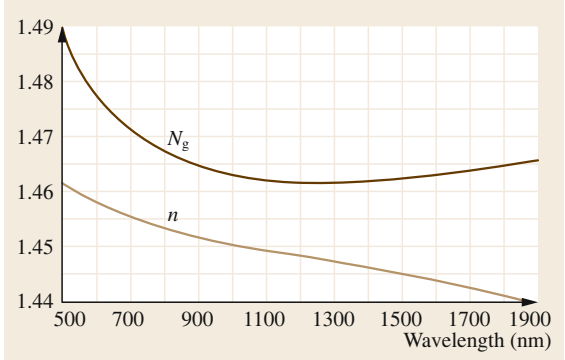

Fig. 3.3 Refractive index n and the group index N_g of pure SiO_2 (silica) glass as a function of wavelength

$E_0 = CE_g(D)$, where $E_g(D)$ is the lowest direct bandgap and C is a constant, typically ≈ 1.5. E_0 has been associated with the main peak in the $\varepsilon_r''(h\nu)$ versus $h\nu$ spectrum. The parameters required to calculate n from (3.23) are listed in Table 3.4 [3.15].

3.2.5 Group Index (N_g)

The group index represents the factor by which the group velocity of a group of waves in a dielectric medium is reduced with respect to propagation in free space, $N_g = c/v_g$, where v_g is the group velocity. The group index can be determined from the ordinary refractive index n via

$$N_g = n - \lambda \frac{dn}{d\lambda}, \tag{3.24}$$

where λ is the wavelength of light. The relation between N_g and n for SiO_2 is illustrated in Fig. 3.3.

3.3 Optical Absorption

The main optical properties of a semiconductor are typically its refractive index n and its extinction coefficient K or absorption coefficient α (or equivalently the real and imaginary parts of the relative permittivity), as well as their dispersion relations (their dependence on the electromagnetic radiation wavelength λ or photon energy $h\nu$) and the changes in the dispersion relations with temperature, pressure, alloying, impurities, and so on. A typical relationship between the absorption coefficient and the photon energy observed in a crystalline semiconductor is shown in Fig. 3.4, where various possible absorption processes are illustrated. The important features of the behavior of the α versus $h\nu$ can be summarized as follows:

1. Free-carrier absorption due to the presence of free electrons and holes, an effect that decreases with increasing photon energy
2. An impurity absorption band (usually narrow) due the various dopants
3. Reststrahlen or lattice absorption in which the radiation is absorbed by vibrations of the crystal ions
4. Exciton absorption peaks that are usually observed at low temperatures and are close the fundamental absorption edge; and
5. Band-to-band or fundamental absorption of photons, which excites an electron from the valence to the conduction band.

Type 5 absorption has a large absorption coefficient and occurs when the photon energy reaches the bandgap energy E_g. It is probably the most important absorption effect; its characteristics for $h\nu > E_g$ can be predicted using the results of Sect. 3.3.3. The values of E_g, and its temperature shift, dE_g/dT, are therefore important factors in semiconductor-based optoelectronic devices. In nearly all semiconductors E_g decreases with temperature, hence shifting the fundamental absorption to longer wavelengths. The refractive index n also changes with temperature. dn/dT depends on the wavelength, but for many semiconductors $(dn/dT)/n \approx 5 \times 10^{-5}\,K^{-1}$; for example, for GaAs, $(dn/dT)/n = 4 \times 10^{-4}\,K^{-1}$ at $\lambda = 2\,\mu m$. There is a good correlation between the refractive indices and the bandgaps of semiconductors in which, typically, n decreases as E_g increases; semiconductors with wider bandgaps have lower refractive indices. The refractive index n and the extinction coefficient K (or α) are related by the Kramers–Kronig relations. Thus, large increases in the absorption coefficient for $h\nu$ near and above the bandgap energy E_g also result in increases in the refractive index n versus $h\nu$ in this region. Optical (and some structural) properties of various semiconductors are listed in Table 3.5.

3.3.1 Lattice or Reststrahlen Absorption and Infrared Reflection

In the infrared wavelength region, ionic crystals reflect and absorb light strongly due to the resonance interaction of the electromagnetic (EM) wave field with the transverse optical (TO) phonons. The dipole oscillator

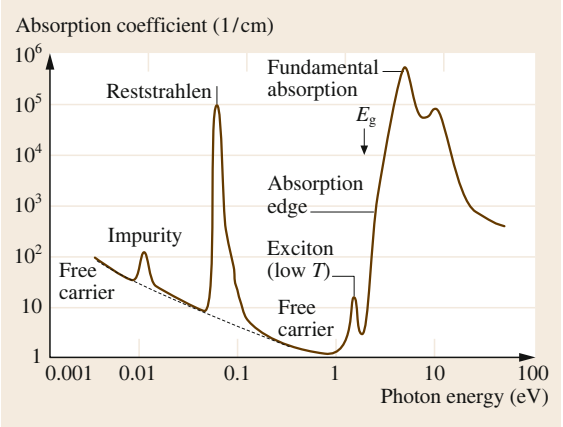

Fig. 3.4 Absorption coefficient plotted as a function of the photon energy in a typical semiconductor, illustrating various possible absorption processes

model based on ions driven by an EM wave results in

$$\varepsilon_r = \varepsilon_r' - i\varepsilon_r'' = \varepsilon_{r\infty} + \frac{\varepsilon_{r\infty} - \varepsilon_{r0}}{\left(\frac{\omega}{\omega_T}\right)^2 - 1 + i\frac{\gamma}{\omega_T}\left(\frac{\omega}{\omega_T}\right)}, \tag{3.25}$$

where ε_{r0} and $\varepsilon_{r\infty}$ are the relative permittivity at $\omega = 0$ (very low frequencies) and $\omega = \infty$ (very high frequencies) respectively, γ is the loss coefficient per unit reduced mass, representing the rate of energy transfer from the EM wave to optical phonons, and ω_0 is a resonance frequency that is related to the *spring* constant between the ions. By definition, the frequency ω_T is

$$\omega_T^2 = \omega_0^2\left(\frac{\varepsilon_{r\infty} + 2}{\varepsilon_{r0} + 2}\right). \tag{3.26}$$

The loss ε_r'' and the absorption are maxima when $\omega = \omega_T$, and the wave is attenuated by the transfer of energy to the transverse optical phonons, so the EM wave couples to the transverse optical phonons. At $\omega = \omega_L$, the wave couples to the longitudinal optical (LO) phonons. Figure 3.5 shows the optical properties of AlSb [3.16] in terms of n, K and R versus wavelength. The peaks in the extinction coefficient K and reflectance R occur over roughly the same wavelength region, corresponding to the coupling of the EM wave to the transverse optical phonons. At wavelengths close to $\lambda_T = 2\pi/\omega_T$, n and K peak, and there is strong absorption of light (which corresponds to the EM wave resonating with the TO lattice vibrations), and then R rises sharply.

3.3.2 Free-Carrier Absorption (FCA)

An electromagnetic wave with sufficiently low frequency oscillations can interact with free carriers in

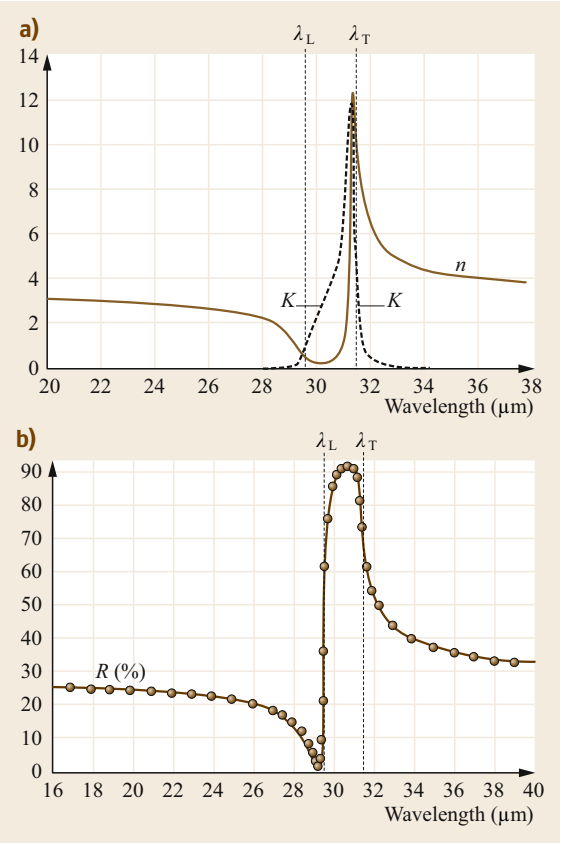

Fig. 3.5a,b Infrared refractive index n, extinction coefficient K **(a)**, and reflectance R **(b)** of AlSb. Note that the wavelength axes are not identical, and the wavelengths λ_T and λ_L, corresponding to ω_T and ω_L respectively, are shown as *dashed vertical lines*. (After [3.16])

a material and thereby drift the carriers. This interaction results in an energy loss from the EM wave to the lattice vibrations through the carrier scattering processes. Based on the Drude model, the relative permittivity $\varepsilon_r(\omega)$ due to N free electrons per unit volume is given by

$$\varepsilon_r = \varepsilon_r' - i\varepsilon_r'' = 1 - \frac{\omega_p^2}{\omega^2 - i\omega/\tau} ,$$
$$\omega_p^2 = \frac{Ne^2}{\varepsilon_0 m_e} , \qquad (3.27)$$

where ω_p is a plasma frequency that depends on the electron concentration, while τ is the relaxation time of the scattering process (the mean scattering time). For metals where the electron concentration is very large, ω_p is of the order of $\approx 10^{16}$ rad/s, at ultraviolet (UV) frequencies, and for $\omega > \omega_p$, $\varepsilon_r \approx 1$, and the reflectance becomes very small. Metals lose their free-electron reflectance in the UV range, thus becoming UV-transparent. The reflectance does not fall to zero because there are other absorption processes such as interband electron excitations or excitations from core levels to energy bands. Plasma edge transparency, where the reflectance almost vanishes, can also be observed in doped semiconductors. For example, the reflectance of doped InSb has a plasma edge wavelength that decreases with increasing free-carrier concentration [3.17]. Equation (3.27) can be written in terms of the conductivity σ_0 at low frequencies (DC) as

$$\varepsilon_r = \varepsilon_r' - i\varepsilon_r'' = 1 - \frac{\tau\sigma_0}{\varepsilon_0[(\omega\tau)^2 + 1]} - i\frac{\sigma_0}{\varepsilon_0\omega[(\omega\tau)^2 + 1]} . \qquad (3.28)$$

In metals, σ_0 is high. At frequencies where $\omega < 1/\tau$, the imaginary part $\varepsilon_r'' = \sigma_0/(\varepsilon_0\omega)$ is normally much more than 1, and $n = K \approx \sqrt{\varepsilon_r''/2}$, so that the free-carrier attenuation coefficient α is then given by

$$\alpha = 2k_0K \approx \frac{2\omega}{c}\left(\frac{\varepsilon_r''}{2}\right)^{1/2} \approx (2\sigma_0\mu_0)^{1/2}\,\omega^{1/2} . \qquad (3.29)$$

Furthermore, the reflectance can also be calculated using $n = K \approx \sqrt{\varepsilon_r''/2}$, which leads to the well-known *Hagen–Rubens* relationship [3.18]

$$R \approx 1 - 2\left(\frac{2\omega\varepsilon_0}{\sigma_0}\right)^{1/2} . \qquad (3.30)$$

In semiconductors, one typically encounters $\sigma_0/(\varepsilon_0\omega) < 1$, since the free-electron concentration is small, and we can treat n as constant due to various other polarization mechanisms such as electronic polarization. Since $2nK = \varepsilon_r''$, the absorption coefficient becomes [3.19]

$$\alpha = 2k_0K \approx \frac{2\omega}{c}\left(\frac{\varepsilon_r''}{2n}\right) = \frac{\sigma_0}{nc\varepsilon_0[(\omega\tau)^2 + 1]} . \qquad (3.31)$$

At low frequencies where $\omega < 1/\tau$, we have $\alpha(\lambda) \propto \sigma_0/n(\lambda)$ so that α should be controlled by the DC conductivity, and hence the amount of doping. Furthermore, α will exhibit the frequency dependence of the refractive index n ($\alpha(\lambda) \propto 1/n(\lambda)$), in which n will typically be determined by the electronic polarization of the crystal.

At high frequencies where $\omega > 1/\tau$,

$$\alpha \propto \frac{\sigma_0}{\omega^2} \propto N\lambda^2 , \qquad (3.32)$$

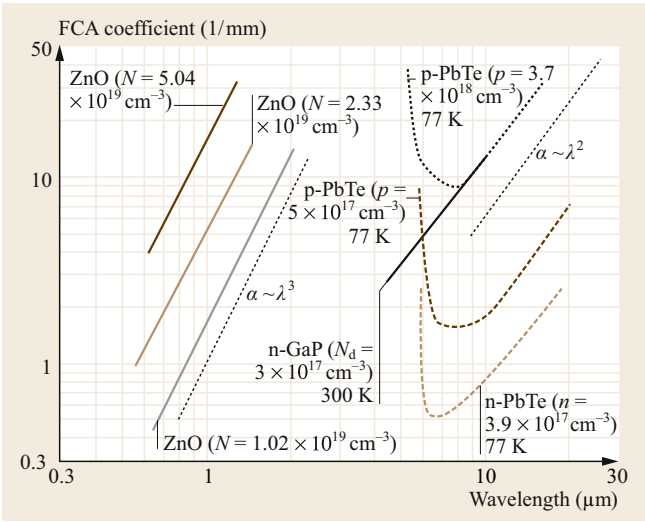

Fig. 3.6 Free-carrier absorption in n-GaP at 300 K [3.20], p- and n-type PbTe [3.21] at 77 K and In doped n-type ZnO at room temperature. (After [3.22])

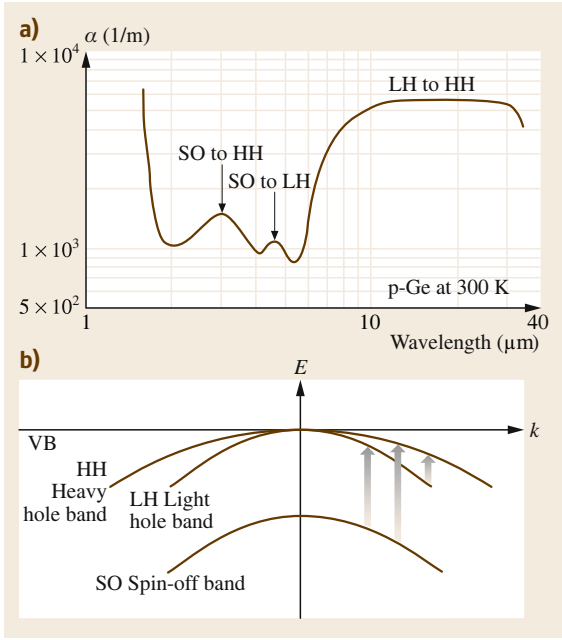

Fig. 3.7 **(a)** Free-carrier absorption due to holes in p-Ge [3.27]. **(b)** The valence band of Ge has three bands; heavy hole, light hole and spin-off bands

where α is proportional to N, the free-carrier concentration, and λ^2. Experimental observations on FCA in doped semiconductors are in general agreement with these predictions. For example, α increases with N, whether N is increased by doping or by carrier injection [3.23]. However, not all semiconductors show the simple $\alpha \propto \lambda^2$ behavior. A proper account of the field-driven electron motion and scattering must consider the fact that τ will depend on the electron energy. The correct approach is to use the Boltzmann transport equation [3.24] with the appropriate scattering mechanism. FCA can be calculated using a quantum-mechanical approach based on second-order time-dependent perturbation theory with Fermi–Dirac statistics [3.25].

Absorption due to free carriers is commonly written as $\alpha \propto \lambda^p$, where the index p depends primarily on the scattering mechanism, although it is also influenced by the compensation doping ratio, if the semiconductor has been doped by compensation, and the free-carrier concentration. In the case of lattice scattering, one must consider scattering from acoustic and optical phonons. For acoustic phonon scattering $p \approx 1.5$, for optical phonon scattering $p \approx 2.5$, and for impurity scattering $p \approx 3.5$. The observed free-carrier absorption coefficient will then have all three contributions

$$\alpha = A_{\text{acoustic}}\lambda^{1.5} + A_{\text{optical}}\lambda^{2.5} + A_{\text{impurity}}\lambda^{3.5} \,. \quad (3.33)$$

Inasmuch as α for FCA depends on the free-carrier concentration N, it is possible to evaluate the latter from the experimentally measured α, given its wavelength dependence and p as discussed by [3.26]. The free-carrier absorption coefficients α (mm^{-1}) for GaP, n-type PbTe and n-type ZnO are shown in Fig. 3.6.

Free-carrier absorption in p-type Ge demonstrates how the FCA coefficient α can be dramatically different than what is expected from (3.33). Figure 3.7a shows the wavelength dependence of the absorption coefficient for p-Ge over the wavelength range from about 2 to 30 μm [3.27]. The observed absorption is due to excitations of electrons from the spin-off band to the heavy hole band, from the spin-off band to the light hole band, and from the light hole band to the heavy hole band, as marked in the Fig. 3.7b.

3.3.3 Band-to-Band or Fundamental Absorption

Crystalline Solids

Band-to-band absorption or fundamental absorption of radiation is due to the photoexcitation of an electron from the valence band to the conduction band. There are two types of band-to-band absorptions, corresponding to direct and indirect transitions.

A direct transition is a photoexcitation process in which no phonons are involved. The photon momentum is negligible compared with the electron momentum, so that when the photon is absorbed, exciting an electron from the valence band (VB) to the conduction band (CB); the electron's k-vector does not change. A direct

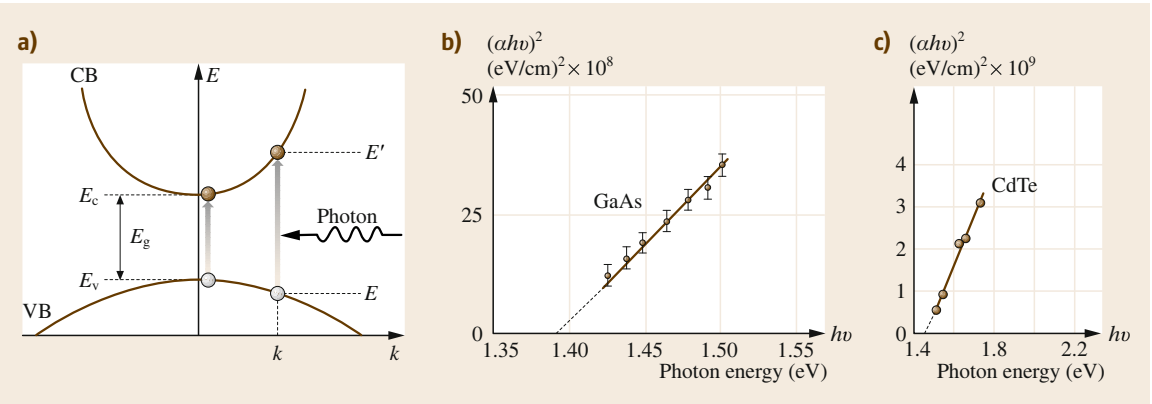

Fig. 3.8 **(a)** A direct transition from the valence band (VB) to the conduction band (CB) through the absorption of a photon. Absorption behavior represented as $(\alpha h\nu)^2$ versus photon energy $h\nu$ near the band edge for single crystals of **(b)** p-type GaAs, from [3.28] and **(c)** CdTe. (After [3.29])

transition on an $E-k$ diagram is a vertical transition from an initial energy E and wavevector k in the VB to a final energy E' and a wavevector k' in the CB where $k' = k$, as shown in Fig. 3.8a. The energy $(E' - E_c)$ is the kinetic energy $(\hbar k)^2/(2m_e^*)$ of the electron with an effective mass m_e^*, and $(E_v - E)$ is the kinetic energy $(\hbar k)^2/(2m_h^*)$ of the hole left behind in the VB. The ratio of the kinetic energies of the photogenerated electron and hole depends inversely on the ratio of their effective masses.

The absorption coefficient α is derived from the quantum-mechanical probability of transition from E to E', the occupied density of states at E in the VB from which electrons are excited, and the unoccupied density of states in the CB at $E + h\nu$. Thus, α depends on the joint density of states at E and $E + h\nu$, and we have to suitably integrate this joint density of states. Near the band edges, the density of states can be approximated by a parabolic band, and α rises with the photon energy following

$$\alpha h\nu = A(h\nu - E_g)^{1/2} , \tag{3.34}$$

where the constant $A \approx [e^2/(nch^2 m_e^*)](2\mu^*)^{3/2}$ in which μ^* is a reduced electron and hole effective mass, n is the refractive index, and E_g is the direct bandgap, with minimum $E_c - E_v$ at the same k value (see [3.3] for the derivation). Experiments indeed show this type of behavior for photon energies above E_g and close to E_g, as shown in Fig. 3.8b for a GaAs crystal [3.28] and in Fig. 3.8c for a CdTe crystal [3.29]. The extrapolation to zero photon energy gives the direct bandgap E_g, which is about 1.40 eV for GaAs and 1.46–1.49 eV for CdTe. For photon energies very close to the bandgap energy, the absorption is usually due to exciton absorption, especially at low temperatures, and is discussed later in this chapter.

In indirect bandgap semiconductors, such as Si and Ge, the photon absorption for photon energies near E_g requires the absorption and emission of phonons during the absorption process, as illustrated in Fig. 3.9a. The absorption onset corresponds to a photon energy of $(E_g - h\vartheta)$, which represents the absorption of a phonon with energy $h\vartheta$. For the latter, α is proportional to $[h\nu - (E_g - h\vartheta)]^2$. Once the photon energy reaches $(E_g + h\vartheta)$, then the photon absorption process can also occur by phonon emission, for which the absorption coefficient is larger than that for phonon absorption. The absorption coefficients for the phonon absorption and emission processes are given by [3.30]

$$\alpha_{\text{absorption}} = A[f_{BE}(h\vartheta)][h\nu - (E_g - h\vartheta)]^2 ; \quad h\nu > (E_g - h\vartheta) , \tag{3.35}$$

and

$$\alpha_{\text{emission}} = A[(1 - f_{BE}(h\vartheta)][h\nu - (E_g + h\vartheta)]^2 ; \quad h\nu > (E_g + h\vartheta) , \tag{3.36}$$

where A is a constant and $f_{BE}(h\vartheta)$ is the Bose–Einstein distribution function at the phonon energy $h\vartheta$, $f_{BE}(h\vartheta) = [\exp(h\vartheta/(k_B T)) - 1]^{-1}$, where k_B is the Boltzmann constant and T is the temperature. As we increase the photon energy in the range $(E_g - h\vartheta) < h\nu < (E_g + h\vartheta)$, the absorption is controlled by $\alpha_{\text{absorption}}$ and the plot of $\alpha^{1/2}$ versus $h\nu$ has an intercept of $(E_g - h\vartheta)$.

On the other hand, for $h\nu > (E_g + h\vartheta)$, the overall absorption coefficient is $\alpha_{\text{absorption}} + \alpha_{\text{emission}}$, but at slightly higher photon energies than $(E_g + h\vartheta)$, α_{emission} quickly dominates over $\alpha_{\text{absorption}}$ since $f_{BE}(h\vartheta) \gg 1 - f_{BE}(h\vartheta)$. Figure 3.9b shows the behavior of $\alpha^{1/2}$ versus

photon energy for Si at two temperatures for $h\nu$ near band edge absorption. At low temperatures, $f_{BE}(h\vartheta)$ is small and $\alpha_{absorption}$ decreases with decreasing temperature, as apparent from Fig. 3.9b. Equations (3.35) and (3.36) intersect the photon energy axis at $(E_g - h\vartheta)$ and $(E_g + h\vartheta)$, which can be used to obtain E_g.

An examination of the extinction coefficient K or ε_r'' versus photon energy for Si in Fig. 3.2 shows that absorption peaks at certain photon energies, $h\nu \approx 3.5$ and 4.3 eV. These peaks are due to the fact that the joint density of states function peaks at these energies. The absorption coefficient peaks whenever there is a direct transition in which the E versus $\boldsymbol{k}$ curve in the VB is parallel to the E versus $\boldsymbol{k}$ curve in the CB, as schematically illustrated in Fig. 3.9a, where a photon of energy $h\nu_{12}$ excites an electron from state 1 in the VB to state 2 in the CB in a direct transition, i. e., $\boldsymbol{k}_1 = \boldsymbol{k}_2$. Such transitions where E versus $\boldsymbol{k}$ curves are parallel at a photon energy $h\nu_{12}$ result in a peak in the absorption versus photon energy behavior, and can be represented by the condition that

$$(\nabla_{\boldsymbol{k}} E)_{CB} - (\nabla_{\boldsymbol{k}} E)_{VB} = 0\,. \tag{3.37}$$

The above condition is normally interpreted as the joint density of states reaching a peak value at certain points in the Brillouin zone called van Hove singularities. Identification of peaks in K versus $h\nu$ involves the examination of all E versus $\boldsymbol{k}$ curves of a given crystal that can participate in a direct transition. The silicon ε_r'' peaks at $h\nu \approx 3.5$ eV and 4.3 eV correspond to (3.37) being satisfied at points L, along $\langle 111\rangle$ in $\boldsymbol{k}$-space, and X along $\langle 100\rangle$ in $\boldsymbol{k}$-space, at the edges of the Brillouin zone.

In degenerate semiconductors, the Fermi level E_F is in a band; for example, in the CB for a degenerate n-type semiconductor. Electrons in the VB can only be excited to states above E_F in the CB rather than to the bottom of the CB. The absorption coefficient then depends on the free-carrier concentration since the latter determines E_F. Fundamental absorption is then said to depend on band filling, and there is an apparent shift in the absorption edge, called the *Burstein–Moss shift*. Furthermore, in degenerate indirect semiconductors, the indirect transition may involve a nonphonon scattering process, such as impurity or electron-electron scattering, which can change the electron's wavevector $\boldsymbol{k}$. Thus, in degenerate indirect bandgap semiconductors, absorption can occur without phonon assistance and the absorption coefficient becomes

$$\alpha \propto [h\nu - (E_g + \Delta E_F)]^2\,, \tag{3.38}$$

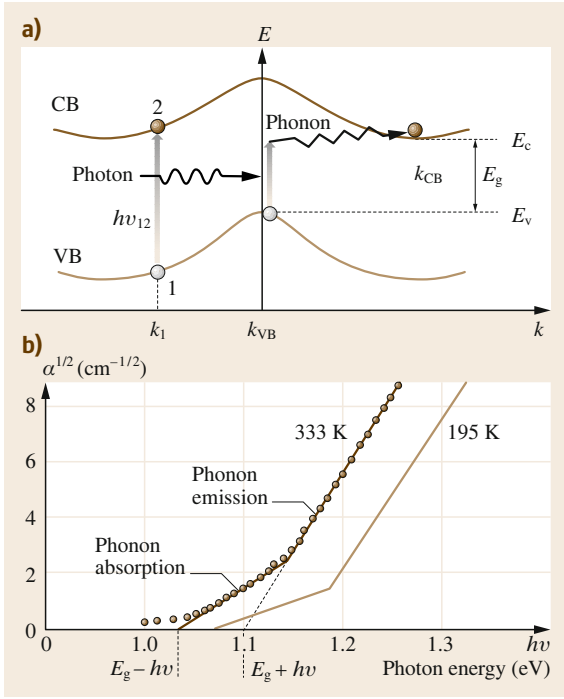

Fig. 3.9 **(a)** Indirect transitions across the bandgap involve phonons. Direct transitions in which dE/dk in the CB is parallel to dE/dk in the VB lead to peaks in the absorption coefficient. **(b)** Fundamental absorption in Si at two temperatures. The overall behavior is well described by (3.35) and (3.36)

where ΔE_F is the energy depth of E_F into the band measured from the band edge.

Heavy doping of degenerate semiconductors normally leads to a phenomenon called bandgap narrowing and bandtailing. Bandtailing means that the band edges at E_v and E_c are no longer well-defined cut-off energies, and there are electronic states above E_v and below E_c where the density of states falls sharply away with energy from the band edges. Consider a degenerate direct bandgap p-type semiconductor. One can excite electrons from states below E_F in the VB, where the band is nearly parabolic, to tail states below E_c, where the density of states decreases exponentially with energy into the bandgap, away from E_c. Such excitations lead to α depending exponentially on $h\nu$, a dependence that is called the *Urbach rule* [3.31, 32], given by

$$\alpha = \alpha_0 \exp\left(\frac{h\nu - E_0}{\Delta E}\right)\,, \tag{3.39}$$

where α_0 and E_0 are material-dependent constants, and ΔE, called the Urbach width, is also a material-dependent constant. The Urbach rule was originally

reported for alkali halides. It has been observed for many ionic crystals, degenerately doped crystalline semiconductors, and almost all amorphous semiconductors. While exponential bandtailing can explain the observed Urbach tail of the absorption coefficient versus photon energy, it is also possible to attribute the absorption tail behavior to strong internal fields arising, for example, from ionized dopants or defects.

Amorphous Solids

In a defect-free crystalline semiconductor, a well-defined energy gap exists between the valence and conduction bands. In contrast, in an amorphous semiconductor, the distributions of conduction band and valence band electronic states do not terminate abruptly at the band edges. Instead, some electronic states called the tail states encroach into the gap region [3.33]. In addition to tail states, there are also other localized states deep within the gap region [3.34]. These localized tail states in amorphous semiconductors are contributed by defects. The defects in amorphous semiconductors are considered to be all cases of departure from the normal nearest-neighbor coordination (or normal valence requirement). Examples of defects are: broken and dangling bonds (typical for amorphous silicon); over- and under-coordinated atoms (such as 'valence alternation pairs' in chalcogenide glasses); and voids, pores, cracks and other macroscopic defects. Mobility edges exist, which separate these localized states from their extended counterparts; tail and deep defect states are localized [3.35–37]. These localized tail and deep defect states are responsible for many of the unique properties exhibited by amorphous semiconductors.

Despite years of intensive investigation, the exact form of the distribution of electronic states associated with amorphous semiconductors remains a subject of some debate. While there are still some unresolved theoretical issues, there is general consensus that the tail states arise as a consequence of the disorder present within amorphous networks, and that the width of these tails reflects the amount of disorder present [3.38]. Experimental results (from, for example, [3.39, 40]) suggest exponential distributions for the valence and conduction band tail states in a-Si:H, although other possible functional forms [3.41] cannot be ruled out. *Singh* and *Shimakawa* [3.37] have derived separate effective masses of charge carriers in their extended and tail states. That means the density of states (DOS) of extended and tail states can be represented in two different parabolic forms. The relationship between the absorption coefficient and the distribution of electronic states for the case of a-Si:H may be found in [3.37, 42–44].

The existence of tail states in amorphous solids has a profound impact upon the band-to-band optical absorption. Unlike in a crystalline solid, the absorption of photons in an intrinsic amorphous solid can also occur for photon energies $\hbar\omega \leq E_0$ due to the presence of tail states in the forbidden gap. E_0 is the energy of the optical gap, which is usually close to the mobility gap – the energy difference between the conduction band and valence band mobility edges.

In a crystalline semiconductor, the energy and crystal momentum of an electron involved in an optical transition must be conserved. In an amorphous semiconductor, however, only the energy needs to be conserved [3.36, 37]. As a result, for optical transitions caused by photons of energy $\hbar\omega \geq E_0$ in amorphous semiconductors, the approach of a joint density of states is not applicable [3.37, 45]. One has to consider the product of the densities of both conduction and valence electronic states when calculating the absorption coefficient [3.37, 46]. Assuming that both the valence band and conduction band DOS functions have square-root dependencies on energy, one can derive the absorption coefficient α as [3.37]

$$(\alpha\hbar\omega)^{1/2} = B^{1/2}(\hbar\omega - E_0)\,, \tag{3.40}$$

where, if one assumes that the transition matrix element is constant,

$$B = \frac{1}{nc\varepsilon_0}\left(\frac{e}{m_e^*}\right)^2\left(\frac{L(m_e^* m_h^*)^{3/2}}{2^2\hbar^3}\right)\,, \tag{3.41}$$

where m_e^* and m_h^* are the effective masses of an electron and a hole respectively, L denotes the average interatomic separation in the sample, and n is the refractive index. Plotting $(\alpha\hbar\omega)^{1/2}$ as a function of $\hbar\omega$ yields a straight line that is usually referred to as Tauc's plot, from which one can determine the optical gap energy E_0 experimentally. Equation (3.40) is also known as Tauc's relation and B as *Tauc*'s constant [3.47]. Experimental data from many, but not all, amorphous semiconductors and chalcogenides fit to (3.40) very well. Deviations from Tauc's relation have been observed. For instance, some experimental data in a-Si:H fit much better to a cubic root relation given by *Mott* and *Davis* [3.36]

$$(\alpha\hbar\omega)^{1/3} = C(\hbar\omega - E_0) \tag{3.42}$$

and therefore the cubic root has been used to determine the optical gap E_0. Here C is another constant.

If one considers that the optical transition matrix element is independent of photon energy [3.37, 48], one finds that the cubic root dependence on photon energy can be obtained only when the valence band and conduction band DOS depend linearly on energy. Using such DOS functions, the cubic root dependence has

been explained by *Mott* and *Davis* [3.36]. Another way to obtain the cubic root dependence has been suggested in [3.49]. Using (3.40), *Sokolov* et al. [3.49] have modeled the cubic root dependence on photon energy by considering the fluctuations in the optical bandgap due to structural disorder. Although their approach gives a way of getting the cubic root dependence, Sokolov et al.'s model is hardly different from the linear density of states model suggested by *Mott* and *Davis* [3.36]. *Cody* [3.50] has shown an alternative approach using a photon energy-dependent transition matrix element. Thus, the absorption coefficient is obtained as [3.37]

$$(\alpha\hbar\omega) = B'(\hbar\omega)^2(\hbar\omega - E_0)^2 \,, \tag{3.43}$$

where

$$B' = \frac{e^2}{nc\varepsilon_0}\left(\frac{\left(m_e^* m_h^*\right)^{3/2}}{2\pi^2\hbar^7 \nu\rho_A}\right) Q_a^2 \,, \tag{3.44}$$

and Q_a is the average separation between the excited electron and hole pair in an amorphous semiconductor, ν denotes the number of valence electrons per atom and ρ_A represents the atomic density per unit volume.

Equation (3.43) suggests that $(\alpha\hbar\omega)$ depends on the photon energy in the form of a polynomial of order 4. Then, depending on which term of the polynomial may be more significant in which material, one can get square, cubic or fourth root dependences of $(\alpha\hbar\omega)$ on the photon energy. In this case, (3.43) may be expressed as

$$(\alpha\hbar\omega)^x \propto (\hbar\omega - E_0) \,, \tag{3.45}$$

where $x \leq 1/2$. Thus, in a way, any deviation from the square root or Tauc's plot may be attributed to the energy-dependent matrix element [3.37, 46]. Another possible explanation has been recently discussed by *Shimakawa* and coworkers on the basis of fractal theory [3.51].

Another problem is how to determine the constants B (3.41) and B' (3.44), which involve the effective masses of an electron and a hole. In other words, how do we determine the effective masses of charge carriers in amorphous solids? Recently, a simple approach [3.37, 46] has been developed to calculate the effective masses of charge carriers in amorphous solids. Different effective masses of charge carriers are obtained in the extended and tail states. The approach applies the concepts of tunneling and effective medium, and one obtains the effective mass of an electron in the conduction extended states, denoted by m_{ex}^*, and in the tail states, denoted by m_{et}^*, as

$$m_{ex}^* \approx \frac{E_L}{2(E_2 - E_c)a^{1/3}} m_e \,, \tag{3.46}$$

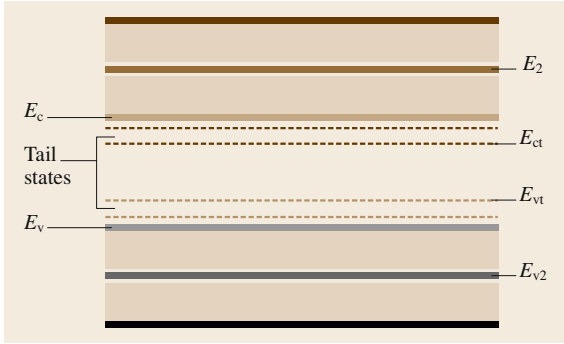

Fig. 3.10 Schematic illustration of the electronic energy states E_2, E_c, E_{ct}, E_{vt}, E_v and E_{v2} in amorphous semiconductors. The *shaded region* represents the extended states. Energies E_2 and E_{v2} correspond to the centers of the conduction and valence extended states and E_{ct} and E_{vt} represent the ends of the conduction and valence tail states respectively

and

$$m_{et}^* \approx \frac{E_L}{(E_c - E_{ct})b^{1/3}} m_e \,, \tag{3.47}$$

where

$$E_L = \frac{\hbar^2}{m_e L^2} \,. \tag{3.48}$$

Here $a = N_1/N < 1$, N_1 is the number of atoms contributing to the extended states, $b = N_2/N < 1$, N_2 is the number of atoms contributing to the tail states such that $a + b = 1$ $(N = N_1 + N_2)$, and m_e is the free-electron mass. The energy E_2 in (3.46) corresponds to the energy of the middle of the extended conduction states, at which the imaginary part of the dielectric constant becomes maximum (Fig. 3.10; see also 3.2).

Likewise, the effective masses of the hole m_{hx}^* and m_{ht}^* in the valence extended and tail states are obtained, respectively, as

$$m_{hx}^* \approx \frac{E_L}{2(E_v - E_{v2})a^{1/3}} m_e \,, \tag{3.49}$$

and

$$m_{ht}^* \approx \frac{E_L}{(E_{vt} - E_v)b^{1/3}} m_e \,, \tag{3.50}$$

where E_{v2} and E_{vt} are energies corresponding to the half-width of the valence extended states and the end of the valence tail states respectively; see Fig. 3.10.

Using (3.46) and (3.47) and the values of the parameters involved, different effective masses of an electron

Table 3.6 Effective mass of electrons in the extended and tail states of a-Si:H and a-Ge:H calculated using (3.46) and (3.47) for $a = 0.99$, $b = 0.01$ and $E_{ct} = E_{vt} = E_c/2$. E_L is calculated from (3.48). All energies are given in eV. Note that since the absorption coefficient is measured in cm^{-1}, the value used for the speed of light is in cm/s ([a] [3.52]; [b] [3.53]; [c] [3.33]; [d] [3.54])

	L (nm)	E_2	E_c	E_L	$E_c - E_{ct}$	m^*_{ex}	m^*_{et}
a-Si:H	0.235[a]	3.6[b]	1.80[c]	1.23	0.9	0.34 m_e	6.3 m_e
a-Ge:H	0.245[a]	3.6	1.05[d]	1.14	0.53	0.22 m_e	10.0 m_e

are obtained in the extended and tail states. Taking, for example, the density of weak bonds contributing to the tail states as 1 at.%, so $b = 0.01$ and $a = 0.99$, the effective masses and energies E_L calculated for hydrogenated amorphous silicon (a-Si:H) and germanium (a-Ge:H) are given in Table 3.6.

According to (3.46), (3.47), (3.49) and (3.50), for sp^3 hybrid amorphous semiconductors such as a-Si:H and a-Ge:H, effective masses of the electron and hole are expected to be the same. In these semiconductors, since the conduction and valence bands are two equal halves of the same electronic band, their widths are the same and that gives equal effective masses for the electron and the hole [3.37, 55]. This is one of the reasons for using $E_{ct} = E_{vt} = E_c/2$, which gives equal effective masses for electrons and holes in the tail states as well. This is different from crystalline solids where m^*_e and m^*_h are usually not the same. This difference between amorphous and crystalline solids is similar to, for example, having direct and indirect crystalline semiconductors but only direct amorphous semiconductors.

Using the effective masses from Table 3.6 and (3.41), B can be calculated for a-Si:H and a-Ge:H. The values thus obtained with the refractive index $n = 4$ for a-Si:H and a-Ge:H are $B = 6.0 \times 10^6\,cm^{-1}\,eV^{-1}$ for a-Si:H and $B = 4.1 \times 10^6\,cm^{-1}\,eV^{-1}$ for a-Ge:H, which are an order of magnitude higher than those estimated from experiments [3.36]. However, considering the quantities involved in B (3.41), this can be regarded as a reasonable agreement.

In a recent paper, *Malik* and *O'Leary* [3.56] studied the distributions of conduction and valence band electronic states associated with a-Si:H. They noted that the effective masses associated with a-Si:H are material parameters that are yet to be experimentally determined. In order to remedy this deficiency, they fitted square-root DOS functions to experimental DOS data and found that $m^*_h = 2.34 m_e$ and $m^*_e = 2.78 m_e$.

The value of the constant B' in (3.44) can also be calculated theoretically, provided that Q_a is known. Using the atomic density of crystalline silicon and four valence electrons per atom, *Cody* [3.50] estimated $Q_a^2 = 0.9\,Å^2$, which gives $Q_a \approx 0.095\,nm$, less than half the interatomic separation of 0.235 nm in a-Si:H, but of the same order of magnitude. Using $\nu = 4$, $\rho_A = 5 \times 10^{28}\,m^{-3}$, $Q_a^2 = 0.9\,Å^2$, and extended state effective masses, we get $B' = 4.6 \times 10^3\,cm^{-1}\,eV^{-3}$ for a-Si:H and $1.3 \times 10^3\,cm^{-1}\,eV^{-3}$ for a-Ge:H. Cody estimated an optical gap, $E_0 = 1.64\,eV$, for a-Si:H, which, using (3.43), gives $\alpha = 1.2 \times 10^3\,cm^{-1}$ at a photon energy of $\hbar\omega = 2\,eV$. This agrees reasonably well with the $\alpha = 6.0 \times 10^2\,cm^{-1}$ used by Cody. If we use interatomic spacing in place of Q_a in (3.44), we get $B' = 2.8 \times 10^4\,cm^{-1}\,eV^{-3}$, and then the corresponding absorption coefficient becomes $3.3 \times 10^3\,cm^{-1}$. This suggests that, in order to get an estimate, one may use the interatomic spacing in place of Q_a if the latter is unknown. Thus, both B and B' can be determined theoretically, a task not possible before due to a lack of knowledge of the effective masses in amorphous semiconductors.

The absorption of photons of energy less than the bandgap energy $\hbar\omega < E_0$ in amorphous solids involves the localized tail states and hence follows neither (3.40) nor (3.42). Instead, the absorption coefficient depends on the photon energy exponentially, as given in (3.39), giving rise to Urbach's tail. *Abe* and *Toyozawa* [3.57] have calculated the interband absorption spectra in crystalline solids, introducing the Gaussian site diagonal disorder and applying the coherent potential approximation. They have shown that Urbach's tail occurs due to static disorder (structural disorder). However, the current stage of understanding is that Urbach's tail in amorphous solids occurs due to both thermal effects and static disorder [3.50]. More recent issues in this area have been addressed by *Orapunt* and *O'Leary* [3.48].

Keeping the above discussion in mind, the optical absorption in amorphous semiconductors near the absorption edge is usually characterized by three types of optical transitions corresponding to transitions between tail and tail states, tail and extended states, and extended and extended states. The first two types correspond to $\hbar\omega \leq E_0$, and the third one corresponds to $\hbar\omega \geq E_0$. Thus, the plot of absorption coefficient versus photon energy (α versus $\hbar\omega$) has three different regions, A, B and C respectively, that correspond to these three characteristic optical transitions shown in Fig. 3.11.

In the small absorption coefficient range A (also called the weak absorption tail (WAT), where $\alpha < 10^{-1}\,cm^{-1}$, the absorption is controlled by optical transitions from tail-to-tail states. As stated above, the

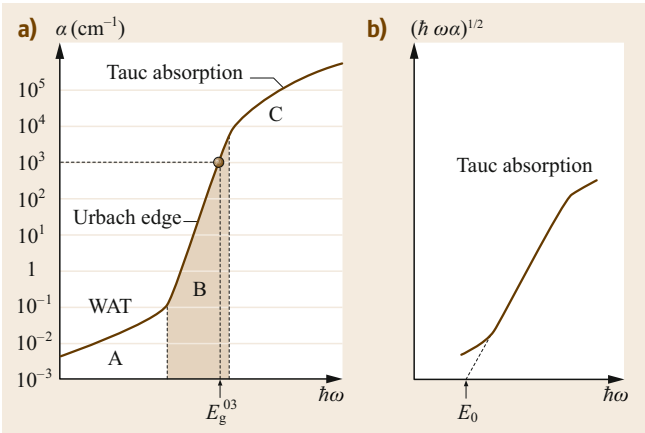

Fig. 3.11a,b Typical spectral dependence of the optical absorption coefficient in amorphous semiconductors. **(a)** In the A and B regions, the absorption is controlled by optical transitions between tail and tail states and tail and extended states respectively, and in the C region it is dominated by transitions from extended to extended states. In domain B, the absorption coefficient follows the Urbach rule (3.39). In region C, the absorption coefficient follows Tauc's relation (3.40) in a-Si:H, as shown in **(b)**

localized tail states in amorphous semiconductors are contributed to by defects. To some extent, the absolute value of absorption in region A may be used to estimate the density of defects in the material. In region B, where typically $10^{-1} < \alpha < 10^{4}\,\mathrm{cm}^{-1}$, the absorption is related to transitions from the localized tail states above the valence band edge to extended states in the conduction band and/or from extended states in the valence band to localized tail states below the conduction band. The spectral dependence of α usually follows the so-called Urbach rule, given in (3.39). For many amorphous semiconductors, ΔE has been related to the width of the valence (or conduction) band tail states, and may be used to compare the *widths* of such localized tail states in different materials; ΔE is typically 0.05–0.1 eV. In region C, the absorption is controlled by transitions from extended to extended states. For many amorphous semiconductors, the α versus $\hbar\omega$ behavior follows the Tauc relation given in (3.40). The optical bandgap, E_0, determined for a given material from the α versus $\hbar\omega$ relations obtained in (3.40), (3.42) and (3.43), can vary as shown in Table 3.7 for a-Si:H alloys.

3.3.4 Exciton Absorption

Excitons in Crystalline Semiconductors

Optical absorption in crystalline semiconductors and insulators can create an exciton, which is an electron and hole pair excited by a photon and bound together through their attractive Coulomb interaction. This means that the absorbed optical energy remains held within the solid for the lifetime of the exciton. There are two types of excitons that can be formed in nonmetallic solids: Wannier or Wannier–Mott excitons and Frenkel excitons. The concept of Wannier–Mott excitons is valid for inorganic semiconductors such as Si, Ge and GaAs, because in these materials the large overlap of interatomic electronic wavefunctions enables the electrons and holes to be far apart but bound in an excitonic state. For this reason, these excitons are also called large-radii orbital excitons. Excitons formed in organic crystals are called Frenkel excitons. In organic semiconductors/insulators or molecular crystals, the intermolecular separation is large and hence the overlap of intermolecular electronic wavefunctions is very small and electrons remain tightly bound to individual molecules. Therefore, the electronic energy bands are very narrow and closely related to individual molecular electronic energy levels. In these solids, the absorption of photons occurs close to the individual molecular electronic states and excitons are also formed within the molecular energy levels [3.59]. Such excitons are therefore also called molecular excitons. For a more detailed look at the theory of Wannier and Frenkel excitons, readers may like to refer to *Singh* [3.59].

In Wannier–Mott excitons, the Coulomb interaction between the hole and electron can be viewed as an effective hydrogen atom with, for example, the hole establishing the coordinate reference frame about which the reduced mass electron moves. If the effective masses of the isolated electron and hole are m_e^* and m_h^* respectively, their reduced mass μ_x is given by

$$\mu_x^{-1} = \left(m_e^*\right)^{-1} + \left(m_h^*\right)^{-1} . \tag{3.51}$$

Note that in the case of so-called hydrogenic impurities in semiconductors (both shallow donor and acceptor impurities), the reduced mass of the nucleus takes the place of one of the terms in (3.51) and hence the re-

Table 3.7 Optical bandgaps of a-$Si_{1-x}C_x$:H films obtained from Tauc's (3.40), Sokolov et al.'s (3.42) and Cody's (3.43) relations. (After [3.58])

duced mass is given to good approximation by the effective mass of the appropriate carrier. When the exciton is the carrier, the effective masses are comparable and hence the reduced mass is markedly lower; accordingly, the exciton binding energy is markedly lower than that for hydrogenic impurities. The energy of a Wannier–Mott exciton is given by (e.g., [3.59])

$$E_x = E_g + \frac{\hbar^2 K^2}{2M} - E_n \,, \tag{3.52}$$

where E_g is the bandgap energy, $\hbar K$ is the linear momentum, M $(= m_e^* + m_h^*)$ is the effective mass associated with the center of mass of an exciton, and E_n is the exciton binding energy given by

$$E_n = \frac{\mu_x e^4 \kappa^2}{2\hbar^2 \varepsilon^2} \frac{1}{n^2} = \frac{\mathrm{Ry}^x}{n^2} \,, \tag{3.53}$$

where e is the electronic charge, $\kappa = 1/(4\pi\varepsilon_0)$, ε is the static dielectric constant of the solid, and n is the principal quantum number associated with the internal excitonic states $n = 1(s), 2(p), \ldots$ (Fig. 3.12). According to (3.53), the excitonic states are formed within the bandgap below the conduction band edge. However, as the exciton binding energy is very small (a few meV in bulk Si and Ge crystals), exciton absorption peaks can only be observed at very low temperatures. Ry^x is the so-called effective Rydberg of the exciton given by $\mathrm{Ry}(\mu_x/m_e)/\varepsilon^2$, where $\mathrm{Ry} = 13.6\,\mathrm{eV}$. For bulk GaAs, the exciton binding energy ($n = 1$) corresponds to about 5 meV. Extrapolating from the hydrogen atom model, the extension of the excitonic wavefunction can be found from an effective Bohr radius a_B^* given in terms of the Bohr radius as $a_B = h^2/(\pi e^2)$; that is, $a_B^* = a_B(\varepsilon/\mu_x)$. For GaAs this corresponds to about 12 nm or about 21 lattice constants – in other words the spherical volume of the exciton radius contains $\approx (a_B^*/a_0)^3$ or ≈ 9000 unit cells, where a_0 is the lattice constant of GaAs. As $\mathrm{Ry}^* \ll E_g$ and $a_B^* \gg a_0$, it is clear from this example that the excitons in GaAs are large-radii orbital excitons, as stated above. It should be noted that the binding energies of excitons in semiconductors tend to be a strong function of the bandgap. The dependences of Ry^x (exciton binding energy) and a_B^*/a_0 on the semiconductor bandgap are shown in Fig. 3.13a and b respectively. For excitons with large binding energies and correspondingly small radii (approaching the size of a lattice parameter), the excitons become localized on a lattice site, as observed in most organic semiconductors. As stated above, such excitons are commonly referred to as Frenkel excitons or molecular excitons. Unlike Wannier-based excitons, which are typically dissociated at room temperature, these excitations are stable at room temperature. For the binding energies of Frenkel excitons, one can refer to *Singh* for example [3.59].

Excitons can recombine radiatively, emitting a series of hydrogen-like spectral lines, as described by (3.52). In bulk (3-D) semiconductors such as GaAs, ex-

citon lines can only be observed at low temperatures: they are easily dissociated by thermal fluctuations. On the other hand, in quantum wells and other structures of reduced dimensionality, the spatial confinement of both the electron and hole wavefunctions in the same layer ensures strong excitonic transitions of a few meV below the bandgap, even at room temperature. Excitonic absorption is well located spectrally and very sensitive to optical saturation. For this reason, it plays an important role in nonlinear semiconductor devices (nonlinear Fabry–Perot resonators, nonlinear mirrors, saturable absorbers, and so on). If the valence hole is a heavy hole, the exciton is called a heavy exciton; conversely, if the valence hole is light, the exciton is a light exciton. For practical purposes, the excitonic contribution to the overall susceptibility around the resonance frequency ν_{ex} can be written as

$$\chi_{exc} = -A_0 \frac{(\nu - \nu_{ex}) + i\Gamma_{ex}}{(\nu - \nu_{ex})^2 + \Gamma_{ex}^2(1+S)} , \tag{3.54}$$

where Γ_{ex} is the linewidth and $S = I/I_S$ the saturation parameter of the transition. For instance, in GaAs MQW, the saturation intensity I_S is as low as $1\,kW/cm^2$, and Γ_{ex} ($\approx 3.55\,meV$ at room temperature) varies with the temperature according to

$$\Gamma_{ex} = \Gamma_0 + \frac{\Gamma_1}{\exp(\hbar\omega_{LO}/kT) - 1} , \tag{3.55}$$

where $\hbar\Gamma_0$ is the inhomogeneous broadening ($\approx 2\,meV$), $\hbar\Gamma_1$ is the homogeneous broadening ($\approx 5\,meV$), and $\hbar\omega_{LO}$ is the longitudinal optical phonon energy ($\approx 36\,meV$). At high carrier concentrations (provided either by electrical pumping or by optical injection), the screening of the Coulomb attractive potential by free electrons and holes provides an efficient mechanism for saturating the excitonic line.

The above discussion refers to so-called free excitons formed between conduction-band electrons and valence-band holes. According to (3.52), such an excitation is able to move throughout a material with a given center-of-mass kinetic energy (second term on the right-hand side). It should be noted, however, that free electrons and holes move with a velocity $\hbar(dE/dk)$ where the derivative is taken for the appropriate band edge. To move through a crystal, both the electron and the hole must have identical translational velocities, restricting the regions in k-space where these excitations can occur to those with $(dE/dk)_{electron} = (dE/dk)_{hole}$, commonly referred to as critical points.

A number of more complex pairings of carriers can also occur, which may also include fixed charges or ions. For example, for the case of three charged entities with one being an ionized donor impurity (D+), the following possibilities can occur: (D+)(+)(−), (D+)(−)(−) and (+)(+)(−) as excitonic ions, and (+)(+)(−)(−) and (D+)(+)(−)(−) as biexcitons or even bigger excitonic molecules [3.60]. Complexity abounds in these systems, as each electronic level possesses a fine structure corresponding to allowed rotational and vibrational levels. Moreover, the effective mass is often anisotropic. Note that when the exciton or exciton complex is bound to a fixed charge, such as an ionized donor or acceptor center in the material, the exciton or exciton complex is referred to as a bound exciton. Indeed, bound excitons may also involve neutral fixed impurities. It is usual to relate the exciton in these cases to the center binding them; thus, if an exciton is bound to a donor impurity, it is usually termed a donor-bound exciton.

Excitons in Amorphous Semiconductors

The concept of excitons is traditionally valid only for crystalline solids. However, several observations in the photoluminescence spectra of amorphous semiconductors have revealed the occurrence of photoluminescence associated with singlet and triplet excitons [3.37]. Applying the effective mass approach, a theory for the Wannier–Mott excitons in amorphous semiconductors has recently been developed in real coordinate space [3.37, 46, 55, 61]. The energy of an exciton thus derived is obtained as

$$W_x = E_0 + \frac{P^2}{2M} - E_n(S) , \tag{3.56}$$

where P is the linear momentum associated with the exciton's center of motion and $E_n(S)$ is the binding energy of the exciton, given by

$$E_n(S) = \frac{\mu_x e^4 \kappa^2}{2\hbar^2 \varepsilon'(S)^2 n^2} , \tag{3.57}$$

where

$$\varepsilon'(S) = \varepsilon \left[1 - \frac{(1-S)}{A}\right]^{-1} , \tag{3.58}$$

where S is the spin (S being $= 0$ for singlet and $= 1$ for triplet) of an exciton and A is a material-dependent constant representing the ratio of the magnitude of the Coulomb and exchange interactions between the electron and the hole of an exciton. Equation (3.57) is analogous to (3.53) obtained for excitons in crystalline solids for $S = 1$. This is because (3.53) is derived within the large-radii orbital approximation, which neglects the exchange interaction and hence is valid only for triplet excitons [3.59, 62]. As amorphous solids lack

long-range order, the exciton binding energy is found to be larger in amorphous solids than in their crystalline counterparts; for example, the binding energy is higher in hydrogenated amorphous silicon (a-Si:H) than in crystalline silicon (c-Si). This is the reason that it is possible to observe both singlet and triplet excitons in a-Si:H [3.63] but not in c-Si.

Excitonic Absorption

Since exciton states lie below the edge of the conduction band in a crystalline solid, absorption to excitonic states is observed below this edge. According to (3.53), the difference in energy in the bandgap and the excitonic absorption gives the binding energy. As the exciton-photon interaction operator and excited electron and hole pair and photon interaction operator depend only on their relative motion, then these interactions take the same form for band-to-band and excitonic absorption. Therefore, to calculate the excitonic absorption coefficient, one can use the same form of interaction as that used for band-to-band absorption, but one must use the joint density of states. Using the joint density of states, the absorption coefficient associated with the excitonic states in crystalline semiconductors is obtained as [3.37]

$$\alpha\hbar\omega = A_x(\hbar\omega - E_x)^{1/2} \tag{3.59}$$

with the constant

$$A_x = \frac{4\sqrt{2}\,e^2|p_{xv}|^2}{nc\sqrt{\mu_x}\,\hbar^2}\ ,$$

where p_{xv} is the transition matrix element between the valence and excitonic bands. Equation (3.59) is similar to that seen for direct band-to-band transitions, discussed above (3.60), and is only valid for the photon energies $\hbar\omega \geq E_x$. There is no absorption below the excitonic ground state in pure crystalline solids. Absorption of photons to excitonic energy levels is possible through either the excitation of electrons to higher energy levels in the conduction band and then nonradiative relaxation to the excitonic energy level, or through the excitation of an electron directly to the exciton energy level. Excitonic absorption occurs in both direct and indirect semiconductors.

In amorphous semiconductors, the excitonic absorption and photoluminescence can be quite complicated. According to (3.56), the excitonic energy level is below the optical bandgap by an energy equal to the binding energy given in (3.57). However, there are four transition possibilities:

1. Extended valence to extended conduction states
2. Valence to extended conduction states
3. Valence extended to conduction tail states and
4. Valence tail to conduction tail states.

These possibilities will have different optical gap energies, E_0, and different binding energies. Transition 1 will give rise to absorption in the free exciton states, transitions 2 and 3 will give absorption in the bound exciton states, because one of the charge carriers is localized in the tail states, and absorption through transition 4 will create localized excitons, which are also called geminate pairs. This can be visualized as follows: if an electron-hole pair is excited by a high-energy photon through transition 1 and forms an exciton, initially its excitonic energy level and the corresponding Bohr radius will have a reduced mass corresponding to both charge carriers being in extended states. As such an exciton relaxes downward nonradiatively, its binding energy and excitonic Bohr radius will change because its effective mass changes in the tail states. When both charge carriers reach the tail states (transition 4), their excitonic Bohr radius will be maintained although they are localized.

The excitonic absorption coefficient in amorphous semiconductors can be calculated using the same approach as presented in Sect. 3.3.3, and similar expressions to (3.40) and (3.43) are obtained. This is because the concept of the joint density of states is not applicable in amorphous solids. Therefore, by replacing the effective masses of the charge carriers by the excitonic reduced mass and the distance between the excited electron and hole by the excitonic Bohr radius, one can use (3.40) and (3.43) to calculate the excitonic absorption coefficients for the four possible transitions above in amorphous semiconductors. However, such a detailed calculation of the excitonic transitions in amorphous semiconductors is yet to be performed.

3.3.5 Impurity Absorption

Impurity absorption can be observed as the absorption coefficient peaks lying below fundamental (band-to-band) and excitonic absorption. It is usually related to the presence of ionized impurities or, simply, ions. The peaks occur due to electronic transitions between ionic electronic states and the conduction/valence band or due to intra-ionic transitions (within d or f shells, between s and d shells, and so on). The first case leads to intense and broad lines, while the characteristics of the features arising from the latter case depend on whether or not these transitions are allowed by parity selection rules. For allowed transitions, the absorption peaks are quite intense and broad, while forbidden transitions produce weak and narrow peaks. General reviews of this topic may be found in *Blasse* and *Grabmaier* [3.64], *Henderson* and *Imbusch* [3.65] and *DiBartolo* [3.66].

In the following section, we concentrate primarily on the properties of rare earth ions, which are of great importance in modern optoelectronics.

Optical Absorption of Trivalent Rare Earth Ions: Judd–Ofelt Analysis

Rare earths (REs) is the common name used for the elements from Lanthanum (La) to Lutetium (Lu). They have atomic numbers of 57 to 71 and form a separate group in the periodic table. The most notable feature of these elements is an incompletely filled 4f shell. The electronic configurations of REs are listed in Table 3.8. The RE may be embedded in different host materials in the form of divalent or trivalent ions. As divalent ions, REs exhibit broad absorption-emission lines related to allowed 4f→5d transitions. In trivalent form, REs lose two 6 s electrons and one 4f or 5d electron. The Coulomb interaction of a 4f electron with a positively charged core means that the 4f level gets split into a complicated set of manifolds with energies, to a first approximation, that are virtually independent of the host matrix because the 4f level is well screened from external influences by the 5s and 5p shells [3.67]. Figure 3.14 shows an energy level diagram for the low-lying $4f^N$ states of the trivalent ions embedded in $LaCl_3$. To a second approximation, the exact construction and precise energies of the manifolds depend on the host material, via crystal field and via covalent interactions with the ligands surrounding the RE ion. A ligand is an atom (or molecule or radical or ion) with one or more unshared pairs of electrons that can attach to a central metallic ion (or atom) to form a coordination complex. Examples of ligands include ions (F^-, Cl^-, Br^-, I^-, S^{2-}, CN^-, NCS^-, OH^-, NH_2^-) and molecules (NH_3, H_2O, NO, CO) that donate a pair of electrons to a metal atom or ion. Some ligands that share electrons with metals form very stable complexes.

Optical transitions between 4f manifold levels are forbidden by a parity selection rule that states that the wavefunctions of the initial and final states of an atomic (ionic) transition must have different parities for them to be permitted. Parity is a property of any function (or quantum mechanical state) that describes the function after mirror reflection. Even functions (states) are symmetric (identical after reflection, for example a cosine function), while odd functions (states) are antisymmetric (for example a sine function). The parity selection rule may be partially removed for an ion (or atom) embedded in host material due to the action of the crystal field, which gives rise to *forbidden lines*. The crystal field is the electric field created by a host material at the position of the ion.

The parity selection rule is weakened by the admixture of 5d states with 4f states and by the disturbed RE ion symmetry due to the influence of the host, which increases with the covalency. Higher covalency implies stronger sharing of electrons between the RE ion and the ligands. This effect is known as the nephelauxetic effect. The resulting absorption-emission lines are characteristic of individual RE ions and quite narrow because they are related to forbidden inner shell 4f transitions.

Judd–Ofelt (JO) analysis allows the oscillator strength of an electric dipole (ED) transition between two states of a trivalent rare earth (RE) ion embedded in a particular host lattice to be calculated. The possible states of an RE ion are often referred to as $^{2S+1}L_J$, where $L = 0, 1, 2, 3, 4, 5, 6 \ldots$ determines the electron's total angular momentum, and is conventionally represented by the letters S, P, D, F, G, I. The term $(2S + 1)$ is called the spin multiplicity and represents the number of spin configurations, while J is the total angular momentum, which is the vector sum of the overall (total) angular momentum and the overall spin ($J = L + S$). The value $(2J + 1)$ is called the multiplicity and corresponds to the number of possible combinations of overall angular momentum and overall spin that yield the same J. Thus, the notation $^4I_{15/2}$ for the ground state of Er^{3+} corresponds to the term $(J, L, S) = (15/2, 6, 3/2)$, which has a multiplicity of $2J + 1 = 16$ and a spin multiplicity of $2S + 1 = 4$. If the wavefunctions $|\psi_i\rangle$ and $|\psi_f\rangle$ correspond to the initial ($^{2S+1}L_J$) and final ($^{2S'+1}L_{J'}$) states of an electric dipole transition of an RE ion, the line strength of this transition, according to JO theory, can be calculated

using

$$S_{\mathrm{ed}} = \left|\langle\psi_f\left|H_{\mathrm{ed}}\right|\psi_i\rangle\right|^2 = \sum_{k=2,4,6}\Omega_k\left|\left\langle f_\nu^N S'L'J'\left|U^{(k)}\right|f_\nu^N SLJ\right\rangle\right|^2 , \tag{3.60}$$

where H_{ed} is the ED interaction Hamiltonian, Ω_k are coefficients reflecting the influence of the host material, and $U^{(k)}$ are reduced tensor operator components, which are virtually independent of the host material, and their values are calculated using the so-called intermediate coupling approximation [3.70]. The theoretical values of S_{ed} calculated from this are compared with the values derived from experimental data using

$$S_{\mathrm{exp}} = \frac{3hcn}{8\pi^3 e^2\langle\lambda\rangle}\frac{2J+1}{\chi_{\mathrm{ed}}}\int_{\mathrm{band}}\frac{\alpha(\lambda)}{\rho}\mathrm{d}\lambda , \tag{3.61}$$

where $\langle\lambda\rangle$ is the mean wavelength of the transition, h is the Plank constant, c is the speed of light, e is the elementary electronic charge, $\alpha(\lambda)$ is the absorption coefficient, ρ is the RE ion concentration, n is the refraction index and the factor $\chi_{\mathrm{ed}} = (n^2+2)^2/9$ is the so-called local field correction. The key idea of JO analysis is to minimize the discrepancy between experimental and calculated values of line strength, S_{ed} and S_{exp}, by choosing the coefficients Ω_k, which are used to characterize and compare materials, appropriately. The complete analysis should also include the magnetic dipole transitions [3.71]. The value of Ω_2 is of prime importance because it is the most sensitive to the local structure and material composition and is correlated with the degree of covalence. The values of Ω_k are used to calculate radiative transition probabilities and appropriate radiative lifetimes of excited states, which are very useful for numerous optical applications. More detailed analysis may be found in, for example, [3.71]. Ω_k values for different ions and host materials can be found in *Gschneidner Jr.* and *Eyring* [3.72].

3.3.6 Effects of External Fields

Electroabsorption and the Franz–Keldysh Effect

Electroabsorption is the absorption of light in a device where the absorption is induced by an applied (or changing) electric field within the device. Such a device is an electroabsorption modulator. There are three fundamental types of electroabsorption processes. In the Franz–Keldysh process, a strong applied field modifies the photon-assisted probability of an electron tunneling from the valence band to the conduction band, and thus it corresponds to an effective reduction in the *bandgap energy*, inducing the absorption of light with photon energies of slightly less than the bandgap. It was first observed for CdS, in which the absorption edge was observed to shift to lower energies with the applied field; that is, photon absorption shifts to longer wavelengths with the applied field. The effect is normally quite small but is nonetheless observable. In this type of electroabsorption modulation, the wavelength is typically chosen to be slightly smaller than the bandgap wavelength so that absorption is negligible. When a field is applied, the absorption is enhanced by the Franz–Keldysh effect. In free-carrier absorption, the concentration of free carriers N in a given band is changed (modulated), for example, by an applied voltage, changing the extent of photon absorption. The absorption coefficient is proportional to N and to the wavelength λ of the light raised to some power, typically 2–3. In the confined Stark effect, the applied electric field modifies the energy levels in a quantum well. The energy levels are reduced by the field by an amount proportional to the square of the applied field. A multiple quantum well (MQW) pin-type device has MQWs in its intrinsic layer. Without any applied bias, light with photon energy just less than the quantum well (QW) exciton excitation energy will not be significantly absorbed. When a field is applied, the energy levels are lowered and the incident photon energy is then sufficient to excite an electron and hole pair in the QWs. The relative transmission decreases with the reverse bias V_{r} applied to the pin device. Such MQW (pin) devices are usually not very useful in the transmission mode because the substrate material often absorbs the light (for example a GaAs/AlGaAs MQW pin would be grown on a GaAs substrate, which would absorb the radiation that excites the QWs). Thus, a reflector would be needed to reflect the light back before it reaches the substrate; such devices have indeed been fabricated.

The Faraday Effect

The Faraday effect, originally observed by Michael Faraday in 1845, is the rotation of the plane of polarization of a light wave as it propagates through a medium subjected to a magnetic field parallel to the direction of propagation of the light. When an optically inactive material such as glass is placed in a strong magnetic field and plane-polarized light is sent along the direction of the magnetic field, the emerging light's plane of polarization is rotated. The magnetic field can be applied, for example, by inserting the material into the core of a magnetic coil – a solenoid. The specific rotatory power induced, given by θ/L, has been found to be proportional to the magnitude of the applied magnetic

Table 3.9 Verdet constants for some materials

Material	Quartz	Flint glass	Tb-Ga garnet	Tb-Ga garnet	ZnSe	Crown glass	NaCl
λ (nm)	589.3	632	632	1064	633	589.3	589.3
ϑ (rad m^{-1} T^{-1})	4.0	4.0	−134	−40	118	6.4	10

field $\boldsymbol{B}$, which gives the amount of rotation as

$$\theta = \vartheta \boldsymbol{B} L \,, \tag{3.62}$$

where L is the length of the medium, and ϑ is the so-called Verdet constant, which depends on the material and the wavelength of the light. The Faraday effect is typically small. For example, a magnetic field of $\approx$ 0.1 T causes a rotation of about 1° through a glass rod of length 20 mm. It appears that *optical activity* is induced by the application of a strong magnetic field to an otherwise optically inactive material. There is, however, an important distinction between natural optical activity and the Faraday effect. The sense of rotation θ observed in the Faraday effect for a given material (Verdet constant) depends only on the direction of the magnetic field $\boldsymbol{B}$. If ϑ is positive, for light propagating parallel to $\boldsymbol{B}$, the optical field $\boldsymbol{E}$ rotates in the same sense as an advancing right-handed screw pointing in the direction of $\boldsymbol{B}$. The direction of light propagation does not change the absolute sense of rotation of θ. If we reflect the wave to pass through the medium again, the rotation increases to 2θ. The Verdet constant depends not only on the wavelength λ but also on the charge-to-mass ratio of the electron and the refractive index $n(\lambda)$ of the medium through

$$\vartheta = -\frac{(e/m_\mathrm{e})}{2c} \lambda \frac{\mathrm{d}n}{\mathrm{d}\lambda} \,. \tag{3.63}$$

Verdet constants for some materials are listed in Table 3.9. Terbium gallium garnet is commercially used in optical isolators.

3.4 Optical Characterization

Various methods have been developed for the determination of optical constants of solids. They differ with respect to sample geometry (bulks, thin films, multilayers, powders etc.) and optical properties (absorbing and nonabsorbing). In this section we are mainly concerned with bulk samples and thin films with flat surfaces. From available experimental techniques we select those based on two fundamental properties of light (used as a probe) – its intensity and polarization. Generally, both the light intensity and polarization change upon light interaction with the sample and if measured in suitable configurations they can be used for the determination of the material refractive index and the extinction coefficient. Optical transmittance, reflectance and ellipsometry parameters are convenient measurable quantities.

Normal incidence optical transmittance is defined as a ratio of light intensity of transmitted and incident waves, $T = I^\mathrm{t}/I^\mathrm{i}$. Reflectance is usually measured for oblique incidence and therefore depends on light polarization and angle of incidence. It is convenient to define optical reflectance for two linear polarizations: p represents the electric intensity vector oscillations in parallel direction with respect to the plane of incidence and s represents the electric intensity vector oscillations in perpendicular direction with respect to the plane of incidence. Reflectance is then defined by the relation $R_\mathrm{p,s} = I^\mathrm{r}_\mathrm{p,s}/I^\mathrm{i}_\mathrm{p,s}$ as the ratio of reflected and incident beam intensities for specific polarizations. Experimentally, easily accessible transmittance and reflectance can be related to transmission and reflection coefficients of a sample

$$T = |t|^2 \,, \qquad t = \frac{\hat{E}^\mathrm{t}}{\hat{E}^\mathrm{i}} \tag{3.64}$$

$$R_\mathrm{p,s} = |r_\mathrm{p,s}|^2 \,, \qquad r_\mathrm{p,s} = \frac{\hat{E}^\mathrm{r}_\mathrm{p,s}}{\hat{E}^\mathrm{i}_\mathrm{p,s}} \,, \tag{3.65}$$

where amplitudes of electric fields of incident, reflected and transmitted waves are complex amplitudes $\hat{E} = E_0 \mathrm{e}^{\mathrm{i}\phi}$ of a plane electromagnetic wave

$$E = E_0 \mathrm{e}^{\mathrm{i}\phi} \mathrm{e}^{\mathrm{i}(\omega t - kr)} = \hat{E} \mathrm{e}^{\mathrm{i}(\omega t - kr)} \,. \tag{3.66}$$

All discussed cases of transmission and reflection are presented in Figs. 3.15–3.18 together with explicit expressions of incident, reflected and transmitted waves. It should be noted here that transmission and reflection coefficients are generally complex numbers providing information not only on the amplitude change but also on the phase change of the wave. On the other hand, transmittance and reflectance are real quantities that do not carry phase change information as they measure the ratio of light intensities

$$I = \frac{1}{2} c \varepsilon_0 E_0^2 \,. \tag{3.67}$$

An elegant way to get access to a phase change is by measuring the polarization state of the reflected or

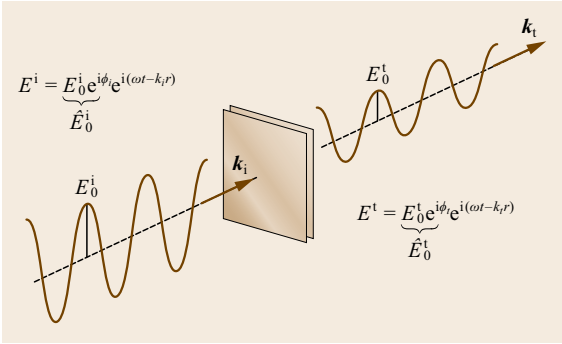

Fig. 3.15 Incident and transmitted waves in the case of normal incidence transmittance measurement

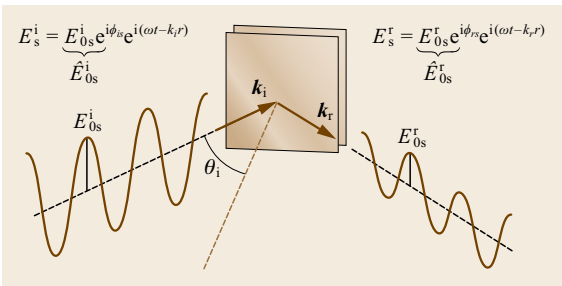

Fig. 3.16 Incident and reflected s-polarized waves in the case of oblique incidence reflectance measurement

transmitted wave with respect to the polarization state of the incident wave. The change of polarization is often represented by two angles Ψ, Δ that are, in the case of reflection, defined by the relation

$$\tan\Psi \mathrm{e}^{\mathrm{i}\Delta} = \frac{r_{\mathrm{p}}}{r_{\mathrm{s}}} \,. \tag{3.68}$$

The polarization state of a reflected wave – that is analyzed – generally takes an elliptical form, therefore this experimental method is called *ellipsometry*. The geometrical meaning of angles Ψ, Δ follows from their definition. Consider a linearly polarized incident wave with equal contributions (equal amplitudes) of p- and s-components that are in phase (Fig. 3.18). In the reflected wave, due to different reflection coefficients r_{p} and r_{s}, the p- and s- components are generally mutually shifted by an angle difference $\phi_{\mathrm{rp}} - \phi_{\mathrm{rs}}$ that equals the ellipsometric angle Δ. Furthermore, the amplitudes of p- and s- components in a reflected wave are no more equal and their ratio $E_{0\mathrm{p}}^{\mathrm{r}}/E_{0\mathrm{s}}^{\mathrm{r}}$ equals $\tan\Psi$. This interpretation is consistent with following mathematical treatment of relation (3.68)

$$\frac{r_{\mathrm{p}}}{r_{\mathrm{s}}} = \frac{E_{0\mathrm{p}}^{\mathrm{r}} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{rp}}} / E_{0\mathrm{p}}^{\mathrm{i}} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{ip}}}}{E_{0\mathrm{s}}^{\mathrm{r}} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{rs}}} / E_{0\mathrm{s}}^{\mathrm{i}} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{is}}}} = \frac{E_{0\mathrm{p}}^{\mathrm{r}}}{E_{0\mathrm{s}}^{\mathrm{r}}} \mathrm{e}^{\mathrm{i}(\phi_{\mathrm{rp}} - \phi_{\mathrm{rs}})} = \tan\Psi \mathrm{e}^{\mathrm{i}\Delta} \,. \tag{3.69}$$

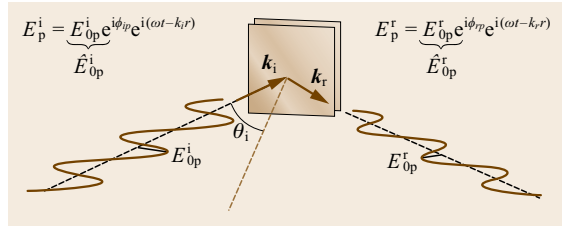

Fig. 3.17 Incident and reflected p-polarized waves in the case of oblique incidence reflectance measurement

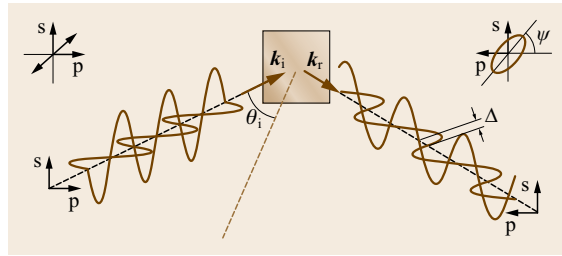

Fig. 3.18 Linearly polarized incident wave with equal contributions of s- and p-components reflected from the sample surface. The geometrical meaning of ellipsometric angles Ψ and Δ is indicated

For selected sample geometries, transmission and reflection coefficients can be expressed analytically in the frame of phenomenological electromagnetic theory [3.73]. Optical constants are explicitly covered in these expressions and therefore the measurable quantities of optical reflectance, transmittance and ellipsometry angles can be used for determination of the material refractive index and the extinction coefficient. This will be discussed in more detail for the case of single interface (bulk) and thin film materials in the following sections.

A large number of books and articles cover instrumental aspects of reflectance and transmittance measurements in different spectral ranges. For a broad overview of this field the reader is referred to [3.74] and references therein. Instrumentation of spectroscopic ellipsometers is discussed in detail by monographs devoted to spectroscopic ellipsometry [3.75–77]. Historically, the first ellipsometers that were developed were null ellipsometers. In this configuration, the orientation of the polarizer and compensator are adjusted such that the light reflected from the sample is linearly polarized. The analyzer is then rotated to the position that the light intensity on the detector is extinguished or *nulled*. From the positions of the polarizer, compensator and analyzer, the ellipsometric angles Ψ and Δ can be calculated. This configuration, if performed in four equivalent zones, can be very accurate and with low systematic errors. However, even when automated, this

approach is relatively slow and measurements are time consuming. In order to speed up measurements, rotating analyzer/polarizer ellipsometers were developed. In these systems, either the analyzer or polarizer is continuously rotated at a constant angular velocity (typically about 10–100 Hz) about the optical axis. The operating characteristics of both of these configurations are similar. However, the rotating polarizer system requires the light source to be totally unpolarized. Any residual polarization in the source results in a source of measurement error unless corrected. Similarly, a rotating analyzer system is susceptible to the polarization sensitivity of the detector. However, solid-state semiconductor photodetectors have extremely high polarization sensitivities. Thus, commercial systems tend to use rotating analyzer systems where residual polarization in the source is not an issue. Fourier analysis of the variation of the amplitude of the detector signal provides values for Ψ and Δ. Such systems can provide high-speed and accurate measurements. Spectroscopic ellipsometers extend the concepts developed for measurements at a single wavelength to measurements at multiple wavelengths. Being able to measure the dispersion in optical constants with wavelength adds another dimension to the analysis, permitting unambiguous determination of material and structure parameters.

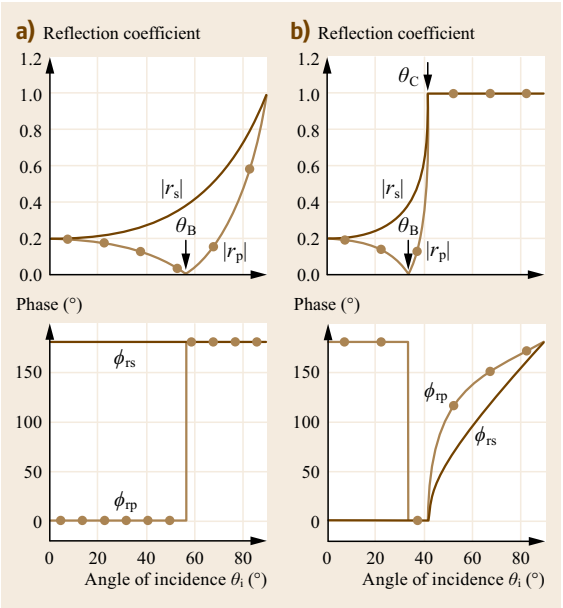

Fig. 3.19a,b Incident angle dependence of single interface reflection coefficient (its absolute value and phase) for a p- and s-polarized wave. Fresnel relations with $n_i = 1$; $n_t = 1.5$ **(a)** and $n_i = 1.5$; $n_t = 1$ **(b)** were used. Brewster θ_B and critical θ_C angles are also indicated

3.4.1 Bulk Samples

The term *bulk* is used here for samples with (at least locally) flat surfaces and for samples that are made from:

1. Absorbing materials thick enough with respect to penetration depth of light – used as a probe – that it senses only the sample surface (and not the backside of the sample or its deeper interfaces).
2. Nonabsorbing materials thick enough with respect to coherence length of the light – used as a probe – or shaped in such a geometry that light interference in the sample can be neglected.

For optical characterization of samples of type 1, reflection configuration is the most convenient, whereas for samples of type 2, refraction (possibly combined with reflection) is usually used.

First we will consider the determination of optical constants of absorbing bulk materials. In this case light senses only the sample surface, hence reflection coefficients for p- and s-polarized waves get the form of Fresnel equations derived for single interface

$$r_p = \frac{N_t \cos\theta_i - N_i \cos\theta_t}{N_t \cos\theta_i + N_i \cos\theta_t}\,,$$
$$r_s = \frac{N_i \cos\theta_i - N_t \cos\theta_t}{N_i \cos\theta_i + N_t \cos\theta_t}\,, \qquad (3.70)$$

where N_i and N_t are (complex) refractive indices of the ambient and sample respectively [3.73]. It is useful to shortly discuss the dependence of reflection coefficients on the incidence angle θ_i (angle of refraction is denoted by θ_t and can be calculated by Snell's law). Figure 3.19 represents incident angle dependence of absolute values of p- and s-reflection coefficients and their phases. Two cases are distinguished: (a) the ambient is optically rarer; and (b) the ambient is optically denser with respect to the sample. The angle of incidence where the r_p coefficient becomes zero is called the *Brewster angle* θ_B. However, for optically absorbing samples, the r_p coefficient does not reach a zero value. Instead, its angle dependence forms a nonzero minimum there and its position is called the *principal angle*. When the ambient is optically denser then the critical angle θ_c can be distinguished. For incidence angles greater than the critical, both reflection coefficients are equal in absolute value to unity. Total reflection is observed under these conditions. Calculations of reflectance and ellipsometry parameters for a specific angle of incidence is straightforward using Fresnel equations (3.70) and definition relations (3.65) and (3.69).

However, precaution must be used when approximating a surface of a bulk material with a single interface. A single interface is an ideal structure that presents an abrupt and sharp change of refractive index

across a planar interface between two semi-infinitive spaces – in our case, the ambient and sample. In practice it is rather difficult to prepare such surfaces. Mechanical polishing of a sample surface usually causes a so-called *Beilby overlayer* that accumulates various defects due to the mechanism of polishing [3.78]. This damaged layer can be reduced in thickness if a proper polishing process is selected or removed by electropolishing. The Beilby overlayer may present different optical properties than the bulk and, if not carefully considered, erroneous optical constants are determined. Alternatively, sample cutting or cleaving in a vacuum or the deposition of an optically thick film is possible. Ellipsometry as a phase sensitive method is extremely sensitive to the surface quality; and it is made use of for ultrathin film or overlayer characterization. The following sections cover selected approaches used to derive optical constants from reflectance and ellipsometry measurements carried out on sample surfaces that can be successfully approximated by the single interface model. For further use we provide here also the Fresnel formulae of transmission coefficients for a single interface

$$t_\mathrm{p} = \frac{2N_\mathrm{i}\cos\theta_\mathrm{i}}{N_\mathrm{t}\cos\theta_\mathrm{i} + N_\mathrm{i}\cos\theta_\mathrm{t}} ,$$
$$t_\mathrm{s} = \frac{2N_\mathrm{i}\cos\theta_\mathrm{i}}{N_\mathrm{i}\cos\theta_\mathrm{i} + N_\mathrm{t}\cos\theta_\mathrm{t}} . \qquad (3.71)$$

Normal Incidence Reflectivity and Kramers–Kronig Analyses

For normal incidence, p- and s-polarization cannot be distinguished. The reflection coefficient is then polarization-independent and if air is considered as an ambient we get

$$r = \frac{1-n+\mathrm{i}K}{1+n-\mathrm{i}K} . \qquad (3.72)$$

Hence, determination of the refractive index n and extinction coefficient K of the studied material requires knowledge of both the absolute value and phase of the normal incidence reflection coefficient

$$r = |r|\,\mathrm{e}^{\mathrm{i}\phi} = \sqrt{R}\mathrm{e}^{\mathrm{i}\phi} . \qquad (3.73)$$

Experimentally accessible normal incidence reflectivity R provides only the absolute value of the reflection coefficient. However when reflectivity is known in the whole spectral range then the phase of the reflection coefficient can be calculated with the help of the Kramers–Kronig relation [3.79]

$$\phi(\omega) = -\frac{2\omega}{\pi} P \int_0^\infty \frac{\ln\sqrt{R(\omega')}}{\omega'^2-\omega^2}\mathrm{d}\omega' . \qquad (3.74)$$

The final relations for the refractive index and extinction coefficient of the probed material are obtained from

$$n = \frac{1-R}{1+R+2\sqrt{R}\cos\phi} ,$$
$$K = \frac{2\sqrt{R}\sin\phi}{1+R+2\sqrt{R}\cos\phi} . \qquad (3.75)$$

However, in reality, reflectivity cannot be measured in the *whole* spectral range covering all frequencies. Nevertheless, the Kramers–Kronig relation (3.74) can still be used when the extrapolation of the experimentally available spectrum of reflectivity is carefully done in both spectral limits. Often this method combines visible (VIS), ultraviolet (UV) and vacuum ultraviolet (VUV) spectrophotometry or synchrotron facility to cover as wide a spectral range as possible. For the high energy of photons, the surface quality (mainly surface roughness) becomes extremely important; for nonnegligible roughness, a correction on light scattering lost in the reflected beam must be considered [3.80]. As an example of an application of the Kramers–Kronig approach we provide a normal incidence reflectivity spectrum recorded on PZT and the corresponding calculated spectra of the PZT refractive index and extinction coefficient in Fig. 3.20.

Oblique Incidence Reflectivity R_p and R_s

Even if a wide spectral range is not experimentally available for a normal incidence reflectivity measurement, we can still make use of reflectance measurements – carried out for oblique incidence – and determine optical constants of material from these spectra. Fresnel relations (3.70) inserted into definitions (3.65) make a link between reflectance for p- and s-waves and optical constants of the material

$$R_\mathrm{s} = \frac{(Y-u)^2+v^2}{(Y+u)^2+v^2} ,$$
$$R_\mathrm{p} = \frac{(\varepsilon_1-Zu)^2+(\varepsilon_2-Zv)^2}{(\varepsilon_1+Zu)^2+(\varepsilon_2+Zv)^2} , \qquad (3.76)$$

where

$$Y = n_\mathrm{i}\cos\theta_\mathrm{i} , \quad Z = \frac{n_\mathrm{i}}{\cos\theta_\mathrm{i}} ,$$
$$\varepsilon_1 = n_\mathrm{t}^2 - K_\mathrm{t}^2 , \quad \varepsilon_2 = 2n_\mathrm{t}K_\mathrm{t} , \quad \varepsilon_3 = (n_\mathrm{i}\cos\theta_\mathrm{i})^2 ,$$
$$2u^2 = \varepsilon_1 - \varepsilon_3 + \sqrt{(\varepsilon_1-\varepsilon_3)^2+\varepsilon_2^2} ,$$
$$2v^2 = \varepsilon_3 - \varepsilon_1 + \sqrt{(\varepsilon_1-\varepsilon_3)^2+\varepsilon_2^2} .$$

These equations are highly nonlinear and moreover transcendental, therefore only approximate inverse solutions exist [3.81]. Presently, numerical methods and

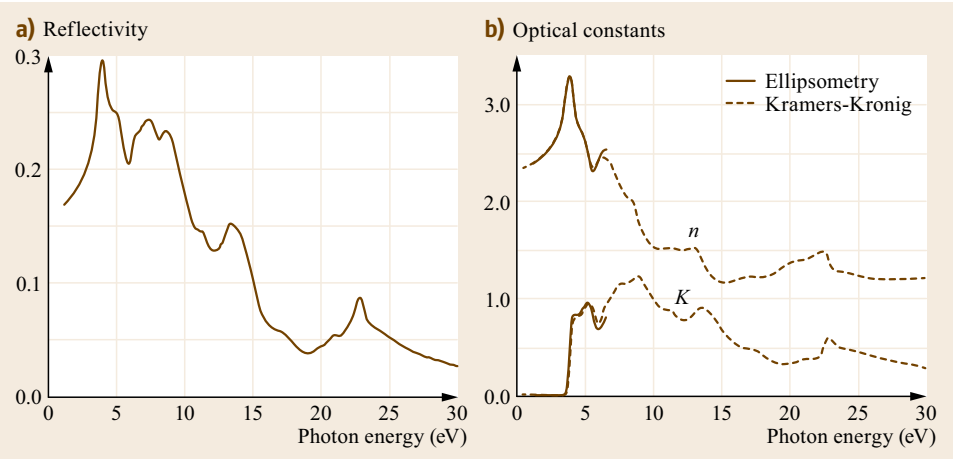

Fig. 3.20a,b Normal incidence reflectivity of PZT **(a)** and its complex refractive index **(b)** determined by Kramers–Kronig relations. Experimental data recorded on a synchrotron facility UVSOR, Japan. Comparison with ellipsometry is also presented

nonlinear fitting of experimental spectra of R_s and R_p can be routinely performed to adjust searched optical constants.

Ellipsometry

The determination of optical constants of a material from ellipsometry parameters Ψ and Δ recorded on a bulk sample is straightforward. It can be shown [3.82] that the complex refractive index of a material can be expressed as

$$n - \mathrm{i}K = \sqrt{\sin^2\theta_\mathrm{i}\left(1+\tan^2\theta_\mathrm{i}\left(\frac{1-\rho}{1+\rho}\right)^2\right)}\,, \quad (3.77)$$

where ρ represents the ratio of Fresnel reflection coefficients for p- and s-polarized waves; $\rho = r_p/r_s$ and the ambient is assumed to be air. Since the angle of incidence θ_i is set in the experiment, the two parameters measured from the experiment (Ψ and Δ) for a given wavelength can be used to deduce the complex parameter ρ and further, two remaining unknown variables in the equation above – namely, n and K. Alternatively, we can reformulate relation (3.77) and express the real and imaginary part of the material dielectric permittivity as an explicit function of ellipsometry parameters

$$\varepsilon_1 = n^2 - K^2 = \sin^2\theta_\mathrm{i}\left[1+\left(\tan^2\theta_\mathrm{i} \times \frac{\cos^2(2\Psi)-\sin^2(2\Psi)\sin^2\Delta}{[1+\sin(2\Psi)\cos\Delta]^2}\right)\right],$$

$$\varepsilon_2 = 2nK = \frac{\sin^2\theta_\mathrm{i}\tan^2\theta_\mathrm{i}\sin(4\Psi)\sin\Delta}{[1+\sin(2\Psi)\cos\Delta]^2}\,. \quad (3.78)$$

The single interface is the only case where the inverse solution is analytically available. For other structures such as thin films, multilayers, and so on, we have to use numerical methods to adjust searched optical and geometrical parameters of a sample. Even if the incidence angle θ_i appears explicitly in relation (3.77), the value of the complex refractive index does not depend on its selection. However, the most precise results are obtained when θ_i is set close to the principal value (or Brewster angle) where $r_p \approx 0$ and r_s and r_p coefficients have significantly different values (Fig. 3.19). Figure 3.21 represents an example of Ψ and Δ measured for incidence angles 55° and 65° on the surface of a pellet pressed from blue organic pigment and the corresponding optical constants determined by relation (3.77). For both incidence angles, the obtained optical constants are nearly identical. On the other hand, if determined n and K are incidence angle-dependent then the approximation of a single interface is no longer valid. In this case, the sample surface may have a more complex structure (for example the presence of an overlayer).

Alternatively, the searched spectral dependence of a complex refractive index may be parameterized by an appropriate function (model dielectric function). Its parameters may be then determined by nonlinear fitting of experimental data Ψ and Δ. For this purpose, ellipsometric spectra for several incidence angles are usually recorded and fitted simultaneously to increase the number of experimental data and hence increase the reliability of the results. Several examples of model dielectric function are provided above in Sect. 3.2. Other examples for specific materials and spectral ranges are available for example in monographs focused on spectroscopic ellipsometry [3.75, 76]. Figure 3.22 presents a model dielectric function of polycrystalline ZnSe defined as a sum of five oscillators whose parameters were fitted against experimental ellipsometric spectra recorded for several incidence angles.

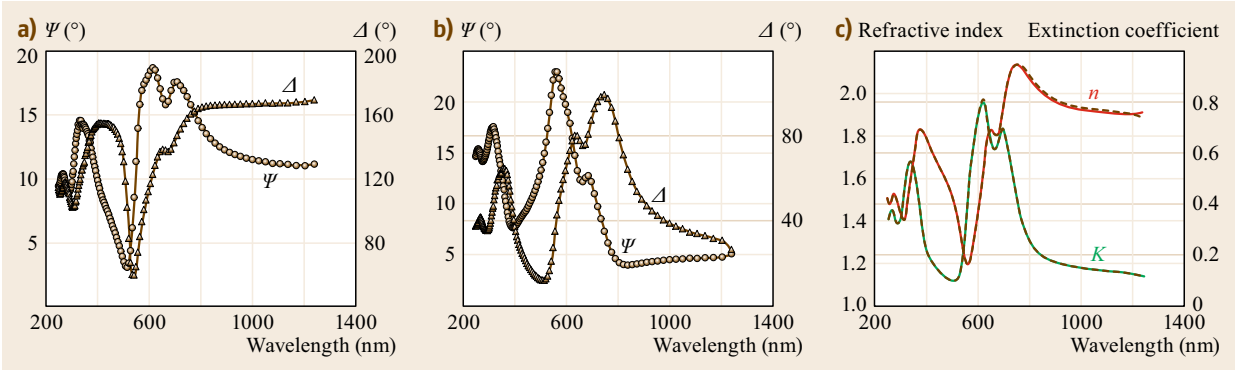

Fig. 3.21a–c Ellipsometric parameters recorded on pressed pellets of blue organic pigment for incidence angle of 55° **(a)** and 65° **(b)** together with refractive index **(c)** determined by analytical formula (3.70)

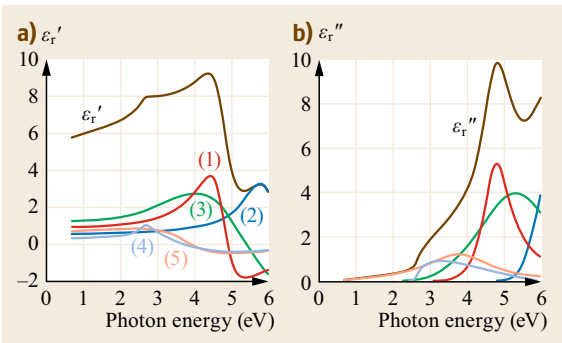

Fig. 3.22a,b Real **(a)** and imaginary **(b)** part of dielectric permittivity of ZnSe determined by spectroscopic ellipsometry. Its deconvolution to five oscillators is also indicated

Ellipsometry is a very precise and sensitive spectroscopic tool but when operated solely in reflection configuration then its sensitivity to low values of material absorption is limited. This is due to the fact that reflected light senses only the sample surface and its close vicinity. It is argued that ellipsometry can provide reliable results for absorption coefficient $\alpha > 10^5\,\mathrm{cm}^{-1}$ [3.83]. If α is in the range 10^3–$10^5\,\mathrm{cm}^{-1}$ usually transmittance spectrum is added and treated simultaneously with ellipsometry data to ensure accurate determination of the absorption coefficient. In the region of low absorption $\alpha < 10^3\,\mathrm{cm}^{-1}$ other techniques such as photocurrent measurement or photothermal deflection spectroscopy are more appropriate [3.84].

Combined Measurement of *T* and *R*

The combined measurement of reflectance and transmittance also enables material absorption determination. This is often done for the study of absorption edge onset of amorphous semiconductors (Fig. 3.11) and glasses where the absorption coefficient is relatively weak. The determination of the absorption coefficient in a spectral range where the penetration depth decreases as the absorption increases is usually realized by measurements of a series of samples with various thicknesses. Samples are usually in the form of plane-parallel plates (both sides polished to defined thickness), hand blown glass bubbles or films deposited on substrates. The absorption coefficient is then expressed by following relation

$$\alpha = \frac{1}{d}\ln\left(\frac{(1-R)^2 + \sqrt{(1-R)^4 + 4R^2T^2}}{2T}\right), \quad (3.79)$$

where d stands for sample thickness.

There is a wide class of materials that in some limited spectral range are nonabsorbing and their optical transparency is extensively used in various applications (optical elements, integrated optics, etc.). In this case, the refractive index has a real value, because its imaginary part (extinction) can be neglected. Of course, the refractive index of these nonabsorbing materials can be determined by most methods mentioned above that were based on light reflection but much more precise are methods based on light refraction, i. e., refractometry.

Minimal Deviation

The refractive indices of dielectrics and semiconductors in a spectral range of their transparency can be determined from a prism of the material of an apex angle, A, by measuring the angle of minimal deviation, D, of radiation passing through the prism as in Fig. 3.23. The refractive index, n, is then given by the relation

$$n = \frac{\sin\frac{1}{2}(A+D)}{\sin\frac{1}{2}A}\,. \quad (3.80)$$

It should be noted here that high quality samples (prisms) free of any volume imperfections and defects

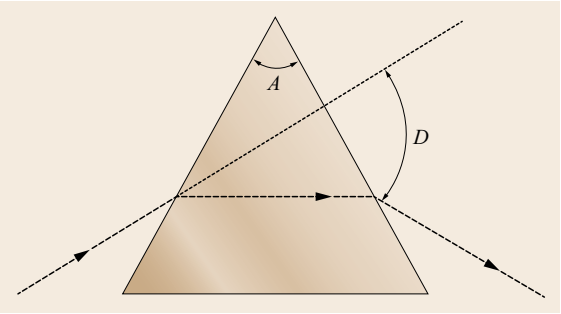

Fig. 3.23 Angle of deviation technique for measuring the refactive index

are required, otherwise scattered radiation in the transmitted beam does not enable a precise determination of the angle of minimal deviation. This technique can give a refraction index in absolute precision of about 0.001.

To complete this section we present one more convenient method for determination of refractive index of nonabsorbing materials based on the critical angle measurement.

Critical Angle

Consider a bulk material with an unknown refractive index, optically coupled to the prism with a known index of refraction (Fig. 3.24). If the angle of incidence is scanned, then an abrupt change of intensity is detected when the angle of incidence reaches the critical angle (onset of total reflection on prism/sample interface) (Fig. 3.19). From the condition of critical angle,

$$n = n_{\mathrm{p}} \sin\theta_{\mathrm{c}} \tag{3.81}$$

we can determine the refractive index of the bulk sample with a high precision of about 0.0005. The condition of total reflection requires that the refractive index of the sample is higher than that of the prism. This technique can also be used for refractive index and thickness determination of transparent films deposited on a substrate. In this case, for some discrete values of incidence angle, the light is coupled as a guided wave to the film. From these angle values, film parameters of interest can be determined and the method itself is referred to as a prism coupler method.

3.4.2 Thin Film Optics

Thin film optics involves multiple reflections of light entering a thin film dielectric (typically on a substrate) so that the reflection and transmission coefficients are determined by multiple wave interference phenomena, as shown in Fig. 3.25.

Consider a thin film coated on a substrate. Assuming that the incident wave has an amplitude of E_0, then

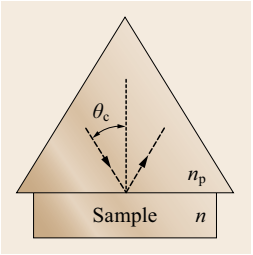

Fig. 3.24 Experimental setup for measuring the refractive index by the critical angle technique

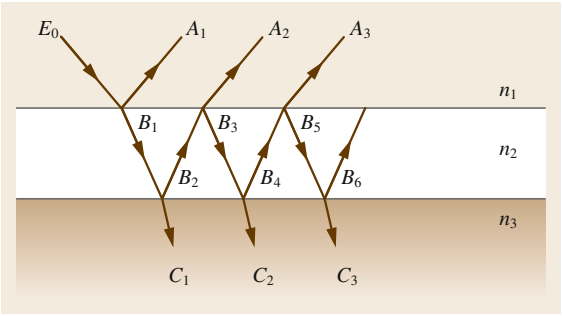

Fig. 3.25 Thin film coated on a substrate and multiple reflections of incident light, where n_1, n_2 and n_3 are the refractive indices of the medium above the thin film, the thin film, and the substrate respectively

there are various transmitted and reflected waves, as shown in Fig. 3.25. We then have the following amplitudes based on the definitions of the reflection and transmission coefficients

$$\begin{aligned}
A_1 &= E_0 r_{12} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{A1}}} \\
A_2 &= E_0 t_{12} r_{23} t_{21} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{A2}}} \\
A_3 &= E_0 t_{12} r_{23} r_{21} r_{23} t_{21} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{A3}}} \\
B_1 &= E_0 t_{12} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{B1}}} \\
B_2 &= E_0 t_{12} r_{23} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{B2}}} \\
B_3 &= E_0 t_{12} r_{23} r_{21} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{B3}}} \\
B_4 &= E_0 t_{12} r_{23} r_{21} r_{23} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{B4}}} \\
B_5 &= E_0 t_{12} r_{23} r_{21} r_{23} r_{21} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{B5}}} \\
B_6 &= E_0 t_{12} r_{23} r_{21} r_{23} r_{21} r_{23} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{B6}}} \\
C_1 &= E_0 t_{12} t_{23} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{C1}}} \\
C_2 &= E_0 t_{12} r_{23} r_{21} t_{23} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{C2}}} \\
C_3 &= E_0 t_{12} r_{23} r_{21} r_{23} r_{21} t_{23} \mathrm{e}^{\mathrm{i}\phi_{\mathrm{C3}}}
\end{aligned} \tag{3.82}$$

and so on, where r_{12} is the reflection coefficient of a wave in medium 1 incident on medium 2, and t_{12} is the transmission coefficient from medium 1 into 2. For simplicity, we will assume normal incidence. The phase change upon traversing the thin film thickness d is $\phi_{\mathrm{C1}} = -(2\pi/\lambda) n_2 d$, where λ is the free space wave-

length. In the following relations the phase ϕ is defined as $\phi = -\phi_{C1}$.

The reflection and transmission coefficients under normal incidence are given by

$$r_1 = r_{12} = \frac{n_1 - n_2}{n_1 + n_2} = -r_{21} \,,$$
$$r_2 = r_{23} = \frac{n_2 - n_3}{n_2 + n_3} \,, \tag{3.83a}$$

and

$$t_1 = t_{12} = \frac{2n_1}{n_1 + n_2} \,, \quad t_2 = t_{21} = \frac{2n_2}{n_1 + n_2} \,,$$
$$t_3 = t_{23} = \frac{2n_3}{n_2 + n_3} \,, \tag{3.83b}$$

where

$$1 - t_1 t_2 = r_1^2 \,. \tag{3.84}$$

The total reflection coefficient is then obtained as

$$r = \frac{A_{\text{reflected}}}{E_0} = r_1 - \frac{t_1 t_2}{r_1} \sum_{k=1}^{\infty} \left(-r_1 r_2 \mathrm{e}^{-\mathrm{i}2\phi}\right)^k \,, \tag{3.85}$$

which can be summed to be

$$r = \frac{r_1 + r_2 \mathrm{e}^{-\mathrm{i}2\phi}}{1 + r_1 r_2 \mathrm{e}^{-\mathrm{i}2\phi}} \,. \tag{3.86}$$

The total transmission coefficient is obtained as

$$t = \frac{C_{\text{transmitted}}}{E_0} = -\frac{t_1 t_3 \mathrm{e}^{\mathrm{i}\phi}}{r_1 r_2} \sum_{k=1}^{\infty} \left(-r_1 r_2 \mathrm{e}^{-\mathrm{i}2\phi}\right)^k$$
$$= \left(\frac{t_1 t_3 \mathrm{e}^{\mathrm{i}\phi}}{r_1 r_2}\right) \frac{r_1 r_2 \mathrm{e}^{-\mathrm{i}2\phi}}{1 + r_1 r_2 \mathrm{e}^{-\mathrm{i}2\phi}} \,, \tag{3.87}$$

which can be summed to be

$$t = \frac{t_1 t_3 \mathrm{e}^{-\mathrm{i}\phi}}{1 + r_1 r_2 \mathrm{e}^{-\mathrm{i}2\phi}} \,. \tag{3.88}$$

Equations (3.86) and (3.88) are very useful when studying the optical properties of thin films coated on a substrate as discussed by *Kasap*, *Ray* and *Gould* in Chap. 28 on Thin Films in this Handbook. Reflection and transmission coefficients of thin film systems for oblique incidence are also expressed by (3.86) and (3.88) respectively. However, single interface reflection and transmission coefficients (r_1, r_2, t_1, t_3) have to be replaced by Fresnel relations for s- and p-polarized waves (Eqs. (3.70) and (3.71)). Moreover, phase change has to be modified to $\phi = (2\pi/\lambda) d (n_2^2 - n_1^2 \sin^2\theta)^{1/2}$, where θ is the incidence angle, to account for oblique propagation of light in the layer. Reflectance of the thin film system is equal to the square of the absolute value of the reflection coefficient of the thin film (3.65). On the other hand, when considering transmittance of the film deposited on a substrate, it must be remembered that expression (3.88) relates the amplitudes of the waves in the media bounding the film (ambient and substrate), but transmitted wave intensity is not measured in the substrate but in free space with a refractive index n_1. Therefore, normal incidence transmittance is related to the transmission coefficient by relation

$$T = \frac{n_3}{n_1} |t|^2 \,. \tag{3.89}$$

In practice, the two most popular approaches for thin film optical characterization are either to analyze optical transmission spectra, which may be observed using a standard spectrophotometer, or ellipsometric investigations in reflection. Both approaches are briefly explained below.

Swanepoel's Analysis of Optical Transmission Spectra

One of the simplest and most practically realizable approaches to the problem was developed by Swanepoel [3.85]. He showed that for a uniform film, with a thickness d, a refractive index n and an absorption coefficient α, deposited on the substrate with a refractive index s, the transmittance can be expressed as

$$T(\lambda) = \frac{Ax}{B - Cx\cos\varphi + Dx^2} \,, \tag{3.90a}$$

where

$$A = 16n^2 s \,, \tag{3.90b}$$
$$B = (n+1)^3 \left(n + s^2\right) \,, \tag{3.90c}$$
$$C = 2\left(n^2 - 1\right)\left(n^2 - s^2\right) \,, \tag{3.90d}$$
$$D = (n-1)^3 \left(n - s^2\right) \,, \tag{3.90e}$$
$$\varphi = 4\pi n d/\lambda \,, \tag{3.90f}$$
$$x = \exp(-\alpha d) \,, \tag{3.90g}$$

and n is a function of λ.

For a nonuniform film with a wedge-like cross-section, (3.90a) must be integrated over the thickness

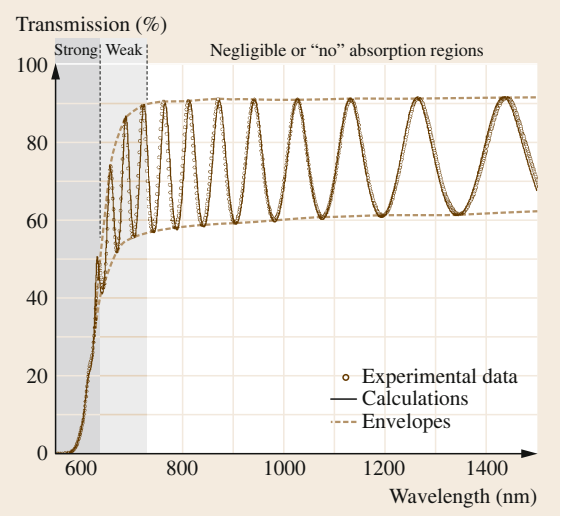

Fig. 3.26 Optical transmission of an a-Se thin film. Calculations are done using (3.90) with the $n(\lambda)$ and $\alpha(\lambda)$ relations shown in Fig. 3.27. The film was prepared by the thermal evaporation of photoreceptor-grade selenium pellets. Film thickness was 2 μm. Tentative regions of strong, weak and negligible absorption are also shown

of the film, giving

$$T_{\Delta d}(\lambda) = \frac{1}{\varphi_2 - \varphi_1} \int_{\varphi_1}^{\varphi_2} \frac{Ax}{B - Cx\cos\varphi + Dx^2} \mathrm{d}x \,, \quad (3.91)$$

where

$$\varphi_1 = 4\pi n\,(d - \Delta d)\,/\lambda$$

and

$$\varphi_2 = 4\pi n\,(d + \Delta d)\,/\lambda \,, \quad (3.92)$$

where d is the average thickness of the film and Δd is the variation of the thickness throughout the illumination (testing) area. The concept behind Swanepoel's method is to construct two envelopes $T_{\mathrm{M}}(\lambda)$ and $T_{\mathrm{m}}(\lambda)$ that pass through the maxima and minima of $T(\lambda)$ and to split the entire spectral range into three regions: negligible absorption, weak absorption and strong absorption regions, as shown in Fig. 3.26.

In the region of negligible absorption, (3.91) yields

$$T_{\mathrm{M/m}} = \frac{\lambda}{2\pi n \Delta d} \frac{a}{\sqrt{1-b^2}} \tan^{-1}\left[\frac{1 \pm b}{\sqrt{1-b^2}} \tan\left(\frac{2\pi n \Delta d}{\lambda}\right)\right] , \quad (3.93)$$

where $a = A/(B+D)$ and $b = C/(B+D)$. The *plus* sign in (3.93) corresponds to transmission maxima and

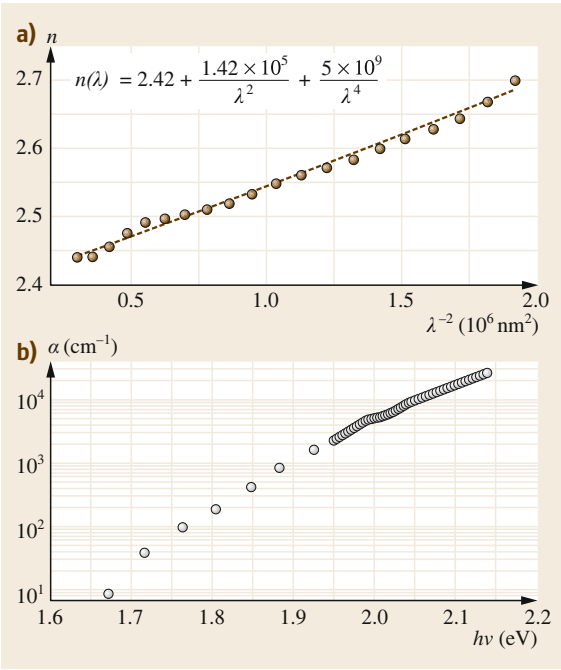

Fig. 3.27 **(a)** The spectral dependence of the refractive index of the a-Se thin film from Fig. 3.26. The *line* corresponds to the Cauchy approximation with the parameters shown on the figure. **(b)** The spectral dependence of the absorption coefficient of the same a-Se thin film

minus to minima. Equation (3.74) is used to find Δd and n.

In the region of weak absorption,

$$T_{\mathrm{M/m}} = \frac{\lambda}{2\pi n \Delta d} \frac{a_x}{\sqrt{1-b_x^2}} \tan^{-1}\left[\frac{1 \pm b_x}{\sqrt{1-b_x^2}} \tan\left(\frac{2\pi n \Delta d}{\lambda}\right)\right] , \quad (3.94)$$

where $a_x = Ax/(B+Dx^2)$ and $b_x = Cx/(B+Dx^2)$. Equation (3.94) allows us to find x and n using the previously found Δd.

The previous results are used to construct $n(\lambda)$ and to create approximations using the Cauchy, Sellmeier or Wemple–DiDominico dispersion equations. An example of a Cauchy approximation is shown in Fig. 3.27.

The positions of the extrema are given by the equation

$$2nd = m\lambda \,, \quad (3.95)$$

where $m = 1, 2, 3, \ldots$ for maxima and $m = 1/2, 3/2, \ldots$ for minima. Therefore, d can be found from the slope of (n/λ) versus m.

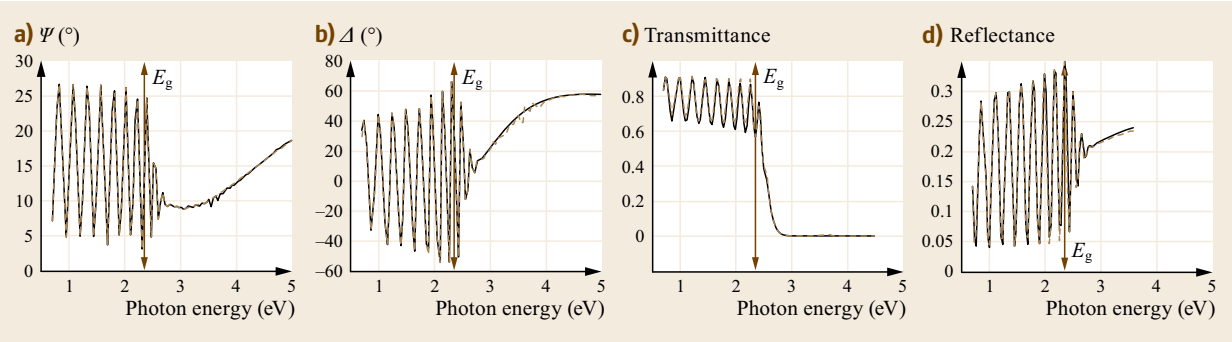

Fig. 3.28a–d Ellipsometric (a,b) transmittance (c) and reflectance (d) spectra recorded on $As_{50}Se_{50}$ amorphous thin film deposited on float glass substrate (experimental data – *black solid lines*) compared with best-fit theoretical spectra (*broken lines*)

In the region of strong absorption, the absorption coefficient is calculated as

$$x = \frac{A - \sqrt{A^2 - 4T_i^2 BD}}{2T_i D}\,, \tag{3.96}$$

where

$$T_i = \frac{2T_M T_m}{T_M + T_m} \tag{3.97}$$

and A, B and D are calculated using the above-mentioned $n(\lambda)$ approximation.

It is worth noting that the division into negligible absorption, weak absorption and strong absorption regions is quite arbitrary and should be checked using trial-and-error methods.

Ellipsometry

An example of ellipsometric spectra recorded in reflection configuration on a thin film is presented in Fig. 3.28. For photon energies lower than bandgap E_g of thin film material, we can distinguish interference phenomena (interference fringes) due to multiple reflections in the film. When photon energy in the spectrum increases and has a higher value than E_g, the onset of light absorption reduces the amplitude of fringes; and for even higher absorption values (higher photon energies) interference fringes completely disappear. In this spectral range, the incident light probes only the film surface, hence the approach derived for a single interface in the previous section can be used. This qualitative interpretation is valid also for the transmittance spectra treated previously by the Swanepoel method.

It should be noted here that in optics term *thin film* is usually used for films with thicknesses significantly smaller than coherence length of interacting (probe) light. In this case, the formalism of totally coherent light can be applied to the study of interference phenomena in the film. Quantitative analyses of ellipsometric spectra can provide information on the geometrical (film thickness) and optical (film complex refractive index) properties of a sample. However, desired optical and geometrical parameters cannot be expressed analytically as explicit functions of experimental Ψ and Δ values as was done previously in the case of a single interface (bulk samples). The solution of this inverse problem requires construction of a sample model. Selected parameters are then adjusted by a numerical procedure where differences between theoretically calculated and experimental spectra are iteratively minimized (nonlinear fitting). Theoretical spectra of Ψ and Δ are easily obtained when r_p and r_s reflection coefficients – determined for the thin film (see (3.86) and related remarks) – are inserted into the definition relation of ellipsometric angles (3.68). Often, it is helpful to add transmittance and reflectance experimental spectra and treat them simultaneously with ellipsometry spectra (recorded for several incidence angles). In this way, we can reduce possible correlations between searched parameters.

As an example of ellipsometry data treatment we present in Fig. 3.28 experimental ellipsometric, transmittance and reflectance spectra compared with best-fit theoretical ones. Spectra were recorded on a chalcogenide $As_{50}Se_{50}$ amorphous film deposited onto float glass. The back side of the substrate was grounded before ellipsometry and reflectance measurements to suppress spurious reflections from this interface. Sample model structure was then designed as a homogenous film sandwiched between two semi-infinitive media: ambient and substrate. In the case of transmittance, the effect of finite substrate was accounted for by equation (3.89). The refractive index of float glass was determined formerly by spectroscopic ellipsometry carried out on a naked substrate considering it as a bulk material (see previous section). Optical constants of the chalcogenide film were parameterized by

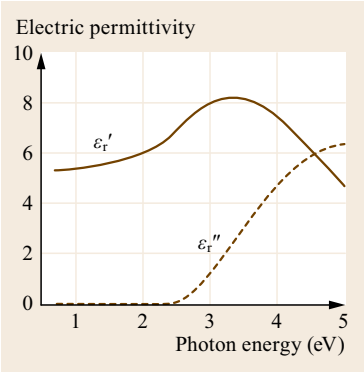

Fig. 3.29 Determined electrical permittivity spectra of $As_{50}Se_{50}$ film with thickness of 1085.5 ± 1.1 nm. Adjusted parameters of Tauc–Lorentz parameterization are $A = 155.16 \pm 1.39$ eV; $E_0 = 4.55 \pm 0.03$ eV; $C = 6.09 \pm 0.09$ eV; $E_g = 2.351 \pm 0.001$ eV; $\varepsilon_\infty = 1.05 \pm 0.01$

a Tauc–Lorentz formula (that is, a combination of the Lorentz oscillator and Tauc absorption edge models) that is the appropriate parameterization for amorphous semiconductors. The imaginary part of electric permittivity ε_r'' at a photon energy E is then expressed as

$$\varepsilon_r'' = \frac{AE_0C\left(E-E_g\right)^2}{\left(E^2-E_0^2\right)^2+CE^2}\frac{1}{E} \qquad E > E_g$$
$$\varepsilon_r'' = 0 \qquad E < E_g$$

and the real part ε_r' can be calculated with the help of Kramers–Kronig relations ((3.9a) and (3.9b)) or by an analytic solution [3.86, 87]. Parameters of the Tauc–Lorentz formula together with the film thickness were free parameters adjusted by the fitting procedure. Figure 3.29 represents the determined spectral dependence of the relative permittivity of $As_{50}Se_{50}$ with adjusted values of searched parameters.

Of course, thin films usually have various defects and nonidealities, for example nonuniform thickness, surface roughness, internal nonuniformities, refractive index gradient, and so on. Ellipsometry is a sensitive method capable of detecting most of the mentioned defects and, moreover, theoretical approaches have been developed to account for them and analyze them. Monographs focused on spectroscopic ellipsometry [3.75–77] and related articles treat these topics.

3.5 Optical Materials

3.5.1 Abbe Number or Constringence

In an optical medium, the Abbe number is defined as the inverse of its dispersive power; that is, it represents the relative importance of refraction and dispersion. There are two common definitions based on the use of different standard wavelengths. The Abbe number ν_d is defined by

$$\nu_d = (n_d - 1)/(n_F - n_C)\,, \tag{3.98}$$

where n_F, n_d and n_C are the refractive indices of the medium at the Fraunhofer standard wavelengths corresponding to the helium d-line ($\lambda_d = 587.6$ nm, yellow), the hydrogen F-line ($\lambda_F = 486.1$ nm, blue) and the hydrogen C-line ($\lambda_C = 656.3$ nm, red) respectively. The Abbe number of a few glasses are listed in Table 3.10. The Abbe number ν_e, on the other hand, is defined by

$$\nu_e = (n_e - 1)/(n_{F'} - n_{C'})\,, \tag{3.99}$$

where n_e, $n_{F'}$ and $n_{C'}$ are the refractive indices at wavelengths of the e-line (546.07 nm), the F′-line (479.99 nm) and the C′-line (643.85 nm) respectively.

The relationship between the refractive index n_d and the Abbe number ν_d is given by the Abbe diagram, where n_d is plotted on the y-axis against its corresponding ν_d value for different glasses, usually with the Abbe numbers decreasing on the x-axis, as shown in Fig. 3.30.

3.5.2 Optical Materials

Optical materials are those crystalline solids and glasses that are commonly used in the construction of optical components, such as lenses, prisms, windows, mirrors and polarizers. In addition to having the required optical properties, such as a well-defined refractive index n with a known dependence on wavelength $n = n(\lambda)$ and temperature, optical materials should also have various other desirable material properties, such as good ho-

Table 3.10 Abbe numbers for a few glasses. PC denotes polycarbonate, PMMA is polymethylmethacrylate, and PS represents polystyrene

Optical glass →	SF11	F2	BaK1	Crown glass	Fused silica	PC	PMMA	PS
ν_d →	25.76	36.37	57.55	58.55	67.80	34	57	31

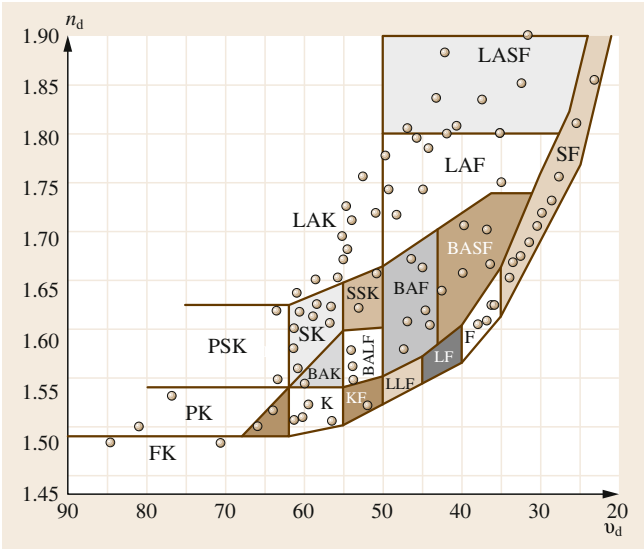

Fig. 3.30 The Abbe diagram is a diagram in which the refractive indices n_d of glasses are plotted against their Abbe numbers in a linear n_d versus ν_d plot and, usually, with the Abbe number decreasing along the x-axis, rather than increasing. A last letter of F or K represents flint or crown glass. Other symbols are as follows: S, dense; L, light; LL, extra light; B, borosilicate; P, phosphate; LA or La, lanthanum; BA or Ba, barium. Examples: BK, dense flint; LF, light flint; LLF, extra light flint; SSK, extra dense crown; PK, phosphate crown; BAK, barium crown; LAF, lanthanum flint

mogeneity (including negligible macroscopic variations in the refractive index), negligible thermal expansion (small α_L, thermal expansion coefficient), resistance to mechanical damage (resistance to scratching), and resistance to chemical degradation (chemical corrosion, staining). Also, in the case of optical glasses, it is desirable to have negligible air (or gas) bubbles incorporated into the glass structure during fabrication (during shaping for example), negligible stress-induced birefringence, negligible nonlinear properties (unless used specifically due to its nonlinearity), and negligible fluorescence. In all of these cases, negligible implies less than a tolerable quantity within the context of the particular optical application. For example, at a given wavelength and for many glass materials used in optics, n should not vary by more than 10^{-5}, while 10^{-6} is required for certain optics applications in astronomy. In addition, they should have good or reliable manufacturability at an affordable cost. There are various useful optical materials that encompass not only single crystals (such as CaF_2, MgF_2, quartz, sapphire) but also a vast range of glasses (which are supercooled liquids with high viscosity, such as flint and crown glasses as well as fused silica). Higher refractive index materials have more refractive power and allow lens designs that need less curvature to focus light, and hence tend to give fewer aberrations. Flint glasses have a larger refractive index than crown glasses. On the other hand, crown glasses are chemically more stable, and can be produced more to specification. While most optical materials are used for their optical properties (such as in optical transmission), certain *optical* materials (auxiliary materials) are used in optical applications such as mirror substrates and optical spacers for their nonoptical properties, such as their negligible thermal expansion coefficients. Some optical properties of selected optical materials and their applications are listed in Table 3.11.

3.5.3 Optical Glasses

Optical glasses are a range of noncrystalline transparent solids used to fabricate various optical components, such as lenses, prisms, light pipes and windows. Most (but not all) optical glasses are either crown (K) types or flint (F) types. K-glasses are usually soda-lime-silica glasses, whereas flint glasses contain substantial lead oxide; hence F-glasses are denser and have higher refractive powers and dispersions. Barium glasses contain barium oxide instead of lead oxide and, like lead glasses, have high refractive indices, but lower dispersions. There are other high refractive index glasses, such as lanthanum- and rare earth-containing glasses. Optical glasses can also be made from various other glass formers, such as boron oxide, phosphorus oxide and germanium oxide. The Schott glass code or number is a special number designation (511 604.253 for Schott glass K7) in which the first three numbers (511) represent the three decimal places in the refractive index ($n_d = 1.511$), the next three numbers (604) represent the Abbe number ($\nu_d = 60.4$), and the three numbers after the decimal (253) represent the density ($\rho = 2.53\,g/cm^3$). A different numbering system is also used, where a colon is used to separate n_d and ν_d; for example, 517:645 for a particular borosilicate crown means $n_d = 1.517$, $\nu_d = 64.5$ (Sect. 3.5.1).

In the Schott glass coding system, optical glasses are represented by letters in which a last letter of K refers to crown, and F to flint. The first letters usually represent the most important component in the glass, such as P in the case of phosphate. The letters Kz (*Kurz*), L (*leicht*) and S (*schwer*) before K or F represent short, light and dense (heavy) respectively (from German). S after K or F means *special*. Examples include: BK, borosilicate crown; FK, fluor crown; PK,

Table 3.11 The refractive indices, n_d, and Abbe numbers, v_d, (3.98) of selected optical materials (compiled from the websites of Oriel, Newport and Melles-Griot); n_d at $\lambda_d = 587.6\,\text{nm}$, α_L is the linear thermal expansion coefficient

Glasses	Transmission (typical, nm)	n_d	v_d	Applications	Comment
Fused silica	175–2000	1.45846	67.8	Lenses, windows, prisms, interferometric FT-IR components. UV lithography	Synthetic. Has UV properties; transmittance and excellent thermal low α_L. Resistant to scratching
SF 11, flint	380–2350	1.78472	25.76	Lenses, prisms	Flint glasses have $v_d < 50$
LaSFN9, flint	420–2300	1.85025	32.17	Lenses, prisms	High refractive index. More lens power for less curvature
BK7, borosilicate crown	380–2100	1.51680	64.17	Visible and near-IR optics. Lenses, windows, prisms, interferometric components	All around excellent optical lens material. Not recommended for temperature-sensitive applications
BaK1, barium crown	380–2100	1.57250	57.55	Visible and near-IR optics. Lenses, windows, prisms, interferometric components	All around excellent optical lens material. Not recommended for temperature-sensitive applications
Optical crown	380–2100	1.52288	58.5	Lenses, windows, prisms, interferometric components	Lower quality than BK7
Pyrex, borosilicate glass		1.43385	66	Mirrors	Low thermal expansion
Crystals					
CaF_2 crystal	170–7000	1.43385	94.96	Lenses, windows for UV optics, especially for excimer laser optics	Sensitive to thermal shock
MgF_2 crystal	150–7000	$n_0 = 1.37774$ $n_e = 1.38956$		Lenses, windows, polarizers, UV transmittance	Positive birefringent crystal. Resistant to thermal and mechanical shock
Quartz, SiO_2 crystal	150–2500	$n_0 = 1.54431$ $n_e = 1.55343$		UV optics. Wave plates. Polarizers	Positive uniaxial birefringent crystal
Sapphire, Al_2O_3 crystal	150–6000	1.7708 (546.1 nm)		UV–far-IR windows, high power laser optics	High surface hardness, scratch resistant. Chemically inert
Auxiliary optical materials					
ULE SiO_2-TiO_2 glass				Optical spacers	Very small thermal expansion
Zerodur, glass ceramic composite		1.5424	56–66	Mirror substrates. Not suitable for transmission optics due to internal scattering	Ultra-low α_L. Fine mixture of glass and ceramic crystals (very small size)

phosphate crown; PSK, dense phosphate crown; BaLK, light barium crown; BaK, barium crown; BaSK, dense barium crown; SSK, extra dense barium crown; ZnK, zinc crown; LaK, lanthanum crown, LaSK, dense lanthanum crown; KF, crown flint; SF, dense flint; SFS, special dense flint; BaF, barium flint; BaLF, barium light flint; BaSF, dense barium flint; LLF, extra light flint; LaF, lanthanum flint.

Acknowledgments. Authors are grateful to Stephen Karrer O'Leary (University of British Columbia, Okanagan Campus) for many insightful discussions on the subject and his invaluable help in the first edition chapter. This work was supported by the grants LM2015082 and CZ.1.05/4.1.00/11.0251 from the Ministry of Education, Youth and Sports of the Czech Republic.

4. Magnetic Properties: From Traditional to Spintronic

Charbel Tannous, Jacek Gieraltowski

This chapter reviews basic concepts used in the traditional macroscopic magnetism in order to understand current and future developments of submicronic spin-based electronics where interplay of electronic and magnetic properties is crucial. Traditional magnetism is based on macroscopic observation and physical quantities are deduced from classical electromagnetism. Physical interpretations are usually made with reference to atomic magnetism where localized magnetic moments and atomic physics prevail, despite the fact that standard ferromagnetic materials such as Fe, Co, and Ni are not localized-type magnets (they have extended s and localized d electronic states). While this picture might be enough to understand some aspects of traditional storage and electromechanics, it is no longer sufficient for the description of condensed matter systems with smaller length scales progressing toward the nanometer range. The precise nature of magnetism (localized, free, or itinerant like Fe, Co, and Ni transition metals) with simultaneous presence of charge and spin of carriers should be considered. In addition, when we deal with thin films or multilayers as in conventional electronics or with reduced dimensionality objects such as wires, pillars, dots, or grains, magnetic properties are expected to be different from three-dimensional conventional bulk systems.

Digital information technology is based on three major constituents:

- Processing of information (transistors, logic gates, CPU, RAM, digital signal processor (DSP), etc.)
- Communication of information (networks, switches, cables, fibers, antennas, etc.)
- Storage of information (hard disks, CD, DVD, Blu-ray, Flash, etc.).

Traditionally, magnetism has been confined to safe storage at the time of the development of bubble and ferrite core technologies when RAM memory belonged to the realm of magnetism. RAM memory is a special type of information storage called primary (nonpermanent) storage to distinguish it from secondary (permanent) or mass storage such as hard disks, floppies, CDs, DVDs, Blu-rays, Flash, etc.

Presently, magnetism is undergoing a very deep transformation because of several recent developments, among which is the progress toward the nanometer scale in integrated circuits. On that length scale, quantum effects become extremely important, and the spin of carriers becomes of interest since it might be conserved over that length scale and, consequently, can be used to carry and manipulate information.

S. Kasap, P. Capper (Eds.), *Springer Handbook of Electronic and Photonic Materials*, DOI 10.1007/978-3-319-48933-9_4

Moreover, magnetism is endowed with at least two particularly interesting features:

1. The absence of dipolar length scale stemming from the absence of monopoles in contrast with the electrical dipole, which leads to easy adaptation to device scaling.
2. The atomic nature of dynamic response, which is equivalent to being universal and of potentially high speed.

Those properties pave the way toward the fabrication of new integrable and fast devices based on charge and spin (spintronic devices) instead of charge only, like in traditional microelectronics. New types of junctions, transistors, logic gates, sensors, and devices can be built in a way such that magnetism will be able to tackle processing of information along with its storage.

Quantum effects have already delivered many products since they are the basis of the GMR effect (Table 4.1) that underlies the recent surge of extremely higher densities in hard disks; nevertheless they are slated for other deeper developments geared toward the building of the basic parts of the *quantum computer* and *quantum communication* devices. The *quantum computer* is based on the *qubit* or the quantum bit, which is the basic unit of information replacing the classical bit. If we consider a sphere, the classical bit can be viewed as an object with two possible states at the north and the south pole of the sphere, whereas a qubit is an object that can sit anywhere on the surface of the sphere (called the *Bloch sphere*, see *Nielsen* and *Chuang* [4.28]). A quantum computer can do massive parallel computations since quantum mechanics is linear. This means one is allowed at any time to access any superposition of states, in contrast to a classical Von-Neumann-type computer where one has access to only a single state at any time (Table 4.1).

Quantum communications are extremely secure since a caller may build a coherent state with the callee and any intrusion can perturb the coherence, providing a very efficient detection.

From the fundamental point of view, one may start with a single magnetic moment representing a magnetic material and study its behavior before indulging into many interacting moments that are the building blocks of magnetic materials. From an applied point of view, the orientation of the moment (left–right or up–down) defines the value of the bit. Once the orientation of the moment has been linked to a bit value, it becomes

important to understand the physical processes, the energetics, and the dynamics of the moment orientation change (moment reversal from left to right or moment flip from up to down) in order to be able to control, alter, and predict the bit value.

This work is organized as follows. We present the traditional elements of magnetism such as the hysteresis loop, conventional types of magnetism and magnetic materials, proceeding toward a brief description of non conventional magnetism useful for understanding new high-tech materials that will make the backbone of future spintronic and quantum information-based devices. In Sect. 4.3, we describe spintronics in more detail, drawing from analogies with standard electronics and describing magnetic quantum dot arrays with a single application based on magnetic vortex devices in the cylindrical dot case. Table 4.1 contains topical works for readers who are interested in additional information that is briefly mentioned or not covered in this work.

4.1 Traditional Magnetism

Classical magnetism relates to magnetic moments and their behavior under external field or mechanical stress or some other perturbing effect. Basically, one writes an energy for the magnetic moment and tries to understand its behavior with time. In order to describe the different magnetic energy terms that control the behavior of a moment, we can start from a single isolated moment in vacuum, at zero temperature $T = 0\,\mathrm{K}$, zero applied magnetic field ($\boldsymbol{H} = 0$), and zero frequency ($f = 0$). It is obvious that the energy is zero from the classical point of view (quantum mechanically, one might say that even at $T = 0\,\mathrm{K}$, there exist quantum fluctuations that might disorient, flip, or reverse the moment).

The next step is to apply a magnetic field ($T = 0\,\mathrm{K}$, $f = 0$); then we obtain the Zeeman energy $E_Z = -\boldsymbol{M} \cdot \boldsymbol{H}$, with $\boldsymbol{M}$ representing the moment. If we place the moment in an unbounded (infinite sized) crystal, there appears a magnetocrystalline anisotropic energy [4.27] characterized (in the uniaxial case such as cobalt) by a constant K (4.5) since the moment will point in a direction (called an easy axis direction) imposed by the crystal's internal symmetry, in contrast to vacuum where $\boldsymbol{M}$ is free to point in any direction. When the crystal has a set of easy axes (or easy planes), the moment will point in one of several directions (or any direction in one or several planes). This occurs in ferromagnetic materials such as iron or nickel possessing cubic anisotropy.

If the body containing the moment has a finite size, a new energy will appear: the demagnetization energy. Magnetic surface charges (poles) induced on the surface bounding the body create a demagnetizing field inside it (outside, it is called a stray field). The demagnetization energy is also called shape anisotropy energy or magnetostatic energy because it is expressed like anisotropy energy as $2\pi N_{\alpha\beta}\boldsymbol{M}_\alpha\boldsymbol{M}_\beta$, where $N_{\alpha\beta}$ is a set of factors (demagnetization coefficients) that depend on body shape (Einstein summation convention is used for repeated indices). In the ellipsoidal shaped body case, the latter expression is exact.

Now suppose we include several local moments in a material. If sites i and j carrying moments $\boldsymbol{M}_i$ and $\boldsymbol{M}_j$, respectively, are close enough (say less than 1 nm), we have an interaction energy called exchange energy (of electrostatic origin) $-A_{ij}\boldsymbol{M}_i.\boldsymbol{M}_j$ that will align moments $\boldsymbol{M}_i$ and $\boldsymbol{M}_j$ if A_{ij} is positive (ferromagnetic interaction). If A_{ij} is negative, the moments will align antiparallel to each other (antiferromagnetic interaction). In a ferromagnet, we have a nonzero net moment, whereas in an antiferromagnet the net moment is zero.

The above description considers localized magnetism in distinct atoms (such in a gas), ions, molecules, or in special materials (like insulators or rare-earth solid state compounds possessing external shell f electrons with a highly atomic-like character). If we have a conducting material with free electrons interacting with localized atoms/ions/molecules, a different type of magnetism, called itinerant magnetism, appears (e.g., transition metals with s and d electrons or magnetic semiconductors, etc.). Nevertheless, it is possible to extend the notion of magnetic moment to that case accounting for the combined effects of free and localized charges modeled as an effective number of Bohr magnetons (Sect. 4.1.1 and Table 4.1).

The different physical mechanisms and types of magnetism briefly described above operate at different length scales. In order to put things into perspective and ponder about what lies ahead in terms of possible developments and hurdles, the summary in Fig. 4.1 displays different mechanisms, characterization methods, and manufacturing processes along with the corresponding length scale. Note that, on the nanometer scale, device size becomes comparable to most ranges of interactions encountered in magnetic materials and this will trigger development of novel effects and fabrication of new devices (Sect. 4.3).

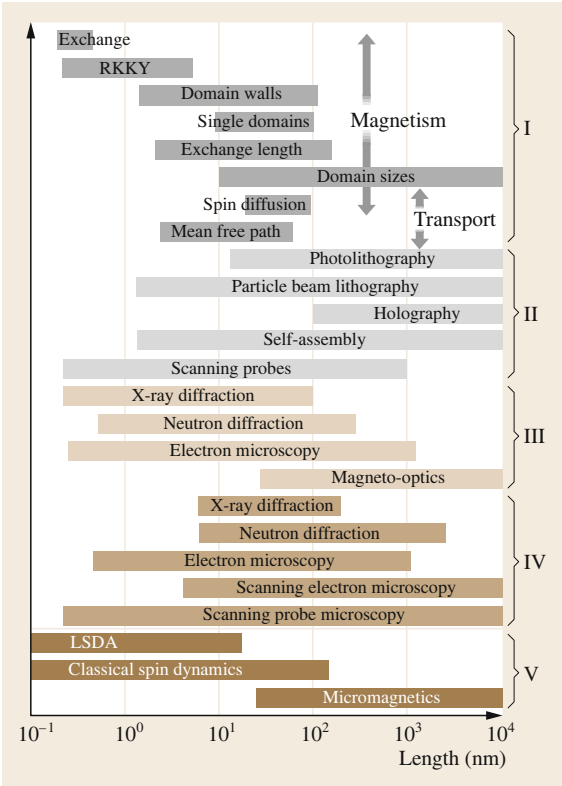

Fig. 4.1 Typical lengths (in nm) encountered in magnetic materials and spintronics with corresponding basic magnetic phenomena. Structures, interactions, and transport are gathered under group I. Group II is for growth and fabrication methods, whereas diagnostic techniques appear under groups III and IV. Group III is for depth-profiling techniques whereas group IV is for surface-probing techniques. Finally, group V is for theoretical analysis and characterization techniques. LSDA (local spin density approximation) is the spin counterpart of the density function theory (DFT) used for traditional band structure calculation. Since most interaction lengths are in the 1−100 nm range, the nanoelectronics device size is comparable to the interaction range. (After [4.29])

4.1.1 Fundamental Magnetic Quantities

Magnetization is the fundamental property exhibited by a magnetic substance originating from its electrons, similar to the electric dipole moment. It can be intrinsic (existing without any external field) or induced by an external magnetic field. In atoms/molecules/ions and rare-earth solids, magnetization is made from individual atomic-like localized magnetic moments. In the solid state, the moment is generally defined from the band structure, and an effective moment can be defined in terms of a Bohr magneton $\mu_B = e\hbar/2m$, the magnetic moment carried by a single electron (e and m are electron absolute charge and mass). Magnetization is a thermodynamic quantity that changes with temperature, mechanical stress, and chemical processes such as alloying [4.30].

Table 4.2 Selected ferromagnetic solids with their saturation magnetization M_s, effective Bohr magneton number n_B, and Curie temperature T_c. (After [4.27])

Substance	M_s (emu/cm^3) at 300 K	M_s (emu/cm^3) at 0 K	n_B at 0 K	Curie T_c (K)
Fe	1707	1740	2.22	1043
Co	1400	1446	1.72	1388
Ni	485	510	0.62	627
Gd	–	2060	7.63	292
Dy	–	2920	10.2	88
MnAs	670	870	3.4	318
MnBi	620	680	3.52	630
CrO_2	515	–	2.03	386
EuO	–	1920	6.8	69

When a field is applied to a magnetic substance, the largest acquired magnetization measured along the direction of the applied field is the saturation magnetization M_s, implying that all moments are aligned parallel to the field. Since temperature T misaligns moments, one defines a $T = 0$ K saturation moment $Nn_B\mu_B$, with N the number of ions atoms or molecules (for a mole $N = N_A$ Avogadro number) and n_B the effective number of Bohr magnetons μ_B. The saturation magnetization M_s value is $N_A n_B \mu_B$ per unit volume (Table 4.2).

n_B is different for atoms/ions/molecules and solids and determined by the electronic state. For example, it is 5 for Fe^{3+} ions (according to Hund rules, see *Jansen* [4.11]) since we have a $3d^5$ atomic configuration (without orbital contribution), whereas for Fe atom it is 2 ($3d^8$ configuration). Trivalent rare earth ions with highly localized 4f orbitals possess magnetic moments determined by $g_J\sqrt{J(J+1)}$, with g_J being the total Landé factor and J the total angular momentum. Transition metal ions possess magnetic moments determined by $2\sqrt{S(S+1)}$ with S being the total spin of the ion (no orbital contribution because of orbital moment quenching, see *Kittel* [4.27]). In the solid state, such as ferromagnetic metals, n_B is determined from the band structure (Table 4.1). In lower dimensions (clusters, dots, thin films, etc.), n_B tends to increase because of lower symmetry and coordination, since high symmetry and coordination tend to decrease it. Among the elements, rare earth ions (Dy^{3+}, Ho^{3+}, and Er^{3+}) possess large values of n_B on the order of 10, whereas in solids, Gd-based garnets [4.16] have n_B on the order of 15 (at $T = 0$ K).

The moment due to an angular momentum is given in the localized case (atoms/ions/molecules) by $-g_L\mu_B L$ (for an orbital angular momentum $\boldsymbol{L}$) with $g_L = 1$ (the orbital Landé factor), or by $-g_S\mu_B S$ (for a spin angular momentum $\boldsymbol{S}$) with $g_S = 2$ (the spin Landé factor). In the case of an atom/ion with a total angular momentum $\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S}$, the moment is given by $-g_J\mu_B J$ with

$$g_J = \frac{3}{2} + \frac{[S(S+1) - L(L+1)]}{[2J(J+1)]} \tag{4.1}$$

the total Landé factor. In the solid state, the Landé factor is determined from the band structure (spin splitting of electron or hole bands in the presence of a magnetic field). It may become negative, anisotropic (tensor), and depends on wavevector $\boldsymbol{k}$. In semiconductors such as InSb: $g = -44$, GaAs: $g = 0.32$, InAs: $g = -12$ at wavevector $\boldsymbol{k} = 0$ [4.11, 21].

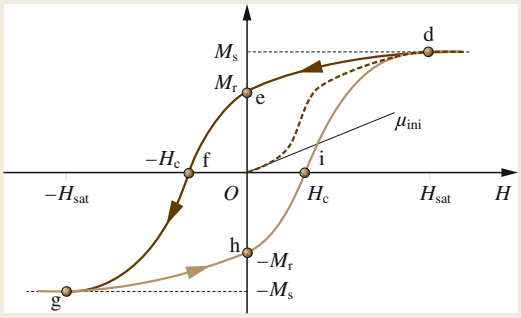

Fig. 4.2 Hysteresis loop with the fundamental points in the $\boldsymbol{M}$–$\boldsymbol{H}$ plane such as saturation magnetization M_s, remanent magnetization M_r, coercive field H_c (at which $M = 0$), and the saturation field $\boldsymbol{H}_{sat}$ (for which $M = M_s$). For a virgin (unmagnetized) material, the initial magnetization curve (*dashed line*) with permeability μ_{ini} are displayed. (After [4.31])

4.1.2 The Hysteresis Loop

When a magnetic field is applied to a ferromagnetic material [4.27], a magnetization change takes place. The best way to understand the underlying phenomena is to plot the value of the magnetization $\boldsymbol{M}$ projected along the direction of the applied field $\boldsymbol{H}$. The locus of the magnetization $\boldsymbol{M}$ measured along the direction of the applied magnetic field $\boldsymbol{M}(\boldsymbol{H})$ versus the field and depicted in the $\boldsymbol{M}$–$\boldsymbol{H}$ plane is the hysteresis loop. The term hysteresis means that when the material is field cycled (i. e., the field $\boldsymbol{H}$ is increased then decreased), two different nonoverlapping curves $\boldsymbol{M}(\boldsymbol{H})$ are obtained. Another point of view involves rather the induction $\boldsymbol{B}$ versus $\boldsymbol{H}$ since it is $\boldsymbol{B}$ that is, in fact, measured. Several points in the $\boldsymbol{M}$–$\boldsymbol{H}$ plane (Fig. 4.2) are worth mentioning. Point d is where the magnetization reaches its largest value M_s (saturation magnetization). Points i and f denote the magnetic fields $\pm H_c$ for which the magnetization is zero. Magnetic field H_c is called the coercive field. It is large for hard materials and small for soft magnets. Points e and h denote remanent magnetization M_r, that is, the leftover magnetization after the applied field is switched off, thus it is the hallmark of permanent magnets.

The ratio M_r/M_s, called squareness, is close to 1 when the applied magnetic field is close to the easy axis and therefore the hysteresis loop is squarer. Once the easy axis (or set of easy axes) is determined, the angle between the easy axis and the magnetic field (say ϕ) is varied and the hysteresis loop is graphed for different angles. When the angle ϕ is increased, the opening of the hysteresis loop is reduced; it is largest when the magnetic field is most parallel to the easy axis and smallest when the magnetic field is most parallel to the so-called hard axis. As shown in Fig. 4.3, characteristics of the hysteresis loop are depicted and for a given temperature and frequency of the applied field H, quantities

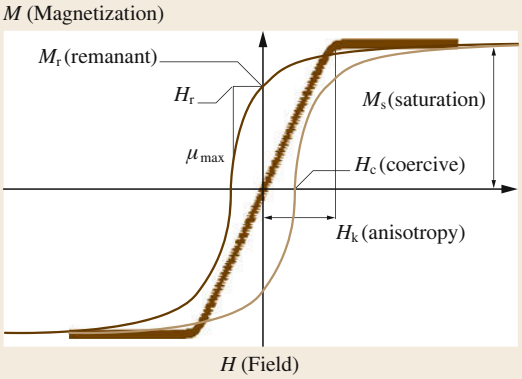

Fig. 4.3 Hysteresis loop obtained for an arbitrary angle ϕ, between the magnetic field and the anisotropy axis (easy axis). Associated quantities such as coercive field H_c, remanent magnetization M_r, and field H_r (given by the intersection of the tangent to the loop at $-H_c$ and the M_r horizontal line) are shown. The tangent to the loop at $-H_c$ is called maximum differential permeability μ_{max}. The *thick line* is the hysteresis loop when the field is along the hard axis and (the anisotropy field H_k) is the field value at the slope break where the magnetization reaches its saturation value M_s. Quantities such as H_c, H_r, M_r, and μ_{max} depend on the angle ϕ. When the field is along the easy axis, the coercive field reaches its largest value (the hysteresis loop is broadest) at which the magnetization jumps (at $\pm H_c$)

such as the remanent magnetization M_r, the remanent field H_r, the coercive field H_c, and the maximum differential permeability μ_{max} all vary with angle ϕ.

In addition, when the temperature varies or the frequency of the field is varied, the hysteresis loop changes and might even disappear altogether above a given temperature (Curie temperature) or be seriously altered by the frequency of the field (see below).

Magnetization Process Point of View

When a magnetic field is applied to a material, a magnetization process is initiated. That means a magnetization change can occur taking any of the following routes. At low applied magnetic fields (and low frequencies), domain boundaries bulge (this is a reversible regime implying that if we decrease the field again, the magnetization will go back to the initial state following the same path). This is called domain nucleation (high-slope path) or pinning process (small slope path). At higher fields, the walls are depinned and free to move. This is an irreversible regime (in contrast to the low field case) meaning that if we decrease the field, the magnetization versus field variation will not follow the same path. This regime corresponds to free domain wall movement. At higher fields (or frequencies), magnetization changes through moment rotation and thus we have two possibilities: if the material is homogeneous, all happens as if we had a single moment in the material. This is the coherent rotation regime (well described by the Stoner–Wohlfarth model, see Table 4.1). On the other hand, if magnetization changes in a nonuniform way (different points in the sample undergo different magnetization changes), we have a curling process. Finally, if the magnetic field is applied along the anisotropy axis (also called the easy axis) and suddenly reversed, the magnetization change is referred to as a switching process. This means the moment jumps from one value to its negative without any rotation process since magnetization is already along the easy axis (Fig. 4.4).

Energetic Point of View

Hysteretic behavior can be viewed as stemming from the motion of the energy minimum versus field. In Fig. 4.5, the field is cycled in a clockwise fashion. The energy minimum is displayed for several values of the field. Hysteresis is shown to arise from the asymmetric behavior of the energy versus magnetization as the field is cycled. Hysteresis loss is given by the area circumscribed by the hysteresis loop. Since soft materials have thinner hysteresis loops (equivalent to smaller coercivity) with respect to hard materials, their losses are smaller.

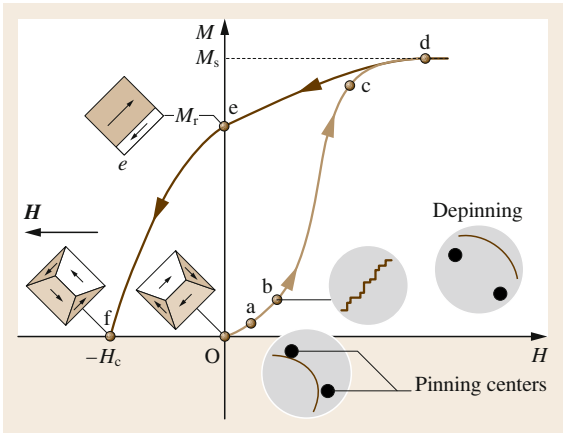

Fig. 4.4 Reversible and irreversible motion of the magnetization M with the field H. For small fields, $H < H_c$ and initial magnetization, Rayleigh's law is valid along a–b but for large H, saturation in M is induced by irreversible domain boundary motion along b–c, followed by rotation of magnetization along c–d. When the field is reversed along d–e–f toward $-H_c$, magnetization motions are not exactly those we had previously, and this is why a different $M(H)$ curve is obtained. Reversible movement at a low field means that domain walls are pinned by impurities and simply bulge under the action of H (0–a), whereas jerky irreversible movement is associated with depinning of the domain walls (a–b), creating Barkhausen noise. Free irreversible movement beyond pinning centers is depicted (*right*). (After [4.31])

Signal Processing Point of View

Consider a time-dependent applied field $\boldsymbol{H}(t)$ as an input signal to the magnetic material and the magnetization $\boldsymbol{M}(t)$ as the output. Then relation $\boldsymbol{M}(t) = \boldsymbol{F}(\boldsymbol{H}(t))$ pertains to a nonlinear filter. A magnetic material acts as a nonlinear filter since $\boldsymbol{M}$ is not proportional to $\boldsymbol{H}$ except at very low fields. A simple illustration of nonlinearity is to observe $\boldsymbol{M}(t)$ as a square signal with a sinusoidal input excitation $\boldsymbol{H}(t)$ (Fig. 4.6). In addition, the material imposes a propagation delay to the signal proportional to the width of the hysteresis loop (twice the coercive field). Hysteretic behavior means that different values of the output are obtained when input excitation is varied (increasing or decreasing). This is generally exploited in control and power systems, for instance.

Information Storage Point of View

Since hysteresis means that different output behavior is observed as the input is increased or decreased, this implies that one obtains a nonzero response ($\boldsymbol{M} \neq 0$) at zero excitation ($\boldsymbol{H} = 0$) called remanence (with value M_r when $\boldsymbol{H} = 0$). The major advantage of remanence

(in addition to its usefulness in permanent magnets) is that information (value of M_r) is stored without any excitation source ($\boldsymbol{H} = 0$). Getting M_r when the signal is decreased (say M_{r1}), we ought to have a different M_r when the signal is increased (say M_{r2}) because of hysteresis. Thus we have a bit value (0 for M_{r1} and 1 for M_{r2}). This contrasts sharply with (non-Flash) electronic storage where a voltage has to be maintained in order to keep the charge (representing information) in place (Chap. 49).

Electromagnetic Compatibility and Frequency Synthesis Point of View

Hysteretic behavior can be viewed as a flux ϕ (corresponding to magnetization $\boldsymbol{M}$) induced in a circuit with an exciting current $i(t)$ at time t (corresponding to field H). The resulting relationship $\phi[i(t)]$ is a nonlinear characteristic that can be expanded as

$$\phi[i(t)] = a_0 + a_1 i(t+\tau) + a_2[i(t+\tau)]^2 + a_3[i(t+\tau)]^3 + a_4[i(t+\tau)]^4 + \cdots , \tag{4.2}$$

where τ accounts for the response delay of the flux (the larger the delay, the broader the hysteresis curve). Ordinary linear inductance of the circuit corresponds to first derivative $[\mathrm{d}\phi/\mathrm{d}i]$ that equals a_1 for a short delay τ. Higher order terms define a nonlinear inductor behavior such that (for a short delay)

$$L(i) = a_1 + 2a_2 i + 3a_3 i^2 + 4a_4 i^3 + \cdots . \tag{4.3}$$

A nonlinear inductor response is interesting in itself from the frequency synthesis point of view since it can generate harmonics and subharmonics off the exciting current $i(t)$ (see, for instance, *Chua* [4.32]).

Time-Dependent Point of View

In spite of different points of view describing hysteresis, some experimentally observed phenomena cannot be explained with the above, such as a particularly important phenomenon known as the magnetic after-effect. Experimentally, one observes a magnetization change with time $\boldsymbol{M}(t)$, despite the fact that the applied field H is kept constant in time, implying a time-dependent hysteresis loop stemming solely from $\boldsymbol{M}(t)$ (Fig 4.7). Therefore, the material must contain units (single domain grains) that respond differently in time, as if each unit had its intrinsic delay; thus magnetization might be written in the form $M(t) = M_0 S(t) \ln(t)$, where $S(t)$ is called the magnetic viscosity. If the response time of each grain is considered of the thermal activation

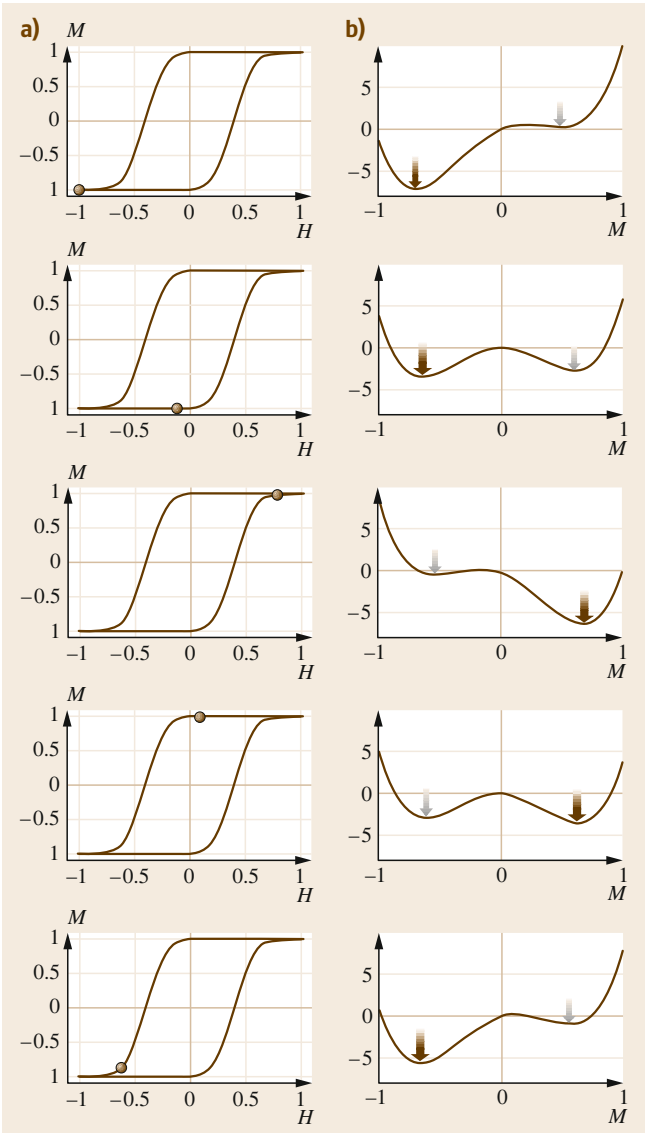

Fig. 4.5 Hysteresis loop (a) and energy as a function of magnetization (b). When field H is varied in the hysteresis loop (indicated by the *round spot*) in a clockwise fashion, the energy changes its form and its absolute minimum indicated by the *thick arrow* moves accordingly. Hysteresis is due to asymmetric energy behavior as the field is cycled

type, that is, following the Néel–Arrhenius formula (Chap. 49) $\tau = \tau_0 \exp(\Delta E/k_B T)$, where τ_0 is an attempt time to cross some energy barrier ΔE (Fig. 4.5) at a temperature T, then after-effect implies that we have a distribution of τ_0 and ΔE values. Calling the corresponding probability density function $g(\tau)$ and M_0 some scale initial magnetization, $\boldsymbol{M}(t)$ is consequently

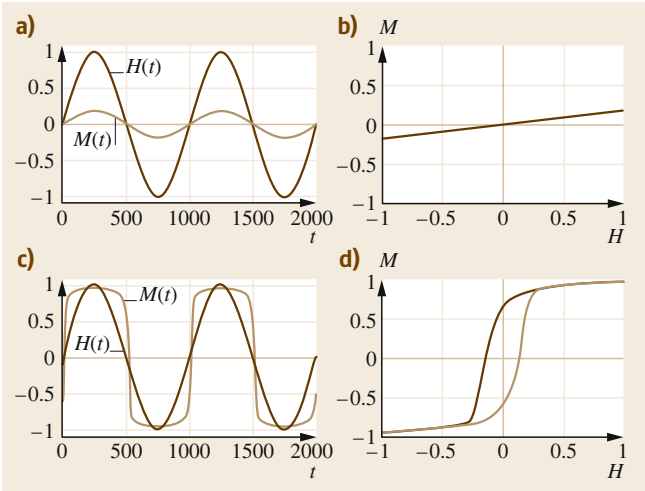

Fig. 4.6a–d Hysteresis loop as an input–output relationship. **(a,c)** The magnetic field $H(t)$ and magnetization $M(t)$ are displayed explicitly as functions of time t. **(b,d)** Resulting input–output relationship (***M*–*H*** characteristic) parametric curve $M(H)$. In **(a,b)** we have an output ($M(t)$), undelayed and proportional to the input $H(t)$ resulting in a paramagnetic (no hysteresis) ***M*–*H*** characteristic. **(c,d)** is an output $M(t)$, delayed and nonlinearly distorted version of the input $H(t)$ resulting in a hysteretic characteristic ***M*–*H***. (After [4.33])

defined as

$$M(t) = M_0 \int_0^\infty g(t) \exp\left(-\frac{t}{\tau}\right) \mathrm{d}\tau \,. \qquad (4.4)$$

In the simple case where we have a single response time τ^*, that is, $g(\tau) = 2\delta(\tau - \tau^*)$, $\boldsymbol{M}(t)$ behaves as $\boldsymbol{M}(t) = M_0 \exp(-t/\tau^*)$.

After analyzing different aspects of the hysteresis loop, we move on to tackle physical processes affecting magnetization behavior. Let us start with small magnetic fields $H < H_c$ with respect to the coercive field. The initial magnetization curve follows Rayleigh's law: $M(H) = \chi_0 H + \alpha_R H^2$, where χ_0 is the low-field susceptibility and α_R the Rayleigh coefficient. Since this law is valid for small fields, it describes the reversible motion of the magnetization.

We move next to description of a domain, which is some physical region inside a material where the magnetization is oriented along some direction.

Typically, when the extent of the material is smaller than the exchange length, one expects a single-domain structure (that contains about 10^{12}–10^{18} atoms, see also Fig. 4.1).

In magnetic materials described by a uniaxial anisotropy K, the expression of the exchange length is $\ell_{ex} = \sqrt{A/K}$ with A being the exchange stiffness constant (typically, $A \approx 10^{-6}$ erg/cm). In soft materials with anisotropy constant $K \approx 0$, the magnetostatic exchange length is used. It is defined as

$$\ell_{ex} = \sqrt{\frac{A}{2\pi M_s^2}}$$

given the magnetostatic energy density is $2\pi M_s^2$.

For instance, a recording medium is considered as being made of small grains made of single domains. As the recording density is increased, the grain size making the recording media decreases and if it is small enough, its magnetization becomes sensitive to thermal energy, that is, it can flip or reverse simply by the effect of temperature. This is called the superparamagnetic effect that traditionally limits longitudinal recording to 100 Gbit/in^2 and (current) perpendicular recording to 1 Tbit/in^2. It was partially solved recently through the introduction of antiferromagnetic coupling between the storage layer and a stabilization layer. Practically, a thin film of ruthenium (7–9 Å thick) is deposited between the storage layer and the stabilization layer (Chap. 49). If the extent of the magnetic material is large, one expects to have a multidomain structure separated by domain walls. A multidomain structure emerges in order to minimize the magnetostatic long-range dipolar interaction energy between the different moments existing in the different domains [4.34].

Since a domain is a piece of a material with the magnetization along a given direction, generally a magnetic material contains many regions where the magnetization is along some direction in order to minimize the magnetostatic energy. Regions with different magnetization orientations can be close to one another, albeit with a boundary called a domain wall (typically containing about 10^2–10^3 atoms, see Fig. 4.1). Saturation occurs when all these regions align along some direction imposed by the external applied field. The domain wall width (in CGS units) is equal to $\pi\sqrt{A/K}$, where A is the typical (nearest neighbor) exchange stiffness and K the typical uniaxial anisotropy (Sect. 4.1.3). It results from competing exchange and anisotropy energies. It is thinner for higher anisotropy or smaller exchange (in Fe it is about 30 nm, whereas in a hard material such as $Nd_2Fe_{14}B$, it is only 5 nm). Its energy is equal to $4\sqrt{AK}$. For bulk materials, it is of the Bloch type, whereas for thin films (i. e., with thickness on the order of the exchange length) it is of the Néel type (Fig. 4.8), again with a width proportional to exchange length $\sqrt{A/2\pi M_s^2}$. A single parameter $Q = 2K/M_s^2$ allows us to discriminate between simple ($Q < 1$) and complex wall profiles ($Q > 1$) [4.35].

During a magnetization process, the irreversible jerky movements of domain walls due to local instabil-

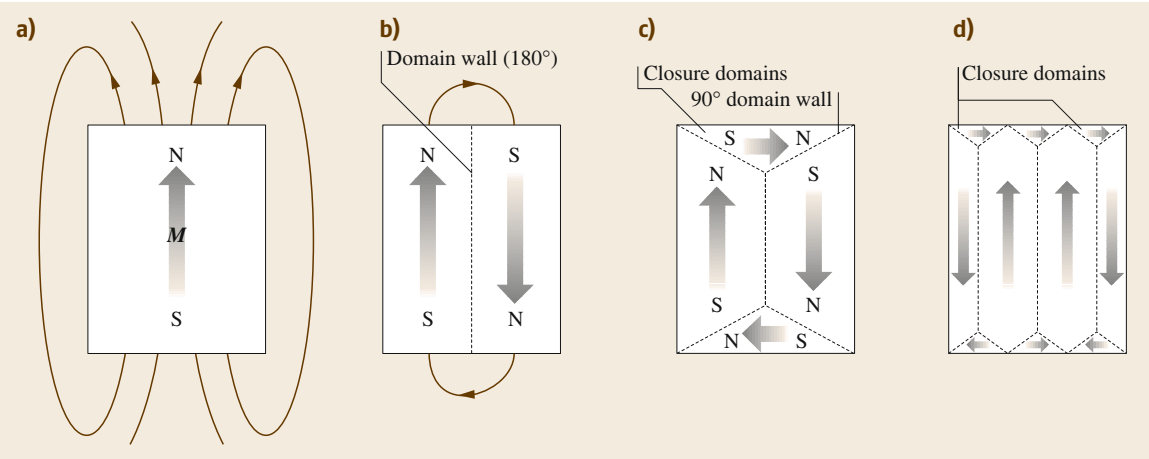

Fig. 4.7a–d Possible domain structures and wall structure in a magnetic material. **(a)** Initial magnetic configuration with a large stray field (outside the material). **(b)** In order to reduce magnetostatic energy (and stray field), domains form, as in a highly anisotropic material. If n domains are formed, the magnetostatic energy is reduced by n. (After [4.27]) **(c)** In a material with small anisotropy, 45° closure domains are formed to minimize the magnetostatic energy. **(d)** As more domains are formed, more walls are also formed until a compromise is reached since it is necessary to minimize the sum of the magnetostatic energy and wall energies. (After [4.31])

ities created by impurities, defects, inclusions, or interactions between domain walls lead to Barkhausen noise in a hysteresis loop cycle. In devices, it is preferred to induce magnetization change by rotation processes (implying that the external magnetic field must be applied along hard axis) that are less noisy.

4.1.3 Intrinsic Magnetic Properties of a Material

The induction $\boldsymbol{B}$ in a linear isotropic material is related to $\boldsymbol{H}$ through the relation $\boldsymbol{B} = \mu_0(\boldsymbol{H} + \boldsymbol{M})$, where μ_0 is the free space permeability and $\boldsymbol{M}$ is the magnetization of the material. Using the relation $\boldsymbol{M} = \chi \boldsymbol{H}$ relating the magnetization to the applied field, one gets $\boldsymbol{B} = \mu_0(1 + \chi)\mathbf{H}$. This leads to the definition of the total permeability $\mu = \mu_0(1 + \chi)$, which yields the constitutive relation $\boldsymbol{B}(\boldsymbol{H}) = \mu \boldsymbol{H}$. The quantity χ is called the susceptibility. In general, nonlinear material possesses nonlinear constitutive equations $\boldsymbol{M}(\boldsymbol{H})$ and $\boldsymbol{B}(\boldsymbol{H})$. A constitutive relation is like the $I(V)$ characteristic of an electronic device. For a linear material, the permeability μ is generally frequency dependent. If losses occur during propagation of an electromagnetic wave in a material resulting from the absorption of magnetic energy, it is possible to extend the definition of permeability to the complex plane (like in dielectrics). Losses are attributed to peaks in the imaginary part of the permeability at the absorption frequencies [4.12]. At low frequencies, losses are attributed to domains, whereas at high frequencies, losses are attributed to

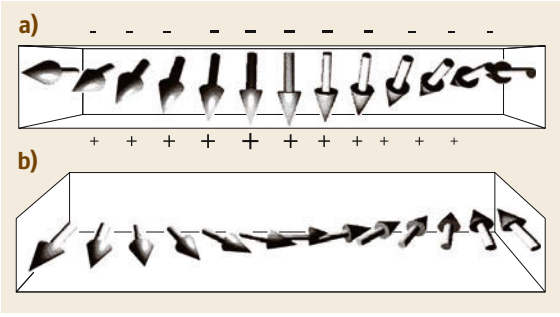

Fig. 4.8a,b Possible domain wall shapes in a magnetic material. **(a)** Bloch type for bulk materials with the magnetization rotating in a vertical plane with the associated poles. **(b)** Néel type for thin films. For these walls, the magnetization rotates in a horizontal plane when the width of the film is smaller than the exchange length. (After [4.36])

rotation processes. Since permeability relates the two vector quantities $\boldsymbol{B}$ and $\boldsymbol{H}$, in a linear anisotropic material (such as a linear crystal), the relation $\boldsymbol{B}(\boldsymbol{H}) = \mu \boldsymbol{H}$ becomes $\boldsymbol{B}_\alpha = \mu_{\alpha\beta}\boldsymbol{H}_\beta$ (Einstein summation convention) and $\mu_{\alpha\beta}$ is a rank-2 ($r = 2$) permeability tensor that has different components according to the relative directions of $\boldsymbol{B}$ and $\boldsymbol{H}$ (nine components in total or 3^r in three dimensions). For a nonlinear anisotropic material, we have $\mu_{\alpha\beta} = \partial B_\alpha / \partial H_\beta$.

When a material is run through a field cycle (hysteresis loop) for the first time, the magnetization $\boldsymbol{M}$ follows a path different from the above $\boldsymbol{M}(\boldsymbol{H})$ lines. That path represents the initial magnetization and the associ-

ated permeability is the initial permeability (Fig. 4.2). If a magnetic material is subjected to a static magnetic field $\boldsymbol{H}$ and a small time-dependent field $\boldsymbol{H}(t)$ (alternating at frequency f) parallel to $\boldsymbol{H}$, the magnetic response is called the longitudinal permeability (at frequency f). This kind of excitation is encountered in ferromagnetic resonance (FMR) problems [4.16].

Alternatively, one may describe magnetic behavior in terms of susceptibility. It relates the magnetization to the applied field in a linear material through $\boldsymbol{M} = \chi\boldsymbol{H}$. For a nonlinear isotropic material, we have $\chi = \partial M/\partial H$ and for a nonlinear anisotropic material, we have $\chi_{\alpha\beta} = \partial M_\alpha/\partial H_\beta$ with the $\boldsymbol{M}$ component along direction α and the $\boldsymbol{H}$ component along β. Any jump in χ signals an important magnetic change in the material. When the temperature is decreased, the Curie temperature signals the onset of ferromagnetic order from paramagnetic disorder, and the Néel temperature signals the onset of antiferromagnetic order from paramagnetic disorder. Magnetic susceptibility spans several orders of magnitude (from about 10^{-5} to $10^6\,\mathrm{cm}^3/\mathrm{mol}$).

The magnetization settles along a direction in order to minimize the sum of the magnetic anisotropy energy and the Zeeman energy provided by the applied field. Since the hysteresis loop changes its shape as we vary the applied field angle, it might reach its largest width for some angle. The field then indicates the easy axis direction, also called the anisotropy axis. The extreme value of the magnetic field is the coercive field $\pm H_\mathrm{c}$ at which the magnetization (switches) jumps to its saturation value $\pm M_\mathrm{s}$ (Fig. 4.9).

When the field is along the hard axis direction, it takes a longer time to align the magnetization slowly by rotation, in sharp contrast to fast switching that occurs when the field is along the easy axis direction. It is easily determined with the hysteresis loop when it is narrowest as the angle of the applied field is varied. At slope break we have the value of the anisotropy field $\pm H_\mathrm{K}$ (Fig. 4.10).

Crystals are generally anisotropic because their microscopic structure is not the same along different directions. Hence, different properties will show up along different orientations of the crystal. Magnetic properties are no special case, and there are special preferred directions along which the magnetization will point. This means there exists some energy contribution that will be minimized when the magnetization settles along these directions. This is the anisotropy energy. On top of being inherent to crystal structure, anisotropy can also be induced by an external field, a change of symmetry (e.g., surface with respect to bulk), or a mechanical deformation. Microscopically, anisotropy originates from spin–orbit coupling. Coercivity increases with anisotropy, that is, hardness increases with anisotropy (Fig. 4.11). Anisotropy energy can be evaluated from the hysteresis loop by determining the loop for various angles between the applied field and the easy axis. In general, it is an expansion of the form

$$\sum_{\alpha,\beta} K_{\alpha\beta} m_\alpha m_\beta + \sum_{\alpha,\beta,\gamma,\delta} K_{\alpha\beta\gamma\delta} m_\alpha m_\beta m_\gamma m_\delta \cdots , \tag{4.5}$$

where $K_{\alpha\beta}, K_{\alpha\beta\gamma\delta}$ are the anisotropy coefficients (second and fourth-order, respectively) and the coefficients m_α, m_β, $m_\gamma, \ldots$ are the components of $\boldsymbol{M}/M_\mathrm{s}$, the magnetization $\boldsymbol{M}$ normalized by the saturation magnetization M_s. α, β, γ are the indices along the crystal x, y, z axes. This means the norm of $\boldsymbol{m}$,

$$|\boldsymbol{m}| = \sqrt{[m_\mathrm{x}^2 + m_\mathrm{y}^2 + m_\mathrm{z}^2]} = 1 .$$

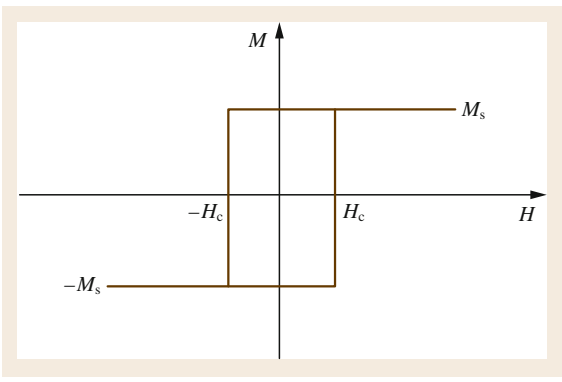

Fig. 4.9 Easy axis hysteresis loop. When the magnetic field is along the anisotropy axis (easy axis) of the material, the hysteresis loop is broadest, and the magnetization jumps (switches) to $\pm M_\mathrm{s}$ at the coercive field $\pm H_\mathrm{c}$

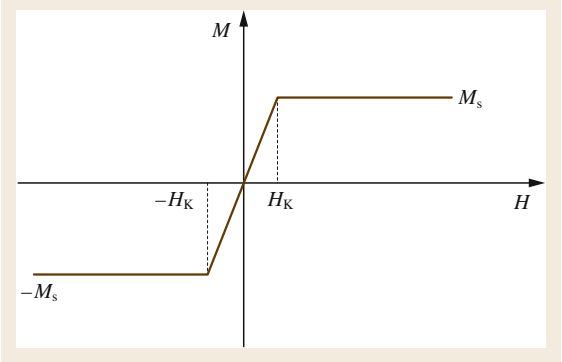

Fig. 4.10 Hard axis hysteresis loop. When the magnetic field is along the hard axis of the material, the hysteresis loop is the thinnest and the magnetization rotates smoothly from a value to another between $\pm H_\mathrm{K}$ the anisotropy field

Uniaxial and Biaxial Anisotropies

Anisotropy energy in the case of crystals with a single dominant axis such as hexagonal (like cobalt), tetragonal, and rhombohedral crystals is called uniaxial. To the lowest approximation, it is given by $K_1 \sin^2\theta$, where K_1 is the anisotropy strength, angle θ being the angle between the magnetization and the easy axis. The next higher approximation allows fourth-order terms to be added to the $K_1 \sin^2\theta$ term. In hexagonal crystals, the fourth-order term is of the form $K_2 \sin^4\theta$. Rhombohedral symmetry allows two fourth-order terms of the form $K_2 \sin^4\theta + K_4 \cos\theta \sin^3\theta \cos 3\phi$. In tetragonal crystals, the fourth-order terms are of the form $K_2 \sin^4\theta + K_4 \cos\theta \sin^4\theta \cos 4\phi$. The easy axis is taken along the z-axis, the angle ϕ is the magnetization polar angle in the x–y plane, and θ is the azimuthal angle.

Anisotropy energy in the case of crystals with two dominant axes such as monoclinic, triclinic, and orthorhombic crystals is called biaxial. It also means that two anisotropy directions exist and are competing. Some other cases are given below (see also Table 4.1 for other definitions).

Cubic Anisotropy. Anisotropy energy in the case of the most symmetric crystals, cubic crystals, is called as such because it relates to the cube's axes. The energy to fourth order is

$$K_1(m_1^2m_2^2 + m_1^2m_3^2 + m_2^2m_3^2) + K_2m_1^2m_2^2m_3^2 \,,$$

where the coefficients m_1, m_2, m_3 are the components of the normalized magnetization $\boldsymbol{M}/M_\mathrm{s}$ with respect to the crystal axes. That is $m_1 = \sin\theta\cos\phi$, $m_2 = \sin\theta\sin\phi$, $m_3 = \cos\theta$. The easy axis, as above, is taken along the z-axis and the angle ϕ is the polar angle in the x–y plane.

Shape Anisotropy. A finite-size magnetic body (ellipsoidal shape is assumed for simplicity) possessing a single uniform magnetization $\boldsymbol{M}$ (represented by its components $\boldsymbol{M}_\alpha$) contains a magnetic energy (also called magnetostatic energy) given by $2\pi N_{\alpha,\beta}\boldsymbol{M}_\alpha\boldsymbol{M}_\beta$ (Einstein summation). The $N_{\alpha\beta}$ coefficients are the demagnetization (akin to depolarization) coefficients of the body determined by its shape. The origin of the terminology is due to the resemblance to the familiar anisotropy energy of the form $K_{\alpha\beta}\boldsymbol{M}_\alpha\boldsymbol{M}_\beta$ (Einstein summation). If a magnetic material contains N moments (atoms, ions, or molecules each carrying a moment $\boldsymbol{\mu}_i$, the energy originating from dipolar coupling energy between the different moments is written as

$$W_\mathrm{dip} = \frac{1}{2}\sum_{i=1}^{\mathrm{N}}\sum_{j=1}^{\mathrm{N}} \frac{\boldsymbol{\mu}_i\cdot\boldsymbol{\mu}_j}{r_{ij}^3} - 3\frac{(\boldsymbol{\mu}_i\cdot\boldsymbol{r}_{ij})(\boldsymbol{\mu}_j\cdot\boldsymbol{r}_{ij})}{r_{ij}^5} \,. \quad (4.6)$$

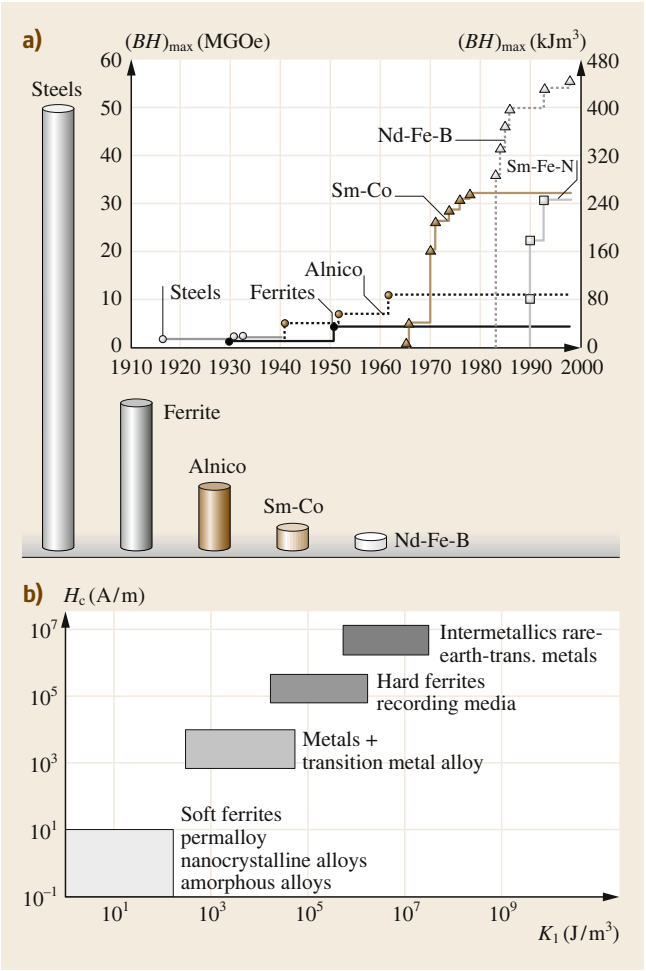

Fig. 4.11 **(a)** Development of hard materials for permanent magnets indicated by the value of the energy density $(BH)_\mathrm{max}$. Below progress is indicated by equivalent volume change with fixed energy density. **(b)** Correlation between coercivity H_c and anisotropy coefficient K_1 for various materials, their magnetic hardness, and corresponding applications. (After [4.17, 24])

where $\boldsymbol{\mu}_i$ and $\boldsymbol{\mu}_j$ are two moments ($i \neq j$) in the material separated by a distance r_{ij}. This energy can be represented by constant coefficients ($N_{\alpha\beta}$) only in the case when the body has an ellipsoidal shape. Hence one can write

$$W_\mathrm{dip} \approx 2\pi N_{\alpha\beta}\boldsymbol{M}_\alpha\boldsymbol{M}_\beta \qquad \text{(Einstein convention)}$$

where the single magnetization $\boldsymbol{M}$ is the sum of all individual moments $\boldsymbol{\mu}_i$.

Surface Anisotropy. A finite-size magnetic body with a not too large bulk anisotropy will have a reorientation of the magnetization close to its surface in order to min-

imize the magnetostatic energy. This can be described by a surface anisotropy that is different from the bulk one. It originates from an abrupt change of symmetry at the interface between the bulk and free surface.

Helical Anisotropy. In a magnetic wire, the magnetization may prefer to lie radially in a plane perpendicular to the wire axis. This is the case of a radial easy axis (radial anisotropy). If it lies in the circumferential direction along the tangent to circles in the plane perpendicular to the wire axis, then we have circular anisotropy. However, if it lies in a plane tangent to the lateral surface of the wire (parallel to the wire axis) and making some angle different from 0° or 90° with any plane perpendicular to the wire axis, then we have helical anisotropy.

Anisotropy from Demagnetization

Demagnetization energy is expressed with coefficients that describe the demagnetization field $\boldsymbol{H}_\mathrm{d}$ inside a finite-size material and created by the bulk magnetization against an applied external magnetic field. The components of the demagnetization field (in the ellipsoidal case) are given by (with Einstein summation) $[\boldsymbol{H}_\mathrm{d}]_\alpha = -2\pi N_{\alpha\beta}\boldsymbol{M}_\beta$ (it is much like the depolarization field in the electrical case). The constant coefficients' ($N_{\alpha\beta}$) representation is valid only in the case the body has an ellipsoidal shape. The coefficients depend on the geometry of the material. Usually one has three positive coefficients along three orthogonal directions (N_{xx}, N_{yy}, N_{zz}) (assuming that the off-diagonal terms are all 0) for simple geometries such as wires, disks, thin films, and spheres. All three coefficients are positive and smaller than 1, and their sum is equal to 1. For a sphere, all three coefficients are equal to 1/3. For a thin film (or a disk), they are given by (0,0,1) if the z-axis is perpendicular to the film (or the disk) lying in the x–y plane. For an infinite length cylindrical wire with its axis lying along the z direction, the values are (1/2,1/2,0).

4.1.4 Traditional Types of Magnetism and Classes of Magnetic Materials

The main traditional types of magnetism are:

- Ferromagnetism
- Antiferromagnetism
- Ferrimagnetism
- Paramagnetism
- Diamagnetism.

However, a larger number of types are given in the review by *Hurd* [4.26] and with promising advances in materials research, we expect new emerging classes as described in Sect. 4.2 of this work dedicated to non conventional magnetic types (Table 4.1).

A ferromagnet is an assembly of magnetic moments interacting with a positive exchange integral that will minimize their energy by adopting a common parallel configuration with a net large value of the total magnetization. Such a definition is valid for localized magnetism and not for itinerant ferromagnets (such as Fe, Ni, and Co transition metals) since one does not have distinct localized moments to define an exchange integral. A ferromagnetic material (itinerant or localized) displays a characteristic hysteresis curve and remanence ($\boldsymbol{M} \neq 0$ for $\boldsymbol{H} = 0$) when one varies the applied magnetic field. When heated, the material loses, in general, this ordered alignment and becomes paramagnetic at the Curie temperature. Ferromagnets are usually metallic; however there are ferromagnetic insulators such as $CrBr_3$, EuO, EuS, and garnets [4.27, 37].

An antiferromagnet is made of an assembly of magnetic moments interacting with a negative exchange integral that will minimize their energy by adopting an antiparallel configuration. Again, such a definition is not valid for itinerant antiferromagnets (such as Cr and Mn transition metals) since one does not have distinct localized moments; thus an exchange integral cannot be defined. The net total magnetization is zero and, therefore, we do not have hysteresis. In the localized magnetism case, it is possible to consider the entire crystal as being made of two interpenetrating sublattices containing moments all parallel inside each sublattice but with the total magnetization of each sublattice opposite to one another. When heated, the material loses, in general, this alternately ordered alignment and becomes paramagnetic at the Néel temperature. Oxides are generally antiferromagnetic insulators except EuO [4.31, 37].

The intermediate order between ferro and antiferromagnets is a ferrimagnet used in microwave devices [4.16]. In the localized case, one considers the crystal as being made of two sublattices, as in the case of an antiferromagnet, with total magnetizations opposing one another. The magnitude of each magnetization is different, resulting in a net total magnetization (called uncompensated case) in contrast to an antiferromagnet.

Another intermediate case is a canted antiferromagnet, also called a weak ferromagnet. This is an assembly of magnetic moments alternating in direction and making a small inclination (canting). The small angle (Fig. 4.12d) between two neighboring moments $\boldsymbol{M}_i, \boldsymbol{M}_{i+1}$ results in a small ferromagnetic moment yielding weak ferromagnetism.

Canting originates from the Dzyaloshinski–Moriya exchange interaction, which is a vectorial exchange

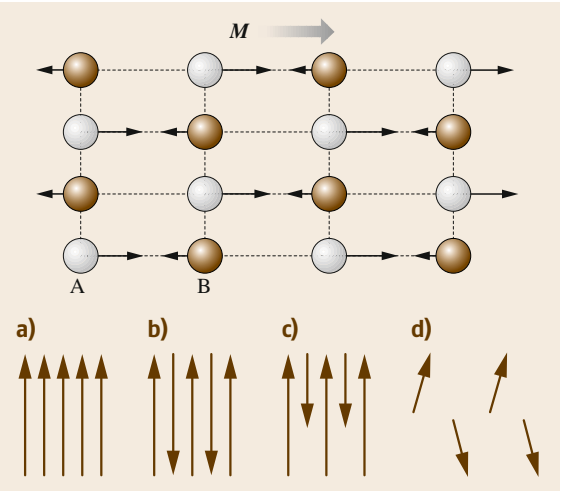

Fig. 4.12a–d Magnetic moment arrangement in an ferrimagnet. Total net magnetization is different from zero. **(a–d)** Comparison of the magnetic arrangements between a ferromagnet **(a)** an antiferromagnet **(b)**, a ferrimagnet **(c)**, and a weak ferromagnet **(d)**. (After [4.31])

interaction between two neighboring localized moments $\boldsymbol{M}_i$ and $\boldsymbol{M}_j$ of the form $D_{ij}\boldsymbol{M}_i \times \boldsymbol{M}_j$ that contrasts with the scalar ordinary exchange interaction of the form $A_{ij}\boldsymbol{M}_i \cdot \boldsymbol{M}_j$. It is responsible for canting (producing a small inclination) two neighboring antiferromagnetic moments that are usually antiparallel in an ordinary antiferromagnet. This is due to asymmetric spin–orbit effects [4.26].

An assembly of magnetic moments oriented at random with a zero total magnetic moment is called a paramagnet. A material of that sort does not display hysteresis or remanence when one varies the applied magnetic field. The magnetic field simply imposes some alignment to the randomly oriented moments. For a paramagnet, the susceptibility χ is positive, many orders of magnitude smaller than ferromagnets, and behaves as $1/(T - T_c)$, where T_c is the Curie temperature. Some materials never order magnetically, not even at low temperature (that implies $T_c = 0\,\mathrm{K}$) where order prevails. On the other hand, some materials are called superparamagnetic with no hysteresis and no remanence but with $T_c = \infty$. This does not mean that they are always ordered but their individual moment is so large (a classical moment corresponds to a quantum angular momentum $J = \infty$, resulting in $T_c = \infty$) that it takes an infinite temperature to destroy it completely [4.27, 37].

A material that combats the influence of a magnetic field by trying to maintain zero induction ($\boldsymbol{B} = 0$) in its midst is diamagnetic (a metal like copper is diamagnetic and superconductors are perfect diamagnets). Linguistically, the term diamagnetic is a misnomer since dia means across, implying the field gets across the material, whereas the opposite is true. When a diamagnetic substance such as a silicon crystal is placed in a magnetic field, the magnetization vector $\boldsymbol{M}$ in the material is in the opposite direction to the applied field. A negative susceptibility can be interpreted as the diamagnetic substance trying to expel the applied field from itself. A substance exhibits diamagnetism whenever the constituent atoms in the material have closed shells and subshells. This means that each constituent atom has no permanent magnetic moment in the absence of an applied field. Covalent crystals and many ionic crystals are typically diamagnetic materials because the constituent atoms have no unfilled subshells. Since the diamagnet tries to minimize the effect of $\boldsymbol{B}$, it expels field lines that can be exploited in magnetic levitation. A superconductor is a perfect diamagnet and a metal at high frequencies is partially diamagnetic since the applied field can penetrate it within the skin-depth layer only. For a diamagnet, the susceptibility χ is constant (no variation with temperature) and is slightly negative. Superconductors have $\chi = -1$ (since $\boldsymbol{B} = 0$ inside a superconductor below critical temperature due to the Meissner effect), whereas χ values of semiconductors are typically (Si: -0.26×10^{-6}, Ge: -0.58×10^{-6}, GaAs: -1.22×10^{-6} as taken from *Harrison* [4.38]) in $\mathrm{cm}^3/\mathrm{mol}$ at room temperature.

Materials with a relatively small coercive field (typically smaller than $1000\,\mathrm{A/m}$) employed in transformer cores and magnetic read heads are called soft magnetic materials. Typically, but not all, simple metals and transition metals and their compounds are soft. Permalloy, amorphous, and nanocrystalline alloys and some ferrites are soft. Amorphous materials are soft since their disordered structure does not favor any direction (no anisotropy energy) whereas nanocrystals possess anisotropy over a short length scale (albeit it can be enhanced with respect to the bulk counterpart). Softness is also measured by the maximum attainable permeability (Table 4.3, soft elements).

In the opposite case, a material with a relatively large coercive field (typically larger than $10\,000\,\mathrm{A/m}$) employed in permanent magnets, motors, and magnetic recording media (disks and tapes) is called a hard magnetic material. This means that stored data is not easily lost since it will require a large field to alter the magnetization value. Typically, but not all rare-earth metals, their compounds, and intermetallics are hard. There are also hard ferrites. Permanent magnets are used in power systems such as in relays and in motors and audio–video equipments such as headphones, videotapes, etc. (Table 4.1 and Fig. 4.11).

Table 4.3 Examples of soft magnetic materials and their hierarchy according to saturation magnetostriction coefficient λ_s. The main composition is successively based on Fe, NiFe, and finally Co. μ_{max} is the maximum differential permeability and H_c is the coercive field. $Fe_{80}\ B_{20}$ is also called Metglass 2605. $Fe_{40}\ Ni_{40}\ P_{14}\ B_6$ is also called Metglass 2826. The highest μ_{max} is attained by $(Fe_{0.8}\ Ni_{0.2})_{78}\ Si_8\ B_{14}$ reaching 2×10^6 after annealing. (After [4.37])

Alloy	H_c (mOe)	μ_{max} (50 Hz)	λ_s
$Fe_{80}\ B_{20}$	40	320 000	$\approx 30\times10^{-6}$
$Fe_{81}\ Si_{3.5}\ B_{13.5}\ C_2$	43.7	260 000	
$Fe_{40}\ Ni_{40}\ P_{14}\ B_6$	7.5	400 000	$\approx 10\times10^{-6}$
$Fe_{40}\ Ni_{38}\ Mo_4\ B_{18}$	12.5–50	200 000	
$Fe_{39}\ Ni_{39}\ Mo_4\ Si_6\ B_{12}$	12.5–50	200 000	
$Co_{58}\ Ni_{10}\ Fe_5\ (Si, B)_{27}$	10–12.5	200 000	$\approx 0.1\times10^{-6}$
$Co_{66}\ Fe_4\ (Mo, Si, B)_{30}$	2.5–5	300 000	

Ferrimagnetic ceramic-like alloys with composition $FeOFe_2O_3$ are called ferrites. The ferrite definition has been extended to $MOFe_2O_3$ with M being a divalent metal (note the trivalent state of Fe in Fe_2O_3). Ferrites are used in microwave engineering, recordings, etc., because of their very low eddy current loss [4.12] and they operate over a large frequency interval (kHz to GHz). Their resistivities may reach a ratio as high as 10^{14} with respect to typical metallic resistivities. They are made by sintering a mixture of metallic oxides $MOFe_2O_3$ with M = Mn, Mg, Fe, Zn, Ni, Cd, etc. Ferrite read heads are nonetheless limited to frequencies below 10 MHz as far as switching is concerned, and that is why several new types of read heads (thin films, anisotropic magneto-resistance (AMR), GMR, spin valves, magnetic tunnel junctions) have been developed in order to cope with faster switching (Chap. 49). Other conventional magnetic materials close to ferrites are discussed next.

Spinels

Alloys with a composition generalizing the ferrite one $(MO)_x(MO)_{1-x}\ Fe_2O_3$ with the structure of $MgAl_2O_4$ (origin of the word spinel) [4.16].

Garnets

Oxides with composition initially issued from the spinel family of the form $(3M_2O_3, 5Fe_2O_3)$ crystallize in the garnet cubic structure $(Ca_3Fe_2(SiO_4)_3)$. They are ferromagnetic insulators of the general formula $M_3Fe_5O_{12}$, where M is a metallic trivalent ion (e.g., $M = Fe^{3+}$). Garnets were been used in memory bubble technology, lasers, and microwave devices (because their ferromagnetic resonance linewidth versus field is small, being on the order of a fraction of an oersted while the resonance frequency is several tens of GHz, see *Wigen* [4.16]), on the basis of another generalization of the formula to $M_3Ga_5O_{12}$. For instance, $Gd_3Ga_5O_{12}$ called GGG (gadolinium gallium garnet) when produced as a thin film, a few microns thick, has perpendicular anisotropy with domains (bubbles) having their magnetization up or down (perpendicularly with respect to the thin film sample plane).

Thus a bit can be stored with a bubble and can be controlled with a small magnetic field. GGG is considered as one of the most perfect artificially made crystals since it can be produced with extremely few defects (less than 1 defect per cm^2). Another nomenclature called the [cad] notation is used with rare-earth iron garnets having the general formula $X_3Y_2Z_3O_{12}$. This notation means dodecahedral (c site is surrounded by 12 neighbors and represented by element X), octahedral (a site is surrounded by 8 neighbors and represented by element Y), and tetrahedral (d site is surrounded by four neighbors and represented by element Z). The most important characteristic of these garnets is the possibility to adjust their composition and, therefore, their magnetic properties according to selected substitutions on the c, a, or d sites. The element X is a rare earth, whereas Y and Z are Fe^{3+}. The magnetization is changed by placing nonmagnetic ions on the tetrahedral d site; increasing the amount of Ga^{3+}, Al^{3+}, Ge^{4+}, or Si^{4+} will decrease the magnetization. On the other hand, increasing the amount of Sc^{3+} or In^{3+} at the octahedral a site will increase the magnetization. Ion substitution can also be used to tailor other magnetic properties (anisotropy, coercivity, magnetostriction, etc.).

Garnets are typically grown with liquid-phase epitaxy with a growth speed that easily reaches 1 µm thickness in 1 min with a very high yield. They were not only in bubble materials but also in magneto-optical displays, printers, optical storage, microwave filters, and integrated optics components, etc. In spite of all these attractive properties, the ease of tunability, and the very high yield, problems soon arose with the access time limitation in bubble memories, since switching frequency was found to be bounded to less than about 10 MHz (see *Wigen* [4.16]; Chap. 49). More recently, garnets are being used in spin–charge interconversion as discussed in the last section.

4.2 Nonconventional Magnetism and Progress Toward Spintronics and Quantum Devices

4.2.1 Types of Exchange and Coupling in Magnetic Materials

In conventional magnetic materials, the strength of the magnetic interactions between two neighboring localized moments i and j (as in atoms/ions/molecules and rare-earths) is described by a direct exchange interaction. The latter is essentially a Coulomb (electrostatic) interaction between the electrons at the i and j sites. The word *exchange* is used since the corresponding overlap integral describing this interaction involves wavefunctions with permuted (exchanged) electron coordinates (in order to respect the Pauli exclusion principle). The exchange energy between sites i and j is given by $A_{ij}\boldsymbol{M}_i\boldsymbol{M}_j$, where $\boldsymbol{M}_i$ and $\boldsymbol{M}_j$ are, respectively, the magnetization at the i and j sites. When $A_{ij} > 0$ energy is minimized when the moments are parallel and when $A_{ij} < 0$ antiparallel configuration of the moments is favored. The energy arising from exchange over a distance r in the continuum limit is approximately AM^2/r^2.

Surrounding the localized moments i and j by an electron gas modifies the nature of their interaction into an RKKY (Ruderman–Kittel–Kasuya–Yoshida, see *Kittel* [4.27]) coupling. The oscillatory interaction occurring between the moments is mediated by the surrounding electron gas. It varies in three-dimensional (3-D) systems as $\cos(2k_F r)/r^3$, where r is the distance between the moments and k_F the Fermi wavevector of the electron gas. The finite value of k_F is responsible for the oscillatory behavior since it produces a cutoff in the Fourier transform [4.27]. It was discovered recently that a two-dimensional (2-D) counterpart of the RKKY interaction exists between two magnetic thin films separated by a metallic spacer [4.39]. The RKKY-like interaction between the two magnetic films across a metallic spacer is oscillatory with respect to the spacer thickness z. Thus it becomes possible to positively (ferro) or negatively couple magnetic layers by changing the thickness z of the sandwiched metallic spacer (Fig. 4.1 for typical lengths). This is extremely useful for thin-film devices (Chap. 49 and Table 4.1).

In planar magnetic technology, the interest is in magnetic thin films and their interactions. Information storage, sensing, spintronics, quantum computing, and other applications of magnetic thin-film devices are the main drive for understanding the nature and extent of magnetic exchange interactions and also coupling effects arising between magnetic 2-D layers in order to tailor appropriate devices. Novelty is expected since the device size is comparable to the interaction range (Fig. 4.1).

The coupling strength of the interaction between two neighboring magnetic films i and j can be modeled by a factor J_{ij}. It is similar to the exchange integral A_{ij} between two neighboring localized moments; however, it involves entire layers generally made from itinerant magnets and not single moments like with A_{ij}. The exchange interaction is of the form $J_{ij}\boldsymbol{M}_i.\boldsymbol{M}_j$, where $\boldsymbol{M}_i$ and $\boldsymbol{M}_j$ are the magnetization per unit surface of films i and j. The main interest of J_{ij} lies in the fact that its range is longer in reduced dimensions (one-dimensional (1-D) and 2-D) with respect to 3-D (for instance, an RKKY-like interaction between two magnetic films across a metallic spacer is oscillatory with a longer range than 3-D since it varies like $1/r^2$ instead of $1/r^3$) and its physics based on complex Fermi wavevectors [4.39] is entirely different from the standard RKKY interaction between localized moments [4.39]. The sign of the interaction depends on the thickness of the metallic spacer. Other types of exchange exist between films such as biquadratic or higher order ones with a generalized Heisenberg form $[J_{ij}\boldsymbol{M}_i \cdot \boldsymbol{M}_j]^n$ with $n \geq 2$ (see The entry related to exchange and coupling in multilayers in Table 4.1).

Interactions between two ferromagnetic (or other type of magnetic) films are not limited to metallic spacers; they may occur across an insulating or semiconducting spacer (Fig. 4.13). Magnetic pinholes generally

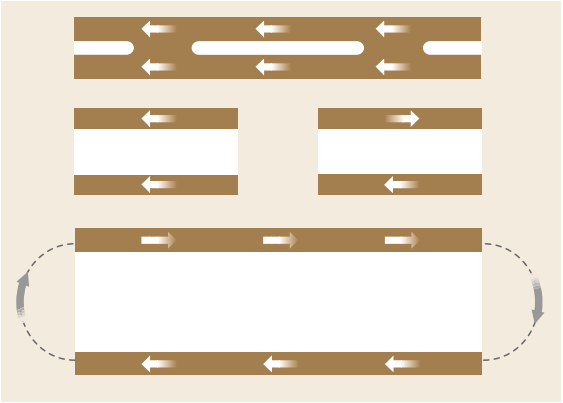

Fig. 4.13 *Top*: ferromagnetic coupling arising from pinholes existing across the spacer. *Middle*: exchange coupled layers that might be ferro (*left*) or antiferromagnetic (*right*) depending on the spacer thickness. *Bottom*: magnetostatic dipolar coupling between the top and bottom layers. (After [4.10])

Table 4.4 Surface energies γ in J/m^2 for magnetic and nonmagnetic materials, listed with respect to their atomic number for the low-energy cleavage surface. These are approximate values, which are difficult to measure in general and are dependent on surface orientation and reconstruction. (After [4.10])

Magnetic metal	Cr	Mn	Fe	Co	Ni	Gd				
γ (J/m^2)	2.1	1.4	2.9	2.7	2.5	0.9				
Transition metal	Ti	V	Nb	Mo	Ru	Rh	Pd	Ta	W	Pt
γ (J/m^2)	2.6	2.9	3.0	2.9	3.4	2.8	2.0	3.0	3.5	2.7
Simple or noble metal	Al		Cu		Ag		Au			
γ (J/m^2)	1.1		1.9		1.3		1.6			
Semiconductor	Diamond		Si		Ge		GaP		GaAs	
γ (J/m^2)	1.7		1.2		1.1		1.9		0.9

γ (J/m^2)	0.34		0.3		0.45		1.2		1.4	

mediate direct ferromagnetic coupling between neighboring multilayers. They are viewed as shorts across the insulating or semiconducting spacer. Néel proposed that conformal roughness (orange-peel model, see *Schulthess* and *Butler* [4.40]) at interfaces can result in ferromagnetic coupling for a moderate thickness of spacer material. Magnetostatic dipolar coupling occurs between the roughness features or between domain walls in the two magnetic layers. In this case, stray flux fields from walls in one film can influence the magnetization reversal process in the other. The Slonczewski loose-spin (see the exchange and coupling in multilayers in Table 4.1) model is based on angular momentum change as experienced by spin-polarized electrons tunneling across an insulating spacer, resulting in a magnetic exchange coupling. The magnitude and sign of the coupling oscillate, depending on the interfacial barrier properties (*Himpsel* et al. [4.10] and Table 4.1).

In the absence of a spacer, the exchange energy per unit surface of ferromagnetic and antiferromagnetic films gives birth to a new phenomenon called exchange bias (a shift of the hysteresis curve of the ferromagnetic film, see the entry in Table 4.1 related to exchange and coupling in multilayers). An important consequence of bias is pinning of the direction of the ferromagnetic moment used in low noise read heads because it hinders noisy (jerky) domain wall motion (Chap. 49). Exchange bias is also called anisotropic exchange and is still relatively poorly understood from the fundamental point of view despite the fact that it was discovered more than 50 years ago.

4.2.2 Thin Magnetic Films

A magnetic film is considered thin if its thickness is smaller than the (bulk defined) exchange length; in other words its thickness corresponds to the spatial extent of a single domain [4.10]. Magnetic thin films possess very attractive and distinct physical properties with respect to their bulk counterparts. For instance, reduced dimensionality, coordination and symmetry lead to magnetocrystalline anisotropy energies that are two or three orders of magnitude larger with respect to bulk (quenching of the orbital angular momentum as in transition metal ions is absent, see *Kittel* [4.27]). Saturation magnetization M_s is also enhanced with respect to bulk since the effective Bohr magneton number n_B per atom/molecule is larger in lower dimensions (for instance, in Nickel clusters n_B might reach 1.8, whereas in the bulk it is only 0.6). Couplings in thin films are also enhanced as in the case of the RKKY-like interaction across a metallic spacer. Coupling between two magnetic layers across a semiconducting spacer or an insulator leads to entirely new interactions, such as the Slonczewski loose-spin model or the Bruno quantum interference model. Other types of couplings or materials may be encountered besides exchange bias (between a ferro and an antiferromagnetic layer) such as spring magnets fabricated from alternating hard and soft thin films (Table 4.1).

Considering the growth of magnetic materials as thin films, we have to recall that these possess distinct physical properties with respect to the materials used in conventional microelectronics such as surface energies. A dominant role is played by surface free energies γ and the interface. They determine the growth modes in thermal equilibrium; the morphology of material B grown on material A depends on the balance between the free surface energies of substrate, overlayer, and interface [4.10]. Transition-metal-based magnetic materials exhibit a relatively high surface energy, owing to their partially filled *d* shell. Noble metal substrates have smaller surface energies and insulating substrates have even smaller ones (Table 4.4).

Additionally, when one performs epitaxial growth of materials, another concern is lattice matching for the different underlayers, as displayed in the tables below along with typical quantities of interest in representative magnetic materials (Table 4.5 and 4.6).

Table 4.5 Lattice-matched combinations of magnetic materials, substrates, and spacer layers. There are two main groups of lattice-matched systems with lattice constants close to 4.0 or 3.6 Å, respectively, after taking 45° rotations of the lattice or doubling the lattice constant. (After [4.10])

First group: magnetic metal $a\sqrt{2}$ (Å) [a (Å)]	Cr (bcc) 4.07 [2.88]	Fe (bcc) 4.05 [2.87]	Co (bcc) 3.99 [2.82]		
Simple or noble metal a (Å)	Al 4.05	Ag 4.09	Au 4.07		
Semiconductor $a/\sqrt{2}$ (Å) [a (Å)]	Ge 3.99 [5.65]	GaAs 4.00 [5.65]	ZnSe 4.01 [5.67]		
Insulator a (Å) [$a/\sqrt{2}$ (Å)]	LiF 4.02 [2.84]	NaCl 5.65 [3.99]	MgO 4.20 [2.97]		
Second group: Material a (Å)	Fe (fcc) 3.59	Co (fcc) 3.55	Ni (fcc) 3.52	Cu 3.61	Diamond 3.57

Table 4.6 Magnetic properties of Fe, Co, and Ni transition metals. Note that the domain wall (DW) thickness and energy are approximate. This is a complement to Table 4.2

Magnetic substance/property	Fe	Co	Ni
Exchange stiffness A (meV)	0.015	0.03	0.020
Anisotropy K_1 (J/m^3) at 300 K	4.8×10^4	45×10^4	-0.5×10^4
Lattice spacing (nm): a Lattice spacing (nm): c	0.29	0.25 0.41	0.35
DW thickness (nm) DW thickness (lattice parameters)	40 138	15 36	100 285
DW energy (J/m^2)	3×10^{-3}	8×10^{-3}	1×10^{-3}

4.2.3 Electronic Properties: Localized, Free, Itinerant Magnetism and Spin-Polarized Band Structure

Building a working device requires understanding not only magnetic properties but also electronic properties and their interplay. The new devices are expected to be made of a variety of magnetic (conventional and unconventional) materials as well as others already known in microelectronics. Insulating oxides (except EuO) and rare-earth compounds with well-localized external shell f electrons are the solid-state representative of atomic-like magnetism. Magnetism of atoms, ions, and molecules deals with well-defined, localized orbitals and individual moments arising from orbital, spin, or total angular momentum. When these moments get close to one another, as in the solid state, they interact Heisenberg wise: $A_{ij}\boldsymbol{M}_i.\boldsymbol{M}_j$ [4.31]. The latter is going to be altered by presence of the surrounding free electron gas. Therefore we have to understand magnetism in a free-electron gas, its counterpart arising from localized moments, and finally its nature when we have the hybrid case (itinerant magnetism) like in a transition metal (free s and localized d electrons). This problem being complicated due to its many-body nature, we rely upon a *one-electron approximation* and spin-polarized band structure [4.11].

In a free-electron gas, one assumes independent noninteracting electrons; therefore many-electron and nonlocal effects (arising from exchange) are not to be taken into account. Magnetism in this case is due to individual electron spin, and it is straightforward to establish so-called Pauli paramagnetism [4.27]. In addition, orbital effects give rise to Landau diamagnetism. The spin-polarized density of states is shifted by the field contribution $\pm\mu_B B$ depending on the spin orientation with respect to induction field $\boldsymbol{B}$. The magnetization in the free-electron Pauli case (simple metals) can be evaluated (at $T = 0$ K) from

$$M = \mu_B(N_\uparrow - N_\downarrow) = \frac{\mu_B}{2}\int_{-\mu_B B}^{E_F} \mathrm{d}EN(E+\mu_B B) - \frac{\mu_B}{2}\int_{\mu_B B}^{E_F} \mathrm{d}EN(E-\mu_B B) \tag{4.7}$$

that yields $M \approx \mu_B^2 N(E_F)B$, where μ_B is the Bohr magneton, $N(E)$ is the free electron, and $N_{\uparrow,\downarrow}(E) = N(E \pm \mu_B B)$ the spin-polarized density of states with respective occupations $N_{\uparrow,\downarrow}$. The Landau diamagnetism (orbital) contribution is a lot more complicated to evaluate, nevertheless it is exactly minus one-third the paramagnetic expression [4.27].

In transition metals (itinerant magnets), states derived from the 3d and 4s atomic levels are responsible for their physical properties. The 4s electrons are more spatially extended (of higher principal quantum number) and determine, for instance, compressibility, whereas the 3d states determine magnetic properties. The 3d electrons propagate throughout the material, hence the term *itinerant magnetism*. The spin-polarized band structure transition of metals is different from that of conventional electronic materials (see Figs. 4.14

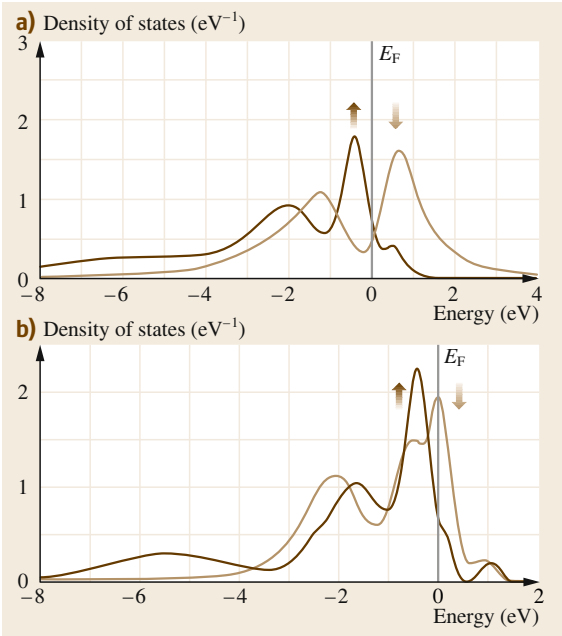

Fig. 4.14a,b Spin-polarized density of states for bcc Fe and fcc Ni. The bands for the spin up (*dark*) electrons are separated from the spin down (*light*) band by the exchange splitting energy (see text). The method used is superior to the LSDA method that yields a noisy density of states. The authors call it LDA + DMFT meaning local density approximation + dynamical mean field theory. (After [4.41])

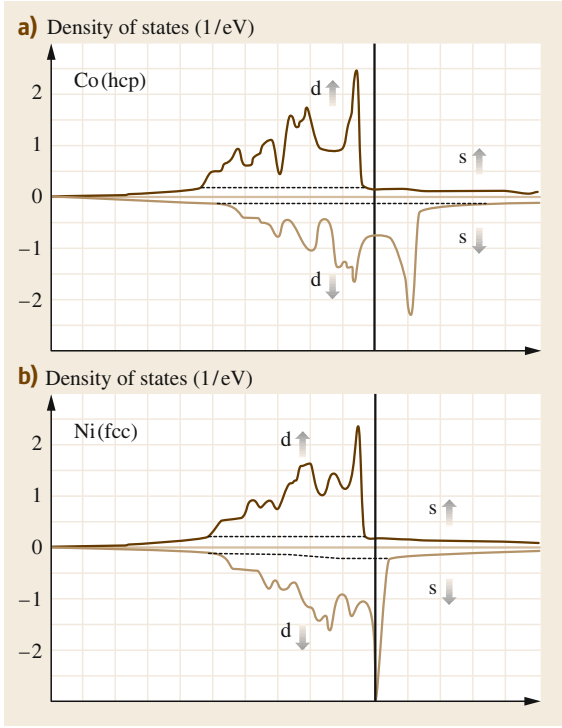

Fig. 4.15a,b Symmetric double-sided representation of the spin-polarized density of states for **(a)** Co and **(b)** Ni (obtained with the LMTO method, i. e., linearized muffin-tin orbitals) with the Fermi level indicated. (After [4.42])

and 4.15 for iron, nickel, and cobalt spin-polarized band structures).

Many metals have an odd number of electrons (in the atomic state), thus one would expect a magnetic material from unpaired spins; however, only five of them are actually magnetic (Cr, Mn, Fe, Ni, and Co are all transition metals with s–d hybridization). Note that copper is diamagnetic with $\chi = -0.77 \times 10^{-6}\,\mathrm{cm}^3/\mathrm{mol}$ at room temperature, Fe, Ni, and Co are ferromagnets, whereas Cr and Mn are antiferromagnets.

Magnetism and related properties in transition metal alloys are not straightforward to model owing to the electrons' itinerant nature. In solids, magnetism arises mainly from electrostatic (Coulomb) electron–electron interactions, namely the exchange interactions, and in magnetic insulators these can be described rather simply by associating electrons appropriately with particular atomic sites so that the Heisenberg exchange $A_{ij}\boldsymbol{M}_i \cdot \boldsymbol{M}_j$ can be used to describe the behavior of such systems. In metallic systems, it is not possible to distribute the itinerant electrons in this way, and such simple pairwise interactions between sites cannot be easily defined. Metallic magnetism is a complicated many-body effect and has attracted significant effort over a long period to understand and describe it [4.10]. A widespread approach is to map this problem onto one involving independent electrons moving in fields set up by all other electrons. It is this aspect which gives rise to the spin-polarized band structure that is often used to explain the properties of metallic magnets such as noninteger values in multiples of the Bohr magneton μ_B. In addition, the compositional structure plays a major role in itinerant magnetism, such as, for instance, in the Ni–Pt alloy. It is an antiferromagnet in the ordered case and ferromagnetic in the disordered case. Itinerant magnetism is comprised between two extreme limits: the localized (rare-earth and insulators) and the completely free electron case (more appropriate to alkalis) as described below. As far as transport is concerned, one may use the Stoner two-band model, which is a two-fluid model (like electrons and holes in semiconductors) with a population of electrons with spin-up and another of spin-down with the corresponding spin-polarized densities of states [4.10].

In ordinary crystalline nonmagnetic materials, the electronic band structure is built from the lattice (pe-

Table 4.7 Spin polarization in several ferromagnetic materials according to several authors. The discrepancies between the different results stem from the various approaches to estimate the density of states at the Fermi level and point to the difficulty of getting a unanimous figure. Note that for a half-metal like CrO_2 or NiMnSb, the polarization is 100%

riodic) potential seen by a single electron (having any state of spin) in the structure. Mathematically, it amounts to solving the Schrödinger equation corresponding to that potential and calculating its eigenfunctions (spin-independent wavefunctions). The eigenvalues versus wavevector are the ordinary bands. In a magnetic material, one has to include electronic exchange effects (originating from the Pauli exclusion principle applied to electrostatic interactions between pairs of electrons leading to nonlocal interactions) with explicit accounting for spin in the wavefunctions. Several methods exist such as the LSDA (local spin density approximation, see Fig. 4.1), which is a spin extension of the LDA (local density approximation) where one builds a local approximation to the exchange interaction from the local density of electrons [4.41]. The LSDA (Fig. 4.1) formalism provides a reliable description of magnetic properties of transition metal systems at low temperatures. It also provides a mechanism for generation of the noninteger effective number

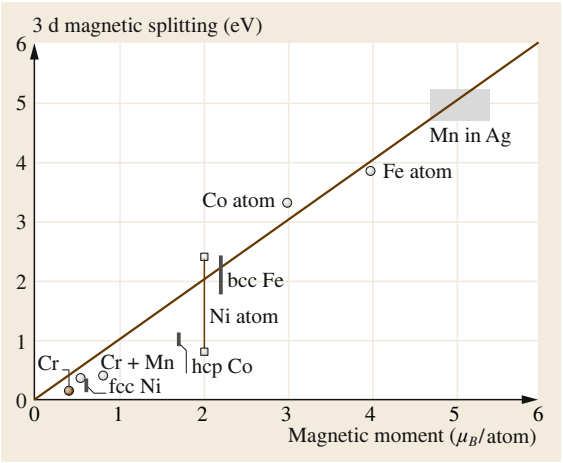

Fig. 4.16 Exchange splitting versus magnetic moment in the Bohr magneton μ_B per atom in 3d transition metals. The *diagonal line* is $1\text{eV}/\mu_B$ and the magnetic moment values (in Bohr magnetons) are given for the atom and the corresponding crystal. (After [4.10])

n_B of Bohr magnetons, together with a plausible account of the many-body nature of magnetic moment formation at $T = 0$ K. The obtained bands depend on spin as depicted in Figs. 4.14 and 4.15. From the spin-dependent band structure, one may obtain the spin-polarized density of states for each spin polarization (up $\uparrow$ or down $\downarrow$, also called majority and minority like in ordinary semiconductors). This nomenclature will eventually be confusing when one starts dealing with metals and semiconductors simultaneously. For the time being, this nomenclature is accepted (Table 4.7), as long as we are dealing solely with magnetic metals and one defines a new type of gap (originating from the exchange interaction) called exchange splitting (Fig. 4.16 and Table 4.8) or the (spin) gap between two spin-dependent bands (Fig. 4.14). This explains the existence of novel materials such as half-metals that ought to be contrasted with semimetals (graphite) where we have a negative electronic gap because of valence and conduction band overlap.

Half-metals (such as CrO_2 and NiMnSb) possess one spin-polarized band (up, for instance) full and the other (down) empty. These materials are very important for spintronics and specially for injecting spin-polarized carriers.

4.3 Spintronics and Quantum Information Devices

Presently, we are witnessing electronics extension toward the treatment of spin and charge instead of charge only, the realm of traditional electronics.

The reason spin becomes interesting and useful stems from the following. As device integration increases and feature length decreases toward the nanometer, the spin of individual carriers (electrons or holes) becomes a good quantum number. This means that the spin value is conserved over nanometric distances (spin diffusion length is typically 5–50 nm). This was not the case in microelectronics; consequently, spin can be used in the nanometer regime to carry useful information. Henceforth carriers transport energy, momentum, charge, and additionally spin. The quantum nature of spin leads to the natural consequence that quantum computers might be made successfully with spintronic components [4.28].

Spintronics, like microelectronics, is based on materials and their physical properties (mechanical, thermal, electrical, magnetic, etc.) as well as the know-how of growing/fabricating thin films and reduced dimensionality objects (quantum dots, quantum wires, quantum pillars, clusters, etc.). The different classical processing steps (epitaxial growth, deposition, oxidation, diffusion, doping, implantation, etching, passivation, thermal insulation, annealing, texturing, sputtering, patterning, etc.) that are well established in microelectronics have to be extended and adapted to tackle magnetism-related electronics. Magnetic interactions have an anisotropic vectorial character in contrast to scalar electrical interactions (based solely on charge) present in conventional microelectronic devices. Magnetism introduces the notions of anisotropy (magnitude, nature, and direction), coercivity, saturation magnetization, etc. that ought to be controlled during growth (magnetic field assisted growth or epitaxial growth has to be developed in order to favor magnetic anisotropy along one or several selected directions).

For instance, in some devices, there is a need to grow amorphous metallic magnetic layers (in order to have a very small anisotropy resulting in a magnetically soft layer), and these might be harder to grow than amorphous semiconductors or insulators (recall that a cooling speed of one million degrees per second is typically needed in order to produce an amorphous metal).

Overall, temperature is a very important parameter in magnetism since above the Curie (or Néel) temperature, ferromagnetism (antiferromagnetism) is lost.

Spin-polarized materials with novel properties emerge, such as half-metallic materials (CrO_2, NiMnSb, etc.), embodying carriers that are completely polarized spin wise (all up or all down).

Since we are dealing mostly with s–d hybridized transition metals, we expect at least three types of spin currents [4.22]: SPC (spin-polarized current) made of free (s-type) spin-polarized carriers, SWC (spin-wave current) carried by undulating localized spins (d-type) (with no dissipative Joule effect produced), and STT (spin-transfer torque) current stemming from the s–d

Table 4.9 Spintronic effects viewed as spin extension of ordinary unpolarized bulk and 2DEG electronics

Spintronic effect or device	Comments	Reference

(double) exchange between free and localized carriers [4.60].

Other types of spin current can be generated by shining circularly polarized light [4.52, 53] over quantum well structures [4.52, 53] over quantum well structures exploiting a special effect originating from spin–orbit interaction in a 2DEG (two-dimensional electron gas) (Table 4.9) and called Rashba coupling [4.22, 23]. A spin current can also be produced with linearly polarized light [4.61] exciting antiferromagnetic materials such as NiO, Fe_2O_3 (hematite), or bismuth ferrite materials. The physical mechanism is based on a nonlinear optical effect called *shift current* (or photovoltaic drift current) produced by second-order interaction with the light electric field in noncentrosymmetric materials such as perovskites [4.61] ($BaTiO_3$, $LiNbO_3$, $KNbO_3$, etc.) of the form $J_i = \sigma_{ijk}E_jE_k$ (second-order extension of Ohm's law $J_i = \sigma_{ij}E_j$).

This is to be added to the wealth of magnetic interactions that can be based on para, dia, ferro, antiferro, or ferrimagnetic materials, which can be simultaneously electrically wise metallic (simple, transition, noble, or rare-earth), insulating, or semiconducting. As an example, multiferroics (see below) that are single-phase materials possessing interconnected electrical, magnetic, and elastic properties can be used as transducers in such multifunctional structures.

In analogy with ordinary electronics, spintronics is based on seven operations:

- *Spin injection*: How can a nonequilibrium density of spin-polarized carriers, that is, electrons with spin up $n_\uparrow$ (or down $n_\downarrow$) or holes with spin up $p_\uparrow$ (or down $p_\downarrow$) be created? Optical injection might be viewed as the spin extension of the Haynes–Shockley experiment. Spin injection can also be done with carbon nanotubes since they do not alter the spin state over large distances (Chap. 49).
- *Spin filtering*: Separating spin-polarized carriers is required in order to avoid spin-flips altering spin states. Thin ferromagnetic layers as in spin valves (Chap. 49) and chiral materials such as monolayers of double-stranded DNA molecules can be used [4.62].
- *Spin manipulation*: How can the spin and charge states of a nonequilibrium density of spin-polarized carriers be altered and controlled?
- *Spin coherence*: How can the spin and charge states of a nonequilibrium density of spin-polarized carriers be maintained over an important propagation length at room (and higher) temperature in the presence of perturbing magnetic stray fields (terrestrial and other)?
- *Spin accumulation*: How can spin-polarized carriers be coherently concentrated without destroying their spin coherence and without inducing spin flips that will destroy the resulting spin value?
- *Spin detection*: How can spin and charge of a nonequilibrium density of spin-polarized carriers be detected nondestructively?
- *Spin pumping*: This is the spin counterpart of charge pumping that occurs by application of a nonlinear ac signal to a semiconductor in order to achieve current rectification [4.63]. In the spin-polarized case, it is translated into the question of spin angular momentum transfer mode from magnetization precession to conduction electrons. It is experimentally feasible [4.64] with a ferromagnet (F) containing a precessing magnetization and a neighboring normal metal (N) into which a spin current is injected through the F–N interface. In summary, the question is related to ways of efficiently generating a continuous spin current from a time-evolving magnetization (viewed as a spin dynamo [4.65]).

In Table 4.9, we display the spin extension of several physical effects that are familiar in conventional electronics.

Many of the effects are simply the extension from a standard semiconductor or a metal to a ferromagnet. For instance, in the Seebeck effect, a thermal gradient ∇T applied to a metal induces an electric voltage along the direction of ∇T. In order to extend this phenomenon to the spin-Seebeck case, a thermal gradient ∇T is applied to a ferromagnet and a spin voltage is generated from thermal excitation of the magnetic moments in the ferromagnet. Those excitations are used to pump a spin current into a neighboring paramagnetic metal. Spin currents can be used for cooling or heating, and the spin-Peltier effect is based on the ability of the spin-up and spin-down currents to transport heat independently [4.57].

SMR (spin-Hall magnetoresistance) is even more interesting since it is related to conversion of charge into spin current (called interconversion) via SHE (spin-Hall effect). SHE implies that a current can be transferred between a noble metal (such as Pt or Au) and a magnetic insulator (such as yttrium iron garnet (YIG)) [4.22] making it the spin counterpart of the displacement current [4.22]. SHE leads to spin accumulations with opposite magnetizations at the edges of a magnetic material perpendicularly to the charge current and derives from the AHE (anomalous Hall effect) [4.22]. The latter is derived as follows. In an ordinary metal, a galvanomagnetic effect is written in terms of resistivity tensor ρ_{ij} that depends on the applied magnetic field $\boldsymbol{H}$ and contains two contribu-

tions: symmetric and antisymmetric like any rank-2 tensor.

Symmetric terms contain even powers of the applied magnetic field $\boldsymbol{H}$, whereas antisymmetric terms contain odd powers of $\boldsymbol{H}$. The lowest order antisymmetric terms are linear in $\boldsymbol{H}$ components and are termed Hall effect terms, whereas the lowest order symmetric terms are quadratic in $\boldsymbol{H}$ components and are termed magnetoresistive.

Let us suppose that ρ_{ij} in terms of field $\boldsymbol{H}$ in an ordinary metal has an expansion to lowest order (in $\boldsymbol{H}$ components) given by

$$\rho_{ij} = a_{ij} + b_{ijk}H_k + \cdots . \tag{4.8}$$

In contrast, when we have a ferromagnet, an additional term due to magnetization $\boldsymbol{M}$ should be added with respect to field $\boldsymbol{H}$ contribution. Thus one may extend the above expansion to

$$\rho_{ij} = a_{ij} + b_{ijk}H_k + c_{ijk}M_k + \cdots . \tag{4.9}$$

The ordinary Hall ($\boldsymbol{H}$ dependent) effect is thus extended to the AHE ($\boldsymbol{M}$ dependent) present in ferromagnets.

Hall terms are given by cross products $\boldsymbol{H} \times \boldsymbol{J}$ (ordinary Hall effect) or $\boldsymbol{M} \times \boldsymbol{J}$ (AHE), whereas magnetoresistance is related to scalar products between $\boldsymbol{M}$ and current density $\boldsymbol{J}$.

4.3.1 Magnetic Signal Processing Devices

Magnetic signal processing devices extend electronic signal processing to include magnetic field action, meaning that arithmetic, logic, memory, and other operations that traditionally belong to the realm of electronics will be performed by devices containing components that are sensitive to magnetic excitation.

An example given in Table 4.10 is an oscillator whose frequency is controlled by a magnetic field (this might be called magnetic agility) instead of an electrical voltage (as in ordinary electronic agility) despite the fact electrical control is generally preferred.

Fabrication of practical magnetic signal processing devices requires replacing magnetic field control by an electrical one (whenever possible) since stray magnetic fields might interfere with device operation. In addition, it is technically difficult to produce large magnetic fields over a nanometer length at present.

The simplest way of replacing magnetic field control is to trigger coupling between electrical and magnetic degrees of freedom by growing composite materials containing both ferromagnetic and ferroelectric elements. Coupling between magnetic and electrical degrees of freedom effects or magnetoelectric coupling is generated, for instance, through elastic interaction between a piezoelectric and a magnetostrictive substance [4.72].

Structures allowing possible magnetoelectric coupling are magnetic superlattices (also called magnonic or metamaterials), the magnetic analog of semiconducting superlattices or photonic structures (with varying dielectric constants) with modulated magnetization, anisotropy, or type (para, dia, ferro, antiferro, ferri).

Multiferroics are single-phase materials that respond to electrical, magnetic, and elastic excitations. They are more versatile than magnetoelectric composites; however their stoichiometry and growth critically affect the value substantially [4.72] of their magnetoelectric coefficient.

Dilute magnetic semiconductors (DMS) contain magnetic elements that are sensitive to magnetic fields and therefore make good candidates for magnetoelectric coupling (Table 4.10).

Substituting magnetic field control by an electrical one is possible in semiconductors through spin–orbit interaction since it allows generation and manipulation of carrier spins by an electric field [4.73].

Spin–orbit interaction has also been shown to allow electric control of spin-waves in single-crystal YIG

waveguides, which paves the way to developing electrically tunable magnonic devices [4.74, 75].

Instead of coupling magnetic and electrical degrees of freedom or substituting magnetic field control by an electrical one, interconverting charge and spin degrees of freedom [4.22, 23] through spin currents, such as SHE described above, will ultimately lead to electric-field control (Tables 4.9 and 4.10).

Recently, voltage-controlled magnetism of Co thin films adjacent to Gd_2O_3 gate oxides was demonstrated [4.76]. Using gate voltages of a few volts, the anisotropy field as well as the saturation magnetization were altered, producing a large magnetic anisotropy energy change of up to $0.73\,erg/cm^2$. Voltage-induced reversible oxidation of the Co layer resulted from a large interfacial electric field and a high oxygen ion (O^{2-}) mobility in Gd_2O_3.

4.3.2 Magnetic Quantum Dot Arrays

Submicron quantum dots based on traditional semiconductor, insulator, or metallic materials are well developed [4.77] with many applications. They can be tailored with lithographical techniques and behave in a fashion similar to synthetic atoms. When arranged in arrays, they can be x–y addressed like random access memories or used in applications such as displays, cameras, sensors, etc.

The magnetic counterparts of quantum dot arrays are being developed with magnetic materials that possess a significantly larger number of possibilities stemming from the wide panel of magnetic materials (see *Hurd* [4.26] for a classification of magnetic materials prior to 1982 and *Kronmueller* and *Parkin* [4.78] for more recent developments).

Magnetic elements are specially adapted to scaling and scale integration since submicron-ordered magnetic dot arrays possess properties such as moment, susceptibility, coercivity, and remanence that are significantly enhanced with respect to their bulk counterparts, given the fact that they are closer to quantum atomic structures with augmented magnetic properties when fabricated on the nanometer scale.

In addition, present quantum dot array fabrication methods are fast and inexpensive with electrochemical template deposition methods, without the need for time-consuming processes based on sophisticated lift-off and deposition techniques borrowed from microelectronics operations, adapted and scaled down to tackle magnetic nanostructures.

In a disk-shaped magnetic quantum dot, several ordered structures can occur such as single domain (with in-plane or out-of-plane magnetization), multiple domains, and vortex excitations that are akin to solitons

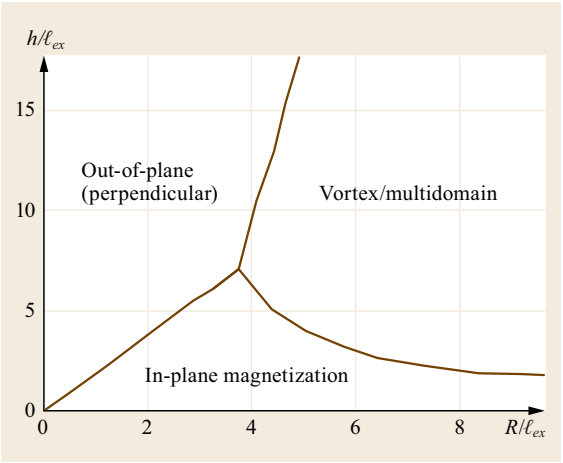

Fig. 4.17 Phase diagram h/ℓ_{ex} versus R/ℓ_{ex} displaying values for which vortex excitations appear in a disk-shaped quantum dot of thickness h and radius R. (After [4.79]) Occurrence of single domains with in-disk plane orientation or perpendicular to it as well as multiple domain regions are indicated

in higher dimension $D \geq 2$ (Fig. 4.17). A cylindrical magnetic quantum dot structure depends on two ratios: h/ℓ_{ex} and R/ℓ_{ex}, where h is the disk thickness and R the radius; ℓ_{ex} is the exchange length (Sect. 4.1).

The phase diagram displaying the regions of occurrence of single domains (with in-plane or perpendicular to plane orientation), multiple domains, and vortex excitations is depicted in Fig. 4.17.

Vortex structures are stable in a disk possessing a radius of several hundred nanometers and a thickness of a few tens of nanometers.

4.3.3 Magnetic Vortex Properties and Applications

A magnetic vortex possesses a central core of about 10 nm diameter with magnetization perpendicular to the x–y plane of the disk. The core magnetization is described by a polarization $p = \pm 1$ that can point in the $\pm z$ direction. Thus it can sense a vertical magnetic field. The core is surrounded by an x–y planar spin flow pattern making a flux-closure magnetization distribution in the plane of the disk. It is characterized by a chirality $C = \pm 1$ that can sense an in-plane magnetic field. Thus a single vortex, being able to sense all spatial components of a magnetic field, is the perfect ingredient of sensitive 3-D magnetometers.

The attractivity of vortex-based magnetic sensors operating at room temperature contrasts sharply with vortex-based superconducting magnetometers that must be cooled at low temperature (helium-4 for traditional

Table 4.11 Magnetic vortex applications in storage, memory, logic, and oscillator arrays

Application	Comments	Reference
Proposal for magnetic logic	Charge and spin operate simultaneously	*Cowburn* [4.80]
Nonvolatile RAM called V-MRAM and AV-MRAM	Not to be confused with vertical MRAM based on stacked ring-shaped GMR cells [4.20, 81]	*Bohlens* et al. [4.82], *VanWaeyenberge* [4.83], *Cowburn* [4.84], *Pigeau* et al. [4.85]
Data storage and memory	A vortex can store 2 bit simultaneously with its polarization and chirality	*Bohlens* et al. [4.82, 86]
Oscillator arrays	Coupled vortex oscillators in arrays of Permalloy disks	*Hanze* et al. [4.87]
Electrical switching of a vortex core in a magnetic disk	Read–write magnetic logic operations	*Yamada* et al. [4.88]
Vortex transistor	A new type of magnetic transistor	*Kumar* et al. [4.89]

superconductors and nitrogen for high-T_c superconductors). Moreover, *Yamada* et al. [4.88] were recently able to perform electrical switching of a vortex core (Table 4.11).

In many areas, magnetometry is needed, for instance, in biology, biomedicine, and geophysics where tensor gradiometry is required in order to determine all 3-D field components and their variation along different spatial directions with respect to Earth coordinates.

Detection of vortices is a very versatile field of research since electron holography [4.90] has been used, as well as magnetoresistance measurement in layered dots with a current traversing the structure along the axial direction (perpendicular to the vortex).

Some vortex detection techniques that perform identification of distinctive magnetization states, such as vortex nucleation and excitation (or switching [4.91]), domain wall motion, ferromagnetic resonance, and spin-wave excitations both in the quasistatic and dynamic regimes, are:

- Differential resistance dV/dI measurement [4.92, 93]
- Spin rectification effect [4.65, 94]
- Inductive methods [4.95, 96]
- RF/microwave transmission measurements [4.97–99]

Wang et al. [4.100] have shown that a resonant magnetic field with 30 mT amplitude stimulates strong axially symmetric magnetization oscillation and forces the vortex core to stay at the center of the disk. The compression of the vortex core by spin-wave excitation leads to fast core reversal [4.100] at 602×10^{-12} s rate. More recently, *Dong* et al. [4.101] managed to confine vortex cores in spin-wave potential wells and obtained core switching times well below 200×10^{-12} s.

The detection range of vortex-sensing magnetometers, being in the kOe range, is too strong for fields usually encountered in biology, biomedicine, and geophysics. Thus we need a conditioning stage for the sensor in order to match its own detection range to another one usually encountered in the above-mentioned areas. The conditioning is made with IMC (integrated magnetic concentrators) that at present possess a gain of 10−100 order of magnitude [4.102].

This gain, defined as the ratio between detectable field in the sensor (kOe) and an external one originating from biological or geophysical sources, is currently being increased steadily with the use of softer materials and better geometrical design to attain at least 1000 [4.103].

In micro-Hall magnetometry where magnetic nanodisks are placed on top of Greek cross-shaped [4.104] Hall plate sensors, vortex motion is detected from their stray-field sensed by Hall voltage measurements.

Another route to vortex detection is through the magnetoelectric effect in layered structures consisting of multiferroic elements or composite elements consisting of alternating piezoelectric layers and giant magnetostrictive elements.

A host of applications exist for vortices (and antivortices their magnetic mirror counterpart) ranging from data storage to magnetic RAM, logic, and information processing devices. More recently a new type of transistor [4.89] based on vortices has been introduced (Table 4.11).

5. Defects in Monocrystalline Silicon

Wilfried von Ammon, Andreas Sattler, Gudrun Kissinger

The aggregation of instrinsic point defects (vacancies and Si interstitials) in monocrystalline silicon has a major impact on the functioning of electronic devices. While agglomeration of vacancies results in the formation of tiny holes (so-called *voids*, around 100 nm in size, which have almost no stress field), the aggregation of Si interstitials exerts considerable stress on the Si matrix, which, beyond a critical size, generates a network of dislocation loops around the original defect. These dislocation loops are typically microns in size. Consequently, they are much more harmful to device functioning than vacancy clusters. However, the feature size in electronic devices has now shrunk below the 100 nm scale, meaning that vacancy aggregates are also no longer acceptable to many device manufacturers.

This chapter is intended to give an introduction to the properties of intrinsic point defects in silicon and the nucleation and growth of their aggregates. Knowledge in this field has grown further over the last decade. It is now possible to accurately simulate the aggregation process so that the defect behavior of semiconductor silicon can be precisely tailored to the needs of the device manufacturer. Additionally, the impact of various impurities on the aggregation process is elucidated.

References 129

As the feature size continues to shrink in device industry and now approaches a design rule of 7 nm, a thorough understanding of defect behavior in bulk silicon is of utmost importance. Three major defect types relevant to device performance have been identified:

1. Vacancy aggregates (known as *voids*, which usually have a size of less than 150 nm)
2. Si interstitial clusters embedded in a network of dislocation loops, each of which extend over several microns (L-pits)
3. Large grown-in oxygen precipitates.

The latter generate stacking faults (OSF) during wafer oxidation. The voids form in the center of the crystal, while L-pits are observed in the outer region. The two concentric defect regions are usually separated by a small OSF ring. The type of defect that develops in the growing crystal is determined by a simple parameter: the ratio of the pull rate to the temperature gradient at the growth interface. In industry, crystals with only one type of defect – voids – are produced almost exclusively. The formation and behavior of voids has been studied intensively and is accurately described by current theoretical models. As the feature size is now smaller than the void size in standard silicon crystals, the growth of so-called *perfect silicon* with almost no detectable defects may be adopted. Furthermore, the doping of crystals with impurities like nitrogen or carbon is being widely investigated. These impurities can significantly reduce the defect size, but they may also have harmful effects, such as enhancing the generation of OSFs. Some models have recently been proposed which may allow us to predict some of the effects of impurities.

5.1 Technological Impact of Intrinsic Point Defects Aggregates

Single intrinsic point defects in silicon – vacancies and interstitials – have not been found to have any negative impact on device performance so far. However, if they aggregate into clusters they can be even detrimental to device functionality. This is also true of extended defects like dislocations. When silicon wafer technology was in its formative years, much of the work devoted to improve wafer quality focused on controlling dislocation density in the silicon crystals, as it was not possible to grow dislocation-free crystals. However, with the introduction of dislocation-free crystal growth processes into mass production, the issue of extended dislocations in relation to bulk silicon quality vanished. As the feature size decreased and the demand for higher device performance increased, it soon became apparent that intrinsic point defects and their aggregation during the cool-down phase of the crystal growth process were having an increasingly negative impact on device performance and yield. Historically, one of the first serious challenges in this regard was the aggregation of Si interstitials in floating zone (FZ)-grown crystals, which results in a local network of dislocation loops (secondary defects), so-called *A-swirls* [5.1] or L-pits [5.2]. Although the diameters of these dislocation loops are only a few microns, they are large enough to generate hot spots in the space charge regions of high-power devices [5.3, 4]. In the second half of the 1980s, the industry began to encounter problems with the early breakdown of the gate oxide in memory devices based on Czochralski (CZ)-grown silicon [5.5]. After intensive gate oxide integrity (GOI) investigations, it was found that the root cause of the gate oxide degradation was tiny micro holes – voids – which were formed by vacancy aggregation during crystal growth [5.6, 7]. Each void is thermally stabilized by an oxide layer present on its inner surface. After wafer polishing, the voids show up as dimples or laser light scattering (LLS) defects on the wafer surface, causing a local thinning of the gate oxide [5.8, 9]. Voids are considerably smaller (less than 150 nm) than A-swirl defects, and so their impact on device performance is only apparent if the location of a void coincides with that of an active element, such as a transistor. In addition, most of these defective transistors can be repaired due to the built-in redundancy of memory chips. Consequently, vacancy aggregates are tolerable for many devices, so long as their density is insignificant compared to those of device process-induced defects. This should be contrasted with A-swirls or L-pits, which always result in permanent device damage due to their large sizes.

Empirically, it has been found that gate oxides 40–50 nm thick are most susceptible to void defects [5.9]. Thinner oxides show higher GOI yields, and when the thickness drops below 5 nm the influence of voids on the GOI yield disappears [5.10, 11]. However, as the feature size continues to shrink, additional adverse effects have been identified, such as shorts between trench capacitors and lack of device reliability [5.12, 13]. As the design rule becomes equal to or less than the void size, these problems are expected to aggravate and device manufacturers may have to switch to materials with extremely small defect sizes or those that contain virtually no defects.

There are three main ways to achieve silicon with no harmful intrinsic point defect aggregates. The first is to grow silicon crystals in a regime where Si interstitials and vacancies are incorporated in equal concentrations (Sect. 5.3.2), resulting in almost complete mutual annihilation of point defects (so-called *perfect* or *pure* silicon) [5.14–17]. The method inevitably involves lower pull rates and very tight control over crystal growth parameters, which yields considerably lower throughput and higher costs, in particular for 300 mm crystal growth.

The second approach is the growth of nitrogen-doped crystals with very fast pull rates (high cooling rates) and subsequent high-temperature ($\approx$1200 °C) wafer annealing [5.18]. Nitrogen doping in conjunction with a fast pull rate decreases the vacancy aggregate size (Sect. 5.3.3 and Sect. 5.3.4) [5.18, 19], meaning that they are easy to dissolve using a high-temperature wafer treatment. Void annihilation first requires the dissolution of the inner oxide layer, which in turn, necessitates the outdiffusion of oxygen. Thus, annealed wafers only exhibit a near-surface defect-free region $\approx$10 µm in depth, which is, however, sufficient for device manufacturing. Annealed wafers also take advantage of the notable mechanical strengthening effects of nitrogen doping [5.20–22], which helps to suppress slippage generation during high-temperature treatment. One very recent development is rapid thermal wafer annealing at a temperature of around 1300 °C. At this temperature, outdiffusion of oxygen is not necessary because the oxygen concentration is usually below that required for oxygen solubility, so the inner oxide layer dissolves throughout the bulk and the voids collapse. This process yields silicon of a similar quality to that resulting from perfect silicon crystal growth.

The third method is the well-known epi wafer approach.

All of these methods require rather precise defect engineering in order to obtain the properties demanded by the device industry, except in the case of pp + epi wafers. Here, the high boron concentration of the substrate suppresses intrinsic point defect aggregation (Sect. 5.3.4) and enhances oxygen precipitation in the bulk. Therefore, this wafer type not only provides a defect-free epi layer, but also provides high slip resistances and superior internal gettering (impurity removal) abilities of metallic contaminants.

5.2 Thermophysical Properties of Intrinsic Point Defects

Understanding intrinsic point defect aggregation undoubtedly requires rather exact knowledge of their respective thermophysical properties.

The intrinsic point defects – vacancies and Si interstitials – can exist in different configurations. Generally, six localized point defect configurations of high symmetry are considered: the vacancy and the split-vacancy on the one hand, and the tetrahedral, the hexagonal, the bond-centered and the [100] split or dumbbell Si interstitial on the other [5.23]. While the localized configuration works rather well for vacancies, theoretical calculations strongly favor an extended configuration of lower symmetry for Si interstitials [5.24, 25]. The extended self-interstitial model was originally proposed to explain the high pre-exponential factor in the coefficient of self-diffusion, and this model now has support from theoretical calculations [5.23, 26, 27]. According to theory, the high value of the pre-exponential factor results from the multitude of self-interstitial configurations with similar energies and the significant lattice relaxations that accompany some of these configurations.

Vacancies and Si interstitials can also exist in various charged states (such as $V^{2+}, V^{+}, V^{0}, V^{-}, V^{2-}$), and at the high temperatures ($> 1000\,^{\circ}\mathrm{C}$) where point defects start to aggregate all states should be present in dynamic equilibrium [5.28]. Due to this equilibration, it is not meaningful to assign a specific charge to vacancies and Si-interstitials, respectively. However, atomistic calculations show that the charged states are much higher in energy and so their populations should be negligible. So far, there is no indication that charged states have any impact on defect aggregation and so they are not considered in current defect nucleation models.

Unfortunately, it is generally not possible to observe intrinsic point defects directly and, consequently, their thermophysical properties cannot be measured directly either. Thus, indirect approaches must be used that involve fitting defect concentrations along with many other parameters. Various experimental systems have been used to infer the thermophysical properties of point defects. The most common of these are metal diffusion experiments where a metallic contaminant such as zinc, gold or platinum is introduced into the bulk via high-temperature drive-in diffusion [5.29–31]. The diffusion rate of the metallic impurity, which is easily detectable using standard methods, is related to the mobility and the concentration of intrinsic point defects (kick-out and Frank–Turnbull mechanism), which provides a way to indirectly probe the behavior of the point defects. These experiments yield good estimates for the product $C_{\mathrm{eq}}D$ of the equilibrium concentration C_{eq} and the diffusivity D for self-interstitials I and vacancies V, respectively. The following values are derived from zinc diffusion results [5.32]

$$C_{\mathrm{I}}^{\mathrm{eq}} D_{\mathrm{I}} = 1.5 \times 10^{26} \exp\left(\frac{-4.95\,\mathrm{eV}}{k_{\mathrm{B}} T}\right) \mathrm{cm}^{-1}\,\mathrm{s}^{-1}$$

and

$$C_{\mathrm{V}}^{\mathrm{eq}} D_{\mathrm{V}} = 1.3 \times 10^{23} \exp\left(\frac{-4.24\,\mathrm{eV}}{k_{\mathrm{B}} T}\right) \mathrm{cm}^{-1}\,\mathrm{s}^{-1}\,.$$

Another frequently used experimental method is the defect analysis of CZ crystals grown with varying pull rates. In this case, the observables are the dynamic responses of the oxidation-induced stacking fault (OSF) ring and the interstitial–vacancy boundary as a function of changes in crystal growth process conditions [5.2, 33–35] (Sect. 5.4). These observables have been quantitatively correlated to intrinsic point defect distributions in crystals and, therefore, can be used to derive thermophysical properties [5.36]. Of particular importance is the complementary nature of crystal growth and metal diffusion experiments with regard to parametric sensitivity. Its sensitivity to self-interstitial and vacancy competition implies that these experiments are suitable for determining some pre-exponential coefficients. The metal diffusion experiments, which can be carried out over a wide range of temperatures, are particularly useful for probing activation energies.

Rapid thermal annealing (RTA) experiments with fast cooling rates have been carried out with silicon wafers to investigate the influence of the free vacancy concentration on oxygen precipitation [5.17, 37]. By heating the wafers to above $1150\,^{\circ}\mathrm{C}$, detectable concentrations of Frenkel pairs are created in the wafer bulk. The wafer is then held at this temperature for around 10 s to allow the self-interstitials to diffuse

out, resulting in a near-equilibration of both interstitials $[C_I^{eq}(T)]$ and vacancies $[C_V^{eq}(T)]$. Following this rapid equilibration, the wafer is rapidly cooled (at rates of $\approx 100\,^{\circ}C/s$) to freeze in the vacancy excess which can subsequently be probed via its impact on oxygen precipitation. This technique is especially useful for gaining information on $[C_V^{eq}(T) - C_I^{eq}(T)]$ at various temperatures [5.38]. Quenching experiments at different holding temperatures are also reported for hydrogen-doped samples, which allow us to quantitatively measure the VH_4 complex [5.39]. From these results, the vacancy formation energy was deduced as $\approx 4\,eV$ with relatively good accuracy.

Experimental data that relate to the recombination coefficient of vacancies and Si interstitials are scarce [5.40, 41]. Nevertheless, there is general agreement that recombination between vacancies and Si interstitials is so fast that the product of the concentrations of both species is always in thermal equilibrium. The exact value is therefore not relevant to subsequent discussion here.

There have been numerous attempts to compute the thermophysical properties of point defects directly by atomistic simulations. The most important aspect of these atomistic calculations is the accuracy of the assumed interatomic interaction. As the ab initio approach, which explicitly considers electronic interactions, is extremely computationally expensive and therefore limited to small systems and zero temperature, most simulations are carried out using empirical potentials, such as the Stillinger–Weber or Tersoff potential functions, discarding explicit representations of electronic interactions. An excellent overview of this field is given by *Sinno* [5.42]. A parameter set that yields rather good results for defect aggregation is shown in Fig. 5.1. It is clear that the difference between the vacancy and Si interstitial concentrations at the melting point is only around 30% in favor of vacancies. On the other hand, vacancies diffuse more slowly than Si interstitials. These two properties are of great relevance to the peculiar defect behavior of silicon.

In the past, fitted values for equilibrium concentrations and diffusivities inferred from various experimental data often spread over many orders of magnitude, meaning that they were of little help. However, in recent years, theoretical methods and the accuracy of experimental data have significantly improved and the predicted values are now in much better agreement with those gleaned from experiments.

Recently, another impact factor became obvious which may have led to different fit results of the thermophysical data of the past. As described in detail later in Sect. 5.3.2, the solubility of the intrinsic point defects is obviously dependent on the thermal stress which is

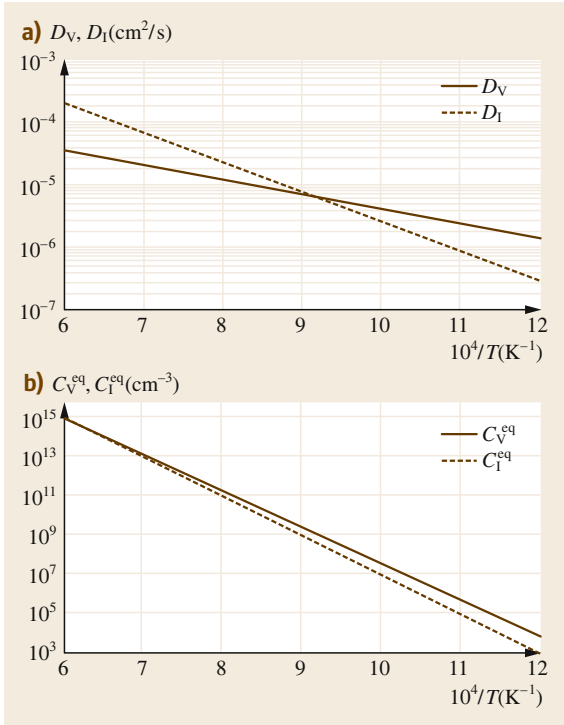

Fig. 5.1a,b Diffusivities and equilibrium concentrations of vacancies and Si interstitials, respectively. (After [5.43])

imposed on the crystal during growth [5.44]. In addition, the diffusivities of the intrinsic point defects are believed to be affected by stress, too. *Sueoka* et al. used density functional theory (DFT) calculations to determine the stress dependence of the formation enthalpies of vacancies and interstitials [5.45]. The best agreement between experimental and simulated values was obtained for plane thermal stress. Sueoka's ab initio calculations lead to the following dependencies of the formation enthalpies of vacancies (H_f^V) and interstitials (H_f^I) on the average plane stress (σ_{ave})

$$H_f^V\,(eV) = 0.308 \times \sigma_{ave}$$

and

$$H_f^I\,(eV) = -0.069 \times \sigma_{ave}$$

with σ_{ave} given in GPa. The relationship is valid in the range $-1\,GPa < \sigma_{ave} < 0\,GPa$, and the average plane stress is defined as $\sigma_{ave} = (\sigma_X + \sigma_Y)/3$. The effect of stress on the formation energies seems small, but these small differences have a notable influence on ξ_{tr} (see (5.1) in Sect. 5.3.2), the parameter which determines the incorporation of the predominant defect type in a growing crystal.

In another work, *Sueoka* et al. [5.46] used DFT calculations to obtain the formation energies of vacancies and interstitials at all sites within a sphere around a dopant atom in silicon [5.46]. This was done for substitutional p-type (B and Ga), neutral (C, Ge, and Sn), and n-type (P, As, Sb, and Bi) dopants. In this way, thermal equilibrium concentrations of vacancies and interstitials were obtained for various dopants and doping levels. For details see [5.46].

5.3 Aggregates of Intrinsic Point Defects

5.3.1 Experimental Observations

As pointed out in Sect. 5.1, the dominant intrinsic point defect aggregates in silicon single crystals are voids and L-pits/A-swirls. Figure 5.2 shows a transmission electron microscope (TEM) image of a void with a 5 nm oxide layer on the inner surface. Oxidation of the inner surface is not observed in FZ crystals due to their very low oxygen contents. The thickness of the oxide layer decreases with increasing cooling rate of the growing crystal. A strain field is generally not observed around the void. Usually, voids exhibit octahedral morphologies, but they can change to platelet or even rodlike shapes if the crystal is doped with nitrogen (Sect. 5.3.4). Under standard growth conditions, twin voids consisting of two partial octahedral voids are predominantly observed [5.47, 48]. At lower oxygen contents and higher cooling rates of the growing crystals, single octahedral voids are preferentially formed [5.49, 50]. Typical sizes range from 70–200 nm depending on the crystal growth conditions. Historically, different notations were introduced for this type of defect depending on their delineation or the detection technique used:

- Crystal originated particle (COP) [5.51]
- Laser light scattering tomography defect (LSTD) [5.2]
- Flow pattern defect (FPD) [5.52]
- D-defects [5.53].

Today, it is generally accepted that they all denote the same defect type: vacancy aggregates.

The TEM image of an L-pit is depicted in Fig. 5.3. The network of perfect dislocation loops characteristic of this defect type is clearly visible. The core of the defect is a self-interstitial aggregate which forms an extrinsic stacking fault [5.55, 56]. When the stacking fault reaches a critical size, the strain exerted on the crystal lattice is relaxed by the generation of dislocation loops. It is believed that the B-swirl observed in FZ crystals [5.57, 58] is most likely related to self-interstitial aggregates with sizes below the critical limit [5.59, 60]. While the B-swirl can be annihilated by appropriate high-temperature treatment, the L-pit/A-swirl is extremely stable.

In the case of epi wafers, voids at the substrate surface are covered by the epilayer and no defects are generated in the epilayer. However, if the layer thickness is very thin (< 1 µm), a dimple remains at the epi-

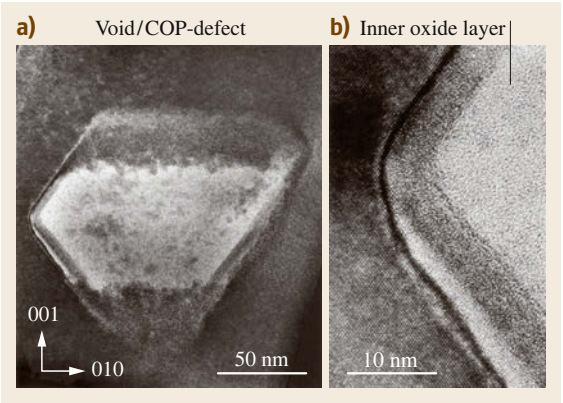

Fig. 5.2a,b TEM picture of a void/COP **(a)**. The inner surface of the void is cover by an oxide layer **(b)**. (After [5.54])

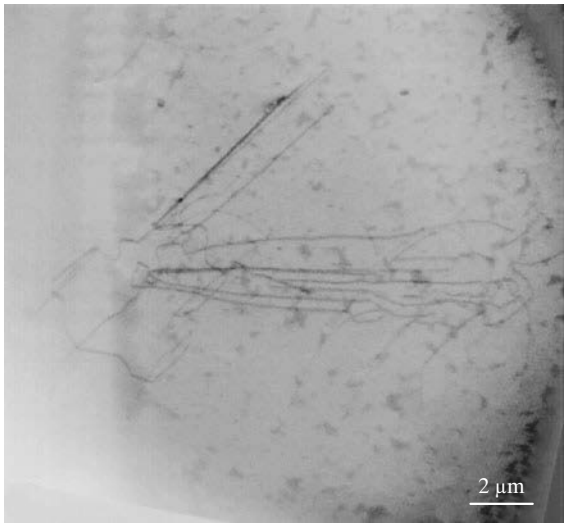

Fig. 5.3 TEM picture of an L-pit. (After [5.55])

layer surface which is detectable by laser light scattering [5.61]. In contrast to voids, L-pits always generate clearly visible and harmful defects in the epilayer [5.62] and are therefore unacceptable to device manufacturers. It is well-established that the pull rate V and the axial temperature gradient G at the growth interface of the growing crystal have the biggest influence on the defect types that develop in the growing crystal [5.33, 34, 63] and their spatial [5.35] as well as their density/size distributions [5.64]. At high pull rates, vacancy-related defects (voids) are observed over the entire crystal volume (Fig. 5.4). When the pull rate is reduced, oxidation-induced stacking faults (OSFs) develop in a small ring-like region near the crystal rim [5.65]. If the pull rate is decreased further, the ring diameter shrinks and L-pits are detected in the area outside the OSF ring [5.2]. No voids are found in this outer region. Thus, the OSF ring obviously represents the spatial boundary between vacancy- and self-interstitial-type defects. At a critical pull rate, the void region and the OSF ring disappear completely and only L-pits are detected. In FZ crystals with their inherently low oxygen contents, no OSF ring is observed as a boundary; instead a defect free-zone is observed as the boundary [5.66].

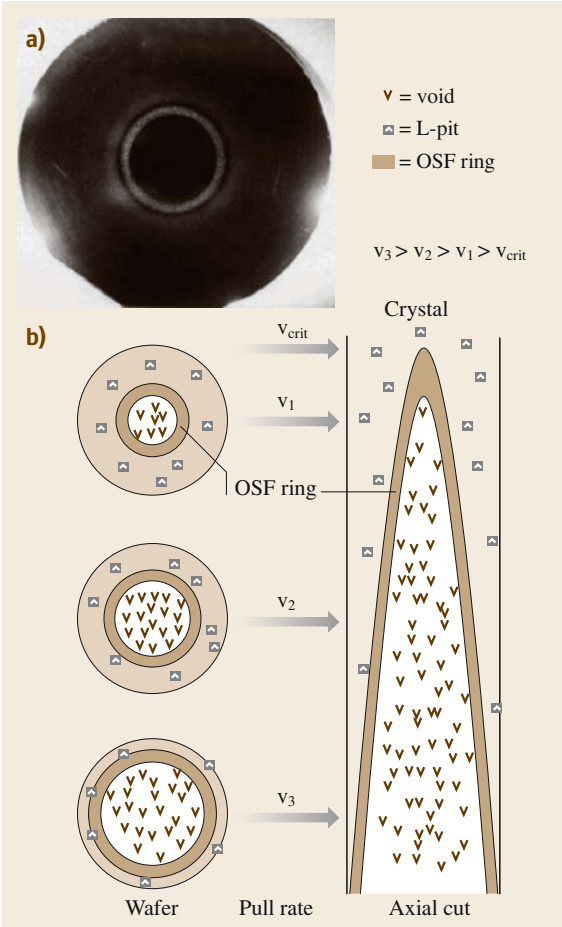

Fig. 5.4a,b Variation in the radial defect behavior of a CZ crystal as a function of pull rate. **(b)** shows a wafer from the crystal part grown with medium pull rate. The defects were delineated by Secco etching

The radial position of the OSF ring can be approximately described by the equation [5.35]

$$\frac{V}{G(r)} = \xi_{tr} = 1.34 \times 10^{-3}\,\mathrm{cm^2\,K^{-1}\,min^{-1}}\,.$$

Here r is the radial position. Recently, somewhat higher values for ξ_{tr} are proposed [5.44]. Thus, the parameter V/G controls the type of grown-in defect: if $V/G > \xi_{tr}$ vacancy aggregates develop, while for $V/G < \xi_{tr}$ Si interstitial-related defects are observed. This was first recognized by *Voronkov* in 1982 [5.63], who derived the following relation between ξ_{tr} and the thermophysical properties of intrinsic point defects

$$\xi_{tr} = \frac{(\Delta H_I + \Delta H_V)\left(D_I C_I^{eq}(T_0) - D_V C_V^{eq}(T_0)\right)}{2k_b T_0^2\left(C_V^{eq}(T_0) - C_I^{eq}(T_0)\right)}\,. \tag{5.1}$$

A further important parameter for the control of grown-in defects is the thermal history of the crystal. While its influence on the type of defect that develops in the growing crystal is negligible, detailed investigations have revealed a strong effect of cooling rate on the defect density/size distribution. For a crystal cooling in the temperature range between roughly 1000 and 1100 °C, there seems to be an exponential relation between the void density N_{void} and the dwell time t (Fig. 5.5) [5.67]. The defect density data in Fig. 5.5 were derived from GOI measurements that can detect much smaller defect sizes than delineation techniques based on etching and/or laser light scattering. The correlation between the various detection methods down to sizes of 0.12 µm was found to be rather good [5.18]. The exact upper value of the above temperature range depends on the crystal growth conditions and will be shown (Sect. 5.3.3) to coincide with the void nucleation temperature. The width of the selected temperature interval, on the other hand, does not have much impact on the above empirical relation. As will be discussed below, the relevant temperature interval is rather small [5.68]. Hence, the dwell time might just as well be replaced by the inverse of the cooling rate at the nucleation temperature.

It was further observed that the average void size increases as dwell time increases (with slower cooling rates) and vice versa (Fig. 5.6) [5.64, 69]. Another

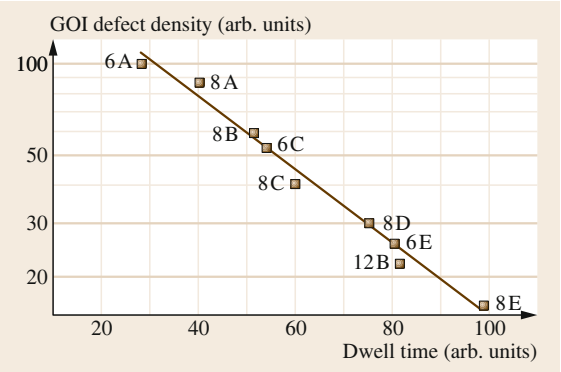

Fig. 5.5 Void density as derived from GOI measurements as a function of the dwell time of the growing crystal at ≈1100 °C. The *straight line* denotes simulation results. The various data points relate to different growth processes. (After [5.64])

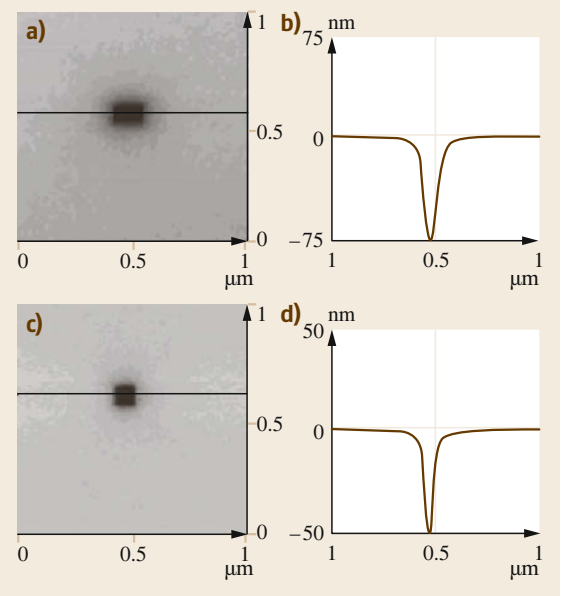

Fig. 5.6a–d Atomic force microscopy measurements of voids at the wafer surface **(a,c)** and their respective depth profiles **(b,d)**. The depth of the surface void is rather close to its original size in the crystal. **(a)** and **(b)** refer to a slowly cooled and **(c)** and **(d)** to a rapidly cooled crystal. (After [5.61])

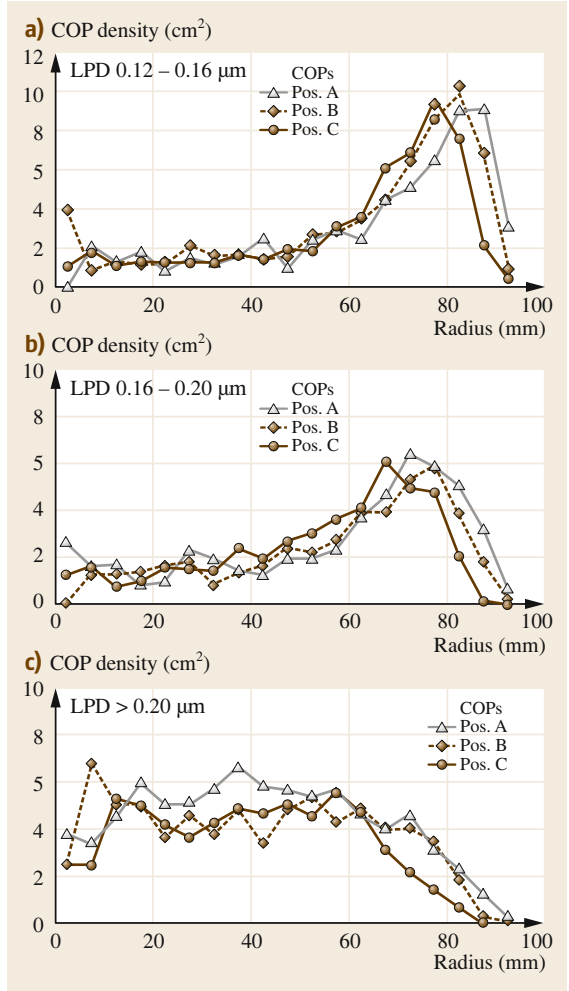

Fig. 5.7a–c Radial variation in the density/size distribution of voids/COPs across a wafer as measured by laser light scattering. The light point defect size (LPD) correlates well to the actual void size. The positions *A*, *B* and *C* relate to different axial crystal positions

striking feature is the characteristic change in the defect density/size distribution across the crystal diameter (Fig. 5.7) [5.70]. While large voids of low density prevail in the crystal center, the distribution gradually shifts to small sizes and high density towards the boundary of the void region. As the cooling rates of the crystal center and rim are almost the same, this remarkable variation in the density/size distribution must be related to the radial inhomogeneity of $V/G(r)$. Unfortunately, similar data are not yet available for L-pits. The behavior of this defect type is more complex, as small interstitial aggregates which do not generate dislocation loops are not detected as L-pits.

Valuable information about the defect nucleation temperature is obtained from transient growth experiments where the pull rate is reduced to zero and the growth process is halted when a certain crystal length has been reached [5.71–73]. After a certain amount of time has elapsed, growth is resumed and the crystal is grown to full length. During the halting period, the various crystal positions are at different temperatures ac-

cording to the axial temperature gradient of the crystal. By analyzing the axial defect behavior of the as-grown crystal, one can identify the temperature ranges where specific defect types nucleate and grow in size. The results of those experiments clearly demonstrated that the nucleation temperature of voids lies between 1000 and 1100 °C and varies with the growth conditions. It was also demonstrated that the nucleation and growth period of the voids occurs over a temperature interval of less than 50 K [5.74]. Void growth is then obviously stopped by the formation of the inner oxide layer. The oxide layer continues to grow down to relatively low temperatures. The scarce data available for L-pits indicate a similar temperature range for nucleation [5.75].

5.3.2 Theoretical Model: Incorporation of Intrinsic Point Defects

The incorporation of intrinsic point defects is the result of two competing fluxes at the growth interface: a vacancy and an interstitial flux which are both directed into the crystal (Fig. 5.8). Each of the two fluxes consists of two components. The first flux component is driven by the advancing growth interface, which generates a convective flux proportional to the pull rate V, and the second is driven by the vacancy/interstitial recombination behind the interface, which creates a concentration gradient and, in turn, a Fickian diffusion flux. The latter is proportional to G. If the pull rate is low, then the Fickian diffusion dominates over the convective flux. As self-interstitials diffuse significantly faster than vacancies, the self-interstitial flux wins over the vacancy flux. During crystal cooling, V–I recombination virtually eliminates the vacancies and the surviving self-interstitials are driven into supersaturation and finally aggregate. On the other hand, at fast pull rates the convective flux dominates and, due to the larger equilibrium concentration of vacancies compared to that of self-interstitials, more vacancies flow into the crystal, resulting in vacancy aggregates. A similar change in the prevailing defect type is obtained when G is varied. The above model, originally proposed by *Voronkov* [5.63], yields the previously mentioned parameter V/G which determines the defect type.

In standard growth processes, G always exhibits a notable increase from the center towards the crystal rim, which (at sufficiently low pull rates) results in a vacancy excess in the center, while Si interstitials dominate at the crystal rim, as indicated in Fig. 5.9. Figure 5.10 illustrates how the radial position of the crossover between ξ_{tr} and $V/G(r)$ and hence the boundary between the void and L-pit regions is shifted when V is varied.

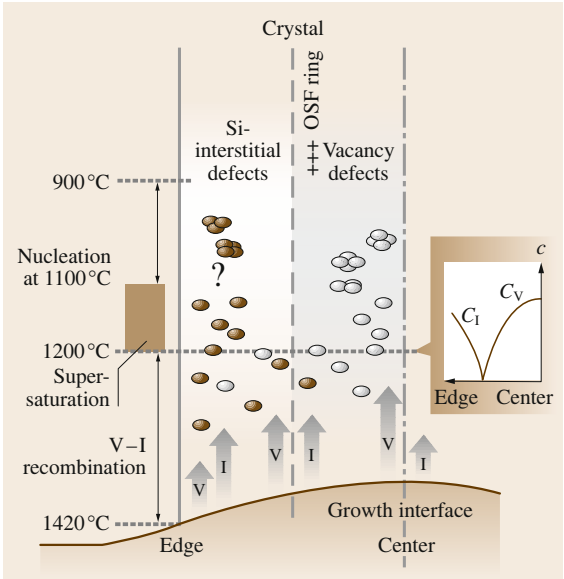

Fig. 5.8 Schematic picture of the incorporation of vacancies (V) and Si interstitials (I), respectively, into the growing crystal. The *insert on the right* shows the radial variation of the remaining species after V–I recombination has ceased and supersaturation starts

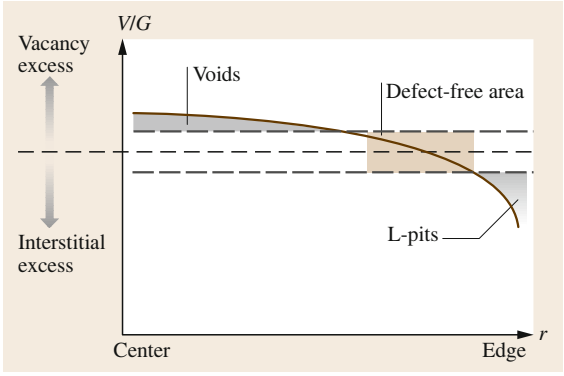

Fig. 5.9 Schematic radial variation in defect types as a function of the radial variation of V/G

The exact value of ξ_{tr} is still under discussion, because G has to be taken directly at the interface where the thermal field in the crystal changes very rapidly [5.35, 76]. Therefore, it has not been possible to accurately measure G at the growth interface [5.77]. Fortunately, computer simulations with sufficiently refined meshes permit a rather accurate calculation of G. Based on these calculations, a value of $0.13\ \mathrm{mm^2\ min^{-1}\ K^{-1}}$ has been determined from growth experiments, with hot zones of different Gs [5.33], which, however, is currently debated again.

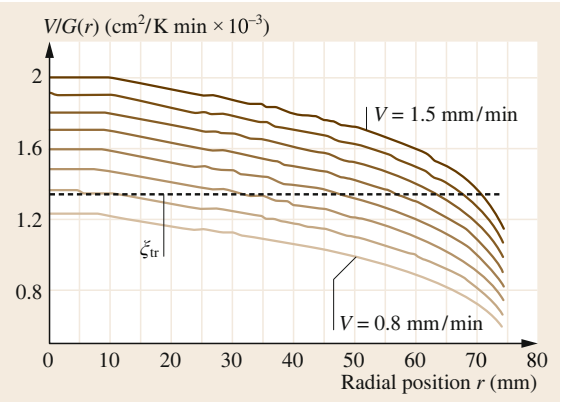

Fig. 5.10 Radial variation in the crossover between the transition value ξ_{tr} and $V/G(r)$ as function of decreasing pull rate V

It should be noted that the above behavior is probably unique to silicon as it stems from the peculiar phenomenon that the vacancy and Si interstitial equilibrium concentrations in crystalline silicon are very similar, but C_v^{eq} is slightly higher than C_I^{eq}, although the diffusivity of Si interstitials exceeds that of vacancies at the melting point. In addition, the quantitative relationship between the relevant parameters which allows the changeover in defect behavior to occur in accessible growth rate regimes is quite astonishing. The time-dependent behaviors of the point defect concentrations are determined by the species conservation equations [5.78]

$$\frac{DC_I}{Dt} = \nabla\left[D_I(T)\nabla C_I - \frac{D_I(T)C_I Q_I^*}{k_b T^2}\nabla T\right] - k_{IV}\left(C_I C_V - C_I^{eq} C_V^{eq}\right) - \frac{\partial}{\partial t}\int_2^\infty n f_I(n,r)\,dn\,, \tag{5.2}$$

where Q_I^* is the reduced heat of transport for Si interstitials, which describes the rate of material flow due to a temperature gradient. A similar expression applies for vacancies (just exchange the I and V notations). The substantial derivative $D/Dt = [\partial/\partial t + V(\partial/\partial z)]$ is defined here as the rate of change of species concentration at a point moving with the velocity (V) of the advancing growth interface. This term relates to the incorporation of species due to convection. The first term on the left-hand side accounts for Fickian diffusion and the second for thermodiffusion. The last term represents the loss of point defects into their aggregates of all possible sizes. This term can be neglected as long as the supersaturation of the surviving species has not increased to the point where cluster nucleation starts. A detailed analysis also reveals that thermodiffusion has no detectable impact. Hence, the simple picture drawn above – which only takes into account convection and Fickian diffusion – is quite reasonable. Based on these simplifications, the incorporated vacancy concentration can be calculated from a simple expression [5.76, 79]

$$C_V(r) \approx \left[C_V^{eq}(T_m) - C_I^{eq}(T_m)\right]\left(1 - \frac{\xi_{tr} G(r)}{V}\right). \tag{5.3}$$

This expression is also applicable to Si interstitials (at $V/G < \xi_{tr}$). It then defines the incorporated Si interstitial concentration C_I with a minus sign.

If V/G approaches ξ_{tr}, then the vacancy and Si interstitial fluxes become equal and both species are annihilated by V–I recombination. Thus, the incorporated V and I concentrations are negligible and no aggregates can form. This particular condition must be met for the growth of so-called perfect and *defect free* silicon, respectively.

Based on the picture outlined above, one would expect to be able to grow crystals which are I-rich in the center and V-rich near the surface by simply engineering the hot-zone and the process conditions in such a way that G is higher in the center than at the rim of the growing crystal (Fig. 5.11). Surprisingly, respective experiments which were carried out some years ago showed that, under such conditions, vacancy aggregates can still prevail in the center and interstitial clusters at the periphery of the crystal [5.80]. The authors explained these findings by the effect of thermo-mechanical stress during growth on the solubility of native point defects by noting that compressive stress increases the solubility of V_s and vice-versa for I_s. As a consequence, the critical value of V/G, where vacancies and interstitials annihilate each other, be-

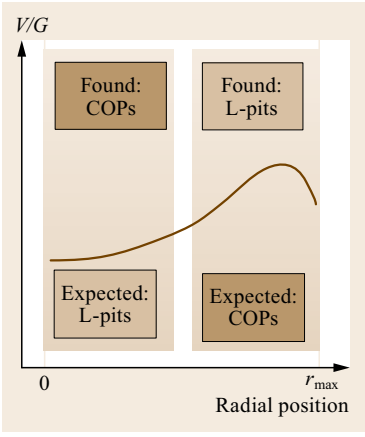

Fig. 5.11 Radial variation of V/G for a special hot zone with compressive stress in the crystal center and tensile stress at the periphery of the growing crystal. Comparison of expected and experimentally found defect behavior

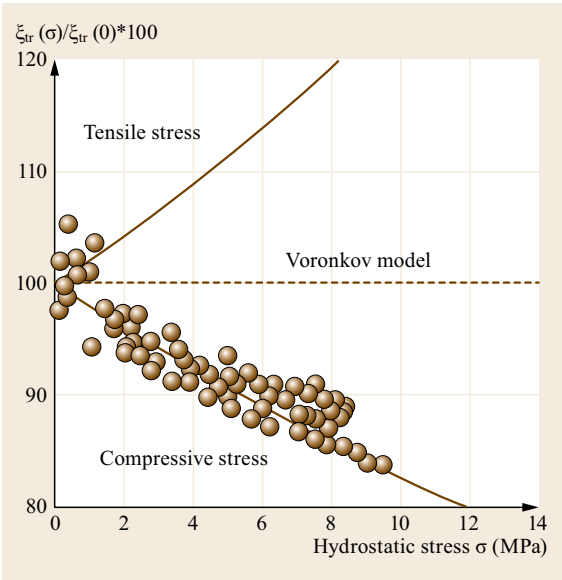

Fig. 5.12 Dependence of $\xi_{tr}(\sigma)/\xi_{tr}(0)$ on tensile and compressive stress in the growing crystal. *Open circles* show the data of *Nakamura* after scaling the hydrostatic stress to account for the differences in elastic parameters used. (After [5.44, Fig. 1], [5.80])

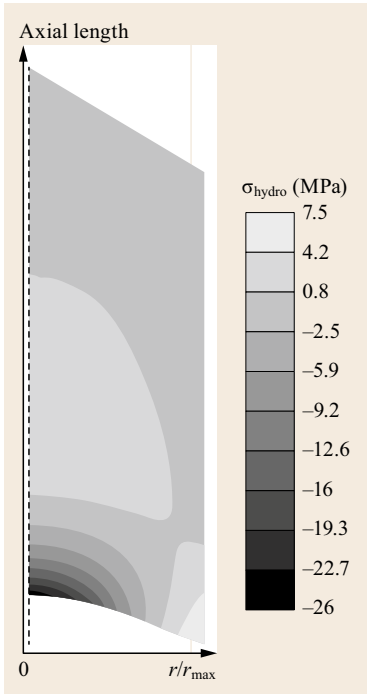

Fig. 5.13 Distribution of stress in a growing crystal which has a similar radial variation of V/G as in Fig. 5.11. However, the stress in the growing crystal is engineered in such a way that *defect free* silicon is obtained

comes a function of the thermo-mechanical stress in the vicinity of the growth interface (5.1). Figure 5.12 shows how $\xi_{tr}(\sigma)/\xi_{tr}(0)$ depends on hydrostatic stress according to [5.80].

The dependence is obtained from the classical expression for $\xi_{tr}(0)$ (5.1) by adding the effect of hydrostatic stress to the formation enthalpy of point defects i. e., by adjusting the volume change due to point defect creation using the same value for both I's and V's for simplicity and neglecting the effect of stress on point defect diffusivity. It should be noted that a more accurate solution is obtained if the diffusion-convection-reaction problem is solved in the full crystal which is especially important for strongly curved interfaces.

Figure 5.13 depicts the distribution of hydrostatic stress and crystal interface shape for a 300 mm crystal where the radial variation of V/G is similar to that of Fig. 5.11, but the thermo-mechanical stress is engineered to balance V/G so that *defect free* silicon can be obtained [5.80]. There is quite large compressive stress in the crystal center and several times smaller tensile stress near the triple point.

The effect of stress on the formation energy of point defects was already discussed by *Tanahashi* et al. [5.81], before the above experiment was carried out, but their estimates were far too low to explain the findings of [5.80]. Recently, *Nakamura* et al. [5.44] published a new set of data showing the dependence of $\xi_{tr}(\sigma)/\xi_{tr}(0)$ on hydrostatic stress. They are in good agreement with Fig. 5.12, if one corrects the effect of the different elastic parameters used in both publications. For a more detailed analysis including extensive atomistic simulations, we refer to the recent literature [5.45, 82, 83].

5.3.3 Theoretical Model: Aggregation of Intrinsic Point Defects

Due to the technological dominance of vacancy-rich silicon, previous theoretical investigations of defect aggregation have mainly focused on the formation of voids. In addition, it was also easier to verify the theoretical results for vacancy aggregation because voids are not obscured by the secondary defect generation that occurs for L-pits.

From Fig. 5.14, it can be seen that, for a standard growth process, the V-supersaturation already begins to build up at around 1200 °C [5.84], which is well above the experimentally determined nucleation temperature of voids (≈ 1100 °C). Thus, the supersaturation C_V/C_V^{eq} necessary to nucleate voids is appreciable, ≈10 [5.78], as estimated from Fig. 5.14. This fact also allows us to decouple the phase where V–I recombination is the major vacancy loss mechanism from the phase where nucleation dominates the vacancy loss, so that one can assume that the cluster formation starts with a fixed concentration which can be cal-

culated from (5.3). For special growth processes that are designed to minimize or even eliminate voids, the starting vacancy concentration after V–I recombination is so small that the beginning of supersaturation (and hence void nucleation) occurs at notably lower temperatures [5.79].

The first vacancy aggregation calculations were performed with a model that was originally developed to simulate oxygen precipitation [5.64, 85]. For the formation of small clusters (less than 20 vacancies), the kinetics are described by chemical rate equations; for larger clusters, the rate equations are expanded into a continuum formulation that yields a single Fokker–Planck equation. The void shape is assumed to be spherical. Input data are the computed temperature field, which can be quite accurately calculated using commercially available standard codes, and the surviving vacancy concentration after V–I recombination has ceased. Besides the physical properties of the vacancies and Si interstitials, the surface energy must also be known, which is estimated to be around 950 erg/cm^2.

As can be seen from Fig. 5.14, the computer simulations yield a nucleation temperature of around 1100 °C, which agrees fairly well with the experimental results. The prediction of the correct aggregation temperature has been a matter of discussion. With the above input data, one ends up with a far lower aggregation temperature than those observed [5.86, 87]. The main reason for this is that the nucleation process does not start as a small octahedral void as previously assumed, but rather as an *amorphous cloud* of vacancies which, after some time, relaxes into an octahedron with (111) facets [5.88]. Proper modeling of this initial nucleation process with atomistic calculations does indeed shift the calculated aggregation temperature into the experimentally observed range.

The results in Fig. 5.14 also demonstrate that a higher cooling rate obviously decreases the nucleation temperature. The origin of this effect is the increased supersaturation, which builds up because there is less time for vacancy consumption. Due to the shift in the nucleation temperature, the residual vacancy concentration after void formation remains higher for fast cooling rates than for slow cooling. This has an important effect on the nucleation of oxygen precipitates, as the latter is strongly enhanced by a higher free vacancy concentration. Figure 5.15 illustrates the evolution of the void density/size distribution during the nucleation period. It is apparent that the maximum of the distribution is shifted to larger void sizes not only due to the growth of the previously nucleated voids, but also due to the fact that the newly nucleated clusters have a larger size. The latter effect results from the decreased supersaturation with higher void density, which, in turn, increases

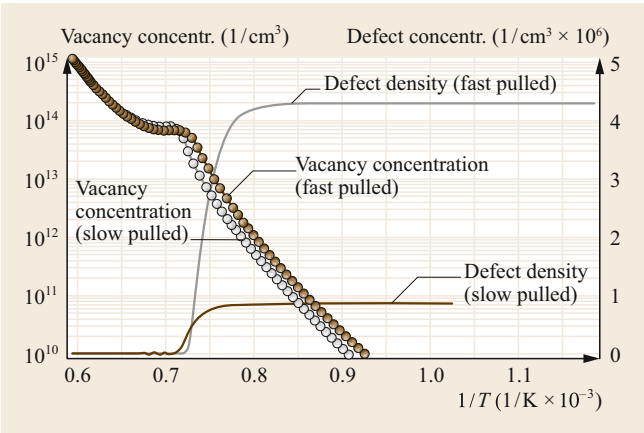

Fig. 5.14 Simulated variation in the vacancy concentration in growing crystals as a function of temperature for rapidly and slowly cooling growth processes. The density of voids nucleated at around 1100 °C and below is shown on the *right scale*

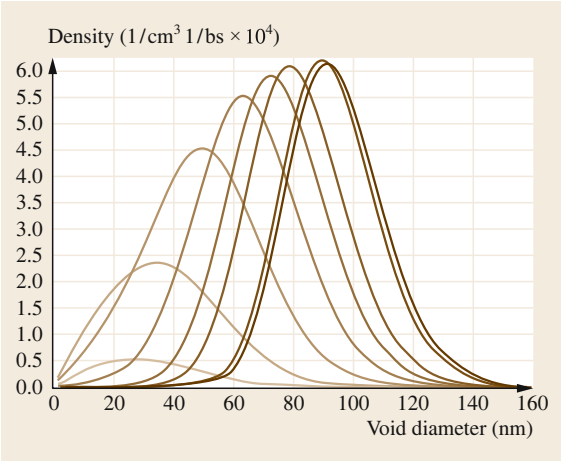

Fig. 5.15 Simulated evolution of the void density–size distribution at various temperatures of the growing crystal. The temperature difference between each curve is 4 K

the critical radius for stable nuclei. Thus, only increasingly large clusters can nucleate towards the end of the nucleation period.

As depicted in Fig. 5.16, a fast cooling rate decreases the cluster size but increases their density and vice versa, which correlates well with the experimental data. The reason for this is the above-mentioned higher supersaturation at fast cooling rates, which entails a larger nucleation rate. The higher cluster density then effectively lowers the residual vacancy concentration. The clusters, however, have no time to grow and so remain small.

A similar effect is obtained when the initial vacancy concentration before the onset of nucleation is

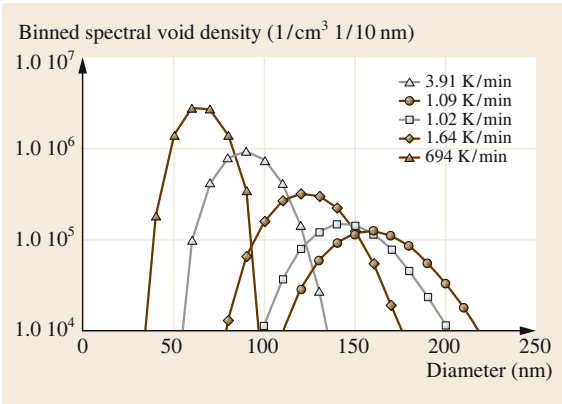

Fig. 5.16 Simulated density/size distributions of voids for growth processes with different cooling rates

reduced [5.89]. A lower vacancy concentration causes a downward shift in the nucleation temperature, where the vacancy diffusivity is lower. As a consequence, they need more time to diffuse to sinks, which in turn drives up supersaturation and so more clusters of a smaller size are formed again. The behavior of the size distribution as a function of the initial vacancy concentration gives a simple explanation for the experimentally found radial variation in the void size distribution in Fig. 5.7. As the initial vacancy concentration decreases towards the crystal rim (Fig. 5.17), the average size of a void shrinks but void density grows. Thus, the density of small voids is low in the center, but increases towards the crystal rim until the vacancy concentration drops below a critical value, where the average void size is below the detection limit. On the other hand, the number of large voids shrinks with decreasing vacancy concentration. Therefore, the density of large COPs is highest in the center. This behavior is also fairly well reproduced by simulation (Fig. 5.18).

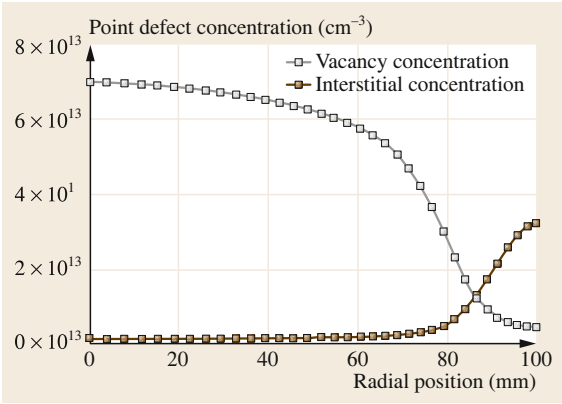

Fig. 5.17 Simulated radial variations in the vacancy and Si interstitial concentrations, respectively. (After [5.70])

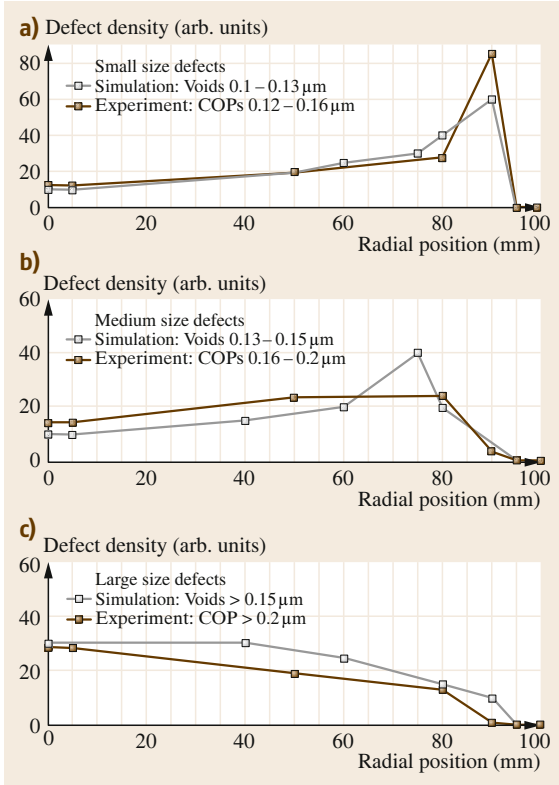

Fig. 5.18a–c Simulated radial variation in the density/size distribution of voids and comparison with experimental data. (After [5.70])

A simple expression that predicts a void density proportional to $q^{3/2}C_V^{-1/2}$ ($q =$ cooling rate, $C_V =$ initial vacancy concentration before nucleation starts) has been derived by *Voronkov* et al. [5.68]. This formula is obviously in excellent agreement with the experimental results (Fig. 5.19). A deviation from the above expression was reported for detached crystals, where significantly higher cooling rates can be achieved (2–70 K/min) [5.90]. In the latter case, this discrepancy was tentatively explained by a suppression of voids in favor of enhanced formation of oxygen precipitates at high cooling rates (> 40 K/min) [5.91]; in other words, so-called *oxide particles* nucleate at around 1100 °C rather than voids.

The $C^{-1/2}$ dependence is more difficult to verify experimentally because a change in the initial vacancy concentration entails a change in the nucleation temperature and so temperature-dependent parameters like diffusivities and equilibrium concentrations must be adjusted. Most of the current aggregation models do not consider the oxidation of the inner void surface, which stops void growth before the vacancies are essentially depleted. This has less impact on the void size

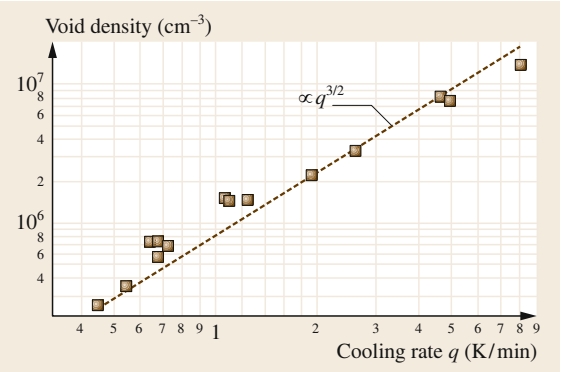

Fig. 5.19 Void density as derived from GOI measurements as a function of cooling rate of the growing crystal. The *straight line* relates to predictions of the $q^{3/2}$ law

distribution but considerably affects the residual vacancy concentration and therefore oxygen precipitation (Sect. 5.4).

The occurrence of double voids is still under discussion. One attempt to explain this phenomenon is based on a partial oxidation of the (111) facets during void growth, which allows the incorporation of further vacancies at the unoxidized residual facet surface [5.92].

5.3.4 Effect of Impurities on Intrinsic Point Defect Aggregation

The influence of impurities on the aggregation of intrinsic point defects has been widely investigated. It was found that many of them can notably modify the defect density and size which is of great technological importance. Many attempts have been made to explain the specific mechanisms. However, a unified theoretical approach has not been achieved. This is also due to the fact that the observed effects occur at concentrations which vary over many orders of magnitude.

Nitrogen

Codoping of silicon crystals with nitrogen is of considerable relevance in technical applications, as nitrogen already has a massive impact on point defect aggregation at very low concentrations. It has long been known to simultaneously suppress interstitial- and vacancy-related defects – A-swirls and D-defects/voids, respectively [5.93] – in floating zone (FZ)-grown crystals. The nitrogen concentrations required are very low ($< 2\times10^{14}$ at/cm^3) and were found to be in the same range as the surviving residual intrinsic point defect concentrations. Owing to the low nitrogen concentration, adverse effects of nitrogen codoping are technically insignificant. Well known is the formation of nitrogen related thermal donors after neutron transmutation doping which, however, can be handled by properly annealing the neutron irradiated ingots [5.94]. Consequently, all FZ grown silicon crystals are nitrogen codoped, today.

In the case of Czochralski (CZ)-grown silicon, nitrogen has been an undesirable dopant in the past, because it enhances the formation of oxidation-induced stacking faults (OSF) [5.95]. As the nitrogen concentration increases, the OSF ring widens [5.96] until it extends over the entire crystal diameter. In addition, due to the comparatively high oxygen concentration (3–8×10^{17} at/cm^3), the desirable defect suppressing effects of nitrogen are largely offset by the interaction of nitrogen and oxygen [5.97]. However, nitrogen still has a notable effect on the defect size: the higher the nitrogen concentration, the lower the defect size [5.18, 98]. This effect is important, because a small defect size is highly favorable for defect annealing [5.16]. It was further found that nitrogen not only reduces the defect size but also systematically changes the void morphology from octahedron to platelet and, finally, to rods or even rod clusters with increasing concentration (Fig. 5.20) [5.99]. Nitrogen doping has gained additional interest as it also strongly enhances oxygen precipitation [5.100–102] which can be used to improve the efficiency of gettering of metallic contaminants in low thermal budget device processes [5.103, 104].

Unfortunately, quantitative data on the chemical and physical properties of nitrogen in silicon are rare. Experimentally, it was found that nitrogen exists as N–N dimers in as-grown silicon [5.105], which has a diffusivity three orders of magnitude higher than oxygen at 1100 °C [5.106]. These diffusion experiments indicate that the N–N dimer is stable up to at least 1270 °C [5.107], which is in line with first-principles

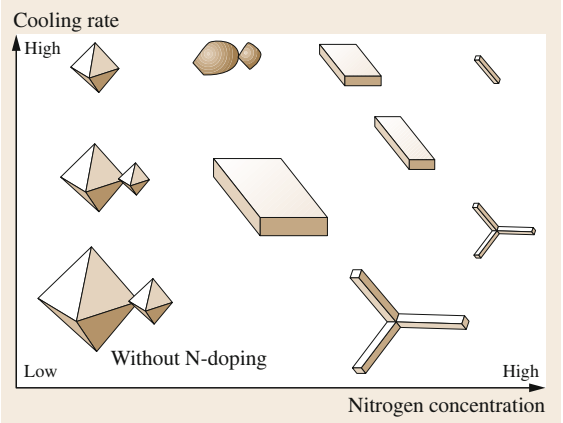

Fig. 5.20 Variation in void morphology as a function of nitrogen concentration and cooling rate of the growing crystal. (After [5.99])

calculations of the N–N dimer configuration [5.108–110]. In contrast with the nitrogen molecule, the N–N dimer in silicon does not have any direct bonds between the two neighboring nitrogen atoms. Experiments with nitrogen-implanted silicon samples heated to melt temperature by a laser pulse and subsequently quenched to room temperature proved that roughly 10% of the nitrogen can be frozen on substitutional sites as single nitrogen atoms [5.111, 112]. The fact that substitutional nitrogen is generally not observed in regularly cooled samples suggests that substitutional nitrogen is not stable in silicon at lower temperatures [5.113].

As the nitrogen concentration needed to suppress A-swirl and D-defects is in the same range as the intrinsic point defect concentration before aggregation, it was suggested that nitrogen directly interacts with vacancies (V) and Si interstitials (I) and thus prevents their aggregation [5.114, 115]. One model proposes that the storage of vacancies in impurity complexes would gradually shift the transition value ξ_{tr} of V/G to higher values which, in turn, would explain the shrinkage of the void region with increasing nitrogen content [5.116]. On the other hand, the model also seems to imply that the A-swirl region simultaneously expands toward the crystal center, which is in conflict with experimental results. In particular, the Li-drift experiments of *Knowlton* et al. [5.117] proved that, despite the suppression of detectable COPs, the extent of the vacancy-rich region does not change due to nitrogen doping. Other attempts are based on the reduction of vacancy diffusivity due to the vacancy–nitrogen interaction [5.118] or on increasing the reaction barrier to vacancy absorption at the void interface [5.119]. However, the fact that nitrogen doping has no impact on the inner oxide layer growth of the voids [5.99] does not support the notion that nitrogen modifies the properties of the void interface. None of these proposals gives any explanation for influence of nitrogen on Si interstitial aggregation.

First-principles calculations by *Sawada* et al. [5.108] and *Kageshima* et al. [5.109] have shown that the N–N dimer can form stable N_2V and N_2V_2 complexes, the latter being more stable due to a larger enthalpy of formation. Based on these results, it has been proposed that the vacancy aggregation is suppressed by the reaction

$$\text{I)} \quad N_2 + V \leftrightarrow N_2V \,,$$

whereas the formation of Si interstitial agglomerates is prevented by the reaction

$$\text{II)} \quad N_2V + I \leftrightarrow N_2 \,.$$

Nitrogen is not likely to be incorporated as a N–N dimer into the crystal. This is concluded from the experimental fact that nitrogen does not evaporate from the silicon melt and so it must be strongly bound to silicon atoms, which is not possible for a nitrogen molecule. It was therefore proposed that single nitrogen atoms are incorporated on interstitial (N_I) as well as substitutional sites (N_s) at the growth interface [5.120]. Behind the growth interface, the highly mobile interstitial nitrogen atoms then quickly form N–N dimers via $N_I + N_I \leftrightarrow N_2$ and nitrogen-vacancy complexes via $N_I + N_s \leftrightarrow N_2V$ inside the crystal. A ratio of $[N_I] : [N_S] = 7 : 1$, which corresponds to 12% of the nitrogen at substitutional sites, has been determined from FZ crystals grown with various nitrogen contents. This is in good agreement with the above-mentioned experimental findings for substitutional nitrogen. As vacancies and Si interstitials have very similar concentrations at the melting point, reactions (I) and (II) mainly act as an additional V–I recombination path during crystal cooling, with only marginal impact on the levels of N_2 and N_2V. However, when recombination is complete and the vacancies or the Si interstitials have been wiped out, reaction (I) or (II) prevents the aggregation of the surviving species. Using this model, it has been possible to determine the radial variations of vacancies and Si interstitials in FZ crystals before the onset of defect aggregation [5.120]. This was achieved by measuring the radial extension of the COP and A-swirl region as a function of the nitrogen concentration. The result is in excellent agreement with theoretical predictions (Fig. 5.21). Surprisingly, the experimental data could not be fitted by assuming that the formation of N_2V_2 complexes prevails, as predicted by theoretical calculations. It is not clear whether the reaction to N_2V_2 is hampered by a high-energy barrier.

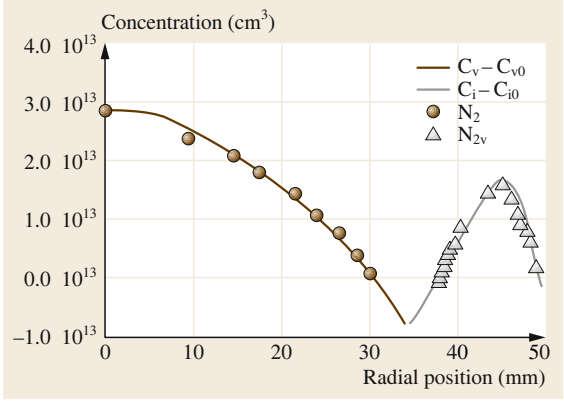

Fig. 5.21 Radial vacancy and Si interstitial distributions as derived from a FZ crystal grown with an axially varying nitrogen concentration. $C_{V0} = 8.8 \times 10^{12}$ at/cm^3 and $C_{I0} = 7.7 \times 10^{12}$ at/cm^3. The *solid* and *dashed lines* refer to simulation results. (After [5.120])

None of the above mentioned models can explain why the effect of nitrogen on defect aggregation is strongly diminished in CZ crystals. It is clear that the well-known interaction between nitrogen and oxygen, which results in the formation of N_xO_y complexes [5.121], is probably the origin of the vanishing nitrogen effect. However, it is also known that, despite oxygen levels of 5-6 $\times 10^{17}$ at/cm^3, ample unreacted nitrogen is left in oxygen- and nitrogen-doped as-grown crystals to suppress defect aggregation [5.122]. It is therefore necessary to look for a mechanism that significantly reduces the concentration of free nitrogen dimers at the nucleation temperature of voids and L-pits, but reestablishes their concentrations at lower temperatures. As the experimentally confirmed N_2O complex is only stable up to about 700 °C [5.121, 123], it has been proposed [5.120] that nitrogen reacts with oxygen at high temperatures according to

$$\text{III)} \quad 2\text{NO} \leftrightarrow \text{N}_2 + 2\text{O}_\text{i} \; .$$

The existence of the NO complex has been theoretically predicted by *Gali* et al. [5.124] and, more recently, has also been experimentally confirmed [5.125, 126]. It has a similar structure to the N_2 complex but with a smaller binding energy. Due to the large excess of oxygen over nitrogen, it has been assumed that the equilibrium of reaction (III) is on the left-hand side near the melting point and so very little N_2 is available. As the temperature decreases, the equilibrium gradually shifts to the right-hand side and more and more N_2 is generated. If the temperature at which N_2 starts to develop in sufficient quantities is below the vacancy aggregation temperature, the formation of voids is not suppressed. If the N_2 formation temperature is above the vacancy aggregation temperature, void formation depends on how much N_2 is available in relation to the vacancy concentration at the void nucleation temperature. The higher the N_2 formation temperature, the more N_2 is available to reduce the number of vacancies by reaction (I). According to reaction (III), the formation temperature of N_2 should increase with lower oxygen and higher nitrogen concentrations. Lower free vacancy concentrations and therefore lower aggregation temperatures result in voids of smaller size but higher density, in agreement with the experimental findings.

After void nucleation, the free vacancy concentration drops rapidly and the above reaction (I) reverses, giving $N_2V \rightarrow N_2 + V$, which slows down the decay of free vacancies. Thus, the N_2V-complex acts as an interim reservoir for vacancies – its formation before void formation removes vacancies and its dissociation after void formation releases them again [5.96]. In conjunction with the lower vacancy aggregation temperature, this results in a notable increase in free vacancy concentration during this cool-down phase compared to nitrogen-free material (Fig. 5.22). As free vacancies are known to strongly favor the nucleation of oxygen precipitates, the latter effect gives a simple explanation for the observed strong enhancement of oxygen precipitation in nitrogen-doped CZ crystals (Sect. 5.4).

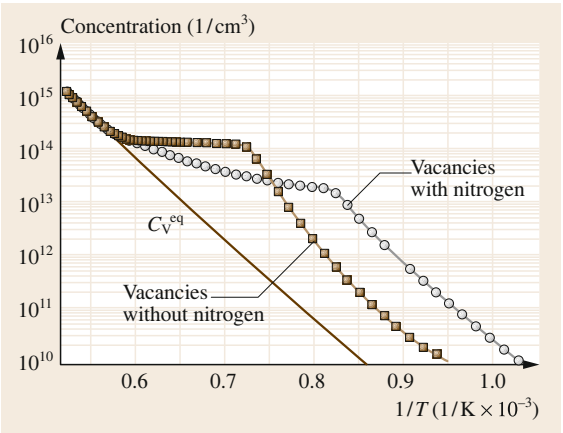

Fig. 5.22 Simulated variations in the vacancy concentration as a function of temperature for a nitrogen-doped and an undoped crystal

The remarkable variation in the void morphology as a function of the nitrogen content is still under discussion. A similar change in morphology is also known for oxygen precipitates. In this case, the effect can be interpreted in terms of the balance between the relaxation energy of the lattice strain and the interfacial energy. However, TEM investigations do not reveal any lattice strain around voids, and so another mechanism is required to explain the varying void morphology.

Boron

Boron doping affects the intrinsic point defect aggregation in a similar way to nitrogen doping, but much higher concentrations are required [5.127]. These high concentration are technologically relevant as highly boron doped wafers are widely used as substrates for epitaxial layers in the electronic industry. It was found that the COP region as well as the diameter of the OSF ring starts to shrink when the boron content exceeds roughly 5 $\times 10^{18}$ at/cm^3 (Fig. 5.23). In contrast with nitrogen, OSF formation is not enhanced and the width of the OSF ring remains unchanged with increasing boron concentration. At around 10^{19} at/cm^3, the COPs and the OSF ring disappear in the center of the crystal. More recently, it was reported that L-pits are also suppressed in the same concentration range [5.128] which is in line with the well known defect-free quality of pp + epi wafers [5.62] (Sect. 5.3.1).

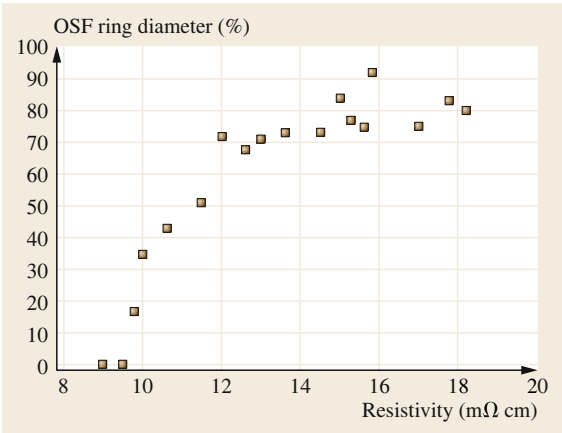

Fig. 5.23 Variation in the OSF ring diameter as a function of the boron concentration. (After [5.129])

Dornberger et al. [5.69] suspected that changes in the equilibrium concentrations and diffusivities of intrinsic point defects in the presence of high boron concentrations would modify the transition value ξ_{tr} of the parameter V/G as a function of the boron content. *Voronkov* and *Falster* [5.87] also proposed a modification of equilibrium concentrations as a result of the shift in the Fermi level due to the high boron concentration. Based on this approach, the latter authors calculated a shift in the transition value ξ_{tr} which would account for the observed shrinkage of the void region. However, *Vanhellemont* et al. recently carried out ab initio calculations which demonstrated that vacancies at the melting temperature of silicon are neutral independent of the position of the Fermi level [5.130]. As with nitrogen doping, the ξ_{tr} shift entails the simultaneous appearance of L-pits in the outer crystal region and a shrinking void region, which is in conflict with experimental results of boron doped crystals, as well. Another attempt by *Sinno* et al. [5.131] considers reversible reactions between boron and intrinsic point defects, in particular self-interstitials. The formation of BI and B_2I complexes consumes self-interstitials which would otherwise be annihilated by recombination. As recombination consumes the remaining self-interstitials, BI and B_2I start to dissociate again according to le Chatelier's principle. As a result, the self-interstitial concentration increases, which shifts the point defect balance towards the intersitial-rich side, causing the void region to shrink. No comment is made about whether or not the model is also able to account for the suppression of L-pit formation by storing supersaturated self-interstitials in boron complexes. Recently, *Sueoka* et al. presented a model which considers the variation of formation energies of intrinsic point defect around dopant atoms and, thus, the change of equilibrium concentrations of vacancies and Si interstitials in dependence on the dopant concentration [5.46]. In case of boron, their results correctly predicted the behaviour of the void region as a function of the boron concentration, but the simultaneous suppression of L-pits was not reproduced. They suspected that, in contrast with vacancies, the Fermi level effect cannot be neglected for self interstitials which would turn them into positively charged species [5.132]. The suppression of interstitial clusters could then be explained by the Coulomb repulsive force. However, the debate on whether or not Si interstitials are charged or neutral is not yet settled.

Carbon

Carbon doping is also known to impact intrinsic point defect aggregation. It has been reported that the void region in the crystal center disappears upon carbon doping [5.59, 133], while the region of Si interstitial aggregates is widened; in other words, carbon does not inhibit the formation of L-pits/A-swirl. This behavior appears to be in line with the model put forward in [5.116], which predicts an upward shift of ξ_{tr} for carbon doping and, in turn, an enlargement of the interstitial-rich region.

It was also found that carbon doping reduces the grown-in defect size [5.99, 134]. Although the size reduction is appreciable, the morphology of the voids is not changed, in contrast to the consequences of nitrogen doping. Only a tendency towards multiple void formation was observed. The thickness of the inner oxide layer was found to be similar to that of undoped crystals, which indicates that carbon doping has no influence on the growth of the inner oxide layer. In more recent studies, it was reported that the morphology and size of Si interstitial aggregates changes with increasing carbon concentration [5.128, 135]. The L-pit, which is a local network of dislocation loops, turns into a globular Si interstitial aggregate, probably a stacking fault of Si interstitials. In addition, the density of these defects is notably increased with the carbon content. As with boron, the effect on defect aggregation is only seen at significantly higher concentrations ($\approx 1\times10^{17}\,\mathrm{at/cm^3}$) than for nitrogen. The above model of *Sueoka* et al. was also applied to carbon and showed qualitative agreement with the experimental findings [5.46].

At higher concentrations, carbon is known to enhance oxygen precipitation too [5.136, 137]. As carbon predominantly resides on substitutional sites, it is very unlikely that, as in the case of nitrogen doping, a higher residual vacancy concentration is responsible for the stronger oxygen precipitation. On the other hand, the small carbon atom exerts a local tensile strain on the surrounding lattice and attracts Si interstitials to form C_xI_y complexes. Thus, Si interstitials ejected into the

lattice by growing oxygen precipitates are effectively removed and, in turn, further precipitate growth is not retarded by a build-up of Si interstitial supersaturation. The enhanced oxygen precipitation may also be related to heterogeneous nucleation at small carbon aggregates [5.138].

Antimony, Arsenic and Phosphorus

In recent years, the effect of n-type dopants in high concentrations like antimony, arsenic and phosphorus have been been investigated in detail [5.128, 139–142]. Similar to boron, highly n-doped wafers are used as substrates for epitaxial layers which are mainly needed for high power devices. In contrast with highly boron doped crystals, all of these n-dopants expand the void region with increasing concentration. e.g., crystals, which are grown under conditions that make them Si interstitial rich (L-pits), are transformed into vacancy rich with strong void formation upon a Sb doping level of $3\times10^{17}\,\mathrm{at/cm^3}$ [5.139]. This is also in line with older measurements on Sb doped floating zone grown crystals where the defect behaviour was shifted from Si interstitial rich (A-swirl) to vacancy rich (D-defects) by Sb doping [5.143]. The void density increases with higher dopant concentrations. However, beyond a certain critical concentration, the void density sharply drops and no defects are observed anymore. The critical level obviously depends on the dopant and is highest for phosphorus and lowest for antimony (Fig. 5.24). The void density is rather uniform across the crystal diameter and also disappears uniformly beyond the critical dopant concentration. The morphology of the voids changes with the n-dopant [5.142]. For Sb-doping, single voids were observed, only, while, in case of P-doping, one quarter of the voids was detected as double voids. More than 50% double voids were found in As-doped crystals. Unlike nitrogen, carbon and boron, oxygen precipitation is not notably affected by the n-dopants, but is rather similar to the behaviour of lightly doped wafers.

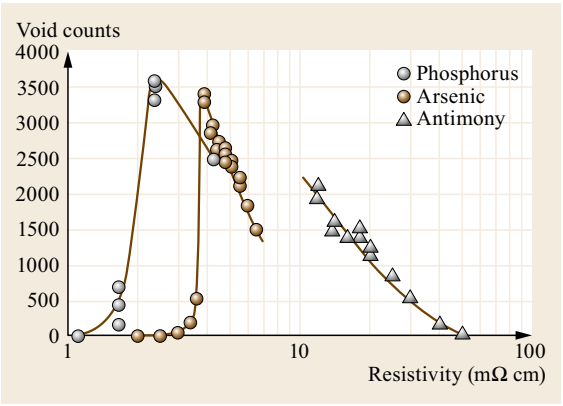

Fig. 5.24 Void counts in dependence of the resistivity for P-doped (*grey circles*), As-doped (*brown circles*) and Sb-doped crystals (*grey triangles*). (After [5.142])

All proposed models explain the observed effects by assuming a shift of ξ_{tr} to lower values. While *Voronkov* et al. [5.144, 145] attribute the shift of ξ_{tr} to vacancy and Si interstitial trapping by the dopants, respectiviely, and can also reproduce the sharp drop of the void density beyond the critical dopant concentration [5.141], *Sueoka* et al. again apply their above mentioned model predicting a change of the formation energy of vacancies and self interstitials in the presence of n-dopants which results in a similar shift of ξ_{tr} [5.46].

5.4 Formation of OSF Ring

The ring-like distributed OSFs are oxygen precipitates with platelet shapes that grow particularly large at the edge of the void region, and exceed a critical size necessary to create stacking faults during subsequent wafer oxidation there [5.146]. The critical radius of the grown-in platelets is $\approx 70\,\mathrm{nm}$. The formation of OSFs can be suppressed if the cooling rate of the growing crystal is increased (this means, for example, that OSFs are not found in oxygen-doped FZ crystals [5.129] which have very high cooling rates) or if the oxygen content is decreased.

The peculiar ring-like distribution is a consequence of the well-known strong enhancement of oxygen precipitation by vacancies [5.38, 147]. The reason for this is that the absorption of vacancies allows the oxygen precipitate, which occupies twice as much volume as the corresponding silicon lattice, to nucleate and grow without building up notable strain energy. As will be described below, the radially inhomogeneous oxygen precipitation is a consequence of a substantial radial inhomgeneity of the free vacancy concentration in contrast to the rather flat radial profile of oxygen.

The vacancy concentration, as pointed out previously, has its maximum at the center of the growing crystal after V–I recombination has ceased (Fig. 5.25). Therefore, the critical supersaturation for void formation is first reached at the crystal center at relatively high temperatures. Hence, the free vacancies are quickly consumed in this area. As the crystal cools, voids are also nucleated in the regions of lower initial vacancy

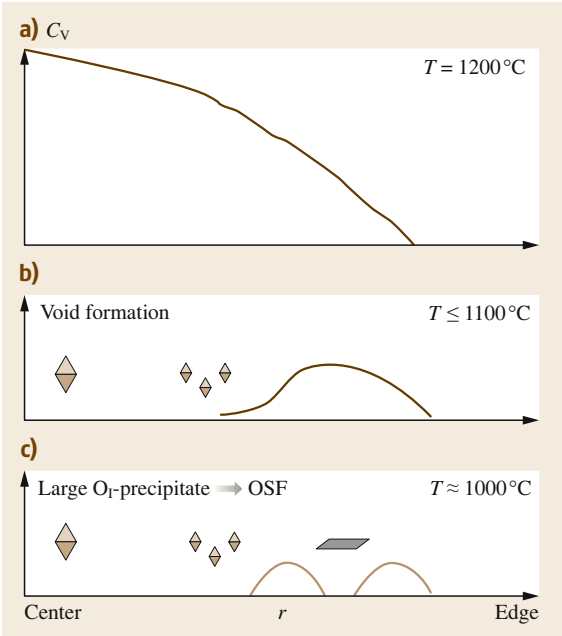

Fig. 5.25a–c Schematic evolution of the radial vacancy profile and accompanying void and large O_I-precipitate formation at decreasing temperatures

concentration, meaning that vacancy consumption then also occurs further away from the crystal center. As the removal of vacancies is enhanced at higher temperatures, where the diffusivity is large, the radial vacancy distribution finally drops to a minimum in the crystal center, and the maximum of the residual vacancies gradually moves toward the V/I boundary upon further cooling. Because of this shifted vacancy maximum, the first oxygen aggregates nucleate close to the V/I boundary on the vacancy-rich side. The relatively high nucleation temperature at this position results in larger sizes but lower densities for the corresponding grown-in oxygen precipitates compared to those nucleated at lower temperatures away from the V/I boundary. Consequently, they preferentially reach the critical size for OSF formation during subsequent wafer oxidation. At sufficiently fast crystal cooling rates, the oxygen precipitates are nucleated at higher densities but smaller sizes and cannot grow to the critical size. Thus, OSF formation is prevented, in agreement with experimental findings. The same density/size effect is obtained if the oxygen content is lowered – similar to the behavior of voids – and so OSFs are also suppressed.

The nucleation of the first oxygen precipitates quickly results in the depletion of residual vacancies in their neighborhood. Thus, the previous vacancy maximum at the V–I boundary is then converted into a pronounced minimum which suppresses further nucleation in this area. As a result, two vacancy peaks with a region of large oxygen precipitates in-between is frozen in as the crystal cools down to room temperature (Fig. 5.25). Later on, when the wafers are subjected to further heat treatments, such as a nucleation step at 780 °C followed by a growth step at 1000 °C, new oxygen precipitates with high density are preferentially nucleated at the radial positions of the two remaining vacancy maxima. This results in a distinct profile for the interstitial oxygen concentration after these heat treatments. In the radial band where the large precipitates and the OSF ring are located, the interstitial oxygen concentration is only slightly reduced because further nucleation of precipitates during wafer heat treatment is suppressed there and the comparatively low density of precipitates does not consume much of the interstitial oxygen. On the other hand, the high density bands at the locations

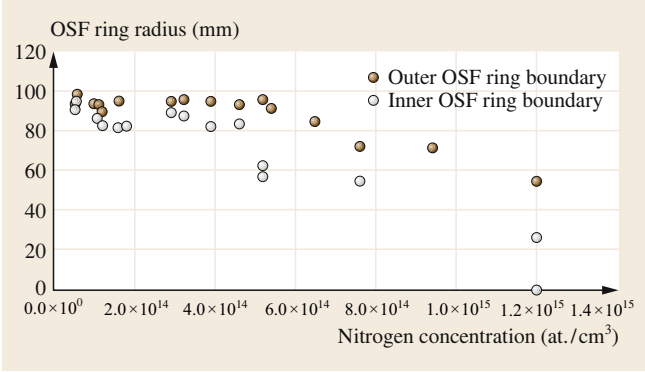

Fig. 5.26 Variations of the outer and inner OSF ring boundaries as a function of the nitrogen concentration. (After [5.96])

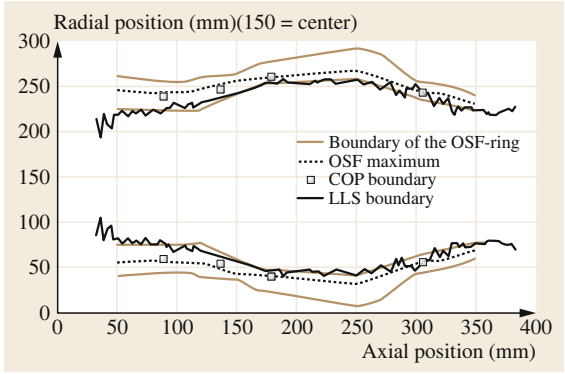

Fig. 5.27 Variations in the OSF ring width and its radial location in comparison to the variations of the COP and LLS boundaries along the crystal axis. The LLS defects were detected on the as-polished wafer surface, which detects only the larger voids, while the COP boundary was determined by LLS measurements after repeated SC1 cleaning, which enlarges the voids to above the LLS detection limit

adjacent to the former vacancy peaks coincide with pronounced minima in the interstitial oxygen content.

Considerable changes in the widths and the radial positions of OSF rings are observed if the crystals are nitrogen-doped. With increasing nitrogen content, the outer and inner OSF ring boundaries are shifted towards the crystal center [5.96]. However, the shift is much larger for the inner OSF ring boundary, resulting in a significant widening of the OSF ring width (Fig. 5.26) until it extends over the entire crystal volume. This behavior was tentatively explained by a schematic model that takes into account the slower build-up of vacancy supersaturation due to the formation of N_2V complexes and the resulting lower void nucleation temperature. The model also predicts that the void and the OSF region overlap, roughly in the area between the inner boundary and the middle of the OSF ring, which is in agreement with experimental data (Fig. 5.27).

In contrast to nitrogen, carbon tends to suppress OSF formation. This is again an indication that the mechanism of the effect of carbon is different. The above-mentioned idea of heterogeneous nucleation due to small carbon clusters may also explain this behavior. As heterogeneous nucleation needs less supersaturation, it prevails over homogeneous nucleation. Furthermore, the density of carbon clusters is much higher than that of homogeneously nucleated oxygen precipitates. Thus, the heterogeneously nucleated oxygen precipitates cannot grow to the critical size due to their large densities.

6. Diffusion in Semiconductors

Derek Shaw

Atomic diffusion in semiconductors refers to the migration of atoms, including host, dopant and impurities. Diffusion occurs in all thermodynamic phases, but the solid phase is the most important in semiconductors. There are two types of semiconductor solid phase: amorphous (including organic) and crystalline. In this chapter we consider crystalline semiconductors and describe the processes by which atoms and defects move between lattice sites. The emphasis is on describing the various conditions under which diffusion can occur, as well as the atomic mechanisms that are involved, rather than on tabulating data. For brevity's sake, we also focus on the general features found in the principal semiconductors from Groups IV, III–V and II–VI; IV–VI and oxide semiconductors are excluded from consideration. It is not surprising that most of the data available in this field relate to the semiconductors that are technologically important – they are used to fabricate electronic and optoelectronic devices. One unavoidable consequence of this technological need is that diffusion data tend to be acquired in a piecemeal fashion.

Diffusion describes the movement of atoms through space, primarily due to thermal motion, and it occurs in all forms of matter. This chapter focuses on atom diffusion in crystalline semiconductors, where diffusing atoms migrate from one lattice site to adjacent sites in the semiconductor crystal. The diffusion of atoms and defects (both native and dopant) is at the heart of semiconductor processing. This includes the growth, post-growth and device construction stages. To achieve required goals, it is essential to control the diffusion aspects which calls for an understanding of what is actually diffusing in a given situation. The needs of device technology have provided the main impetus for investigating atomic diffusion in a semiconductor lattice. As the physical dimensions of devices have shrunk, the problems relating to the understanding of diffusion features in complex structures have multiplied. Common examples relate to degra-

dation of a doped structure, such as a p-n junction or super lattice, and stability of a metal contact or diffusion barrier. *Knez* [6.1] identifies four separate diffusion situations that can arise in the postprocessing of a surface layer located on a substrate (which may itself be a thin layer, for example, HgTe on CdTe):

1. Lateral diffusion of components in the surface layer
2. Diffusion of surface components into the substrate
3. Diffusion of substrate components into the surface layer
4. A diffusion barrier between the surface layer and substrate.

Example 4 is provided by a Cu contact to a Si substrate in which graphene [6.2], Ta_2O_5 and TiO_2 [6.3] films provide diffusion barriers. The graphene films are approximately or equal to a few μm thick in contrast to the metal films which lie between 1 and 4 nm in thickness. The investigation of diffusion phenomena is pursued by both experimental means and by ab initio calculations: the latter are increasingly important in identifying which native defects may be involved.

6.1 Basic Concepts

The mobility of an atom or defect in the crystal lattice is characterized by its diffusivity or diffusion coefficient, D. Diffusion of a species is observed when a concentration gradient exists so that there is a flow down the concentration gradient. For a one-dimensional situation with flow parallel to the x-axis Fick [6.4] gave

$$J = -D\frac{\partial c}{\partial x}\,, \tag{6.1}$$

where J is the flux of atoms or defects per unit area per second and c is the concentration of the diffusing species. Equation (6.1) leads to [6.4]

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial^2 x}\,. \tag{6.2}$$

If the lattice is semi-infinite beyond $x = 0$ and the surface concentration at $x = 0$ is maintained at a constant value of c_0 (6.2) can be solved to give [6.2]

$$c = c_0\,\mathrm{erfc}\left[\left(x/2\sqrt{(Dt)}\right)\right], \tag{6.3}$$

where erfc is the complementary error function. Alternatively if only a fixed amount, M, of the diffusant is deposited on the surface at $x = 0$ and $t = 0$, then (6.2) has the solution [6.4]

$$c = \frac{M}{2\sqrt{\pi Dt}}\exp(-x/4Dt)\,. \tag{6.4}$$

As the kinetic energy, and therefore mobility, of a species increases with temperature, it is found that quite generally D obeys an Arrhenius relation

$$D = D_0\exp(-Q/k_\mathrm{B}T)\,, \tag{6.5}$$

where k_B and T are Boltzman's constant and the temperature, respectively: D_0 and Q are the parameters determined by the diffusion mechanism of the particular atom or defect. Q is known as the activation enthalpy or energy for the diffusion process.

At the atomic level an atom or defect migrates by successive jumps between neighboring lattice sites. In a three-dimensional isotropic lattice consider a species that migrates by jumping from one lattice site to a nearest neighbor site. If the distance between nearest neighbor sites is a and the atom or defect makes n random jumps in time t then the mean-square displacement $\langle R^2\rangle = na^2$ so using Einstein's relation [6.5]

$$D = \frac{na^2}{6t}\,. \tag{6.6}$$

Equation (6.6) applies to random jumps (i. e., successive jumps are completely independent) whereas depending on the diffusion mechanism some correlation between successive jumps can occur. This is accounted for by introducing a correlation factor, f, into the right-hand side of (6.6) ($f \le 1$) [6.5]. Some idea of the magnitudes involved is provided by taking $D = 10^{-12}\,\mathrm{cm}^2/\mathrm{s}$, $t = 10^4\,\mathrm{s}$, $a = 2\times10^{-8}\,\mathrm{cm}$, and $f = 1$ so that the diffusion length $2\sqrt{(Dt)} = 2\,\mu\mathrm{m}$ whereas the total distance traveled $na = 3\,\mathrm{cm}$.

6.2 Diffusion Mechanisms

Two categories of diffusion mechanisms are recognized: defect and nondefect. A simple example of the latter class is the simultaneous jumps of two adjacent atoms in order to exchange sites. There is a general consensus, however, that nondefect mechanisms do not play any significant role in semiconductor diffusion, although nondefect contributions have recently been proposed for self- and dopant diffusion in Si [6.6]. In the elemental semiconductors Si and Ge, vacancies and interstitials are the primary defects. Historically a vacancy was

known as a Schottky defect. In binary compound semiconductors (such as GaAs, GaN, CdTe, ZnO, HgCdTe) there are two sublattices, the anion and cation, so there are vacancies and interstitials for each sublattice together with antisite defects on each sublattice. There is also the possibility of complexes forming between native defects such as the Frenkel pair [6.5] (an interstitial–vacancy complex) and di-vacancies as well as between native defects and dopant species. Further complexity arises due to the various states of ionization of the defects: the defect mobility will depend on its charge state. The relative concentrations of the different charge states will be determined by the position of the Fermi level. It is also important to know in a given situation whether the crystal is electrically intrinsic or extrinsic.

6.2.1 Vacancy and Interstitial Diffusion Mechanisms

In the Si lattice, a vacancy V_{Si} can migrate by a nearest neighbor Si atom jumping into the vacancy (in other words the Si atom and V_{Si} have exchanged sites so that the Si atom has also migrated). Equally a substitutional dopant atom can migrate by jumping into a V_{Si} at a nearest neighbor site. Similarly, in a binary semiconductor such as GaAs, Ga atoms can migrate over the Ga sublattice via jumps into nearest neighbor Ga vacancies, as can dopant atoms substituting on Ga sites. Antisite defects can diffuse by jumping into vacancies in the same sublattice, such as the As antisite in GaAs, As_{Ga}, diffusing by jumps into an adjacent Ga vacancy. For self-interstitials, such as Si_i or Ga_i, their concentrations are sufficiently small for neighboring interstitial sites to be always empty, which means that the occupancy of nearest neighbor sites is not a factor when determining jump rates. If self-interstitial, such as Si_i, pushes an Si atom on a normal lattice site into an interstitial site instead of jumping into a neighboring interstitial site, thereby replacing the displaced Si atom, the process is the *interstitialcy mechanism*. This concept extends to a substitutional dopant atom forming a pair with a self-interstitial, which then migrates with the dopant atom alternating between substitutional and interstitial sites. The *dissociative mechanism* refers to the case of a dopant occupying both interstitial and substitutional sites with migration via interstitial sites. It is also possible for point defects to form complexes which can diffuse as a single entity. Examples are the Frenkel pair $V_{Si}Si_i$, the defect pair formed between a substitutional dopant atom and an adjacent vacancy, and di-vacancies such as $V_{Ga}V_{Ga}$, $V_{Ga}V_{As}$ or $V_{As}V_{As}$. In the case of a mobile (cation–anion) vacancy pair it is feasible that a link can exist between the cation and anion self-diffusivities [6.7].

6.2.2 The Interstitial–Substitutional Mechanism: Dissociative and Kick-Out Mechanisms

The interstitial–substitutional diffusion mechanism arises when a dopant species Z occupies both interstitial and substitutional sites, represented by Z_i and Z_s, respectively, and diffusion is restricted to jumps of Z_i. In this case, we may ask how the Z_s concentration, $[Z_s]$, is linked to the Z_i migration. Consider the diffusion of Z in Si. The dissociative mechanism (also known as the Frank–Turnbull mechanism) is based on the defect interaction

$$Z_i + V_{Si} \rightleftharpoons Z_s \tag{6.7}$$

and application of the law of mass action (LMA) leads to $[Z_i][V_{Si}] \propto [Z_s]$. In the kick-out mechanism, the defect interaction is

$$Z_i + Si_s \rightleftharpoons Z_s + Si_i \tag{6.8}$$

and therefore $[Z_i] \propto [Z_s][Si_i]$. $[Si_s]$ is omitted from equation (6.8) as it is effectively constant because $[Z_i]$, $[Z_s]$, and $[Si_i]$ are generally many orders of magnitude smaller. In order to sustain growth of $[Z_s]$ by either mechanism, it is clearly necessary to have either a supply of V_{Si} or a means of removing Si_i. For simplicity, neutral charge states have been assigned to all the defects in (6.7) and (6.8). A detailed treatment of the kick-out mechanism has been given by *Frank* et al. [6.8]. For in-diffusion of Z, the Frank–Turnbull mechanism consumes vacancies and will therefore tend to reduce the local vacancy concentration, whereas the local self-interstitial concentration will be enhanced by the kick-out mechanism. Out-diffusion of Z reverses the effects on the native defect concentrations.

6.2.3 The Percolation Mechanism

The percolation mechanism [6.9] was proposed to explain group V dopant diffusion in Si at high dopant concentrations ($> \approx 10^{20}\,cm^{-3}$). At low concentrations, diffusion is via dopant–V_{Si} pairs. As the dopant concentration increases, regions occur in the Si lattice where the proximity of the dopant atoms enhances the mobility and concentration of the V_{Si}. Within this network, the diffusivity of dopant–V_{Si} pairs is thereby also enhanced so that the dopant diffusivity increases overall. The percolation network only forms once the dopant concentration exceeds a certain critical value. In principle, this mechanism could extend to other highly doped materials.

6.3 Diffusion Regimes

The mobility of a native defect and/or dopant atom reflects the physical and chemical environment under which diffusion is occurring. Two types of environment arise: conditions of chemical equilibrium and those of chemical nonequilibrium. Diffusion in temperature gradients is excluded although this can occur during cooling (heating) from (to) a diffusion anneal – only isothermal conditions are considered.

6.3.1 Chemical Equilibrium: Self- and Isoconcentration Diffusion

Chemical equilibrium means that the concentrations of all chemical components, including native defects, are uniform and stable throughout the semiconductor sample, and where appropriate (such as in a compound material), the solid is in equilibrium with the ambient vapor of the components so that the level of nonstoichiometry is both defined and controlled. Experimentally this requires diffusion to be carried out in a sealed system. Self-diffusion refers to the diffusion of the host atoms, such as Si atoms diffusing in the Si lattice. Isoconcentration diffusion describes the diffusion of dopant atoms when the same dopant concentration is uniform throughout the sample, such as for As diffusion in Si when (As) is constant. In either case, diffusion can only be observed if some of the diffusing atoms are tagged, such as by using a radioisotope or an isotopically enriched diffusion source. The diffusivity of a tagged or tracer species is related to the concentration of the native defect that provides the diffusion path. Several native defects may be involved, together with their various states of ionization (determined by the Fermi level). Specific relations can be found in *Shaw* [6.10]. A diffusion flux of the tracer arises from a concentration gradient of the tracer, which is not to be confused with a chemical concentration gradient.

6.3.2 Chemical Diffusion (or Diffusion Under Nonequilibrium Conditions)

This category contains all of the diffusion phenomena that are of technological interest and importance. In this case, diffusion occurs due to spatial gradients in the concentrations of the chemical components in the material, which in turn are caused by departures from equilibrium: the diffusion processes are attempting to either restore or achieve equilibrium.

Chemical Self-Diffusion

Chemical self-diffusion describes the process whereby a compound semiconductor changes from one level of nonstoichiometry to another through changes in the native defect populations: there is no change in the chemical composition. Changes in nonstoichiometry can arise due to a change in the ambient partial pressure of one the components (e.g., that of As in the case of GaAs), or through a change in temperature under a controlled component partial pressure. Good examples are provided by the II–VI semiconductors [6.11] and in particular $Hg_{0.8}Cd_{0.2}Te$ [6.12], where p- to n-type conversion is used to form p-n junctions by annealing in Hg vapor. High Hg partial vapor pressures give n-type due to cation donor interstitials and low pressures yield p-type arising from cation vacancies. Changes in the native defect concentrations can lead also to either an increase or decrease in a dopant diffusivity. Equally if two dopants are present they can modify each others diffusivity.

Dopant Diffusion

Suppose we have a dopant diffusing into the semiconductor from a source located at an external surface (such as a surface layer) or in an external phase (such as a gas, vapor, or liquid). The existence of the dopant concentration gradient can lead to various effects which influence the dopant flux. For example, if the dopant diffuses via a vacancy mechanism, then at any position in the diffusion region the increase in the dopant concentration requires a supply of vacancies, so that to maintain local defect equilibrium there must also be an associated vacancy flux. If the dopant controls the position of the Fermi level, then the concentration of ionized native defects will increase or decrease, depending on their charge state, relative to their intrinsic concentrations (the Fermi-level effect). This means that the concentrations of defects having opposite (the same) polarity to the dopant will be increased (decreased). Increases in the concentrations of ionized native defects due to Zn, Si, or Te diffusion into GaAs/GaAlAs superlattice structures explain the disordering of such structures [6.13]. Usually a substitutional dopant will have a different size to that of the host atom it replaces. This size difference creates a local mechanical strain in the lattice which in turn can cause changes in the local concentrations of native defects as well as to jump rates and hence dopant diffusivity [6.14]. If the strain is large enough, misfit dislocations will be generated [6.15], otherwise there will be a strain energy gradient matching the dopant concentration gradient which can enhance or retard the dopant flux [6.16]. A particular scenario is dopant diffusion in strained epilayers. Whether diffusion is enhanced or retarded is a complex matter [6.17]. However, significant effects

are found, such as the decrease in the B diffusivity in strained $Si_{1-x}Ge_x$ epilayers by a factor ≈ 10 as the strain increase from 0 to 0.64 [6.18].

Compositional Interdiffusion (CID)

Compositional interdiffusion (CID) describes component diffusion across the initial interface separating two semiconductors of different chemical composition, such as the interface between an epilayer and its substrate. Chemical composition here refers to major components: dopants and deviations from stoichiometry are excluded as their contribution to the concentrations of the primary chemical components is negligible. The result is a mixing of the components to achieve an ultimate uniform composition. One consequence of this intermixing is the movement of lattice planes known as the Kirkendall effect [6.5]. CID can be exploited in the formation of graded band-gap structures and during material preparation, such as in $Hg_{1-x}Cd_xTe$, where an alternating sequence of HgTe and CdTe epilayers of appropriate thickness are first grown and then interdiffused. CID can also pose problems in the fabrication of multiple quantum wells and superlattice structures when sharp boundaries are necessary. In particular, donor or acceptor diffusion into GaAs-based superlattices can cause essentially complete intermixing on the cation sublattice [6.13]. This phenomenon is also known as diffusion-induced disorder. B or As doping also results in rapid intermixing at a Si/Ge interface [6.19].

Transient-Enhanced Diffusion

Ion implantation is a common procedure for doping a semiconductor surface layer. The implantation process, however, does create a significant amount of lattice damage so that a subsequent anneal stage is required in order to a achieve both full electrical activity of the implanted dopant and recovery from the lattice damage. During the implantation process, the implant ions create collision cascades of vacancies and self-interstitials (an excess of native defects). The postimplant anneal serves to remove or reduce this excess. In addition to vacancy–interstitial recombination, the excess native defects can interact to form clusters (which may also contain implant ions as well as residual impurities) and extended defects such as dislocations and dislocation loops. At the start of the postimplant anneal, the local concentrations of vacancies and self-interstitials in the implant region can greatly exceed equilibrium values and therefore enhance the diffusivity of the implant ion in the implant region. As annealing proceeds, the excess concentrations will diminish and will be reflected in a decreasing dopant diffusivity until values appropriate to local equilibrium are reached. This temporary enhancement in the dopant diffusivity is known as transient enhanced diffusion (TED). The topic is a complex one to analyze quantitatively and detailed consideration of the issues involved in the case of B implants in Si can be found in the review by *Jain* et al. [6.20]. In the fabrication of shallow p-n junctions using ion implants and rapid thermal annealing (RTA), TED can determine the lower limit to the junction depth. TED of B in Si can be reduced with coimplants of Si prior to RTA [6.21]. TED of Be and Si in GaAs has also been described [6.22]. Some workers use the term TED to describe the enhanced diffusivity of a dopant, incorporated during growth, which occurs when the structure is annealed at a lower temperature than the growth temperature, with the consequence that there is an initial supersaturation of the relevant native defects at the anneal temperature.

Segregation, Gettering, Precipitation, and Clustering

A variety of important scenarios arise, involving many of the above regimes, during growth and/or subsequent processing stages of materials and structures. The segregation of acceptor dopants in InP [6.23] and in III–V heterostructures [6.24, 25] has been observed and modeled. The segregation (or accumulation) due to diffusion of the dopant is in effect a partitioning to preferred (higher solubility) regions within the layer structure. Segregation to a surface or boundary can also occur. Gettering describes the segregation, or cleaning up, of a fast diffusing impurity from the active regions of a device structure. Such impurities are typically Group 1B and transition metals and are incorporated either during growth or during subsequent processing. Gettering sites in Si are provided by O precipitates, self-ion implant damage, and nanocavities [6.26]. In contrast, Group 1B impurities in $Hg_{1-x}Cd_xTe$ are gettered by regions of high cation vacancy concentrations [6.27].

Precipitation occurs when a species – whether native defect, dopant, or impurity – becomes supersaturated, and in order to achieve its equilibrium concentration the species excess is removed by the formation of precipitates within the host lattice. A self-interstitial or vacancy excess can be removed through the nucleation of dislocation loops, stacking faults, or voids which then provide sites for precipitation of the remaining excess. In the case of a dopant, impurity, or stoichiometric excess, nucleation of a precipitate can be spontaneous (homogenous) or heterogenous. The latter occurs at the site of an impurity atom (e.g., C atoms in Si serve as nucleation centres for the precipitation of O) or at dislocations, giving rise to the term *decoration*. Growth of any precipitate proceeds via diffusion of the particular species from solution in the matrix to the precipitate and is generally diffusion limited. Equations describing the growth

of precipitates [6.28–31] and voids [6.32] are available. Invariably local stress fields will be present which influence the diffusion and, if present initially, they may also play a role in the nucleation stage. The precipitation and out-diffusion of a species during cooling has also been analyzed [6.33]. The precipitation of O impurities in Si presents a unique case study because of the high [O], its technological importance, and its complexity [6.34, 35]. The rather simpler case of B precipitation in Si has been described by *Solmi* et al. [6.36]. A cluster (or agglomerate) refers to a close configuration of at least a few dopant atoms (with or without associated native defects) or, for a compound, host species. *Solmi* and *Nobili* [6.37] have identified $(2As_{Si} - V_{Si})^0$ and $(4As_{Si} - V_{Si})^+$ clusters in heavily As-doped Si. Heavy C doping [6.38] and B implants [6.39] in Si give rise to self-interstitial clusters with C and B, respectively. In Si, according to *Ortiz* et al. [6.40], if the number of self-interstitials in a cluster exceeds ≈ 10, there is a transition to a {113} defect.

6.3.3 Recombination-Enhanced Diffusion

The local energy released in the nonradiative recombination of excess free carriers can help a diffusing species to surmount the energy barrier separating it from an adjacent lattice site – in other words, the energy barrier facing a jump is effectively reduced. This situation is important in the degradation in performance of device structures which utilizes high excess minority carrier concentrations, such as light-emitting and laser diodes. Transient excess free carriers also arise when a surface is exposed to energetic particle beams as in electron beam microscopy and secondary ion mass spectrometry (SIMS) analysis.

6.3.4 Surface Processing Effects

The concentration of native point defects within the interior of a sample can be altered by surface processes. In the case of Si it is well known that during surface oxidation or nitridation there is injection of Si interstitials or vacancies, respectively. All diffusants can therefore be affected during the processing stage. Ion-beam milling injects Hg interstitials into $Hg_{1-x}Cd_xTe$ in sufficient quantities to convert p-type to n-type. The effects of surface layers can also be significant, for example, an n-type layer on a p-type substrate will have an electric field across the junction which will also be the case if there is a difference in band gaps between the surface layer and substrate.

6.3.5 Short-Circuit Paths

The existence of dislocations and subgrain boundaries in single-crystal material generally provides high diffusivity routes for all atomic species relative to the surrounding lattice. Care is always needed when evaluating experimental data to ensure that bulk or volume diffusion is not masked by short-circuit paths [6.40]. In the case of polycrystalline Si, the grain boundaries may provide high diffusivity routes, as in the cases of As and B [6.41], or retard diffusion, as for Au [6.42]. The situation is a complex one, as grain growth can also occur during any anneal. Ge and Si can both be obtained free of dislocations which is not the case for compound semiconductors. Analysis of diffusion profiles in II–VI compounds shows the diffusant diffusivity to be a factor $\approx 10^{-10}$ greater in a dislocation than in the bulk [6.43]. *Kaur* et al. [6.44] provide a comprehensive account of short-circuit path diffusion.

6.4 Internal Electric Fields

If a concentration gradient of a dopant exists and the semiconductor is electrically extrinsic, free carriers from the dopant, due to their much greater mobility, will diffuse ahead of the parent dopant atoms. This separation creates a local electric field whose direction is such as to pull the ionized dopant atoms after the free carriers (and also to pull the free carriers back). There will also be an associated local space charge. However, if the space charge is negligible then [6.45]

$$2n_i \sinh\left(\frac{qV}{k_B T}\right) = [D^+] - [A^-]\,, \tag{6.9}$$

where V is the local electrostatic potential arising from the ionized donor(s), D^+ and acceptor(s), A^-. q, k_B, and T are the electronic charge, Boltzman's constant, and the absolute temperature, respectively. Neglect of the space charge is justified provided that the diffusion length, $2\sqrt{(Dt)}$, greater than equal to six Debye screening lengths (typically $\approx 10^2$ nm) [6.46]. For planar diffusion parallel to the x-axis the internal electric field, E, due to dopant concentration gradients is obtained from (6.9) as $E = -\partial V/\partial x$. E exerts a force on each ionized dopant atom so for an ionized donor E will create an additional flux $\propto -D(D^+)\partial[D^+]/\partial x$ where $D(D^+)$ is the donor diffusivity. E will cause drift of any other ionized species. For ionized acceptors with $[A^-] < [D^+]$ their drift will be toward $x = 0$. Equation (6.9) is based on the Fermi level being determined by

Maxwell–Boltzman statistics. The situation for the degenerate case requiring Fermi–Dirac statistics has been considered by *Nilsson* [6.47] and *Kroemer* [6.48]

Internal electric fields can arise in other circumstances such as in depletion layers where E must be calculated from Poisson's equation, in graded bandgap structures [6.16, 49], and at the interfaces of heterostructures. Cubic II–VI and III–V strained layer heterostructures grown on the {111} direction are piezoelectric and typical strains from lattice mismatch of $\approx$ 1% can give $E \approx 10^5\,\mathrm{V/cm}$ in the absence of free carrier screening [6.50]. In wurtzite heterostructures based on the Ga and In nitrides, even higher fields are found ($E \approx 10^6\,\mathrm{V/cm}$) due to piezoelectric and spontaneous polarization [6.51]. These fields can be important in CID and chemical self-diffusion.

6.5 Measurement of Diffusion Coefficients

6.5.1 Anneal Conditions

Accurate control of the sample temperature and its ambient conditions are essential if reproducible results are to be obtained in a diffusion anneal. Depending on the time spent at the anneal temperature, the warm-up and cool-down times may also be important. In particular, the cool down maybe a quench or a programmed cooling. An appropriate choice of ambient is needed to preserve the sample surface (to avoid evaporation, surface melting or alloying with the diffusant source for example). For compound semiconductors it is necessary to define the level of nonstoichiometry by controlling the ambient partial vapor pressure of one of the components, such as As for GaAs or Hg for $Hg_{1-x}Cd_xTe$, as this will be a factor in determining the dopant concentration. If the dopant is present in an external phase, rather than an ion implant, knowledge of the phase diagram of all of the components is required [6.52]. Control over the partial pressure is best achieved in a sealed system, typically a fused silica ampoule. Annealing in a vertical or horizontal resistance-heated furnace requires a minimum anneal of 30 to 60 min to avoid uncertainties due to warm-up and cool down. The drive to shallow dopant profiles has been facilitated through RTA techniques. These are based on radiant heating of the sample, and linear heating rates of 100–400 °C/s with cooling rates of up to 150 °C/s are available. RTA however precludes the use of a sealed system and, in this case, a popular means of preventing surface deterioration is to seal the sample with an inert, impervious capping layer, such as SiN.

6.5.2 Diffusion Sources

Consideration is restricted to planar samples with diffusion normal to a principal face. This is a common situation and diffusion of a dopant or tracer species can take place from:

1. A surrounding vapor or gas phase.
2. A surface layer, which may be evaporated, chemically deposited (CVD), or a spun-on silicate glass, all incorporating the diffusant.
3. Epilayers containing the diffusant, which may provide the external surface or be buried within the epitaxial structure.
4. Ion implants of a dopant either directly into the sample surface or into a thin surface layer so as to avoid lattice damage.

It is obviously desirable that negligible diffusion occurs prior to reaching the anneal temperature and similarly there is negligible out-diffusion during the cool down. In self-diffusion experiments, the tracer can be a radiotracer or an isotopically enriched species. A key requirement for either form of tracer is availability, and a radiotracer must have a half-life that is long enough for the experiment to be completed.

6.5.3 Profiling Techniques

Determining the spatial distribution of a diffusant for various anneal times is fundamental to obtaining its diffusion coefficient or diffusivity. Most methods are destructive, as they generally require a bevel section through the diffusion zone or the sequential removal of layers which are normal to the diffusion direction. The two broad profiling techniques are electrical and species specific. Electrical methods are primarily the p-n junction method, spreading resistance and capacitance–voltage profiling. Limitations of the electrical methods are: (i) assumptions are needed to link the electrical data to the diffusant concentration (such as, the diffusant is the only electrically active centre involved and that it is fully ionized); (ii) the assumption that the anneal temperature defect situation is *frozen-in* during cool down (there is no out-diffusion, precipitation, or segregation). Electrical methods are the most direct means of measuring chemical self-diffusivities and can readily detect changes in host concentrations of < 1 part in 10^4. Specie-specific (chemical element

or isotope) profiling means that the chemical concentration of the diffusant is determined regardless of its location(s) in the lattice and of its electrical state. Profiling of the diffusant using a radiotracer has been widely used [6.53], but has now been largely supplanted by secondary ion mass spectrometry (SIMS) which is now the standard procedure for diffusant profiling. This is because SIMS can measure atomic concentrations within the range 10^{16}–$10^{22}\,\mathrm{cm}^{-3}$ with spatial resolutions of at least nanometres per decade of concentration. In favorable cases, the detection limit can approach $10^{13}\,\mathrm{cm}^{-3}$ (1 ppb). Primary factors determining the resolution are progressive roughening of the eroded surface and *knock-on* effects due to the probing ion beam displacing the diffusant to greater depths. A further issue arises when the atomic mass of the diffusant is close to that of the host species.

Nondestructive profiling techniques applicable to CID in quantum well and superlattice structures utilize either high-resolution x-ray diffraction (HRXRD) [6.54] or photoluminescence (PL). The detail in HRXRD patterns reflects the CID profiles at the interfaces and can also reveal the presence of strain in the structures. The use of PL requires the presence of optically active centres in the quantum well. CID changes the shape and depth of the quantum well, which in turn changes the photon energies in PL spectra. HRXRD and PL can also be combined. Neutron reflectometry has been used to measure Si self-diffusion in $^{29}\mathrm{Si}/^{28}\mathrm{Si}$ isotope multilayers [6.55]. Diffusion lengths were in the range 1–6 nm. A particularly useful feature of these nondestructive techniques is that they allow successive anneals to be performed on the same sample.

6.5.4 Calculating the Diffusion Coefficient

Once a planar diffusion profile, representing volume or bulk diffusion has been obtained, the first step is to see if the profile can be fitted to either (6.3) or (6.4), so providing a value for D. If, despite fulfilling the boundary conditions necessary for (6.3) or (6.4), a fit to either of these equations is not possible this indicates that D is a function of c. The dependence of D on c can be established by a Boltzman–Matano analysis provided $c_0(t)$ is constant and $c_{x,t}/c_0$ varies as $x/\sqrt{t}$ [6.52]. More complex situations and profiles require numerical integration of the appropriate diffusion equation(s) with matching to the experimental $c(x)$ versus x profile: in other words, a suitable model with adjustable parameters is used to simulate the observed profiles. The interpretation of HRXRD and/or PL data provides a good example of a simulation scene in which an assumed D, either c-dependent or -independent, is used to calculate the resulting CID profile and its effect on the x-ray patterns and/or PL spectra. Whereas SIMS can detect diffusivities as low as $\approx 10^{-19}\,\mathrm{cm}^2/\mathrm{s}$ the HRXRD limit is $\approx 10^{-23}\,\mathrm{cm}^2/\mathrm{s}$. It is not unusual however in the case of complex profiles to fit consecutive sections of the profile to a Gaussian (i. e., $\exp(-x^2/4Dt)$) dependence and so obtain several diffusivities. This procedure is wholly empirical and, although providing diffusivities with the right order of magnitude, provide little insight of the diffusion mechanisms.

6.6 Hydrogen in Semiconductors

Hydrogen is a ubiquitous element in semiconductor materials. It can be incorporated either deliberately, or inadvertently during growth, or in subsequent processing involving surface treatments where organic solvents, acid, or plasma etching are used. H occupies interstitial sites as H^-, H^+, H^0, and H_2. It will also interact with impurities, dopants, and native defects, which can result in passivation of the defect. H also bonds to the dangling bonds at extended defects. H^- is mobile at room temperature in p-type Ge [6.56]. In Si, H forms the complex $n\mathrm{H}-\mathrm{V_{Si}}$ where $n = 1, 2, 3, 4$ with $\mathrm{H}-\mathrm{V_{Si}}$ being mobile at $\approx 100\,^\circ\mathrm{C}$ [6.57]. The presence of H in Si can enhance the diffusivity of O in Si by two to three orders of magnitude [6.58]. *Mathiot* [6.59] has modeled H diffusion in terms of the simultaneous diffusion of H^-, H^+, and H^0 with the formation of immobile neutral complexes. In polycrystalline Si, the grain boundaries retard H diffusion, so H diffuses faster in the surrounding lattice than in the grain boundary. H is an ever present and important donor impurity in ZnO: interstitial H and H on O sites provide shallow donor states [6.60]. *Fan* et al. [6.61] found H concentrations at the 2% level in as grown ZnO. In $Hg_{0.75}Cd_{0.25}Te$, $n\mathrm{H}-\mathrm{V_{Hg}}$ complexes occur where $n = 1, 2, 3, 4$. The complexes $3\mathrm{H}-\mathrm{V_{Hg}}$ and $4\mathrm{H}-\mathrm{V_{Hg}}$ convert p-type $Hg_{0.75}Cd_{0.25}Te$ to n-type [6.62].

6.7 Diffusion in Group IV Semiconductors

The materials of interest are Ge, Si, Si/Ge alloys, and SiC. Diffusants divide into one of five categories: self-, other group IV's, slow diffusers (typically dopants from Groups III and V), intermediate diffusers, and fast diffusers. A particular feature is that self-diffusion is always slower than the diffusion of other diffusants. With the exception of SiC, which has the zinc blende structure, as well as numerous polytypes (the simplest of which is the wurtzite, 2H–SiC, form), the other members of this group have the diamond lattice structure.

6.7.1 Germanium

The dominant native defect in Ge is the vacancy and self-diffusion is accounted for primarily as due to the singly ionized vacancy acceptor, V_{Ge}^{-}, with a smaller contribution from the neutral vacancy, V_{Ge}^{0} [6.63]. *Werner* et al. [6.64] measured the self-diffusivity D(Ge) between 535 and 904 °C in intrinsic Ge and obtained $D(\mathrm{Ge}) = 13.6\exp(-3.09\,\mathrm{eV}/k_\mathrm{B}T)\mathrm{cm}^2/\mathrm{s}$. Relative to its intrinsic value, D(Ge) is reduced by acceptor doping and increased by donor doping, as would be expected from the dependence on V_{Ge}^{-} [6.65]. The diffusivities of donor dopants (P, As, Sb) are very similar to each other, as are the diffusivities for acceptor dopants (Al, In, Ga). The acceptor group diffusivities, however, are very close in magnitude to the intrinsic D(Ge), whereas those for the donor group are 10^2 to 10^3 times larger. *Bracht* [6.65] has given a detailed account of self- and dopant diffusion in Ge. Li is a fast interstitial diffuser with a diffusivity exceeding the donor group diffusivities by factors of 10^7 to 10^5 between 600 and 900 °C, whereas Cu [6.66] and Au [6.67] are intermediate (dissociative) diffusers. Evidence of the effects of the internal electric field is also available [6.60].

6.7.2 Silicon

Si stands alone due to the intensive investigations that have been lavished on it over many decades. In the early days, diffusion data yielded many perplexing features. Today the broad aspects are understood along with considerable detail, depending on the topic. Diffusion in Si covers many more topics than arise in any other semiconductor and it is still a very active area in R & D. It is now recognized that, apart from foreign purely interstitial species, self-interstitials, Si_i, and vacancies, V_{Si}, are involved in all diffusion phenomena. So far the best self-diffusion results obtained in intrinsic Si are $D_0 = 530\,\mathrm{cm}^2/\mathrm{s}$ and $Q = 4.75\,\mathrm{eV}$ in the temperature range 855−1388 °C [6.66]. Two distinct facets of self- and dopant diffusion in Si are: (a) the diffusivity has two or three components, each with differing charge states; (b) the diffusivity reflects contributions from both Si_i, and V_{Si} [6.6, 63, 67–70]. Thus, the Si self-diffusivity is determined by Si_i and V_{Si} mechanisms and by three separate defect charge states: neutral (0), positive (+), and negative (−). For the common dopants (B, P, As, and Sb), B and P diffuse primarily via the Si_i defect, As diffuses via both Si_i, and V_{Si} defects, whereas Sb diffuses primarily via V_{Si} defects. Two defect charge states are involved for B $(0, 1^+)$, As $(0, 1-)$ and Sb $(0, 1^-)$, and three for P $(0, 1^-, 2^-)$. The situation for Al [6.71], Ga [6.13], and In [6.71] has Si_i dominant for Al and In diffusion whereas both Si_i, and V_{Si} are involved for Ga. The associated charge states are Al $(0, 1^+)$, Ga $(0, 1^+)$ and In (0). The diffusivities of the Group V dopants (P, As, Sb) lie close to each other and are up to a factor ≈ 10 greater than the intrinsic self-diffusivity. The acceptor dopants (B, Al, Ga, In) also form a group with diffusivities that are up to a factor $\approx 10^2$ greater than the donor dopants. A relatively recently observed interesting feature is that the diffusivities of B and P in intrinsic Si depend on the length of the anneal time, showing an initial change until reaching a final value [6.72]. This time effect is attributed to the time needed for equilibration of the Si_i, and V_{Si} concentrations at the anneal temperature.

The data presented by *Tan* and *Gösele* [6.71] show that Au, Pt, and Zn are intermediate (kick-out) diffusers and that H, Li, Cu, Ni, and Fe are fast interstitial diffusers. Recent evidence shows that Ir diffusion occurs by both kick-out and dissociative mechanisms [6.73]. To provide some perspective: at 1000 °C the diffusivity of H is $\approx 10^{-4}\,\mathrm{cm}^2/\mathrm{s}$ compared to a self-diffusivity of $8\times10^{-17}\,\mathrm{cm}^2/\mathrm{s}$. C and O are important impurities because they occur in high concentrations and can affect the electrical properties through forming complexes with other ionized defects. Although O also occupies interstitial sites and diffuses interstitially it should be classed as an intermediate diffuser because a diffusion jump entails the breaking of two Si-O bonds [6.74]. O can be present at concentrations of $\approx 10^{18}\,\mathrm{cm}^{-3}$ with a diffusivity of $0.13\exp(-2.53\,\mathrm{eV}/k_\mathrm{B}T)\mathrm{cm}^2/\mathrm{s}$. C has a diffusivity that is a little larger than those of Group III dopants: its mechanism is unresolved between the kick-out mode or a diffusing complex comprising a Si_i and C_{Si}.

6.7.3 $Si_{1-x}Ge_x$ Alloys

Si and Ge form a continuous range of alloys in which there is a random distribution of either element coupled with a continuous bandgap range. The alloys have

attracted considerable interest from a device perspective and are commonly prepared as epilayers on Si substrates so that the epilayer will generally be in a strained state. Diffusivity data are sparse and, in the case of dopants, is limited to B, P, and Sb. One might expect that the diffusivity $D(Z)$ of dopant Z would increase continuously as x goes from 0 to 1 at any temperature below the melting point of Ge. However, in the case of B, D(B) varies little for $x \lesssim 0.4$; even so, D(B) increases by a factor $\approx 10^3$ from $\approx 10^{-15}\,\mathrm{cm}^2/\mathrm{s}$ in traversing the composition range at 900 °C [6.75, 76]. D(P) increases by a factor of ≈ 4 for x between 0 and 0.24, only to show a decrease at $x = 0.40$ [6.77]. Limited data suggest that D(Sb) rises continuously across the composition range, increasing by a factor $\approx 10^6$ at 900 °C [6.77]. Surface oxidation enhances D(B) and D(P), indicating that the diffusivities are dominated by a self-interstitial mechansim, whereas D(Sb) is reduced by surface oxidation, pointing to a vacancy mechanism. Compressive strain retards D(B) whereas tensile strain gives a marginal enhancement [6.75]. Compressive strain enhances both D(P) and D(Sb) [6.78]. In relaxed samples D(As) increases from $x = 0$ to $x = 1$ and for $x < 0.35$ both interstitial and vacancy mechanisms are involved but only the vacancy mechanism for $x > 0.35$ [6.78]. Overall, some disagreement exists between different workers about the behavior of $D(Z)$, which may well stem from difficulties with characterizing the experimental conditions. Ge and Si self-diffusivities have been obtained [6.79]. Compositional interdiffusion has been characterized in SiGe heterostructures with x between 0.36 and 0.75 [6.80].

6.7.4 Silicon Carbide

Its large bandgap, high temperature stability (SiC sublimes at ≈ 2730 °C), and high dielectric breakdown strength make SiC a suitable material for devices intended for operation at high temperatures and high powers. It also has potential optoelectronic applications. Material characterization is complicated, as SiC occurs in a range of polytypes (different stacking sequences of closed packed layers). Common polytypes are the cubic zinc blende phase 3C–SiC and the hexagonal phases 2H–SiC (wurtzite), 4H–SiC, and 6H–SiC. The refractory nature, polytypism, and variations in stoichiometry introduce difficulties in the measurement of diffusivities. Typical diffusion anneal temperatures for acceptor (B, Al, Ga) and donor (N, P) dopants are in the range 1800–2100 °C. Significant reductions in the diffusion temperature can be achieved through using a thin surface layer of the oxide of the dopant together with annealing in an oxidizing atmosphere [6.81]. Ab initio calculations for single vacancies and antisites in 4H–SiC [6.82] found the antisites Si and C to be both neutral and therefore generally both electrically and optically inactive. The C vacancy is amphoteric with charge states ranging from 2^+ to 2^-. The Si vacancy is also amphoteric with charge states ranging from 1^+ to 3^-. Similar calculations for 3C–SiC predict divalent a donor for both Si and C interstitials [6.83]. *Bockstedte* et al. [6.84] have calculated, using ab initio methods, the activation energies, Q, for self-diffusion in 3C–SiC by vacancies and interstitials. Generally Q is smaller for self-interstitials but the defect charge state is also an important factor. The Si vacancy is predicted to be metastable, readily transforming to the stable complex V_c–C_{Si}: the complex Si_c–V_{Si} is unstable, reverting to V_c.

The Si and C self-diffusivities, D(Si) and D(C), respectively, were measured between 1850 and 2300 °C by *Hong* et al. ([6.85] and references therein) in both 3C–SiC and 6H–SiC. The ratio $D(\mathrm{C})/D(\mathrm{Si}) \approx 650$ in 3H–SiC and ≈ 130 in 6H–SiC. N doping increased D(Si) and marginally reduced D(C). This behavior suggests that native acceptors are important for Si self-diffusion and that native donors are only marginally involved in determining D(C). Of particular interest is that, between the two polytypes, the self-diffusivities in 6H–SiC exceeded those in 3H–SiC by less than a factor ≈ 3. This suggests that diffusivities are insensitive to the particular polytype. More recent measurements of D(C), between 2100 and 2350 °C, in 4H–SiC found diffusivities that were $\approx 10^5$ times smaller than the earlier results for 3H–SiC and 6H–SiC, mainly due to differences in D_0 [6.83]. There is currently no explanation for these huge differences and the question of the reliability of the self-diffusivity data must be considered, particularly with respect to residual impurity levels.

Earlier work by *Vodakov* et al. [6.86] found that the diffusivity of B in six different polytypes of SiC, excluding 3C–SiC, varied by ≤ 30%, not only for diffusion along the c-axis but also perpendicular to it. The diffusivities of some common dopants have been summarized by *Vodakov* and *Mokhov* [6.87]. Diffusion mechanisms for B in 4H– and 6H–SiC have been discussed by *Usov* et al. [6.88]. A recent finding is that an SiO_2 layer on the surface of 6H–SiC greatly enhances B diffusion [6.89], yielding a diffusivity of $\approx 6 \times 10^{-16}\,\mathrm{cm}^2/\mathrm{s}$ at 900 °C. This compares to a temperature of ≈ 1400 °C (extrapolated) for the same diffusivity without an SiO_2 surface layer. Electric fields of $\approx 10^6\,\mathrm{V/cm}$ have been found in 4H/3C/4H–SiC quantum wells due to the spontaneous polarization in the 4H–SiC matrix [6.90].

6.8 Diffusion in III–V Compounds

The III–V binary compounds are formed between the cations B, Al, Ga, In and the anions N, P, As, and Sb. Mutual solubility gives rise to the ternaries such as $Al_{1-x}Ga_xAs$, and to the quaternaries, such as $Al_{1-x}Ga_xAs_{1-y}P_y$. The B compounds offer little more than academic interest, whereas the rest of the III–V family are important materials in both electronic and optoelectronic devices. The nitrides all have the wurtzite structure, with the remaining compounds possessing the zinc blende structure. In view of the wide range of binaries, ternaries, and so on, it is not surprising that diffusivity measurements have focussed mainly on those compounds relevant to devices: essentially GaAs and GaAs-based materials. An important characteristic of these compounds is the high vapor pressure of the anion components; it is the variations in a particular vapor pressure that give rise to significant changes in levels of nonstoichiometry. This means that a proper characterization, at a given temperature, of any diffusivity must specify the doping level and the ambient anion vapor pressure during the diffusion anneal: the latter determines the native defect concentrations in intrinsic samples, and both factors have equal importance in controlling the concentrations under extrinsic conditions. On both the anion and the cation sublattices, the possible native point defects are the vacancy, the self-interstitial and the antisite and all can occur in one or more charge states. Complexes formed between native defects and dopants (inclusive of residual impurities) have also to be considered.

6.8.1 Self-Diffusion

Self-diffusivity data are limited to the Ga and In compounds [6.60, 89], and even here systematic measurements are restricted to GaAs [6.71, 91] and GaSb ([6.91] and references therein). For GaAs, early evidence (based largely on CID in AlGaAs structures), concluded that the Ga self-diffusivity D(Ga) was determined by the triply ionized Ga vacancy V_{Ga}^{3-} and doubly ionized Ga interstitial Ga_i^{2+}. More recent and direct measurements of D(Ga) in Ga isotope structures identified the three vacancy charge states V_{Ga}^{2-}, V_{Ga}^{1-} and V_{Ga}^{0} as being responsible for D(Ga) in intrinsic and lightly doped GaAs; the possibility remains that V_{Ga}^{3-} and Ga_i^{2+} could dominate at high doping levels. Between 800 and 1200 °C the Arrhenius parameters for D(Ga) are $D_0 = 0.64\,cm^2/s$ and $Q = 3.71\,eV$ in intrinsic GaAs under a partial As_4 vapor pressure of ≈ 1 atm. The situation for As self-diffusion is less clear, but the evidence points to the dominance (in the diffusion process) of the neutral As interstitial over the As vacancy (the supposedly dominant native defect, the As antisite, is not involved). Data have been obtained for both Ga and Sb self-diffusion in intrinsic GaSb under Ga and Sb rich conditions. There is a conflict between the results obtained with bulk material and those from heterostructures (see [6.91] and references therein). *Shaw* [6.91] concluded that the defects involved in Ga self-diffusion were the Frenkel pair Ga_iV_{Ga} and V_{Ga} even though the Ga antisite Ga appears to be the dominant native defect. Two parallel mechanisms were also identified for Sb self-diffusion, namely one due to the defect pair Sb_iV_{Ga} and the second due to either to the mixed vacancy pair $V_{Ga}V_{Sb}$ or to the triple defect $V_{Ga}Ga_{Sb}V_{Ga}$. Reliable results for D(Ga) in intrinsic GaP under a partial vapor pressure P_4 of ≈ 1 atm are also available [6.92]: between 1000 and 1190 °C the Arrhenius parameters for D(Ga) are $D_0 = 2.0\,cm^2/s$ and $Q = 4.5\,eV$. Data on the effects of doping and changes in levels of nonstoichiometry are lacking. In GaN the self-diffusivity of N has $D_0 = 1.6\times10^2\,cm^2/s$ and $Q = 4.1\,eV$ [6.93]. This value for Q is in good agreement with the 4.3 eV obtained from first principles calculations for the diffusivity of V_N^{1+} [6.94]. Ab initio calculations show that the N vacancy is a major defect in GaN with a lower formation energy than that for the Ga vacancy [6.95]. The Ga self-interstitial in GaN is reported to be mobile at room temperature [6.96].

6.8.2 Dopant Diffusion

Most of the data on dopant diffusion in the III–Vs refer to GaAs [6.50], notably for Be [6.97], Cd [6.93], C, Si, S, Zn, and Cr [6.70]. The singly ionized acceptors Be, Zn, and Cd (which occupy Ga sites) and the singly ionized donors C and S (which occupy As sites) all diffuse by the kick-out mechanism. The native interstitials involved are Ga_i^{2+} and As_i^0, apart from Be where the data are best accounted for in terms of the singly ionized interstitial Ga_i^{1+}. Si is an amphoteric dopant and at low concentrations it predominantly occupies Ga sites as a singly ionized donor Si_{Ga}^{1+}. At high concentrations compensation starts to occur due to increasing occupancy as a singly ionized acceptor on As sites. At low concentrations Si_{Ga}^{1+} diffusion is attributed to a vacancy mechanism (V_{Ga}^{3-}). Cr sits on Ga sites and is a deep-level acceptor dopant, important in the growth of high resistivity GaAs. Depending on circumstances, it can diffuse by either the kick-out or the Frank–Turnbull mechanism. The creation of extended defects in the diffusion zone by Zn in-diffusion is a well established feature. The same feature has been found by *Pöpping* et al. [6.98] for Zn in-diffusion in GaP. They

further concluded that Zn diffuses via the kick-out process in GaP through the involvement of either Ga_i^{1+} or Ga_i^{2+}. The diffusivity of Mn in GaAs has been measured between 680 and 825 °C in an Ar ambient [6.99] and *Bosi* et al. [6.100] have investigated Ge diffusion in Ge/GaAs epilayers. The diffusion behavior of vanadium in GaN between 1000 and 1100 °C has also been reported [6.101]. H has a significant and important impact in GaN due to its passivation of acceptor dopants and data on its drift, diffusion, and trapping are available [6.100, 101].

6.8.3 Compositional Interdiffusion

The III–V binaries, ternaries, and quaternaries are the bases for the fabrication of numerous quantum well and superlattice structures. The general situation in which the cation and anion sublattices in each layer can contain up to four different components with concentrations ranging from 0 to 100% presents an impossibly complex problem for characterizing diffusion behavior with any rigor. The role of strain and internal electric fields must also be considered as parameters. As a consequence, CID studies have been limited to simpler structures, primarily GaAs–AlAs and GaAs–AlGaAs, with interpretations in terms of known diffusion features in GaAs [6.69]. Doping is an important ingredient of these multilayer structures and it was soon discovered that the acceptors Be, C, Mg, Zn and the donors Si, Sn, S, Se, and Te could all cause complete disorder of the structure through enhancement of the CID process on either or both sublattices [6.70, 102]. An interesting exception, however, is found in GaAs–GaAsSb, where either Si or Be reduce CID. Two generally accepted reasons for these dopant effects are: (i) the Fermi-level effect in which the dopant (acceptor/donor) concentration is high enough to make the semiconductor extrinsic so that the concentrations of native (donor/acceptor) defects are increased; (ii) if the dopant diffuses by the kick-out mechanism then in-diffusion will generate a local excess of the native self-interstitial. Clearly (i) operates for dopants incorporated during growth or by subsequent in-diffusion, whereas (ii) is restricted to in-diffusion. Either way the increase in the local native defect concentration(s) leads to a direct enhancement of CID. In the case of GaAs–GaAsSb, cited earlier, Si will also decrease the concentrations of native donors such as anion vacancies, which would have a direct impact on the reduction of CID on the anion sublattice. On the other hand, Be should increase native donor concentrations and therefore give enhanced CID of the anions, contrary to observation. Overall, the general features of the dopant-induced disordering process seem to be understood but problems still remain. *Harrison* [6.103] has commented on the approximations commonly made when extracting quantitative information from CID data. The demands of III–V device technology present increasing complexity when attempting to understand the physical processes involved, so that recourse to empirical recipes is sometimes needed. This is illustrated by structures comprising GaInNAs quantum wells with GaAs barriers, all enclosed within AlAs outer layers, whose optoelectronic properties can be improved by the judicious choice of time/temperature anneals [6.104].

6.9 Diffusion in II–VI Compounds

Interest in II–VI materials predates that in the III–Vs because of their luminescence properties in the visible spectrum which, based on powder technology, resulted in the application of the bigger bandgap materials (such as ZnS) as phosphors in luminescent screens. The development of crystal growth techniques extended interest in the optoelectronic properties of the wider family of II–VI binary compounds formed between the group II anions Zn, Cd, and Hg and the group VI cations O, S, Se, and Te. As with III–Vs, ternary and quaternary compounds are readily formed. The ternary range of compositions $Hg_{1-x}Cd_xTe$ has proved to be a particularly important family member due to their unique properties and consequent extensive exploitation in infrared systems. ZnS, ZnO, CdS, and CdSe crystallize in the wurtzite structure whereas the remaining binaries have the zinc blende structure. ZnS, CdS, and CdSe can also occur in the zinc blende phase. The Hg compounds all have the zinc blende structure. The native point defects that can occur are similar to the III–Vs; namely, vacancies, self-interstitials, and antisites for the cation and anion sublattices. Recent interest has expanded to include the cation dopants Be, Mg, and Mn, usually in ternary or quaternary systems. A distinctive feature of atomic diffusion in the II–VI compounds is their much higher diffusivities relative to those in Group IV and III–V semiconductors. The relative ease of measurement has ensured that much more self- and dopant data are available compared to the III–Vs. A further difference is that both cation and anion vapor pressures are significant compared to the III–Vs, where the cation vapor pressures are negligible. As a result the level of nonstoichiometry can be varied between cation rich to anion rich. Excess concentrations are typically up to

$10^{19}\,cm^{-3}$. This has the consequence that the solubility of dopants can be controlled by using the partial vapor pressure of one of the components. Unless otherwise stated, the material in the following sections is drawn from the reviews by *Shaw* [6.9, 105–107] and by *Capper* et al. [6.108]. Within the last decade or so much interest has developed in the optoelectronic properties of ZnO and accounts of defects [6.106] and diffusion [6.107] in ZnO are available.

6.9.1 Self-Diffusion

Where the anion self-diffusivity D_A has been measured as a function of the ambient anion or cation partial vapor pressure in undoped material (ZnSe, CdS, CdSe, CdTe, and $Hg_{0.8}Cd_{0.2}Te$), a consistent pattern of behavior has emerged: in traversing the composition range from anion-rich to cation-rich, D_A is inversely proportional to the rising cation partial vapor pressure, P_C, until close to cation saturation, when D_A starts to increase with P_C. Strong donor doping in anion-rich CdS and CdSe had no effect on D_A. This evidence points to either a neutral anion interstitial or a neutral anion anti-site/anion vacancy complex as the diffusion mechanism over most of the composition range, changing to an anion vacancy mechanism as the cation-rich limit is approached.

The situation for cation self-diffusion proves to be more complicated due to different patterns of behavior of the cation self-diffusivity, D_C, across the compounds. In undoped ZnSe, ZnTe, CdTe, and $Hg_{0.8}Cd_{0.2}Te$ (above $\approx 300\,°C$), D_C is largely independent of P_C across the composition range. Such an independence excludes native point defect mechanisms and (excluding nondefect mechanisms) indicates self-diffusion via neutral complexes such as a cation interstitial/cation vacancy pair or a cation vacancy/anion vacancy pair. Donor or acceptor doping increases D_C, pointing to the involvement of ionized native defects or complexes. Cd self-diffusion in Cu doped CdTe between 500 and 900 °C identified the doubly ionized Cd interstitial as the defect involved with a diffusivity of $0.23\exp(-0.99\,eV/k_BT)\,cm^2/s$ [6.109]. The Arrhenius parameters for Zn self-diffusion in undoped ZnSe above 760 °C are $D_0 = 9.8\,cm^2/s$ and $Q = 3.0\,eV$ and those for Hg in undoped $Hg_{0.8}Cd_{0.2}Te$ above 250 °C are $D_0 = 3.8\times10^{-3}\,cm^2/s$ and $Q = 1.22\,eV$. In the case of undoped ZnS, CdS, CdSe, and HgTe D_C generally varies with P_C across the composition range. The simplest variations are found in CdSe and HgTe. In CdSe, D_C can be attributed to the parallel diffusion of singly ionized (1^+) and doubly ionized $(2+)$ Cd self-interstitials. D_C in HgTe initially falls with rising P_C and then increases when crossing the anion-rich to cation-rich boundary, corresponding to diffusion by a singly ionized $(1-)$ Hg vacancy and by a singly ionized $(1+)$ Hg interstitial, respectively. The behavior patterns in ZnS and CdS, however, present substantial problems in their interpretation: donor doping can also enhance D_C, pointing to the participation of an ionized native acceptor mechanism.

6.9.2 Chemical Self-Diffusion

Changes in the electrical conductivity or conductivity type by step changes in P_C in sample anneals have been used to characterize the change in level of nonstoichiometry through the chemical self-diffusivity, D_Δ, in CdS, CdTe, and $Hg_{0.8}Cd_{0.2}Te$. D_Δ obviously describes the diffusion of one or more ionized native defects, but in itself does not identify the defect(s).

In CdS and CdTe, D_Δ is attributed to the singly ionized (1^+) and/or doubly ionized $(2+)$ Cd interstitial; in CdTe, depending on the temperature, D_Δ exceeds D_C by a factor 10^5 to 10^6. Modeling based on the simultaneous in-diffusion and out-diffusion of doubly ionized cation interstitials $(2+)$ and vacancies $(2-)$ gives a satisfactory quantitative account of type conversion (p → n) in $Hg_{0.8}Cd_{0.2}Te$ [6.10].

6.9.3 Dopant Diffusion

Although much information is available on dopant diffusion, it is mainly empirical and it is not uncommon for a dopant diffusivity to be independent of the dopant concentration (as revealed by an erfc profile, which indicates a constant diffusivity for a given diffusion profile) under one set of conditions only to give profiles which cannot be characterized by single diffusivities when the conditions are changed. Equally, the variation of dopant diffusivity with P_C may differ at different temperatures. A further difficulty when attempting to identify a diffusion mechanism is that the local electroneutrality condition is usually not known with any certainty due to significant concentrations of various ionized native defects. A good example of the problems encountered is provided by the diffusion of In in $Hg_{0.8}Cd_{0.2}Te$, where diffusion of the singly ionized (1^-) pair $In_{Hg}V_{Hg}$ can account for some of the diffusion features. Some dopants, however, can present clear-cut diffusion properties which permit a well-defined interpretation. The diffusion of As in $Hg_{0.8}Cd_{0.2}Te$ is one such case [6.110]. All of the observed features of D(As) are accounted for on the basis that: (i) As occupies cation and anion sites as singly ionized donors $(1+)$ and acceptors $(1-)$, respectively; (ii) only the ionized donor is mobile and diffuses by a vacancy mechanism on the cation sublattice; (iii) the diffusion sample is electri-

cally intrinsic throughout, so the As concentration is always less than the intrinsic free carrier concentration.

6.9.4 Compositional Interdiffusion

Empirical information, based on bulk material, exists for CID in the following ternaries: (ZnCdHg)Te, (ZnCd)Se, (ZnCdHg)SSe, CdSeTe, ZnCdS, HgCdTe, and CdMnTe. It might be expected that features evident in the binaries, such as donor doping enhancing the cation diffusivity but having no effect on that of the anion, and the anion diffusivity increasing (decreasing) with anion (cation) partial vapor pressure across most of the composition range, would continue to be seen. This means that in a ternary or quaternary system, donor doping will enhance CID on the cation sublattice, but not on the anion sublattice, and annealing under a high (low) anion (cation) vapor pressure will enhance CID on the anion sublattice. This effect of the anion vapor pressure has been confirmed in CdSSe and CdSeTe and more recently in ZnSSe/ZnSe superlattices [6.111]. In (donor) doping has also been found to enhance the CID of cations in CdMnTe [6.112], as has N (acceptor) doping in ZnMgSSe/ZnSSe superlattices [6.113, 114]. The consequences of doping on CID in the II–VIs are obviously very similar to the III–V situation.

6.10 Nano Volume Diffusion

In view of the importance of nanoscale materials and devices it is appropriate to consider if Fickian diffusion (6.1) occurs in nanoscale systems. An immediate problem is evident in (6.1) which shows that a plane of constant c has a shift velocity of $\mathrm{d}x/\mathrm{d}t \propto 1/\sqrt{t}$ which $\to \infty$ as $t \to$ zero. For $0.3 \leq x \leq \approx 1.6\,\mathrm{nm}$ *Balogh* et al. [6.115] found $x \propto t^{0.7}$ for Si diffusion into amorphous Ge, changing to $x \propto \sqrt{t}$ at larger x. The continuum approach clearly fails as $t \to$ zero and recourse to discrete and atomistic models becomes necessary for describing diffusion on the nanoscale. Whereas in Fickian diffusion the parameters can be measured the parameters for discrete models can only be estimated.

6.11 Diffusion in Molten Semiconductors

So far, this chapter has been concerned with atom diffusion in crystalline semiconductors but diffusion in the liquid state must also be recognized and is termed thermodiffusion. Examples are provided by doping during crystal growth in which the dopant has a greater solubility in the solid than in the liquid, so that there is a diffusion flux of the dopant to the growth interface: if the solubility is less, then there will be a flux away from the interface. In the case of growth of the binary MX, away from the eutectic, if the melt is M or X-rich there will be flux of M or X away from the interface. Temperature gradients will also promote thermodiffusion. However, the existence of convection currents in the melt can replace any thermodiffusion that may be present. Convection can be avoided in a microgravity environment, or by employing a vertical temperature gradient in which the temperature increases with height (as in the temperature gradient zone melting technique), or in nanoscale processing. Thermodiffusion is an essential feature in the fabrication of micro and nano metal doped semiconductor devices [6.116]. The redistribution of a dopant ion implant in Si following pulsed laser annealing has been interpreted in terms of thermodiffusion [6.115]. Thermodiffusion has also been invoked to account for the mixing at an Fe–Si interface resulting from exposure to a 230 MeV Au beam [6.117]. A diffusivity of $10^{-4}\,\mathrm{cm}^2/\mathrm{s}$ for As in liquid Si has been reported arising from As ion implants [6.118–120].

6.12 The Meyer–Neldel Rule

The Meyer–Neldel rule is found to apply to most phenomena that can be characterized by an Arrhenius expression. In the case of a diffusion coefficient $D = D_0 \exp(-Q/k_\mathrm{B}T)$, the rule states that a correlation exists between D_0 and Q. A phenomenological basis for the model has been given by *Dyre* [6.121] and the rule has been examined for diffusivities in Si and Ge by *Khait* et al. [6.122]. In $Hg_{0.8}Cd_{0.2}Te$ a good fit to $\ln D_0 = 15\,Q - 23.7$ is found for twelve self- and impurity diffusivities.

6.13 Conclusions

The first step in a diffusion investigation is to collect empirical data, which then leads to the second step where experiments can be designed to study the effects of the Fermi level (through the background doping level), of the ambient atmosphere (such as oxidizing, inert or vapor pressure of a system component) and of the sample structure (such as in a quantum well, superlattice or MBE layer). The third step is to identify the diffusion mechanism and the associated defects using the experimental results in conjunction with the results from first-principles calculations of defect formation energies and their activation energies for diffusion.

It must also be recognized that Fickian diffusion is not applicable at the nanoscale [6.113].

Clarification of the active processes involved can be gained by numerical modeling (see *Noda* [6.123]). These data then provide the basis for the development of process simulators and defect engineering in which the concentrations and spatial distributions of host atoms, dopants and defects are organized according to requirements. Most progress towards achieving this ideal scenario has been made in Si, GaAs and $Hg_{0.8}Cd_{0.2}Te$. The reality elsewhere is that the boundaries between steps are blurred, with the third step often being taken with inadequate experimental information e.g., as in GaN and ZnO. Much work remains to be done in order to achieve a full understanding of diffusion processes in semiconductors but valuable insights are being provided from first-principles calculations of native defect properties: e.g., the diffusion of O in ZnO [6.121].

6.14 General Reading and References

General background material for diffusion in semiconductors can be found in [6.8, 11, 14, 50]. More specific accounts are given in [6.12, 122] for Si and in [6.6] for Si and Ge. Si, Ge, and GaAs are covered by [6.69]. The III–Vs and II–VIs are dealt with in [6.50] and [6.103] respectively. A review of nanoscale volume diffusion is available in [6.123]. The volumes in the EMIS Datareviews Series (IEE, Stevenage, UK) cover all the important semiconductors. The series *Defects and Diffusion in Semiconductors* ed. by D. J. Fisher (Trans Tech. Publications, Brandrain 6, Switzerland) offers an annual and selective retrospective of recent literature.

7. Photoconductivity in Materials Research

Stephen Reynolds, Monica Brinza, Mohammed L. Benkhedir, Guy J. Adriaenssens

Photoconductivity is the incremental change in the electrical conductivity of a semiconductor or insulator upon illumination. The behavior of photoconductivity with photon energy, light intensity and temperature, and its time evolution and frequency dependence, can reveal a great deal about carrier generation, transport and recombination processes. Many of these processes now have a sound theoretical basis and so it is possible, with due caution, to use photoconductivity as a diagnostic tool in the study of new electronic materials and devices. This chapter describes the main steady-state and transient photoconductivity techniques applied in the investigation of semiconductors whose performance is limited by the presence of localized electronic states. These materials tend to be disordered, and possess low carrier mobilities and short free-carrier lifetimes in comparison with crystalline silicon. They are often prepared as thin films, and are of interest for large-area applications, for example in solar cells, display backplane transistors, photoemissive devices such as organic light-emitting diodes (OLEDs) and medical imagers. However, examples of where these techniques have been useful in the study of defective crystalline semiconductors are also given. The approach followed here is by way of an introduction to the techniques, the physics supporting them, and their applications, it being understood that readers requiring more detailed information will consult the references provided.

Photoconductivity, defined as the increase in conductivity of a material resulting from the absorption of optical photons, has traditionally played a significant role in materials research, most notably in the study of covalently bonded semiconductors and insulators. The basic processes that govern the magnitude of the photocurrent are the generation of free electrons and holes through the absorption of incident photons, their transport through the material under the influence of an electric field, and their recombination. The study of any of those aspects as a function of illumination, temperature and field strength, and their development over time, will offer insights into the structure and electronic properties of the material under investigation. However, given that several processes may be involved in the production of a specific photocurrent, a sufficiently comprehensive dataset is needed to differentiate between alternative interpretations. For instance, a low photocurrent may be the result of a low optical absorption coefficient at the given photon energy, but it may also be due to geminate recombination of the photogenerated electron–hole pairs, or it may reflect the formation of excitons. Photogenerated charge needs to be transported in a material to realize a current, a process which depends upon the effective carrier mobility. This can vary by up to ten orders of magnitude; from around $10^4\,\mathrm{cm}^2/(\mathrm{V\,s})$ in semiconductors such as crystalline Si and GaAs where band transport dominates, to $10^{-6}\,\mathrm{cm}^2/(\mathrm{V\,s})$ or less in disordered inorganic and organic semiconductors where transport is via low-mobility extended state conduction mediated by carrier traps, or by carrier hopping between localized states, or by a combination of such processes depending on temperature and excitation regimes.

Given the complexity of these processes, use of a range of photoconductivity experiments is often advisable, as is the combination of photoconductivity with complementary techniques such as optical absorption, photoluminescence, dark current activation, charge collection, electron paramagnetic resonance and various pump-probe experiments. A robust model should seek to satisfy all observations, as rationally as possible. From a slightly different perspective, one of the major tasks of the electronic materials scientist is to attempt to correlate material (and device) preparation conditions and micro/nanostructure with electronic properties. It follows that structural information, from analytical tools such as electron and scanning probe microscopies, x-ray and electron diffraction and Raman spectroscopy, is also of key importance.

A variety of experimental techniques based on photoconductivity have evolved. The information that can be obtained relates to the mechanisms of generation and recombination of carriers and their transport by drift and diffusion. The physical parameters to be extracted include:

- Optical absorption coefficient
- Quantum efficiency
- Carrier mobility
- Carrier lifetime
- Mobility-lifetime products
- Minority carrier diffusion length
- Density of localized electronic states and their capture and emission properties
- Charge state and energetic location and spatial variations in transport properties.

The information obtained need not be specific to the method, and will depend on the wider context of the measurements. Recombination can be studied via photocurrent decay from the steady state, but the intensity and temperature dependence of steady-state photoconductivity can also be used to identify different recombination mechanisms, while details of the density of states in the bandgap of a semiconductor can be inferred both from the spectral response and temperature dependence of the steady-state photoconductivity and a detailed analysis of transient photoconductivity.

This chapter focuses on the main photoconductivity techniques applied in the investigation of semiconductors whose performance is limited by the presence of localized electronic states. Many are deposited rapidly as thin films, are structurally disordered and tend to possess low carrier mobilities and short free-carrier lifetimes compared to *benchmark* crystalline silicon. Research has been stimulated by their highly successful commercial application for over 70 years, in xerography, solar energy, large-area displays and medical imaging. Photocopiers are a good example of the evolution of thin-film photoconductors, beginning with photoreceptor drums coated with selenium, through amorphous silicon, to organic semiconductors. Each of these materials has been intensively researched with regard to their charge generation and retention properties, using photoconductivity methods.

Finally, mention should be made of the use of computer simulations in photoconductivity studies. This has been an active complementary field of research for over 50 years, and its value in developing a coherent understanding of the physics of photoconductivity, and electronic transport in general, is considerable. The experiments described herein furnish data that can be integrated into, or compared with the predictions of, computer simulations of physical processes, and it is often by *closing the loop* in this way that confirmation of the validity and limitations of proposed physical models or data analysis schemes can best be achieved. In a broader context, simulations are now used routinely in the development of solar cells and other devices.

This book contains several chapters that strongly support this work, and are referred to below. Comprehensive accounts of the principles of photoconductivity may be found in the monographs by *Bube* [7.1, 2], *Ryvkin* [7.3] and *Rose* [7.4]. Detailed information on computer simulation of steady-state and transient photoconductivity, and comparison with experiment, is provided in references [7.5–7]. Background and procedures for computer modeling of solar cells, which has strong relevance to the techniques presented here, is given in [7.8]. Readers wishing to try out their own simulations are encouraged to download *SC-Simul* [7.9], a suite of linked software applicable to both steady-state and transient photoconductivity studies.

7.1 Steady-State Photoconductivity (SSPC)

7.1.1 Definitions and Overview

The simplest photoconductivity experiment uses a constant monochromatic light source to generate equal excess densities of free electrons and holes, $\Delta n = \Delta p$, that lead to a change in the conductivity (Chap. 2) by

$$\Delta\sigma = \sigma_{\mathrm{ph}} = q(\mu_{\mathrm{n}}\Delta n + \mu_{\mathrm{p}}\Delta p)\,, \qquad (7.1)$$

where q is the electronic charge and μ_{n} and μ_{p} are the electron and hole mobilities respectively. σ_{ph} is termed the steady-state photoconductivity, or SSPC. The basic experimental arrangement is illustrated in Fig. 7.1a, where L and A are the length and the cross-sectional area of the sample. When a potential difference V is applied, a photocurrent I_{ph} is recorded. The corresponding photoconductivity $\sigma_{\mathrm{ph}} = I_{\mathrm{ph}}/(AF)$, where $F = V/L$ is the applied electric field. The end surfaces of the sample are normally contacted by metallic electrodes. However, for thin films rather than bulk samples, coplanar electrodes in the form of contact pads are typically prepared by evaporation through a shadow mask onto the film surface, or deposited firstly onto the substrate, which is then coated with the photoconductor. Interdigitated electrodes of the type shown in Fig. 7.1b may be used to increase the photocurrent if required. The contacts to this type of sample are chosen to be ohmic. The current measured in this way is termed a *secondary* photocurrent, since it arises from replenishment of photogenerated carriers exiting the sample in order to maintain charge neutrality. Note that the rate of flow of carriers around the circuit may be many times larger than the rate of flow of photons, by a factor ideally equal to the ratio of the carrier lifetime to its transit time across the sample, $\tau/(L^2/(\mu V))$. This is to be distinguished from the *primary* photocurrent exiting a solar cell for example, where both flows are ideally equal.

A significant fraction of photogenerated carriers may become immobilized by trapping at localized states in the semiconductor (band tails and/or defects) such that not every part of Δn and Δp contributes equally to the photoconductivity in (7.1) (Chap. 9). The effect of trapping is reflected in values for μ_{n} and μ_{p} that are lower than the theoretical free-carrier or band

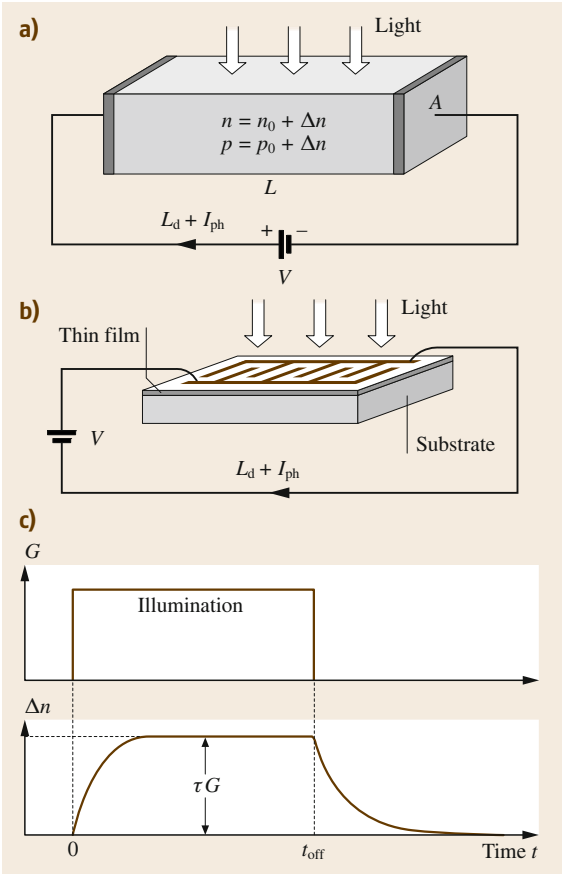

Fig. 7.1 **(a)** Arrangement for photoconductivity measurement. V is the applied voltage, L the sample length and A the cross-sectional area. I_{d}, n_0 and p_0 are the current and the carrier densities in the dark, and I_{ph}, Δn, Δp are the incremental values generated by the illumination. **(b)** Example of interdigitated electrode configuration for a thin film sample. **(c)** Schematic time development of the excess carrier concentration Δn in response to a period of illumination

mobility μ_0. For many materials of interest, either the product $\mu_n \Delta n$ or the product $\mu_p \Delta p$ turns out to be much larger (the majority carrier) than the other (the minority carrier), because of strongly unequal carrier mobilities. For instance, the electron term dominates in intrinsic silicon, while the photocurrent in chalcogenide glasses is carried by holes. In those instances, (7.1) may often be reduced to a one-carrier equation. In $\mu_n \Delta n$ and $\mu_p \Delta p$, the mobility is a material parameter that, in general, will depend on temperature and sample characteristics, while the excess carrier densities Δn, Δp are determined by a combination of material and external parameters. Phenomenologically, the excess density Δn can be written as the product $G\tau_{n,p}$, where G is the rate of generation of free electrons and holes per unit volume, and $\tau_{n,p}$ is the average lifetime of the excess electrons or holes. Substituting into (7.1)

$$\sigma_{ph} = qG(\mu_n \tau_n + \mu_p \tau_p) \,, \tag{7.2}$$

which explicitly displays the mobility-lifetime products frequently used to characterize photoconductors. The relationship between Δn and G is illustrated schematically in Fig. 7.1c. When the light is turned on, Δn increases gradually with time, and eventually reaches the steady-state value we address in this section. When the light is turned off, Δn decays gradually to zero. In the steady state, the generation and recombination rates are equal and constant; in the transient regions, they are not. Time-dependent aspects of photoconductivity are addressed in later sections of this chapter.

The average carrier generation rate G is defined by

$$G = \eta\phi(1-R)\frac{1-\exp(-\alpha d)}{d} \,, \tag{7.3}$$

where η is the quantum efficiency of the generation process, ϕ is the photon flux, the number of photons of energy $E_{ph} = h\nu$ incident on the sample per unit area per unit time, R is the reflection coefficient, α the optical absorption coefficient and d the sample thickness. For monochromatic light, the relation between the intensity I_0 and photon flux is $\phi = I_0/E_{ph}$. A quantum efficiency $\eta < 1$ signifies that not every photon absorbed generates a free electron and hole that contributes to the photocurrent, due to geminate recombination of the carriers, or exciton formation. The values of the parameters η, R and α depend, in general, on the wavelength of the illuminating light. Consequently, monochromatic illumination from a tunable light source can be used to obtain energy-resolved information about the sample, while illumination with white light will provide a global average.

In many measurements on thin films, the condition $\alpha d \ll 1$ will hold over a significant energy range, i. e., when the sample thickness d is small with respect to the optical absorption depth $1/\alpha$. Equation (7.3) can then be simplified to

$$G \cong \eta\phi(1-R)\alpha \,. \tag{7.4}$$

Under these conditions the incident light is uniformly absorbed, and so (neglecting surface effects) G is everywhere constant rather than an average value. Since SSPC is frequently nonlinearly dependent on G, the uniformly absorbed condition is often strongly preferred, especially in quantitative work. However there are instances where nonuniform absorption may be useful, for example to probe surface effects.

The free-carrier lifetimes of excess electrons and holes, τ_n and τ_p, in (7.2) are governed by recombination with carriers of opposite sign. Assuming, for simplicity, the frequently encountered case of photoconductivity dominated by the majority carrier (assumed here to be electrons), the recombination rate can be written as $\tau_n^{-1} = b(p_0 + \Delta p)$, where b is a recombination constant, and p_0 and Δp are the equilibrium and excess minority carrier densities respectively. It then follows that the SSPC may be expressed as

$$\sigma_{ph} \propto \Delta n = G\tau_n = \frac{G}{b(p_0 + \Delta p)} = \frac{G}{b(p_0 + \Delta n)} \,. \tag{7.5}$$

Equation (7.5) indicates that a linear relationship $\sigma_{ph} \propto G$ holds for $\Delta n \ll p_0$ (at low excess carrier density), while higher excitation levels with $\Delta n \gg p_0$ lead to $\sigma_{ph} \propto G^{1/2}$. The resulting linear and quadratic regimes are referred to as *monomolecular* and *bimolecular* recombination. For a given light source and temperature, variations in G correspond to variations in the flux ϕ, and therefore $\sigma_{ph} \propto \phi^{\gamma}$ with the photoconductivity index $0.5 \le \gamma \le 1$. It can also be shown from the above that the response time $\tau \propto \phi^{(\gamma-1)}$. The value of γ also depends on ϕ. However, ϕ is not the only factor that determines the value of γ; intermediate γ values may indicate a $\Delta n \approx p_0$ condition, but they may equally well be a result of an energetic distribution of recombination centers [7.4], as discussed below. In addition, the equilibrium free-carrier densities n_0 and p_0, which play a role in recombination, depend on temperature through the Fermi–Dirac distribution function, thus making recombination a temperature-dependent process.

7.1.2 Example Applications in Materials Research

In photoconductors, recombination is mediated by states in the bandgap. The presence of discrete, or a nar-

row energy range, of trapping levels leads to thermally activated photocurrents, with the activation energy indicating the energetic positions of the traps. *Main* and *Owen* [7.10] and *Simmons* and *Taylor* [7.11] showed that the positive photocurrent activation energy in the monomolecular recombination regime corresponds to the energy above the Fermi level of a donor-like center, while a negative activation energy value in the bimolecular region corresponds to the energy above the valence band edge of an acceptor-like center. Figure 7.2 illustrates this photocurrent behavior for amorphous As_2Se_3 [7.12]. This is characteristic of chalcogenide glasses, where the intrinsic charged defects act as recombination centers [7.13]. SSPC measurements of this type can thus determine the recombination mechanism and the energetic position of discrete defects.

The temperature dependence of the SSPC in amorphous silicon (a-Si:H) does not exhibit a definite activation energy, due to the presence of a more distributed and complex set of traps including band tails and charged and neutral defects (Chaps. 9 and 24). A simplified electronic density of states (DOS) is shown schematically in Fig. 7.3a.

Whenever the DOS in the bandgap of a photoconductor consists of a distribution of traps, quasi-Fermi levels (QFLs) can usefully be defined. In thermal equilibrium, the QFLs and the Fermi level coincide. Under illumination the QFLs *split* from the equilibrium Fermi level such that they define the occupancy of states separately for electrons and for holes. The QFL for electrons may be written

$$E_{\mathrm{Fn}} = E_{\mathrm{F}} + k_{\mathrm{B}}T \ln\left(1 + \frac{\Delta n}{n_0}\right) \qquad (7.6)$$

with an equivalent expression for holes. In the case of the majority carrier, E_{F} may be determined from the activation energy of the dark conductivity σ_{d} and $\Delta n/n_0 = \sigma_{\mathrm{ph}}/\sigma_{\mathrm{d}}$. To a first approximation (see [7.11] for detailed considerations), the QFLs correspond to demarcation energies dividing the DOS into a shallower part, where carriers may be trapped and subsequently emitted, and a deeper part where traps have become recombination centers. This is illustrated in Fig. 7.3b. It is clear that as the QFLs depend on the carrier density, varying the light intensity and temperature will influence the role of a given set of localized states in generation and recombination processes. In addition to the variation with energy of the DOS in the bandgap, the capture and recombination constants for the various centers may also be quite different.

Much progress has been made in understanding photoconductivity in materials with broad distributions of localized states, and in applying SSPC as a diagnostic

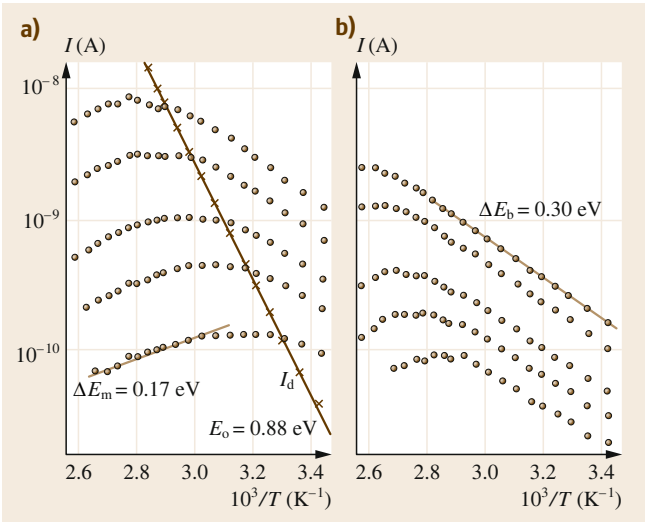

Fig. 7.2a,b Temperature dependence of the steady-state dark and photocurrents in an a-As_2Se_3 sample, **(a)** illuminated at 1.55 eV with intensities of 0.84, 3.5, 9.8, 38 and 120×10^{12} $\mathrm{cm^{-2}s^{-1}}$, and **(b)** illuminated at 1.85 eV with intensities of 0.56, 1.7, 4.6, 27 and 77×10^{12} $\mathrm{cm^{-2}s^{-1}}$. ΔE_{m} and ΔE_{b} represent the photocurrent activation energies in the monomolecular and bimolecular recombination regimes respectively, and E_σ is the activation energy of the dark current I_{d}. (After [7.12])

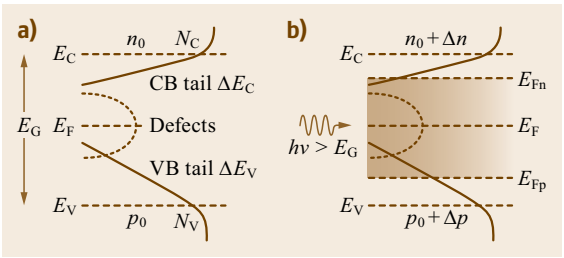

Fig. 7.3 **(a)** Model density of states (DOS) in a disordered semiconductor at thermal equilibrium, electron and hole densities n_0 and p_0 respectively, depicting localized conduction and valence band tail states and defects distributed in midgap. **(b)** Illumination results in splitting of quasi-Fermi levels E_{Fn} and E_{Fp}. Localized states between E_{Fn} and E_{Fp} act as recombination centers, those between E_{Fn} and E_{Fp} and the respective band edges act as carrier traps from which charge is subsequently released

tool. One example is provided by *Brüggemann* [7.14] who studied SSPC in microcrystalline silicon thin films. He applied a result first proposed by *Rose* [7.4] and elaborated by *Bube* [7.2], that the intensity dependence of the SSPC in an intrinsic semiconductor in which electrons are the majority carriers is controlled by local changes in the DOS at E_{Fn}. By adjusting E_{Fn} over a wide range by varying I_0 and T, and measuring γ from

the local slope in a plot of log (σ_{ph}) versus log (I_0), it is possible to reconstruct the DOS in the upper half of the bandgap as a series of segments.

Changing the position of the equilibrium Fermi level by doping also modifies photoconductivity behavior. The effect of n-type doping on the SSPC of a-Si:H has been studied by a number of workers, including *Main* et al. [7.17]. They carried out photoconductivity measurements over a wide range of intensity and temperature, and noted that (i) over certain temperature ranges, around 200 K, values of γ as low as 0.4 could be observed, and (ii) these low values of γ persisted even when the photocurrent was over two orders of magnitude below the dark current. Neither of these results is predicted by the Rose model outlined above. However, they were able to account consistently for the observations in terms of a typical model density of states such as that shown in Fig. 7.3a, but in which recombination takes place solely via defect states. In this case band tails do not act as recombination centers, but are *indirectly* involved as charge reservoirs required to maintain charge neutrality. If the conduction band tail slope ΔE_C is steeper than the valence band tail slope ΔE_V, limiting values of γ in this model are predicted to be $k_B T/\Delta E_V$ at low generation rates, and $\Delta E_C/\Delta E_V$ at high generation rates. Both predictions are borne out experimentally assuming realistic tail slope values (25 meV and 45 meV), and furthermore detailed accordance over the full experimental range was achieved by means of computer modeling. Finally it should be noted that values of $\gamma > 1$ have been observed in a-Si:H, again in conflict with the Rose model, with explanations being offered by a number of workers including *Fritzsche* et al. [7.18] and *Bube* [7.19].

From a materials characterization point of view, SSPC offers the possibility of using (7.4) to determine the absorption coefficient and/or quantum efficiency as a function of the energy of the incoming photons, and thus to explore the bandgap of a semiconductor. When materials with sufficiently well-defined energy levels are studied, local maxima corresponding to specific optical transitions may be seen in the photoconductivity spectra. An example, from the work of *Nesladek* et al. [7.15], is illustrated in Fig. 7.4. This shows the spectrally resolved photocurrent for diamond films prepared by chemical vapor deposition. The rise in photocurrent around 5.5 eV corresponds to the optical bandgap of diamond, while the shoulders at $\approx$ 1.5 eV and $\approx$ 3.5 eV signal the presence of defect distributions

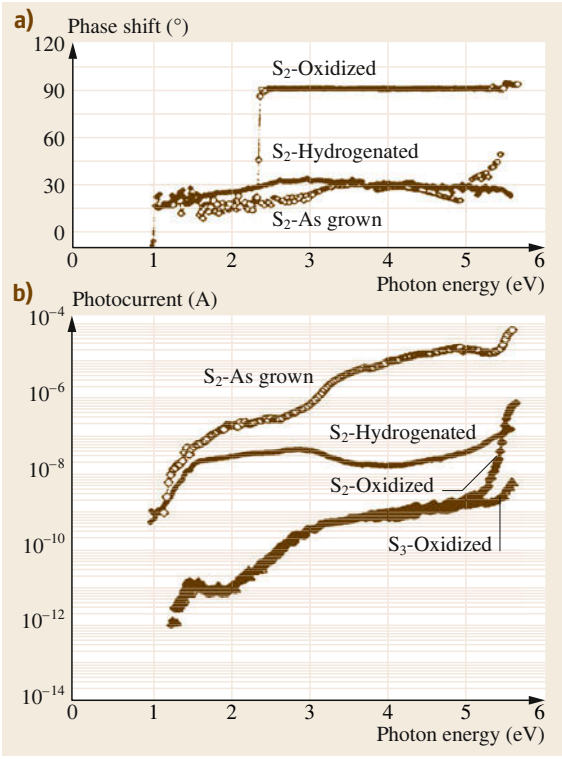

Fig. 7.4a,b Room temperature AC photocurrent spectra, measured at 7 Hz, after various treatments of chemical vapor deposition (CVD) diamond layers deposited at 920 °C (S_2) and 820 °C (S_3). **(a)** Phase shift. **(b)** Magnitude of photocurrent. (After [7.15])

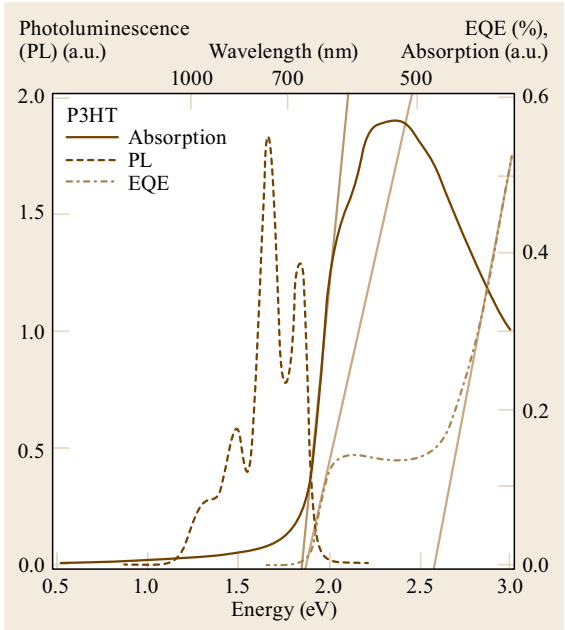

Fig. 7.5 Combination of spectrally-resolved photoconductivity, optical absorption and photoluminescence measurements used to quantify exciton formation in the organic semiconductor P3HT. (After [7.16])

in the bandgap. The data were measured using low-frequency chopped light and a lock-in amplifier. It can be seen that changes in the phase shift between the photocurrent and the chopped light may also reveal specific features in the DOS. This topic is addressed in detail later, in Sect. 7.4 on modulated photoconductivity (MPC).

A further example of the use of spectrally resolved photocurrent, this time to probe organic semiconductors of interest in solar cell development, is shown in Fig. 7.5. *Deibel* et al. [7.16] have measured the quantum efficiency of charge generation in the conjugated polymer P3HT. The onset of strong photogeneration commences at 2.6 eV, compared with a value of 1.9 eV for strong optical absorption in the same sample. The former energy is that required to generate free carriers, whereas the latter is that required to generate an exciton, a bound electron-hole pair (Chap. 3). The difference of 0.7 eV corresponds to the energy required to dissociate the exciton. Photoluminescence (Chap. 38) and photoelectron spectroscopy measurements enable further details of the interactions to be deduced. This example illustrates the benefits of combining a range of measurements to provide linked information on semiconductor properties, which leads in turn to a comprehensive and consistent model.

7.2 Constant Photocurrent Method (CPM) and Related Techniques

7.2.1 CPM

The constant photocurrent method (CPM) is a simple but important development of the basic single-beam measurement described in Sect. 7.1. It was introduced by *Vaněček* et al. [7.20, 21] to determine the optical absorption coefficient $\alpha(E_{\mathrm{ph}})$ of thin-film semiconductors over a very wide range (typically $0.1-10^5\,\mathrm{cm}^{-1}$) as a function of photon energy E_{ph}. In CPM, the photocurrent is kept constant by continually adjusting the light intensity I_0 while E_{ph} is scanned across the spectrum. A constant photocurrent implies that the quasi-Fermi levels have fixed positions, and thus that the free-carrier lifetime τ remains constant.

From (7.2) and (7.4), the photoconductivity of a thin film under uniformly absorbed light ($\alpha d \ll 1$) is

$$\sigma_{\mathrm{ph}} = q\mu\tau(1-R)\eta\alpha\phi\ . \tag{7.7}$$

The product $\alpha\phi$ will thus remain constant, and relative values of α can be determined from it, provided that energy dependencies of the parameters μ, R and η of (7.7) are negligible. The value at which the photocurrent is fixed may be chosen freely, but will in practice be dictated by the low-absorption region of the sample. However, since even low-level photocurrents can still be measured with high precision, the CPM method is especially useful at low values of optical absorption where standard optical transmission measurements lose their accuracy.

It follows from (7.7) that under the above conditions a plot of $1/\phi$ versus E_{ph} will reveal relative values of α. In an improved variant of the CPM technique, termed *absolute* CPM (ACPM) [7.21], optical transmission through the film is measured at the same time as the photocurrent, and the data from the two measurements are combined in order to remove optical interference fringes [7.22] and to calibrate the system using the *Ritter–Weiser* formula [7.23]. The experimental arrangement used in absolute CPM measurements is shown schematically in Fig. 7.6. Depending on requirements, the sample may be mounted in a cryostat to enable operation over a wide temperature range. The choice of monochromator system is important, since at long wavelengths second-order output can easily dominate the sample photocurrent to give erroneous readings. A double monochromator plus order filters are recommended to maintain second- and higher-order output and scattered light below one part in 10^5.

The CPM experiment may be operated with either DC or AC illumination, but as discussed later, the absorption spectra obtained need not be identical. Most researchers use low-frequency AC illumination (chopped light, < 10 Hz) to measure the sample photocurrent and detector outputs, since values may be small (nA to pA) and thus prone to electrical noise and interference

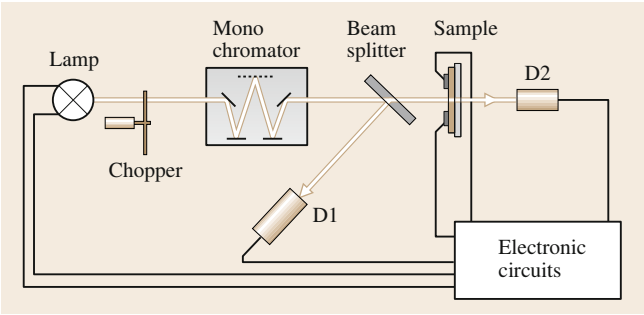

Fig. 7.6 Schematic diagram of an *absolute* CPM setup. Photodetector D1 is used to measure the intensity of light incident on the sample, while detector D2 measures the transmitted light. These signals plus the sample photocurrent are recorded by electronics, the latter being maintained constant by control of the lamp current. Details of operation are given in the text. (After [7.21])

whose effects are minimized by lock-in detection. The CPM measurement process proceeds as follows. The lamp current is adjusted until the sample photocurrent equals the set-point value and remains steady. Readings are taken from the calibrated detectors D1 (proportional to the intensity of the incident beam) and D2 (the transmitted beam). The monochromator wavelength is then decremented, and the lamp current adjusted until the photocurrent once more equals the set-point, D1 and D2 are read, and so on until the desired end point of the wavelength scan is reached. Normally the process is carried out in a closed loop, by means of a control algorithm running on a PC. Depending upon the desired precision, the 30–100 measurement points may take several hours to collect since settling times may be long. For a detailed exposition of calibration and calculations required to generate the final absolute CPM spectrum, the reader is referred to [7.20, 21].

While it is of course useful to know $\alpha(h\nu)$ for a material per se, for example when designing a thin-film solar cell, a wealth of additional information may be extracted. The initial work by *Vaněček* et al. [7.20] was directed at an investigation of thin-film silicon, and CPM emerged as an important technique of choice for assessing material quality as a function of deposition rate, substrate temperature, process gas composition, light exposure and subsequent degradation, and many other factors. Essentially, $\alpha(E_{\mathrm{ph}})$ is a result of all permitted electronic transitions in a given sample. The integral representing this is referred to as the joint density of states (Chap. 3). If a particular set of transitions is dominant, this will be evidenced in the local behavior of $\alpha(E_{\mathrm{ph}})$. The two CPM *figures of merit* most commonly quoted for intrinsic a-Si:H in the literature relate to (i) the Urbach tail slope, the characteristic energy of the exponential rise in optical absorption observed in many disordered materials, and a measure of the degree of structural or compositional disorder, and (ii) the defect shoulder (or bump) in α below the Urbach tail typically at a photon energy of 1.2 eV, that is considered a measure of the dangling bond density. In both cases, transitions from filled states (below the Fermi level) to empty states close to or above the conduction band edge predominate (but see below), since the electron is the majority carrier. It follows that the Urbach energy in a-Si:H revealed by CPM is largely a measure of the valence band tail slope.

As the electronic DOS $g(E)$ is implicitly involved in determining α, it seems reasonable to suppose that there should be an inverse process that enables $g(E)$ to be obtained from α. This turns out to be quite straightforward, provided transitions are limited to those indicated above, and current is carried by a single mobile carrier. The simplest expression, obtained by assuming a constant conduction band DOS and $T = 0$, is that $g(E_{\mathrm{c}} - E_{\mathrm{ph}}) = K\mathrm{d}\alpha/\mathrm{d}E_{\mathrm{ph}}$ between E_{v} and E_{F} [7.24]. The constant K depends on the values of the interaction matrix element and the DOS at the conduction band edge. More elaborate and potentially more accurate procedures assume a parabolic conduction band DOS [7.25], though generally only transitions from filled localized states to electron transport states are considered.

Main et al. [7.26] extended the CPM experiment analysis (on a-Si:H) to include the possibility of optical excitation from the valence band into unoccupied deep defect states (above E_{F}), followed by *thermal emission* into the conduction band. These transitions are weak at high frequencies but significant at low frequencies and DC. Thus DC CPM will tend to return a larger α than AC CPM. These workers also demonstrated that the density of empty states (above E_{F}) could be probed by comparing the AC and DC CPM limiting values.

An increasingly wide range of thin-film semiconductors have been studied by CPM. *Bacioglu* et al. [7.27] determined the Urbach tail slope and estimated the deep defect density in amorphous silicon oxide a-SiO_x : H with varying oxygen concentration [O], calibrated from the Si-O-Si IR stretching peak. Both parameters show a strong dependence, with a linear increase in tail slope from 55 to 120 meV as [O] increases from 0 to 50% and an increase in α at 1.2 eV by a factor of 50 over the same range. This suggests that the compositional disorder of additional oxygen in the structure broadens the band tail, and also results in a greater number of Si dangling bonds. *Willekens* et al. [7.28] studied the organic semiconductors MEH-PPV and PCBM using CPM, both separately and in blended form for application in bulk heterojunction solar cells. They observed differences between the spectra, consistent with charge transfer between components in the blend. *Sharma* et al. [7.29] investigated nanocrystalline CdSe films using CPM following light-soaking and thermal annealing, and report a series of systematic changes in Urbach tail energy and optical bandgap. *Ishihara* et al. [7.30] have demonstrated the usefulness of CPM as a probe of deep defects when investigating transport properties and stability of In-Ga-Zn-O (IGZO) thin films for use in oxide TFTs. This information enabled them to modify preparation to reduce the defect density, which in turn improved threshold voltage stability.

7.2.2 Dual Beam Photoconductivity (DBP)

Like the constant photocurrent method discussed above, the dual-beam photoconductivity (DBP) technique is used to determine the subbandgap optical absorption in a photoconductor [7.31]. DBP achieves constant life-

time conditions by directing an additional constant, uniformly absorbed, *bias* beam of approximately the bandgap energy at the sample. This beam must be set to maintain a generation rate larger than that from the monochromator *probe* beam, throughout the scan. DBP eliminates the need for slow and tedious adjustments of the probe beam required to maintain constant photocurrent conditions in CPM. The probe beam photon energy range may thus be scanned more rapidly than for CPM, using a simpler control and measurement system. DBP requires a very similar experimental setup to CPM, with the addition of a bias light. This may be in the form of a laser beam, directed at the sample obliquely so that the detectors do not become overloaded by it. The probe beam is optically chopped, enabling the resulting sample photocurrent to be separated from the DC bias beam current by lock-in detection and amplification. Similarly, any stray light from the bias beam reaching the optical detectors will be rejected.

A feature of the DBP measurement is that the sample QFLs are more widely split, since the constant DC bias current must be larger than a typical constant photocurrent value in CPM. The resulting differences in occupancy of deep states mean that $\alpha(E_p)$ values recorded by the two techniques may not agree. However the difference(s) can also be used to advantage; the occupancy can be varied predictably by measuring the DC photocurrent, and DBP spectra recorded at different bias beam intensities may be interpreted to yield additional information on defect densities [7.32]. Defect capture properties and charge state, and the presence of surface states, may also be inferred in some cases. An example may be found in *Güneş* et al. [7.33], who studied differences in spectra from annealed and light-soaked hydrogenated amorphous silicon samples in the deep defect region. *Remes* et al. [7.34] have reported that residual nitrogen contamination in nanocrystalline diamond can be identified using this technique.

7.2.3 Fourier-Transform Photocurrent Spectroscopy (FTPS)

The use of a FT spectrometer to record spectrally resolved photocurrent in thin films was first reported by *Inushima* et al. [7.36], and developed as a quantitative technique (FTPS) by *Vaněček* et al. [7.37]. The concept is a development based around a standard technique used in analytical chemistry for many years, the Fourier-transform infrared (FTIR) spectrometer. This technique consists of recording and Fourier-transforming *interferograms* produced by a Michelson setup illuminated by an appropriate broadband light source. In absorption mode, the sample of interest is placed between the light output from the interferometer and a broadband detector, and the interferogram is recorded as the detector output versus optical path difference. The interferogram is then Fourier-transformed and normalized to a background spectrum, yielding a *conventional* IR spectrum of absorbtance versus wavelength. The FT technique effectively scans all wavelengths in parallel and thus has an inherent speed advantage over conventional sequential dispersive spectroscopies. The optical throughput is much higher, so there are considerable benefits in terms of noise cancellation. Overall this makes for a faster, lower noise and potentially higher-resolution approach.

These advantages were recognized as being applicable to the measurement of photoconductive electronic materials at low absorbtance levels [7.36, 37], since the *detector* in the FTIR system may also play a dual role as the *sample*. Many commercial FTIR setups possess an external detector input. In FTPS therefore, the interferogram is recorded by a *detector* consisting of the photoconductor of interest. The photocurrent is amplified and presented to the external input. The scan is carried out, Fourier-transformed, and normalized to a background spectrum previously recorded using a calibrated broadband detector, to yield the absorbtance spectrum of the photoconductor.

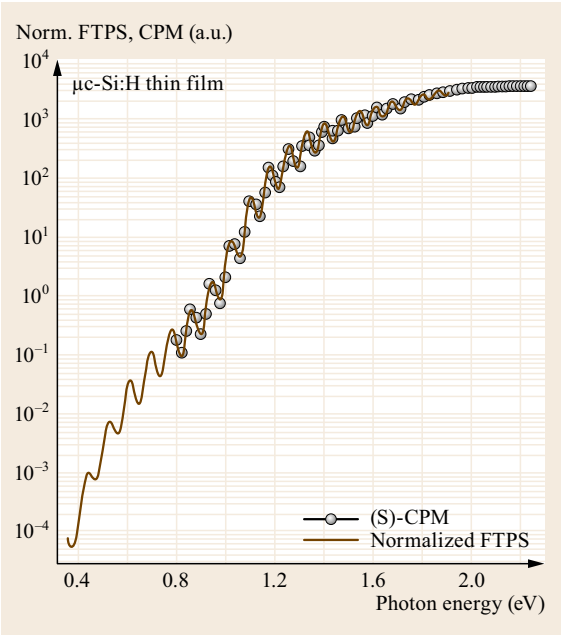

Fig. 7.7 Normalized FTPS spectrum (*full line*) compared with the standard CPM spectrum (*circles*), measured on the same microcrystalline silicon sample. Note good correspondence between the spectra, and greatly extended range of sensitivity available from FTPS. (After [7.35])

The applicability of the FTPS method to a wide range of materials, including amorphous silicon, microcrystalline silicon, diamond layers, nanocrystalline diamond and very thin organic films, was demonstrated in a later publication by *Vaněček* et al. [7.35]. The technique is highly sensitive, and in some cases may be used to extend the measurement of absorptance from the parts per million limit of CPM, to parts per *billion*, as shown in Fig. 7.7 [7.35]. As with standard CPM, interference fringes may appear on an as-recorded spectrum of a thin film. There is no direct equivalent of the transmission measurement used in the absolute CPM approach to remove the fringes, but it is possible to do so if an auxiliary *filter*, optically identical to the sample, is available. The two measurements, with and without filter, can be processed to obtain the thin-film interference-free absorbtance spectrum, by means of the *Ritter–Weiser* formula [7.23]. The FTPS method has been used diagnostically on both films and solar cells. Unlike CPM, the sample photocurrent cannot be kept constant in FTPS, as the interferogram necessarily covers a wide intensity range. However, as with DBP, a constant carrier lifetime may be imposed by applying a uniformly absorbed DC optical bias beam.

It may be concluded that FTPS has several advantages over CPM and DBP, specifically reduced scan time and increased sensitivity, and few disadvantages. A review of the technique and its applications is provided by *Holovsky* [7.38]. Recently, FTPS has been used to extend the range of quantum efficiency measurements on a-Si:H solar cells [7.39]. The increased signal-to-noise ratio over CPM was found to improve resolution of the deep DOS in this case. The use of FTPS to study deep defects in a PbS nanocrystal solar cell has helped quantify aging effects [7.40]. It seems likely that FTPS will enjoy greater usage in the study of photoconductors and photodevices in the coming years, as its potential advantages over other spectrally resolved photocurrent techniques become more widely known.

7.3 Steady-State Photocarrier Grating Method (SSPG)

The SSPG method, first described by *Ritter* et al. [7.41], enables the ambipolar diffusion length L of a semiconductor thin film to be determined. This is a particularly important parameter in materials targeted for use as absorber layers in solar cells, as well as in fundamental studies. The method consists in measuring the photoconductance of a coplanar sample illuminated by a two-beam system when (i) the beams are coherent and form interference fringes parallel to the electrodes, and (ii) the beams are incoherent and superpose as a spatially uniform illumination. A detailed review of the SSPG technique, its theoretical basis, interpretation and applications has been provided by *Brüggemann* [7.42].

A basic experimental arrangement is shown in Fig. 7.8a. Two polarizers are used, to define the plane of polarization (P_1), and to adjust the intensity of the beam emerging from the laser (by rotation of P_2). The beam splitter (BS) provides the requisite two interfering beams. The transmitted beam (main beam) is reflected by the plane mirror M_1 on to the sample S. The reflected beam (probe beam) is likewise reflected by M_2. The intensity of the probe beam is reduced to around 10% of the main beam, ensuring that the modulation amplitude remains small. The sample is mounted on a movable stage, enabling the angle θ between the two beams to be varied by adjustment of M_1 and M_2. The spatial period of the sinusoidal intensity variation, shown in Fig. 7.8b is given by

$$\Lambda = \frac{\lambda}{2\sin\left(\frac{\theta}{2}\right)} . \tag{7.8}$$

A half-wave retarding plate H may be selected and placed in the path of the main beam, at an angle of 45° to the plane of polarization. This rotates the main beam at the sample by 90° relative to the probe beam, and the two beams superpose incoherently. An optical chopper is placed in the path of the probe beam, enabling lock-in detection of the sample secondary photocur-

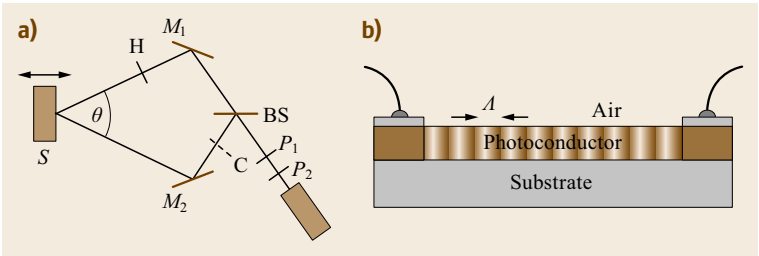

Fig. 7.8 **(a)** SSPG experimental arrangement; optical elements are as described in the text. **(b)** Formation of interference fringes at sample. (After [7.42])

rent under a small external voltage bias. The lock-in amplifier readings U_C and U_I, under coherent and incoherent illumination conditions respectively are recorded for a series of values of Λ, yielding the parameter

$$\beta(\Lambda) = \frac{U_C}{U_I} . \tag{7.9}$$

In turn, β is related to L by

$$\beta(\Lambda) = 1 - \frac{2Z}{\left[1 + \left(\frac{2\pi L}{\Lambda}\right)^2\right]^2} , \tag{7.10}$$

where Z is a constant between 0 and 1, related to various material and system parameters. Low values of Z can indicate poor definition of the grating due to surface light scattering or other inhomogeneities.

Equation (7.10) may be linearized by plotting $1/\Lambda^2$ versus $[2/(1-\beta)]^{1/2}$, yielding a straight line $y = ax - b$, from which $L = 1/2\pi\sqrt{b}$ and $Z = a^2/b^2$ are obtained.

Often the majority carrier $\mu\tau$ product is significantly larger than the minority carrier value, in which case the ambipolar quantity L is determined primarily by the *minority* carrier. The corresponding *majority* carrier product $\mu\tau$ may be determined from the steady-state photoconductivity at the same generation rate, yielding two important figures of merit

$$(\mu\tau)_{\min} = \left(\frac{kT}{2q}\right) L^2, \quad (\mu\tau)_{\text{maj}} = \frac{\sigma_{\text{ph}}}{qG} . \tag{7.11}$$

The SSPG method has been used to investigate diffusion lengths and minority-carrier $\mu\tau$ products in a range of thin-film silicon based semiconductors, including hydrogenated amorphous silicon and silicon-germanium [7.43], polymorphous silicon [7.44] and microcrystalline silicon [7.45]. It has also been applied to thin-film solar cell materials such as GaN [7.46], $CuGaSe_2$ [7.47] and polymer blends [7.48]. Semicommercial automated systems have been developed [7.49]. DOS spectroscopies based on SSPG and moving grating techniques have also been demonstrated [7.50, 51].

The usefulness of the SSPG method in optimization of thin film semiconductor properties is dependent on a number of factors:

1. The position of the Fermi level in a semiconductor changes in response to variations in preparation conditions, doping and degradation effects. This may alter the recombination kinetics and, as a consequence, the diffusion length. Thus it is possible, for example, for L to increase without there being a corresponding improvement in material *quality*.
2. As the method relies upon a uniform photocarrier grating being established, surface roughness or interior structure may scatter light and reduce its uniformity, resulting in inconsistencies and/or inaccuracies in the results.
3. Photocurrents in the SSPG experiment may be small compared with the dark current and this may restrict measurements, especially on doped materials and intrinsic materials at room temperature and above.

These factors are discussed in detail by *Brüggemann* [7.42] and references therein.

7.4 Modulated Photocurrent Spectroscopy (MPC)

7.4.1 MPC Background and Experiment

MPC is a density-of-states spectroscopy, introduced by *Oheda* [7.52] in 1981, used to probe the energetic distribution of unoccupied trap states in the energy gap of a photoconductor. MPC involves the illumination of a coplanar photoconductor sample as shown in Fig. 7.9 with a quasimonochromatic above-gap light source, which is amplitude modulated, typically within the frequency range 0.1 Hz–100 kHz. An LED is a highly suitable source, though chopped light from a monochromator may also be used. A voltage bias is applied to the sample, and the amplitude and phase of the photocurrent relative to the excitation is measured versus modulation frequency using a phase sensitive detector (lock-in amplifier). Generally, the photocurrent lags the light, though there are instances where a genuine phase *lead* may occur.

Both amplitude and phase are sensitive to the transport processes taking place, and both are of use when calculating the DOS versus electron energy. It is important to note that the states probed directly by this experiment are empty trap states that capture majority carriers. This is unlike CPM, where majority carriers are ejected from filled trap states by absorption of a subgap photon. Thus the two techniques are complementary; in the case of amorphous silicon for example, MPC supplies information about the DOS *above* E_F, and CPM about the DOS *below* E_F (but see [7.26]).

Some means of accurately calibrating the amplitude and phase of the light at the sample is essential, as phase shifts introduced by the measurement electron-

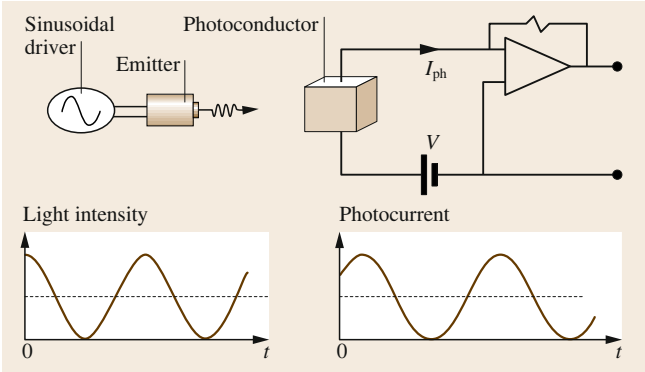

Fig. 7.9 Schematic diagram of an MPC measurement system (*upper frames*), and phase relationship between the exciting light intensity and the photocurrent (*lower frames*)

ics must be eliminated to obtain accurate and consistent results. This may be achieved by connecting a fast pin photodiode to the input of the current pre-amplifier, in addition to the sample. A calibration scan is carried out, with the light source incident on the pin diode and the sample blocked to light, but still electrically connected to the pre-amplifier. Then, the MPC experiment is performed by blocking the pin diode and directing the light at the sample. Complications can arise at high frequency, since *feed-forward* of the electric field from the modulation drive electronics can leak into the preamplifier by capacitive coupling. This manifests itself as a clear phase-leading signal trend. Another source of bogus signals entering the system is the presence of ground loops. Generally it is beneficial to optically isolate the phase reference, or to disable the ground shield on the coaxial cable. A further obstacle is presented by the dark current. AC coupling of instruments will introduce a parasitic phase lead, especially at low frequency. Thus when measuring small photocurrents below 10 Hz in DC mode, it may be necessary to introduce a stable DC offset current at the input to the preamplifier to cancel the dark current, and thus avoid signal overload.

Finally, the sample amplitude is normalized to the calibration amplitude, and the sample phase corrected by subtracting the calibration phase, at each frequency. To probe a suitably wide energy range, several scans at sample temperatures typically between 120 K and 350 K are carried out.

7.4.2 MPC Density of States Analysis

It is possible to extract the DOS from MPC amplitude and phase data by application of straightforward formulae. The degree of success depends upon the sharpness of features to be resolved in the DOS, their energy separation, and the method of analysis chosen. While there are a number of approaches that differ in detail, there are two limiting cases termed the high frequency (HF) and the low frequency (LF) regimes. The former concerns the emission of carriers from traps, the latter the recombination of carriers. A review of the development of these techniques is given by *Kleider* et al. [7.53].

HF MPC

We consider the single carrier case (electrons), with a single species of trap whose capture coefficient is C_n. The electron capture frequency into a set i of traps of density N_{ti} closely spaced in energy and centered at E_i is $\omega_{ti} = C_n N_{ti}$. The emission frequency into transport states just above E_c is $\omega_{ei} = \nu \exp(-E_i/(k_B T))$, where ν is the attempt-to-escape frequency. The capture properties are governed by the trap density, and the emission properties by the trap energy depth. From detailed balance considerations, $\omega_{ti} = \omega_{ei}$ for each set of traps.

The frequency separating the HF from the LF regime is related to the energy at which traps become recombination centers, the quasi-Fermi level E_{Fn}, by $\omega_{Fn} \approx \nu \exp(-E_{Fn}/(k_B T))$ (Sect. 7.1.2). For intrinsic amorphous silicon, ν is often taken as $10^{12}\,\mathrm{s}^{-1}$, and E_F is around 0.8 eV below E_c. Assuming low-level illumination such that the photocurrent is equal to the dark current, $E_{Fn} \approx E_F$, yields $\omega_{Fn} = 0.04\,\mathrm{rad\,s}^{-1}$ at 300 K. The HF regime lies above this, i. e., where the angular frequency of the applied modulation $\omega > \omega_{Fn}$. This threshold depends on the DC generation rate and the temperature. For example, increasing the illumination intensity at constant temperature (300 K) so that the photocurrent equals 100 times the dark current will move E_{Fn} closer to E_c by $k_B T \ln(100) = 0.12\,\mathrm{eV}$, and increase ω_{Fn} by 100.

In the HF regime, the measured AC photocurrent is furnished predominantly by states whose emission frequency matches the modulation frequency. By solving the rate equations, two useful, though mathematically approximate, relationships linking the DOS to the amplitude and phase of the photocurrent at ω are obtained [7.54, 55]

$$N(E_{\omega n}) = \left(\frac{2}{\pi k_B T}\right)\left(\frac{\mu_n}{C_n}\right)(qAFG_\omega)\left[\frac{\sin(\phi_{n\omega})}{I_{n\omega}}\right] \tag{7.12}$$

and

$$N(E_{\omega n}) = \left(\frac{1}{k_B T}\right)\left(\frac{\mu_n}{C_n}\right)(qAFG_\omega) \times \omega \frac{\mathrm{d}}{\mathrm{d}\omega}\left[\frac{\cos(\phi_{n\omega})}{I_{n\omega}}\right], \tag{7.13}$$

where

$$E_{\omega n} = E_c - k_B T \ln\left(\frac{\nu_n}{\omega}\right). \tag{7.14}$$

G_ω is the AC generation rate. From detailed balance considerations, $\nu_n = C_n N_c$ where N_c is the effective density of states in the conduction band. Typical values are $N_c \approx 10^{20}\,\mathrm{cm}^{-3}$ and $C_n \approx 10^{-8}\,\mathrm{cm}^3\,\mathrm{s}^{-1}$.

Performing the HF MPC experiment over a range of temperatures provides several DOS *sections*, together covering a wide energy range. These sections should overlap provided the data lie within the HF regime and the above parameters are correctly matched. This is more convincing if there is a visible bump or shoulder in the DOS. As the DOS is temperature-independent, any feature should remain fixed at a specific energy for all sections, pinned by a correct choice of ν. A range of capture properties is possible, depending on the type of trap. It might therefore be argued that without additional information HF MPC cannot deliver the absolute DOS, but only the product $N_t C_n$.

An equivalent set of equations for holes may be derived, and in general both electrons and holes will contribute to the photocurrent and thus to the apparent DOS. There is no means of distinguishing between these contributions. However, given the ratio μ/C appears as a scaling factor in (7.12) and (7.13) the HF DOS technique will tend to probe either the upper or the lower half of the bandgap, controlled by trapped electrons or trapped holes.

Of the two expressions, (7.12) is capable of resolving features in the DOS of the order of $k_B T$ apart in energy, whereas (7.13) has an improved resolution, of order $k_B T/2$. The price to pay is a poorer signal-to-noise ratio in the latter case, since a derivative of the experimental data must be taken. Their relative merits have been compared in detail using computer simulations and by experiments on amorphous silicon, which we return to later.

LF MPC

The LF MPC technique is based on the relationship between the recombination lifetime and the DOS at the quasi-Fermi level for trapped carriers. *Koropecki* et al. [7.56] showed that for the LF MPC experiment the DOS at a probe energy E_{pr} is given by

$$N(E_{pr}) = \frac{\tau_R G_{DC}}{k_B T \ln(2)}\,, \tag{7.15}$$

where

$$\tau_R = \frac{\tan(\phi)}{\omega} \quad \text{and} \quad E_{pr} = E_{Fn} + \frac{4}{3} k_B T \ln(2)\,. \tag{7.16}$$

τ_R is obtained from the slope of a plot of tan (ϕ) versus ω, and E_{Fn} from the ratio of the photocurrent to the dark current (Sect. 7.1.2).

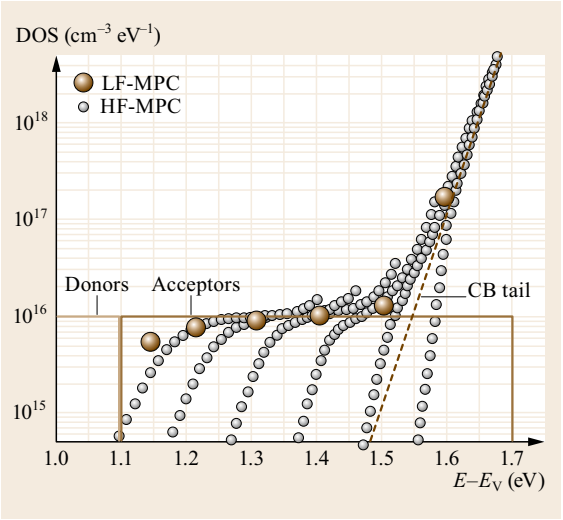

Fig. 7.10 Comparison of HF and LF MPC techniques. The model DOS shown was used to computer generate MPC $I(\omega)$ data over the range 100–350 K in 50 K steps, interpreted using (7.12) and (7.15) to yield the DOS points shown (*gray circle* and *brown circle*). The range of validity of HF MPC is illustrated by a rapid fall in the apparent HF DOS close to the QFL at each temperature. (After [7.57])

The effectiveness of the LF technique in comparison to the HF technique has been investigated in detail [7.56], and a comparison based on data generated by a computer model is shown in Fig. 7.10. The primary advantages of the LF technique are (i) since LF MPC is performed at higher generation rates, the signal-to-noise ratio of the recovered signal is improved; and (ii) the relationship does not involve the attempt to escape frequency. From (ii) it follows that the intersection of the two techniques may therefore be used as a calibration to deduce the trap parameters. This and other developments in interpretation are explored by *Schmidt* et al. [7.57]. One apparent disadvantage of LF MPC in comparison to HF MPC is that the improved resolution offered by (7.13) is not available.

7.4.3 MPC Applications

Following the initial demonstration of MPC by *Oheda* [7.52] in 1981, development was focused on prototype disordered semiconductors such as amorphous As_2Se_3 [7.58, 59], a-Si:H [7.55, 60] and alloys such as a-Si:Ge:H [7.61]. An example of the use of MPC in the study of light-induced defect creation and subsequent thermal annealing in polymorphous silicon [7.62] is shown in Fig. 7.11. Application has extended to a wider range of materials, including the following examples: *Gorgolis* et al. [7.63] have studied the DOS in thin films

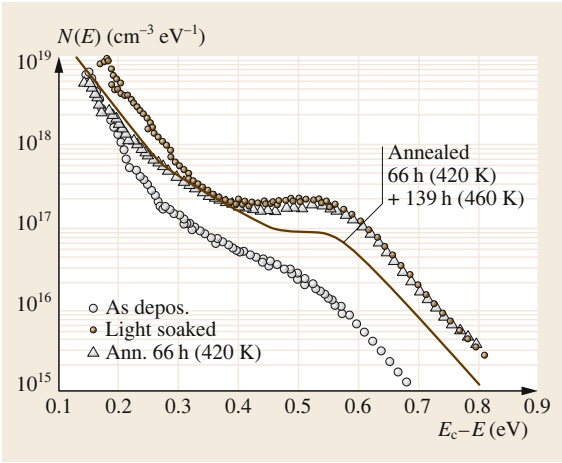

Fig. 7.11 DOS below the CB edge of a polymorphous silicon sample deposited at 423 K and measured by MPC as follows: (i) as-deposited (*gray dots*), (ii) after light soaking (*brown dots*), (iii) annealed for 66 h at 420 K (*triangles*), (iv) annealed for further 139 h at 460 K (*solid line*). (After [7.62])

of the oligomeric semiconductor pentacene, used in thin-film transistor applications. They conclude that localized states in this material comprise exponentially distributed band tails due to disorder, plus a Gaussian distribution of metastable deep defects that arise from impurities. $CuGaSe_2$ films similar to those used in chalcopyrite solar cells have been studied by *Krysztopa* et al. [7.64]. They identified five distinct defect species, correlated with Cu-rich and Ga-rich phases, and measured their capture properties. Results were consistent with junction capacitance measurements on defect levels. The hole conductor a-GeTe and phase-change alloy a-$Ge_2Sb_5Te_5$ were investigated by *Luckas* et al. [7.65], who identified features in the spectrum associated with defects, and demonstrated that correlation of MPC spectra at different temperatures was substantially improved when variations in the bandgap with temperature are taken into account. *Erslev* et al. [7.66] mapped a wide energy range of localized gap states in the transparent semiconductor amorphous zinc tin oxide (ZTO). They confirmed that the conduction band tail is extremely steep (10 meV), consistent with the known high electron mobility in ZTO despite its amorphous structure.

7.5 Switch-on and Switch-off Transients

7.5.1 Switch-on Transient

Immediately after switch-on, G is constant and the photocarrier density evolves with time, through trapping, emission, and recombination. This may be highly complex, depending on material properties and external conditions of intensity and temperature. However there may be circumstances where the situation can be simplified, for example through an assumption of a specific DOS profile, or if certain processes are considered to dominate over a particular time interval.

The switch-on regime has not been greatly studied in comparison to SSPC, or the switch-off regime covered in the following subsection, due to the complexity introduced if both G and R are nonzero. However *Kastner* and *Monroe* [7.67], and *Street* [7.68] analyzed switch-on assuming an exponentially distributed tail of states. They followed what is referred to as the TROK [7.69, 70] model, coined from the initials of the authors, which was successful in explaining steady-state photoconductivity in a number of disordered semiconductors, and other aspects of transient photoconductivity addressed later (Chap. 9). In the steady state, it is predicted that $\sigma_{ph} \propto G^{\gamma}$, where $\gamma = (1-\alpha)^{-1}$, the dispersion parameter $\alpha = k_B T/\Delta E_0$, and $\Delta E_0 = k_B T_0$ is the characteristic energy of the exponential band tail DOS, $g(E) = N_0 \exp(-E/\Delta E_0)$. The early part of the switch-on characteristic was predicted to follow $\sigma_{ph}(t) \propto t^{\alpha}$, with σ_{ph} directly proportional to G, which was confirmed experimentally for a-Si:H. Detailed behavior depends on the ratio of trapping and recombination coefficients. In some instances overshoot of the steady-state value is predicted, and has been observed. Although the possibility of utilizing switch-on as a more detailed probe of trapping and recombination has been identified [7.67, 68], relatively little further work has since taken place.

Some ten years earlier, *Main* [7.71] observed a linear increase in switch-on photocurrent at times of the order of 100 ns, in the chalcogenide glass As_2Te_3, as reproduced in Fig. 7.12a. Assuming deep trapping and recombination to be negligible, he attributed this to the progressive filling of a discrete set, or a rapidly falling (linear or Gaussian) tail, of shallow traps. These traps maintain a *reservoir* of charge, in quasi-thermal equilibrium with the band, with the ratio of free to trapped charge remaining constant over the duration of the linear rise in current. In this case the trap-limited mobility is given by

$$\mu_{\text{eff}} = \frac{\left(\frac{\mathrm{d}I_{\text{ph}}}{\mathrm{d}t}\right)_{t\approx 0}}{q\phi F \eta L(1-R)} \,. \tag{7.17}$$

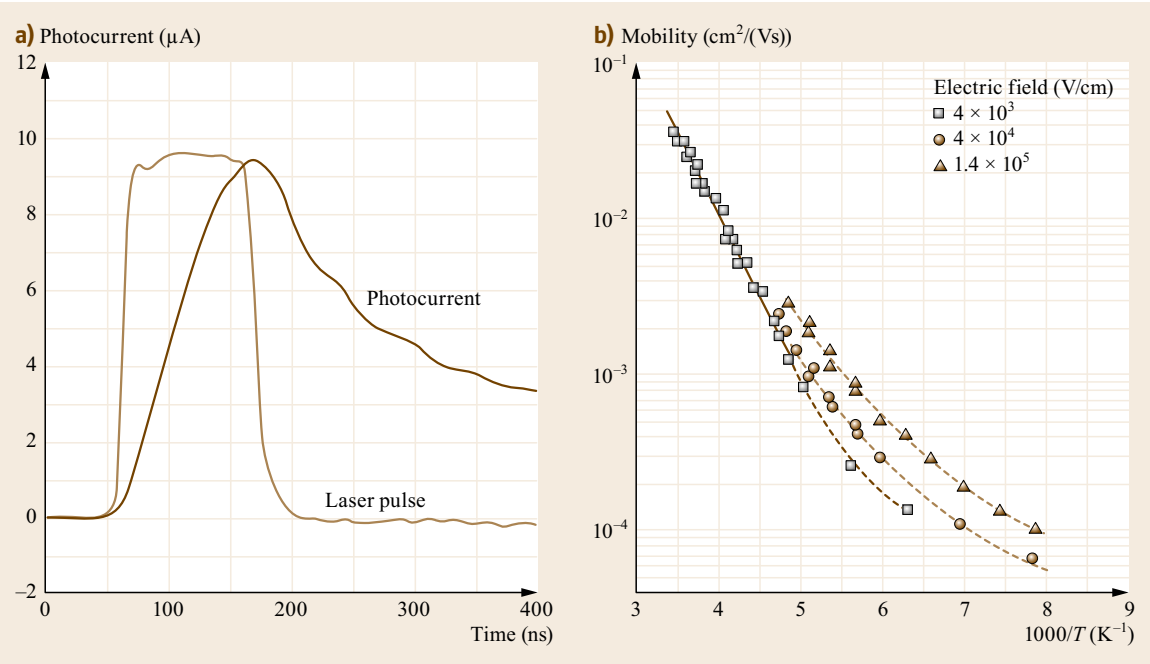

Fig. 7.12 **(a)** Switch-on measurement on an As_2Te_3 sample. The photocurrent increases approximately linearly over the duration of the pulse. **(b)** The rate of current increase is interpreted to yield a shallow-trap limited mobility that is temperature- and electric field-dependent. (After [7.71])

As shown in Fig. 7.12b μ_{eff} is thermally activated, with an activation energy related to the reservoir depth. This may be compared with the well-established procedure for measuring trap-limited mobility, the time-of-flight (TOF) or *Spear* method described later. The switch-on method could be used as an alternative if the dielectric relaxation time is short relative to the TOF drift time, where the uniform field assumption is invalidated. However, TOF has the advantage that it can also be used to measure both electron and hole mobilities separately.

7.5.2 Switch-off Transient

At switch-off the generation term is eliminated from the rate equation that describes the nonequilibrium carrier distribution, but the recombination kinetics are not immediately altered. Consequently, the initial photocurrent decay is governed by whatever recombination mode existed under SSPC conditions. Because of the presence of traps, the initial decay is not directly related to the free carrier lifetime, since carriers trapped at the instant the light is switched off must be emitted to the band at least once to become free, and in general may be trapped and emitted many times before they recombine. Given that in addition, recombination may be a monomolecular or a bimolecular process, the switch-off current is expected to exhibit a rich variety of forms. *Main* et al. [7.72] reviewed this topic by means of analysis supported by computer simulation. For parity with existing work they assumed an exponential band tail and examined the current decay under strong or weak retrapping conditions, governed by the relative probabilities of free carrier capture by traps and recombination centers. These conditions may be selected by the value of G prior to switch-off. It was shown that even for this relatively simple DOS, the initial rate of decay of current need not involve emission from or multitrapping in states near the quasi-Fermi energy, and thus any analysis making such an assumption will be limited in its range of validity. This demonstrates the value of computer modeling in supporting interpretation of photocurrent behavior.

In a different context, the switch-off photocurrent decay in (usually crystalline or polycrystalline) semiconductors with relatively well-defined deep trap(s) has yielded a mainstream tool, in use for some 40 years; it is often termed photoinduced current transient spectroscopy (PICTS), [7.73]. PICTS involves measurement of the quasi-exponential decay of photocurrent associated with emission from discrete or narrow bands of traps at a given energy depth, using the rate-window concept. Trap density and trapping coefficients are obtained from a series of measurements versus temperature, often in conjunction with addi-

tional complementary measurements, enabling species of traps to be identified. This is a different scenario to the broadly distributed DOS discussed above, though the influence of strong and weak retrapping and recombination mechanisms is of importance in both cases.

7.6 Transient Photocurrent Spectroscopy (TPC)

7.6.1 TPC Principles

In the transient photoconductivity (TPC) experiment, free carriers are excited into the bands of a semiconductor sample at time $t = 0$ by a short pulse of uniformly absorbed above-gap light. Since the carrier distributions are in thermal equilibrium at the beginning of the experiment, the trapping sites for electrons above E_F and for holes below E_F are empty, and photogenerated carriers are not excluded from any of those sites. Trapping is dependent on the density of states, a high density resulting in a rapid trapping rate. When a carrier becomes trapped it is immobilized until emitted some time later, in a thermally activated process with the trap depth being the activation energy. As shallower states release trapped carriers sooner, retrapping will lead to increased occupation of the deeper states as time proceeds, and a consequent reduction in the free carrier density. This *thermalization* of charge to progressively deeper energies continues until recombination sets in, at which point charge is stripped away. This is manifested as a steeper fall in the measured current, often at times > 1 s at 300 K. However this does not correspond to the free carrier recombination time, as on average carriers spend far more time in traps than in the band.

The TPC experiment is carried out in secondary photocurrent mode, making use of the photoconductive gain. The current, measured over as wide a time range as possible, will contain information on the density of localized states and their depth. How that information might reliably be extracted to yield the DOS versus energy is considered shortly.

7.6.2 TPC Experiment

The TPC experimental setup is shown in Fig. 7.13. Carriers may be generated by means of a pulse of order 1 ns in duration, typically from a nitrogen-pumped dye laser. Longer pulses from an overdriven LED may also be used. Peak laser powers of the order of 100 kW need to be attenuated, typically by a factor of 1000, to avoid saturating the traps one wishes to measure. The transient current decay is recorded using a fast oscilloscope, with an analogue bandwidth of around 1 GHz, signals being transferred to a PC for further processing. The current transient fidelity at short times is limited by RC time constants and impedance matching, to around 1–5 ns. Performance may also be limited by electromagnetic interference from the laser, which can be reduced by screening and/or by use of a fiber-optic delay line. Repetitive averaging is highly effective in reducing uncorrelated noise.

At short times the transient current may be recorded as the volt-drop across a low-value sampling resistor, 50 Ω being a common choice, but *RC* limitations mean a larger value of resistor is often unsatisfactory at longer times and a fast transimpedance pre-amplifier is a better option. A suitable unit provides a gain of 10^5–10^9 V/A with a rise time of 100 ns–1 ms. The pre-amp may usefully possess a DC offset option to enable the dark current to be nulled. At long times a recording limit is often imposed by the drift of dark current, and so a stable cryostat is desirable. It is important to note that sufficient time should be allowed between pulses to enable the system to return close to thermal equilibrium, otherwise deep traps may become significantly filled during repetitive averaging.

The current transient can contain useful information out to some 100 s, thus a dynamic range of around ten orders of magnitude in both time and current may be necessary. To achieve this necessitates the transient be-

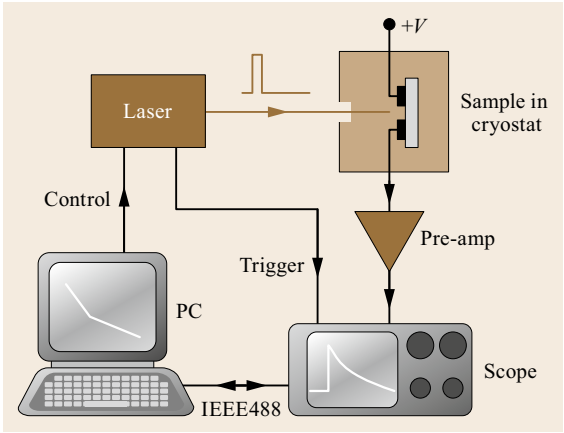

Fig. 7.13 Typical coplanar TPC measurement system. A similar arrangement is used for TOF except the sample is a sandwich structure as shown in Fig. 7.17, $+V$ is a bias step rather than DC, and the laser pulse is delayed for 0.1–1 μs e.g., by means of a reel of optical fiber

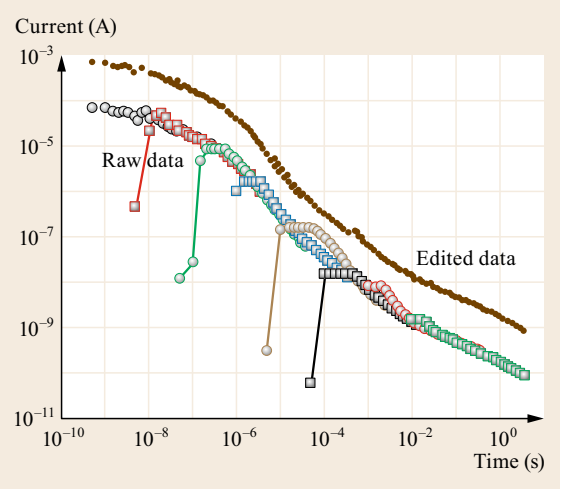

Fig. 7.14 Sections of TPC decays obtained from an a-Si:H sample at room temperature, recorded at progressively longer times (and with greater current amplification). By overlapping the sections and then removing obvious instrumental artifacts, a generally smooth and consistent curve extending over some ten orders of magnitude of time may be obtained

ing recorded in 4–6 sections, overlapped and edited to give a single log-log trace for subsequent processing, as illustrated in Fig. 7.14. Several such traces are measured over the temperature range 100–400 K to give broad energy coverage.

7.6.3 TPC Density-of-States Analysis

Central to the TROK model introduced earlier is the concept of the thermalization energy

$$E_{\mathrm{th}} = k_{\mathrm{B}} T \ln(\nu t) \,. \tag{7.18}$$

This is the energy at which traps will, on average, have released once after a time t. In the case of a purely exponential tail of states, the traps that control the instantaneous current are located at this energy depth. Provided the experimental temperature is less than the band tail temperature ($T < T_0$) the TROK analysis yields $I(t) \propto t^{-(1-\alpha)}$, i. e., the current decays according to a power law that is related directly to the DOS slope. Essentially exponential distributions have been shown to dominate the valence band tail of equilibrated amorphous As_2Se_3 samples over a wide energy range [7.74], but there are few other examples of extensive featureless decays.

In general, the instantaneous current is the outcome of a range of kinetic interactions, and $I(t)$ versus t cannot be mapped to the DOS in such a simple way. For example, if in addition to the band tail there is a *bump* in the DOS at deeper energies due to a species of defects, *capture* into this bump will commence at a time when the thermalizing charge has reached a depth in the tail at which the bump DOS equals the band tail DOS (assuming both have the same capture coefficient). This may abruptly reduce the measured current, but it does not signify anything *unusual* existing in the DOS at E_{th}.

To enable TPC to be applied reliably as a *DOS spectroscopy* requires circumstances such as these to be interpreted correctly, and the fact that both trapping and emission may in general contribute to the measured current throughout the time range requires a more holistic treatment. This has been a topic of interest for several decades, and a variety of techniques for inverting the $I(t)$ curve have emerged [7.75–77]. The more enduring of these involve either Fourier [7.78] or Laplace [7.79, 80] transformations. As the impulse response and the HF-MPC response constitute a Fourier transform pair, a discrete Fourier transformation of the entire TPC time series may be carried out to obtain the frequency domain response

$$\begin{aligned} I(\omega_{\mathrm{n}}) &= \sum_k i(t_k)[\cos(\omega_{\mathrm{n}} t) - \mathrm{j}\sin(\omega_{\mathrm{n}} t)]\Delta t_k \\ &= i_{\mathrm{p}} - \mathrm{j} i_{\mathrm{q}} \,. \end{aligned} \tag{7.19}$$

The in-phase i_{p} and quadrature i_{q} components define the amplitude and phase terms input to the HF-MPC expressions (7.12)–(7.14) presented earlier. This pathway to extracting the DOS makes no a priori assumptions as to its form, though it includes some mathematical approximations, and may suffer from artifacts due to short-time data restrictions. The DFT approach [7.78] has proved to be robust, and is applicable to both pre- and post-recombination regimes. Its performance has been characterized rigorously by inverting computer-simulated $i(t)$ curves generated from model DOS distributions, and then comparing the result with the model [7.78–80]. Figure 7.15 shows an example of two FT DOS methods, of lower and higher resolution, applied to the study of band tails and defects in a-Si:H.

Experimentally, the main advantage of the TPC approach over MPC as a DOS spectroscopy is that the high-frequency limit is somewhat extended. At a given temperature, this may result in improved definition of shallow states. There may be discrepancies [7.81] between the two techniques regarding the recovery of deep levels, since the DC optical bias inherent in HF-MPC alters the occupancy of these states whereas TPC either does not do so, or does so rather differently. Strictly speaking, HF-MPC should be compared to TPC with the addition of optical bias.

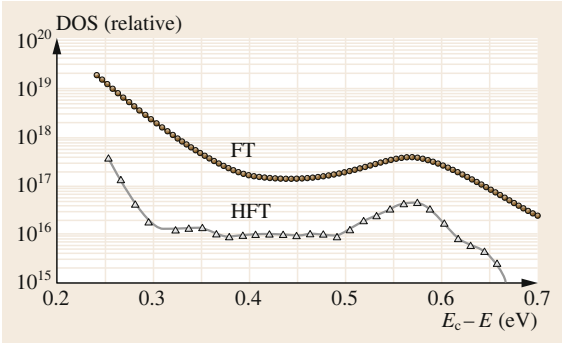

Fig. 7.15 DOS below the conduction band edge in a-Si:H, obtained through Fourier transformation of identical TPC decays. The curve marked *FT* uses the analysis of (7.12). *HFT* is a high-resolution analysis described in [7.77]. The latter offers improved resolution of both band-tail and defect *bump*, at the expense of somewhat increased noise

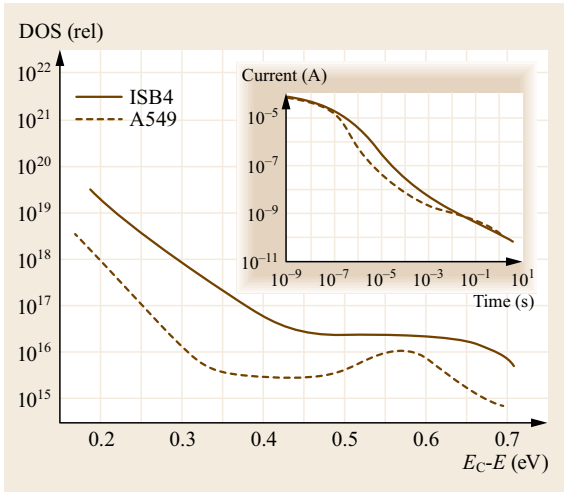

Fig. 7.16 Comparison of DOS in two samples of a-Si:H. Sample ISB4 is from a commercial PECVD reactor. Falling solar-cell efficiency was traced to a number of quality control issues. The conduction band tail slope (35 meV) and deep defect density (7×10^{15} cm^{-3}) were both poor compared with sample A549 University of Dundee *A* gear PECVD material (24 meV and 1.5×10^{15} cm^{-3} respectively). *Inset* shows current-time curves

7.6.4 TPC Applications

Unlike the time-of-flight (TOF) technique discussed below, TPC has the disadvantage that it cannot be used to measure carrier mobility, or at least not directly. In addition, the current-time curve is determined by transport of majority carriers, and thus TPC DOS spectroscopy is restricted to probing the localized states with which majority carriers interact. It is only occasionally possible to probe the DOS on the other side of the bandgap, and this somewhat by accident – in n-type amorphous silicon, the current decay at intermediate times is controlled by emission of holes from the valence band tail [7.82]. However TPC has the advantage of simplicity; there are normally no issues with dielectric relaxation time, space-charge or difficult contacts, and the current measured in the prerecombination region is generally comfortably large. As current is traveling in the plane of the film it may be useful to compare results with the TOF technique applied to the same material, where current travels through the film. In this way, anisotropies in defect density and band tail profile in microcrystalline silicon have been identified [7.83]. A further benefit of the coplanar technique is that it is possible to estimate surface versus bulk defect densities by comparing results using uniformly absorbed and strongly absorbed light respectively [7.84].

Figure 7.16 illustrates how TPC has assisted in identifying a quality control problem in an industrial amorphous silicon PECVD reactor. The reader should not however surmise that practical application is restricted to thin silicon films. Similarly to MPC, TPC has been used to study transport in a diverse range of materials, including short-chain organic molecules [7.85], spray-coated WO_3 [7.86], crystalline CdTe:Sn [7.87] and TiO_2 single crystals [7.88].

7.7 Time-of-Flight (TOF) and Related Techniques

7.7.1 TOF Mobility and DOS Measurements

The time-of-flight (TOF) measurement technique, initially referred to as the *Spear* method, was developed in the 1960s from the Haynes–Shockley experiment as a means of measuring transport properties in low-mobility, high-resistivity semiconductors such as chalcogenide glasses [7.89]. A recent review of the technique has been given by *Bronger* [7.90].

While the experimental setup is similar to that of TPC shown in Fig. 7.13, there are key differences:

1. The sample is in sandwich configuration, typically 1–100 μm thick.
2. The contacts must be blocking to carriers.
3. At least one contact is semitransparent.

A typical TOF sample configuration is shown in Fig. 7.17. Thin metal films forming Schottky contacts

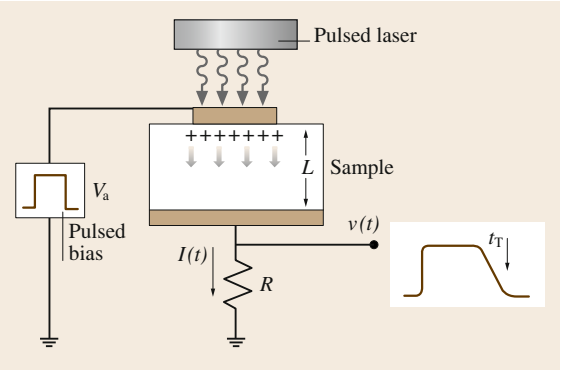

Fig. 7.17 TOF measurement sample arrangement, shown for the case of holes drifting through length L under a positive applied voltage V_a. Transit time is t_T

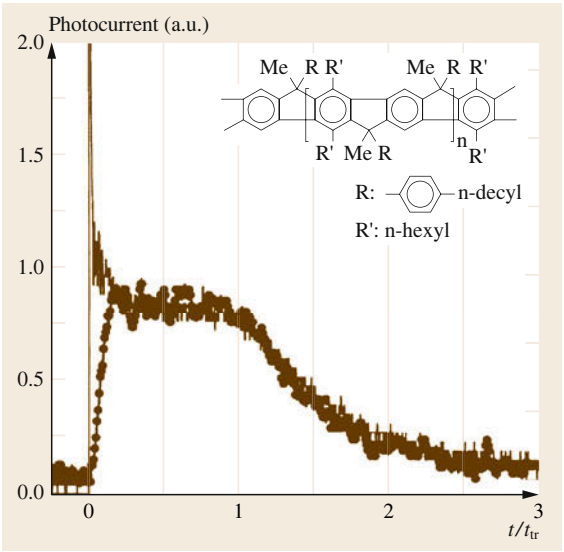

Fig. 7.18 Time-of-flight transients measured at 243 K in methyl-substituted ladder-type poly(para)phenylene (MeLPPP) with 60 kV/cm (*line*) and 300 kV/cm (*dot*) applied, and normalized to a transit time set to 90% of the pretransit current. The *inset* shows the chemical structure of MeLPPP. (After [7.91])

(Chap. 8), or a p-i-n or other solar cell type structure, are commonly employed. The measurement procedure is as follows. A reverse-bias voltage step is applied, establishing a uniform electric field $F = (V_a + V_{bi})/L$, where L is the sample length and V_{bi} the built-in voltage. Following a brief settling time, a strongly absorbed (laser) light pulse generates a sheet of carriers close to one or other contact. In hole TOF for example, the laser is directed at the positive contact; excess electrons are removed rapidly, and excess holes drift across the sample to be extracted at the negative contact. Neither carrier is replenished, as the contacts are blocking. This primary photocurrent is recorded as an equivalent displacement current in the external circuit. What may be seen is a period of relatively constant drift mobility, as carriers traverse the sample, followed by a period where the current falls more rapidly, as carriers are extracted. This is illustrated in Fig. 7.18 for the organic semiconductor MeLPPP [7.91]. The changeover in behavior denotes the transit time t_T, the average time taken for carriers to cross the sample, and the resulting *drift mobility* is $\mu_D = L/(F\,t_T)$. The experiment may be carried out by directing the laser at either side, so that in principle both electron and hole drift mobilities may be determined from separate experiments on the same sample. It should be noted that the electric field remains constant for a period somewhat less than the dielectric relaxation time, which thus defines the maximum timescale of the experiment. The photocharge must be limited to a fraction of the product CV_a, where C is the sample capacitance, to avoid distortion of the field.

Many materials exhibit dispersive transport [7.75], due to capture and subsequent emission of carriers from traps distributed at various energy depths, rather than conventional diffusion of the charge sheet. In such cases it is often more revealing to plot the current-time curve on a log-log scale. Figure 7.19 shows a temperature series of hole transits in amorphous silicon (Chap. 25) deposited by the expanding thermal plasma technique [7.92], as an illustration. A geometric construction may be made to define the transit time, or alternatively, the time at which a proportion (say 50%) of the total charge has been collected may be adopted. In dispersive transport the mobility is not a constant for a given material, since charge remaining in the sample for longer will have an opportunity to become more deeply trapped, which further delays its progress. Thus a TOF experiment performed at low electric field will yield a lower mobility than that at high field. It is thus important to report sample details and experimental conditions when comparing data from sample to sample, and from lab to lab [7.93]. Figure 7.19 illustrates that as the experimental temperature is decreased at constant electric field, the current is reduced and the transit is lengthened. The total collected charge however remains constant.

A complication in the TOF experiment is that if deep trapping occurs it may produce an artifact similar in appearance to a transit [7.94], but is distinguishable by its field independence. A high density of deep traps will thus curtail the useful TOF time range.

While majority carriers dominate photocurrents in TPC, TOF allows independent measurements of ma-

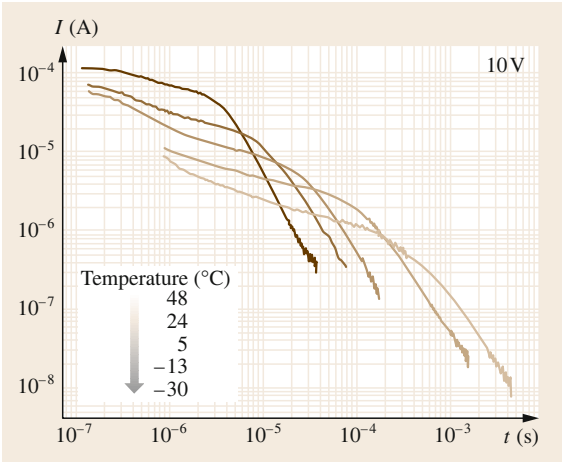

Fig. 7.19 Example of TOF hole transients measured at several temperatures, with 10 V applied across a 5.6 µm-thick a-Si:H sample grown in an expanding thermal plasma at 0.85 nm/s and 250 °C substrate temperature, sandwiched between Mo contacts. (After [7.92])

jority and minority carrier interactions with localized states, and separate examinations of the conduction and valence band sides of the bandgap is possible. Following TROK [7.69, 70] in the case of purely exponential band tails, pre- and post-transit currents take the form $I(t) \propto t^{-(1-\alpha)}$ and $I(t) \propto t^{-(1+\alpha)}$, respectively. Since $\alpha = k_B T/\Delta E_0$, the conduction band tail slope is obtained from electron TOF, and the valence band tail slope from hole TOF. The curves in Fig. 7.19 may thus be interpreted in terms of an exponential valence band tail, at least to first order. Just as with TPC, the current-time curves may be analyzed spectroscopically to yield a less prescriptive DOS, using procedures such as the Fourier transformation method. The approach is valid for both recombination (TPC) and extraction (TOF) of carriers, since analytically both are represented by a generic *time constant*.

In the post-transit regime, current arises from emission of carriers that are more likely to be extracted than to be retrapped as deeply again. Here DOS analysis need consider only a distribution of emission times, simplifying interpretation [7.94]. Specific procedures offering higher energy resolution under these conditions have also been developed [7.95].

TOF is now a well-established characterization technique, used in the study of a wide range of contemporary thin-film electronic materials. The main criteria concerning its applicability are that:

1. The dielectric relaxation time must be sufficiently long to allow a constant electric field to be maintained over the transit.
2. Suitable blocking contacts must be established.
3. A sample of appropriate thickness must be prepared for transit times to lie within the measurement window.

A wide range of organic semiconductors (Chap. 37) satisfy these criteria, and TOF in combination with complementary techniques has supported the advancement of transport models in this field [7.96]. TOF has also been applied successfully in the study of a wide range of inorganic semiconductors, including:

- Microcrystalline silicon [7.83, 97]
- Crystalline CdTe and CdZnTe [7.98]
- Single-crystal diamond [7.99]
- Polycrystalline CIGS [7.100]
- Sillenite ($Bi_{12}TiO_{20}$) [7.101].

7.7.2 Interrupted Field TOF (IFTOF)

The IFTOF experiment pioneered by *Kasap* et al. [7.102] differs from the time-of-flight experiment described in the previous section, in that the applied field that drives the photogenerated carrier packet through the sample is turned off for some period of time before the carriers have completed their transit. As illustrated in Fig. 7.20, a lower current intensity is measured when the field is turned on again, signaling that some carriers have become immobilized in deep traps. The fall in current versus interruption time t_i, enables the deep-trapping lifetime of the carriers to be evaluated. By *precharging* a sample with carriers of one polarity

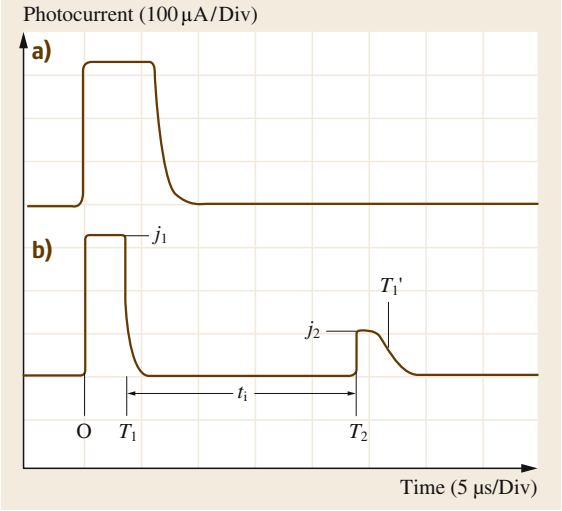

Fig. 7.20a,b Comparison of current traces obtained in **(a)** TOF, and **(b)** IFTOF experiments. The electric field is turned off in **(b)** for a length of time t_i. (After [7.102])

before performing an IFTOF experiment that drifts carriers of the opposite polarity through the sample, recombination parameters can also be studied [7.103].

Another modification involves generating free carriers through one contact and drifting the slower carrier into the sample, followed by a second pulse through the other contact, which sends faster carrier in the opposite direction. The two packets will cross, and some will recombine, affecting the observed currents and providing a way to study recombination. An example of this technique applied to amorphous selenium is given in *Haugen* and *Kasap* [7.104]. a-Se was one of the earliest amorphous semiconductors to be studied in detail, driven by its application at that time in xerography. While selenium is no longer used in this role, it remains an important x-ray photoconductor in flat-panel medical x-ray imaging (Chap. 45). A combination of TOF and IFTOF has been used to study the relaxation of arsenic-stabilized a-Se, following deposition, annealing and cooling to room temperature [7.105], and the influence of the stabilizer on the properties of oxygen and chlorine doped a-Se [7.106]. Both electron and hole mobilities may be studied independently in this way.

7.8 Other Photoconductivity-Related Techniques

This chapter has for the most part addressed how photoconductivity may be used as a tool in the detection, identification and measurement of electronic and/or optical properties of photoconductors. We conclude with brief descriptions of three techniques, related directly to photoconductivity, that do not feature elsewhere in this *handbook* but which readers may find relevant to their fields of interest.

7.8.1 Surface Photovoltage (SPV)

This technique involves the detection of changes in contact potential between a semiconductor and an electrode (Kelvin probe) placed close to its surface, under varying illumination conditions. A space-charge region forms in the bulk close to the surface, balanced by charge residing in surface states. Light incident on the semiconductor generates free charge, which redistributes under the built-in field. The steady-state charge distribution is sensitive to the semiconductor ambipolar diffusion length L, which in turn is reflected in the SPV. Details may be found in [7.107].

Measurement of L involves stepping the wavelength of the incident light, and adjusting its intensity after each step so as to maintain a constant SPV. Each wavelength corresponds to a specific absorption depth $1/\alpha$ in the semiconductor, and the value of L is obtained as the intercept of a plot of light intensity versus absorption depth. SPV is a popular technique for measuring L, particularly in bulk materials, although inaccuracies are claimed to arise when used on thin films.

SPV is versatile and may be configured to measure surface state density, and charge separation lengths in materials such as molecular clusters and quantum dots. It also forms the basis of a surface potential microscopy (Kelvin probe force microscopy) [7.108] when combined with an AFM system. The electrostatic force between tip and semiconductor is adjusted to zero by application of a bias potential, whose value is plotted versus position to yield a surface map.

7.8.2 Spin-Dependent Recombination

As was discussed in Sect. 7.1, recombination is influenced both by material properties and by external parameters. A further external variable, alongside temperature and light intensity, is afforded by the possibility of altering recombination kinetics by means of spin flipping. For a recombination event to occur, both electron and hole must form a singlet spin state. Recombination via the more probable triplet state is excluded, but may be enabled by flipping one of the spins by spin resonance. Thus by shining light on a photoconductive sample and scanning in an electron spin resonance (ESR) system, the resonance condition may be detected as a decrease in photoconductivity [7.109]. This detection method, termed electrically detected magnetic resonance or EDMR, is is many orders of magnitude more sensitive than a standard ESR experiment, which measures absorbed power using a microwave bridge. When combined with measured g-values and conductivity changes, spin-dependent photoconductivity provides detailed information on recombination pathways, and may be applied to devices such as solar cells and LEDs as well as to material samples.

7.8.3 Time-Resolved Microwave Conductivity (TRMC)

TRMC consists of measuring changes in microwave reflectivity of a photoconductor when excess photogenerated carriers are created by a short flash of light. The reflectivity is proportional to the free carrier density,

yielding a transient decay over many orders of magnitude of time similar to the TPC method. A principal advantage is that it is a contactless technique, not requiring deposition of electrodes on to the sample, and may thus be used with powders, aggregates or nanoporous materials difficult or impossible to measure using TPC. This has led to the adoption of TRMC when working with large surface area materials such as TiO_2 [7.110], used in photocatalysis and dye-sensitized solar cells where surface interactions are of primary importance.

Acknowledgments. The authors are grateful to the Engineering and Physical Sciences Research Council, and the Fonds voor Wetenschappelijk Onderzoek – Vlaanderen for financial support of parts of this work. Particular thanks are due to Dr. C. Main and Dr. A.C. Reynolds, for their critical reading of the manuscript and constructive comments. Finally, we are indebted to colleagues and students past and present, and to the numerous academic visitors to the Dundee and Leuven labs, from whom we have learned much and share many fond memories.

8. Electronic Properties of Semiconductor Interfaces

Winfried Mönch

In this chapter, we discuss electronic properties of semiconductor interfaces. Semiconductor devices contain metal–semiconductor, insulator–semiconductor, insulator–metal, and/or semiconductor–semiconductor interfaces. The electronic properties of these interfaces determine characteristics of the device. The band structure lineup at all these interfaces is determined by one unifying concept, the continuum of interface-induced gap states (IFIGS). These intrinsic interface states are the wave function tails of electron states that overlap the fundamental band gap of a semiconductor at the interface; in other words, they are caused by the quantum mechanical tunneling effect. IFIGS theory quantitatively explains the experimental barrier heights of well-characterized metal–semiconductor or Schottky contacts as well as the valence-band offsets of semiconductor–semiconductor interfaces or semiconductor heterostructures. Insulators are viewed as semiconductors with wide band gaps.

In his pioneering article entitled *Semiconductor Theory of the Blocking Layer*, *Schottky* [8.1] finally explained the rectifying properties of metal–semiconductor contacts, which had first been described by *Braun* [8.2], as being due to a depletion of the majority carriers on the semiconductor side of the interface. This new depletion-layer concept immediately triggered a search for a physical explanation of the barrier heights observed in metal–semiconductor interfaces, or Schottky contacts as they are also called in order to honor Schottky's many basic contributions to this field.

The early *Schottky–Mott* rule [8.3, 4] proposed that n-type (p-type) barrier heights were equal to the difference between the work function of the metal and the electron affinity (ionization energy) of the semiconductor. A plot of the experimental barrier heights of various metal–selenium rectifiers versus the work functions of the corresponding metals did indeed reveal a linear correlation, but the slope parameter was much smaller than unity [8.4]. To resolve the failure of the very simple and therefore attractive Schottky–Mott rule, *Bardeen* [8.5] proposed that electronic interface states in the semiconductor band gap play an essential role in the charge balance at metal–semiconductor interfaces.

Heine [8.6] considered the quantum-mechanical tunneling effect at metal–semiconductor interfaces and noted that *for energies in the semiconductor band gap, the volume states of the metal have tails in the semiconductor*. *Tejedor* and *Flores* [8.7] applied this same idea to semiconductor heterostructures where, for energies in the band-edge discontinuities, the volume states of one semiconductor tunnel into the other. The continua of interface-induced gap states (IFIGS), as these evanescent states were later called, are an intrinsic property of semiconductors and they are the *fundamental* physical mechanism that determines the band-structure lineup at both metal–semiconductor contacts and semiconductor heterostructures: in other words, at all semiconductor interfaces. Insulator interfaces are also included in this, since insulators may be de-

scribed as wide-gap semiconductors. Figure 8.1 shows schematic band diagrams of an n-type Schottky contact and a semiconductor heterostructure.

The IFIGS continua derive from both the valence- and the conduction-band states of the semiconductor. The energy at which their predominant character changes from valence-band-like to conduction-band-like is called their branch point. The position of the Fermi level relative to this branch point then determines the sign and the amount of the net charge in the IFIGS. Hence, the IFIGS give rise to intrinsic interface dipoles. Both the barrier heights of Schottky contacts and the band offsets of heterostructures thus divide up into a zero-charge-transfer term and an electric-dipole contribution.

From a more chemical point of view, these interface dipoles may be attributed to the partial ionic character of the covalent bonds between atoms right at the interface. Generalizing *Pauling*'s [8.8] electronegativity concept, the difference in the electronegativities of the atoms involved in the interfacial bonds also describes the charge transfer at semiconductor interfaces. Combining the physical IFIGS and the chemical electronegativity concept, the electric-dipole contributions of Schottky barrier heights as well as those of heterostructure band offsets vary proportional to the difference in the electronegativities of the metal and the semiconductor and of the two semiconductors, respectively.

The theoreticians appreciated Heine's IFIGS concept at once. The initial reluctance of most experimentalists was motivated by the observation that the predictions of the IFIGS theory only marked upper limits for the barrier heights observed with *real* Schottky contacts [8.9]. *Schmitsdorf* et al. [8.10] finally resolved this dilemma. They found a linear decrease in the effective barrier heights with increasing ideality factors for their Ag/n-Si(111) diodes. Such behavior has been observed for all of the Schottky contacts investigated so far. *Schmitsdorf* et al. attributed this correlation to patches of decreased barrier heights and lateral dimensions smaller than the depletion layer width [8.10, 11]. Consequently, they extrapolated their plots of effective barrier height versus ideality factor to the ideality factor determined by the image-force or *Schottky* effect [8.12] alone; in this way, they obtained the barrier heights of the laterally homogeneous contacts. The barrier heights of laterally uniform contacts can also be determined from capacitance–voltage measurements (C/V) and by applying ballistic-electron-emission microscopy (BEEM) and internal photoemission yield spectroscopy (IPEYS). The I/V, C/V, BEEM, and IPEYS data agree within the margins of experimental error.

Mönch [8.13] found that the barrier heights of laterally homogeneous Schottky contacts as well as the experimentally observed valence-band offsets of semiconductor heterostructures agree excellently with the predictions of the IFIGS-and-electronegativity theory.

8.1 Experimental Database

8.1.1 Barrier Heights of Laterally Homogeneous Schottky Contacts

I/V Characteristics

The current transport in real Schottky contacts occurs via thermionic emission over the barrier provided the doping level of the semiconductor is not too high [8.14]. For doping levels larger than approximately $10^{18}\,\mathrm{cm}^{-3}$, the depletion layer becomes so narrow that tunnel or field emission through the depletion layer prevails. The current–voltage characteristics then become ohmic rather than rectifying.

For thermionic emission over the barrier, the current–voltage characteristics of n-type Schottky contacts may be written as [8.13]

$$I_{\mathrm{te}} = I_{\mathrm{s}} \exp\left(\frac{e_0 V_{\mathrm{c}}}{n k_{\mathrm{B}} T}\right)\left(1 - \exp\left(\frac{-e_0 V_{\mathrm{c}}}{k_{\mathrm{B}} T}\right)\right) , \quad (8.1)$$

where

$$I_{\mathrm{s}} = A A_{\mathrm{R}}^{*} T^2 \exp\left(\frac{-\Phi_{\mathrm{Bn}}^{\mathrm{eff}}}{k_{\mathrm{B}} T}\right) \quad (8.2)$$

is the saturation current and A is the diode area, A_{R}^{*} is the effective Richardson constant of the semiconductor, and k_{B}, T, and e_0 are Boltzmann's constant, the temperature, and the electronic charge, respectively. The effective Richardson constant is defined as

$$A_{\mathrm{R}}^{*} = \frac{4\pi e_0 k_{\mathrm{B}} m_{\mathrm{n}}^{*}}{h^3} = A_{\mathrm{R}} \frac{m_{\mathrm{n}}^{*}}{m_0} , \quad (8.3)$$

where $A_{\mathrm{R}} = 120\,\mathrm{A\,cm^{-2}\,K^{-2}}$ is the Richardson constant for thermionic emission of nearly free electrons into vacuum, h is Planck's constant, and m_0 and m_{n}^{*} are the vacuum and the effective conduction-band mass of electrons, respectively. The externally applied bias V_{a} divides up into a voltage drop V_{c} across the depletion layer of the Schottky contact and an IR drop at the series resistance R_{s} of the diode, so that $V_{\mathrm{c}} = V_{\mathrm{a}} - IR_{\mathrm{s}}$. For *ideal* (intimate, abrupt, defect-free, and, above all, laterally homogeneous) Schottky contacts, the effective zero-bias barrier height $\Phi_{\mathrm{Bn}}^{\mathrm{eff}}$ equals the difference $\Phi_{\mathrm{Bn}}^{\mathrm{hom}} - \delta\Phi_{\mathrm{if}}^{0}$ between the homogeneous barrier height and the zero-bias image-force lowering [8.13]

$$\delta\Phi_{\mathrm{if}}^{0} = e_0 \left[\frac{2 e_0^2 N_{\mathrm{d}}}{(4\pi)^2 \varepsilon_{\infty}^2 \varepsilon_{\mathrm{b}} \varepsilon_0^3}\left(e_0 \left|V_{\mathrm{i}}^{0}\right| - k_{\mathrm{B}} T\right)\right]^{1/4} , \quad (8.4)$$

where N_{d} is the donor density, $e_0|V_{\mathrm{i}}^{0}|$ is the zero-bias band bending, ε_{∞} and ε_{b} are the optical and the bulk dielectric constant, respectively, and ε_0 is the permittivity of vacuum. The ideality factor n describes the voltage dependence of the barrier height and is defined by

$$1 - \frac{1}{n} = \frac{\partial \Phi_{\mathrm{Bn}}^{\mathrm{eff}}}{\partial e_0 V_{\mathrm{c}}} . \quad (8.5)$$

For *real* diodes, the ideality factors n are generally found to be larger than the ideality factor

$$n_{\mathrm{if}} = \left(1 - \frac{\delta\Phi_{\mathrm{if}}^{0}}{4 e_0 |V_{\mathrm{i}}^{0}|}\right)^{-1} , \quad (8.6)$$

which is determined by the image-force effect only.

The effective barrier heights and the ideality factors of real Schottky diodes fabricated under experimentally identical conditions vary from one specimen to the next. However, the variations of both quantities are correlated, and the $\Phi_{\mathrm{Bn}}^{\mathrm{eff}}$ values become smaller as the ideality factors increase. As an example, Fig. 8.2 displays $\Phi_{\mathrm{Bn}}^{\mathrm{eff}}$ versus n data for Ag/n-Si(111) contacts with $(1\times1)^{\mathrm{i}}$-unreconstructed and $(7\times7)^{\mathrm{i}}$-reconstructed interfaces [8.10]. The dashed and dash-dotted lines are the linear least-squares fits to the data points. The linear dependence of the effective barrier height on the ideality factor may be written as

$$\Phi_{\mathrm{Bn}}^{\mathrm{eff}} = \Phi_{\mathrm{Bn}}^{\mathrm{nif}} - \varphi_{\mathrm{p}}(n - n_{\mathrm{if}}) , \quad (8.7)$$

where $\Phi_{\mathrm{Bn}}^{\mathrm{nif}}$ is the barrier height at the ideality factor n_{if}. Several conclusions may be drawn from this relation. First, the $\Phi_{\mathrm{Bn}}^{\mathrm{eff}} - n$ correlation shows that more than one physical mechanism determines the barrier heights of *real* Schottky contacts. Second, the extrapolation of $\Phi_{\mathrm{Bn}}^{\mathrm{eff}}$ versus n curves to n_{if} removes all mechanisms that

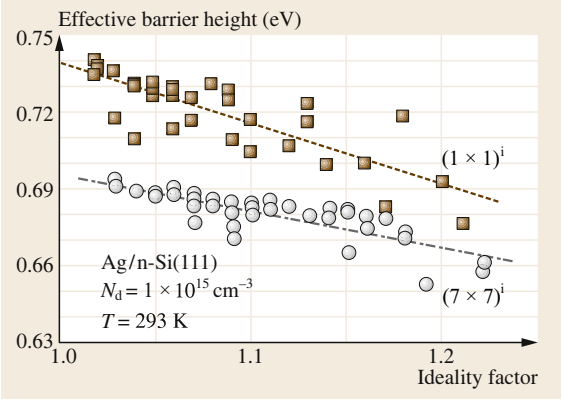

Fig. 8.2 Effective barrier heights versus ideality factors determined from I/V characteristics of Ag/n-Si(111)-$(7\times7)^{\mathrm{i}}$ and -$(1\times1)^{\mathrm{i}}$ contacts at room temperature. The *dashed* and *dash-dotted* lines are the linear least-squares fits to the data. (After [8.10])

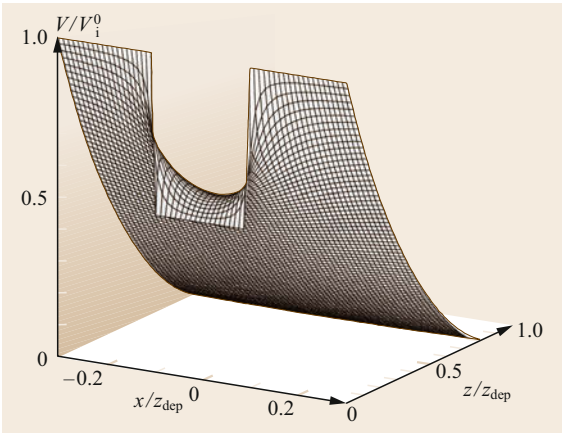

Fig. 8.3 Calculated potential distribution underneath and around a patch of reduced interface potential embedded in a region of larger interface band-bending. The lateral dimension and the interface potential reduction of the patch are set to two-tenths of the depletion layer width z_{dep} and one-half of the interface potential of the surrounding region. (After [8.13])

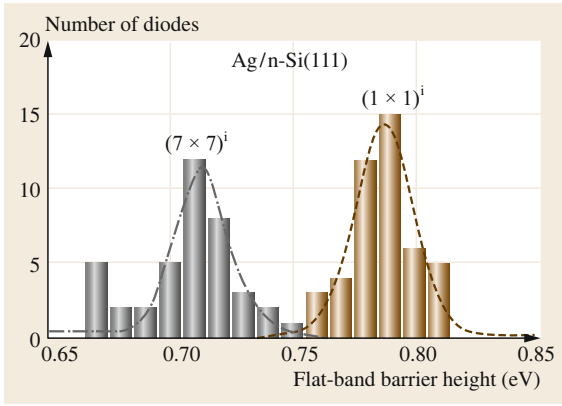

Fig. 8.4 Histograms of flat-band barrier heights determined from C/V characteristics of Ag/n-Si(111)-$(7 \times 7)^i$ and -$(1 \times 1)^i$ contacts at room temperature. The data were obtained with the same diodes discussed in Fig. 8.2. The *dashed* and *dash-dotted lines* are the Gaussian least-squares fits to the data. (After [8.10])

cause a larger bias dependence of the barrier height than the image-force effect itself from consideration. Third, the extrapolated barrier heights Φ_{Bn}^{nif} are equal to the zero-bias barrier height $\Phi_{Bn}^{hom} - \delta\Phi_{if}^{0}$ of the laterally homogeneous contact.

The laterally homogeneous barrier heights obtained from Φ_{Bn}^{eff} versus n curves to n_{if} are not necessarily characteristic of the corresponding *ideal* contacts. This is illustrated by the two data sets displayed in Fig. 8.2, which differ in the interface structures of the respective diodes. Quite generally, structural rearrangements such as the $(7 \times 7)^i$ reconstruction are connected with a redistribution of the valence charge. The bonds in perfectly ordered bulk silicon, the example considered here, are purely covalent, and so reconstructions are accompanied by electric $Si^{+\Delta q} - Si^{-\Delta q}$ dipoles. The Si(111)-(7×7) reconstruction is characterized by a stacking fault in one half of its unit mesh [8.15]. *Schmitsdorf* et al. [8.10] quantitatively explained the experimentally observed reduction in the laterally homogeneous barrier height of the $(7 \times 7)^i$ with regard to the $(1 \times 1)^i$ diodes by the electric dipole associated with the stacking fault of the Si(111)-(7×7) reconstruction.

Patches of reduced barrier height with lateral dimensions smaller than the depletion layer width that are embedded in large areas of laterally homogeneous barrier height is the only known model that explains a lowering of effective barrier heights with increasing ideality factors. In their phenomenological studies of such patchy Schottky contacts, *Freeouf* et al. [8.11] found that the potential distribution exhibits a saddle point in front of such nanometer-size patches of reduced barrier height. Figure 8.3 explains this behavior. The saddle-point barrier height strongly depends on the voltage drop V_c across the depletion layer. Freeouf et al. simulated the current transport in such patchy Schottky contacts and found a reduction in the effective barrier height and a correlated increase in the ideality factor as they reduced the lateral dimensions of the patches. However, they overlooked the fact that the barrier heights of the laterally homogeneous contacts may be obtained from Φ_{Bn}^{eff} versus n plots, by extrapolating to n_{if}.

It has to be mentioned that the effective barrier heights and the ideality factors of *real* Schottky contacts generally vary as a function of temperature. The so-called Richardson plots $\ln(I_s/T^2)$-versus-$1/T$ will neither result in correct values of effective barrier heights nor will the effective Richardson constants obtained equal the theoretical values because such graphs inherently assume the barrier heights to be independent of temperature [8.16–18] in contrast to what is experimentally observed with real Schottky contacts.

C/V Characteristics

Both the space charge and the width of the depletion layers at metal–semiconductor contacts vary as a function of the externally applied voltage. The space-charge theory gives the variation in the depletion layer capacitance per unit area as [8.13]

$$C_{dep} = \left(\frac{e_0^2 \varepsilon_b \varepsilon_0 N_d}{2} \left[e_0 \left(|V_i^0| - V_c \right) - k_B T \right] \right)^{1/2} . \quad (8.8)$$

The current through a Schottky diode biased in the reverse direction is small, so the *IR* drop due to the series resistance of the diode may be neglected. Consequently, the extrapolated intercepts on the abscissa of $1/C_{\mathrm{dep}}^2$ versus V_{a} plots give the band-bending $e_0|V_{\mathrm{i}}^0|$ at the interface, and together with the energy distance $W_{\mathrm{n}} = W_{\mathrm{F}} - W_{\mathrm{cb}}$ from the Fermi level to the conduction band minimum in the bulk, one obtains the flat-band barrier height $\Phi_{\mathrm{Bn}}^{\mathrm{fb}} \equiv \Phi_{\mathrm{Bn}}^{\mathrm{hom}} = e_0|V_{\mathrm{i}}^0| + W_{\mathrm{n}}$, which equals the laterally homogeneous barrier height of the contact.

As an example, Fig. 8.4 displays the flat-band barrier heights of the same Ag/n-Si(111) diodes that are discussed in Fig. 8.2. The dashed- and dash-dotted lines are the Gaussian least-squares fits to the data from the diodes with $(1\times1)^{\mathrm{i}}$ and $(7\times7)^{\mathrm{i}}$ interface structures, respectively. Within the margins of experimental error, the peak C/V values agree with the laterally homogeneous barrier heights obtained from the extrapolations of the I/V data shown in Fig. 8.2. These data clearly demonstrate that barrier heights characteristic of laterally homogeneous Schottky contacts can be only obtained from I/V or C/V data from many diodes fabricated under identical conditions rather than from a single diode. However, the effective barrier heights and the ideality factors vary as a function of the diode temperature. Hence, the effective barrier heights and ideality factors evaluated from the I/V characteristics for one and the same diode recorded at different temperatures are also suitable for determining the corresponding laterally homogeneous barrier height [8.13].

Ballistic-Electron-Emission Microscopy

In BEEM [8.19], a tip injects almost monoenergetic electrons into the metal film of a Schottky diode. These tunnel-injected electrons reach the semiconductor as ballistic electrons provided that they lose no energy on their way through the metal. Hence, the collector current I_{coll} is expected to set in when the ballistic electrons surpass the metal–semiconductor barrier; in other words, if the voltage V_{tip} applied between tip and metal film exceeds the *local* potential barrier $\Phi_{\mathrm{Bn}}^{\mathrm{loc}}(z)/e_0$. *Bell* and *Kaiser* [8.20] derived the square law

$$I_{\mathrm{coll}}(z) = R^* I_{\mathrm{tip}} \left(e_0 V_{\mathrm{tip}} - \Phi_{\mathrm{Bn}}^{\mathrm{loc}}(z)\right)^2 \qquad (8.9)$$

for the BEEM $I_{\mathrm{coll}}/V_{\mathrm{tip}}$ characteristics, where I_{tip} is the injected tunnel current. BEEM measures *local* barrier heights; most specifically, the saddle-point barrier heights in front of nanometer-sized patches rather than their lower barrier heights right at the interface.

BEEM is *the* experimental tool for measuring spatial variations in the barrier height on the nanometer-scale. The local barrier heights are determined by fitting relation (8.9) to measured $I_{\mathrm{coll}}/V_{\mathrm{tip}}$ characteristics recorded at successive tip positions along lateral line scans. Figure 8.5 displays histograms of the local BEEM barrier heights of two Pd/n-6*H*-SiC(0001) diodes [8.21]. The diodes differ in their ideality factors, 1.06 and 1.49, which are close to and much larger, respectively, than the value $n_{\mathrm{if}} = 1.01$ determined solely by the image-force effect. Obviously, the *nanometer-scale* BEEM histograms of the two diodes are identical, although their *macroscopic* ideality factors and therefore their patchinesses differ. Two important conclusions were drawn from these findings. First, these data suggest the existence of two different types of patches: intrinsic and extrinsic ones. The intrinsic patches might be correlated with the random distributions of the ionized donors and acceptors which cause nanometer-scale lateral fluctuations in the interface potential. A few gross interface defects of extrinsic origin, which escape BEEM observations, are then responsible for the variations in the ideality factors. Second, Gaussian least-squares fits to the histograms of the local BEEM barrier heights yield peak barrier heights of 1.27 ± 0.03 eV. Within the margins of experimental error, this value agrees with the laterally homogeneous value of 1.24 ± 0.09 eV, which was obtained by extrapolation of the linear least-squares fit to a $\Phi_{\mathrm{Bn}}^{\mathrm{eff}}$ versus n plot to n_{if}. The nanometer-scale BEEM histograms and the macroscopic I/V characteristics thus provide identical barrier heights of laterally homogeneous Schottky contacts.

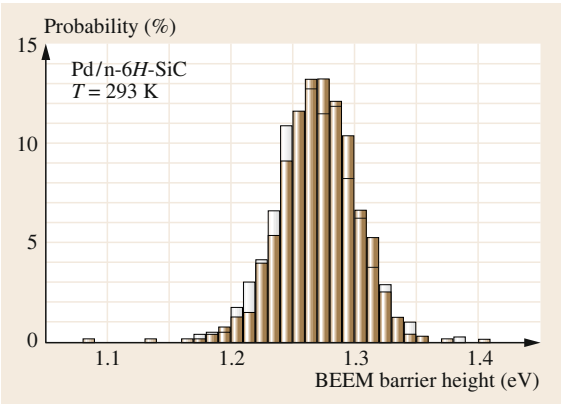

Fig. 8.5 Histograms of local BEEM barrier heights of two Pd/n-6*H*-SiC(0001) diodes with ideality factors of 1.06 (*gray solid bars*) and 1.49 (*empty bars*). The data were obtained by fitting the square law (8.9) to 800 BEEM $I_{\mathrm{coll}}/V_{\mathrm{tip}}$ spectra each. (After *Im* et al. [8.21])

Internal Photoemission Yield Spectroscopy

Metal–semiconductor contacts show a photoelectric response to optical radiation with photon energies smaller than the width of the bulk band gap. This effect is caused by photoexcitation of electrons from the metal over the

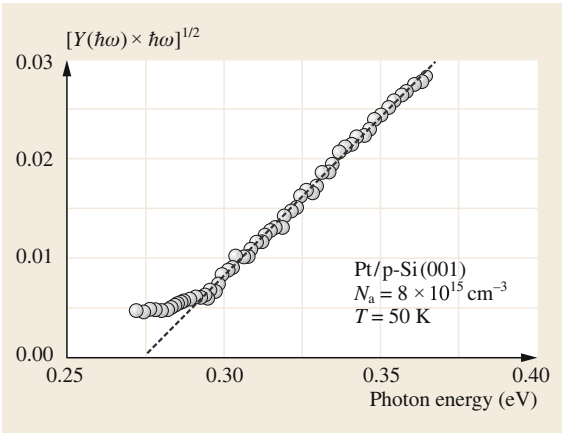

Fig. 8.6 Spectral dependence of the internal photoemission yield of a Pt/p-Si(001) diode versus the photon energy of the exciting light. The *dashed line* is the linear least-squares fit to the data for photon energies larger than 0.3 eV. (After *Turan* et al. [8.23])

interfacial barrier into the conduction band of the semiconductor. Experimentally, the internal photoemission yield, which is defined as the ratio of the photoinjected electron flux across the barrier into the semiconductor to the flux of the electrons excited in the metal, is measured as a function of the energy of the incident photons. Consequently, this technique is called internal photoemission yield spectroscopy (IPEYS). *Cohen* et al. [8.22] derived that the internal photoemission yield varies as a function of the photon energy $\hbar\omega$ as

$$Y(\hbar\omega) \propto \frac{1}{\hbar\omega}\left(\hbar\omega - \Phi_{\mathrm{Bn}}^{\mathrm{IPEYS}}\right)^2 . \qquad (8.10)$$

Patches only cover a small portion of the metal–semiconductor interface, so the threshold energy $\Phi_{\mathrm{Bn}}^{\mathrm{IPEYS}}$ will equal the barrier height $\Phi_{\mathrm{Bn}}^{\mathrm{hom}}$ of the laterally homogeneous part of the contact minus the zero-bias image-force lowering $\delta\Phi_{\mathrm{if}}^{0}$.

In Fig. 8.6, experimental $(Y(\hbar\omega)\times\hbar\omega)^{1/2}$ data for a Pt/p-Si(001) diode [8.23] are plotted versus the energy of the exciting photons. The dashed line is the linear least-squares fit to the data. The deviation of the experimental $(Y(\hbar\omega)\times\hbar\omega)^{1/2}$ data towards larger values slightly below and above the threshold is caused by the shape of the Fermi–Dirac distribution function at finite temperatures and by the existence of patches with barrier heights smaller and larger than $\Phi_{\mathrm{Bn}}^{\mathrm{hom}}$.

8.1.2 Band Offsets of Semiconductor Heterostructures

Semiconductors generally grow layer-by-layer, at least initially. Hence, core-level photoemission spectroscopy (PES) is a very reliable tool and the one most widely used to determine the band-structure lineup at semiconductor heterostructures. The valence-band offset may be obtained from the energy positions of core-level lines in x-ray photoelectron spectra recorded with bulk samples of the semiconductors in contact and with the interface itself [8.24]. Since the escape depths of the photoelectrons are on the order of just 2 nm, one of the two semiconductors must be sufficiently thin. This condition is easily met when heterostructures are grown by molecular beam epitaxy (MBE) and photoemission spectra (PES) are recorded during growth interrupts. The valence-band discontinuity is then given by (Fig. 8.7)

$$\begin{aligned}\Delta W_{\mathrm{v}} &= W_{\mathrm{vir}} - W_{\mathrm{vil}} = W_{\mathrm{i}}(n_{\mathrm{r}}l_{\mathrm{r}}) - W_{\mathrm{i}}(n_{\mathrm{l}}l_{\mathrm{l}}) \\ &\quad + [W_{\mathrm{vbr}} - W_{\mathrm{b}}(n_{\mathrm{r}}l_{\mathrm{r}})] - [W_{\mathrm{vbl}} - W_{\mathrm{b}}(n_{\mathrm{l}}l_{\mathrm{l}})] ,\end{aligned} \qquad (8.11)$$

where $n_{\mathrm{r}}l_{\mathrm{r}}$ and $n_{\mathrm{l}}l_{\mathrm{l}}$ denote the core levels of the semiconductors on the right (r) and the left (l) side of the interface, respectively. The subscripts i and b characterize interface and bulk properties, respectively. The energy difference $W_{\mathrm{i}}(n_{\mathrm{r}}l_{\mathrm{r}}) - W_{\mathrm{i}}(n_{\mathrm{l}}l_{\mathrm{l}})$ between the core levels of the two semiconductors at the interface is determined from energy distribution curves of photoelectrons recorded during MBE growth of the heterostructure. The energy positions $W_{\mathrm{vbr}} - W_{\mathrm{b}}(n_{\mathrm{r}}l_{\mathrm{r}})$ and $W_{\mathrm{vbl}} - W_{\mathrm{b}}(n_{\mathrm{l}}l_{\mathrm{l}})$ of the core levels relative to the valence-band maxima in the bulk of the two semiconductors are evaluated separately.

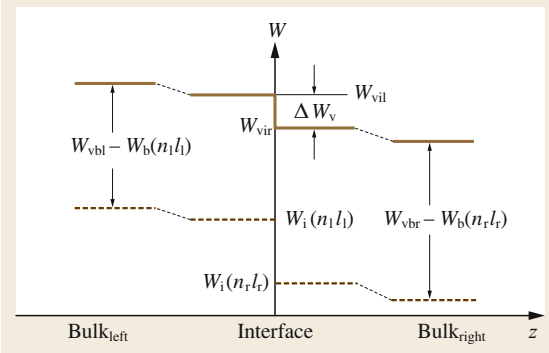

Fig. 8.7 Schematic energy band diagram at semiconductor heterostructures. W_{vb} and W_{vi} are the valence-band maxima and $W_{\mathrm{b}}(nl)$ and $W_{\mathrm{i}}(nl)$ are the core levels in the bulk and at the interface, respectively. The subscripts l and r denote the semiconductors on the right and the on the left side of the interface. ΔW_{v} is the valence-band offset. The *thin dashed lines* account for possible band-bending from space-charge layers

Another widely used technique for determining band offsets in heterostructures is internal photoemission yield spectroscopy. The procedure for evaluating the IPEYS signals is the same as described in Sect. 8.1.1.

8.2 IFIGS-and-Electronegativity Theory

Because of the quantum-mechanical tunneling effect, the wave functions of bulk electrons decay exponentially into vacuum at surfaces or, more generally speaking, at solid–vacuum interfaces. A similar behavior occurs at interfaces between two solids [8.6, 7]. In energy regions of Schottky contacts and semiconductor heterostructures where occupied band states overlap a band gap, the wave functions of these electrons will tail across the interface. The only difference to solid–vacuum interfaces is that the wave function tails oscillate at solid–solid interfaces. Figure 8.8 schematically explains the tailing effects at surfaces and semiconductor interfaces. For the band-structure lineup at semiconductor interfaces, only the tailing states within the gap between the top valence and the lowest conduction band are of any real importance since the energy position of the Fermi level determines their charging state. These wave function tails or interface-induced gap states (IFIGS) derive from the continuum of the virtual gap states (ViGS) of the complex semiconductor band structure. Hence, the IFIGS are an intrinsic property of the semiconductor.

The IFIGS are made up of valence-band and conduction-band states of the semiconductor. Their net charge depends on the energy position of the Fermi level relative to their branch point, where their character changes from predominantly donor- or valence-band-like to mostly acceptor- or conduction-band-like. The band-structure lineup at semiconductor interfaces is thus described by a zero-charge-transfer term and an electric dipole contribution.

In a more chemical approach, the charge transfer at semiconductor interfaces may be related to the partly ionic character of the covalent bonds at interfaces. *Pauling* [8.8] described the ionicity of single bonds in diatomic molecules by the difference between the electronegativities of the atoms involved. The binding energies of core-level electrons are known to depend on the chemical environment of the atoms or, in other words, on the ionicity of their chemical bonds. Figure 8.9 displays experimentally observed chemical shifts for Si(2*p*) and Ge(3*d*) core levels induced by metal adatoms on silicon and germanium surfaces as a function of the difference $X_m - X_s$ between the Pauling atomic electronegativity of the metal and that of the semiconductor atoms. The covalent bonds between metal and substrate atoms still persist at metal–semiconductor interfaces, as ab-initio calculations [8.25] have demonstrated for the example of Al/GaAs(110) contacts. The pronounced linear correlation of the data displayed in Fig. 8.9 thus justifies the application of Pauling's electronegativity concept to semiconductor interfaces.

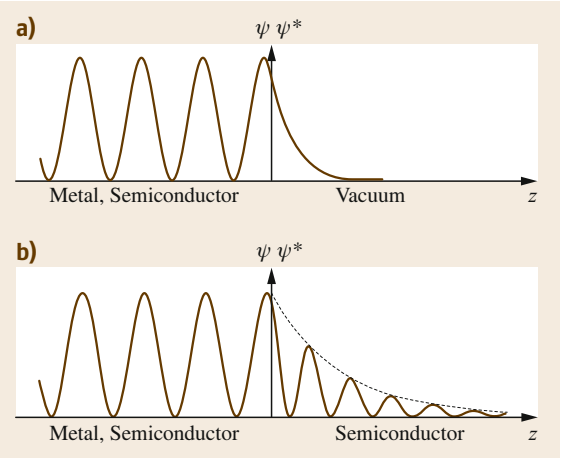

Fig. 8.8a,b Wave functions at clean surfaces **(a)** and at metal–semiconductor and semiconductor–semiconductor interfaces **(b)** (schematically)

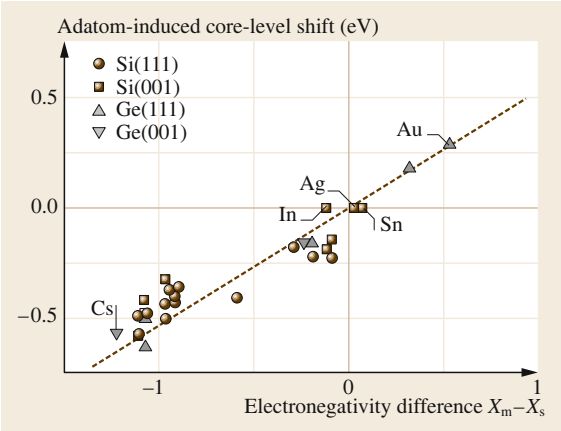

Fig. 8.9 Chemical shifts of Si(2*p*) and Ge(3*d*) core levels induced by metal adatoms on silicon and germanium surfaces, respectively, as a function of the difference $X_m - X_s$ in the metal and the semiconductor electronegativities in Pauling units. (After [8.13])

The combination of the physical IFIGS and the chemical electronegativity concept yields the barrier heights of ideal p-type Schottky contacts and the valence-band offsets of ideal semiconductor heterostructures as

$$\Phi_{\mathrm{Bp}} = \Phi^{\mathrm{p}}_{\mathrm{bp}} - S_{\mathrm{X}}(X_{\mathrm{m}} - X_{\mathrm{s}}) \tag{8.12}$$

and

$$\Delta W_{\mathrm{v}} = \Phi^{\mathrm{p}}_{\mathrm{bpr}} - \Phi^{\mathrm{p}}_{\mathrm{bpl}} + D_{\mathrm{X}}(X_{\mathrm{sr}} - X_{\mathrm{sl}}) \,, \tag{8.13}$$

respectively, where $\Phi^{\mathrm{p}}_{\mathrm{bp}} = W_{\mathrm{bp}} - W_{\mathrm{v}}(\Gamma)$ is the energy distance from the valence-band maximum to the branch point of the IFIGS or the p-type branch-point energy. It has the physical meaning of a zero-charge-transfer barrier height. The slope parameters S_{X} and D_{X} are explained at the end of this section.

The IFIGS derive from the ViGS of the complex band structure of the semiconductor. Their branch point is an average property of the semiconductor. *Tersoff* [8.26] calculated the branch-point energies $\Phi^{\mathrm{p}}_{\mathrm{bp}}$ of Si, Ge, and 13 of the III–V and II–VI compound semiconductors. He used a linearized augmented plane-wave method and the local density approximation. Such extensive computations may be avoided. *Mönch* [8.27] applied *Baldereschi*'s concept [8.28] of mean-value k-points to calculate the branch-point energies of zincblende-structure compound semiconductors. He first demonstrated that the quasi-particle band gaps of diamond, silicon, germanium, 3C-SiC, GaAs, and CdS at the mean-value k-point equal their average or dielectric band gaps [8.29]

$$W_{\mathrm{dg}} = \frac{\hbar\omega_{\mathrm{p}}}{\sqrt{\varepsilon_{\infty} - 1}} \,, \tag{8.14}$$

where $\hbar\omega_{\mathrm{p}}$ is the plasmon energy of the bulk valence electrons. Mönch then used Tersoff's $\Phi^{\mathrm{p}}_{\mathrm{bp}}$ values, calculated the energy dispersion of the topmost valence band in the empirical tight-binding approximation (ETB), and plotted the resulting branch-point energies at the mean-value k-point versus the widths of the dielectric band gaps W_{dg}. The linear least-squares fit to the data of the zincblende-structure compound semiconductors [8.30]

$$\Phi^{\mathrm{p}}_{\mathrm{bp}} = 0.449 W_{\mathrm{dg}} - [W_{\mathrm{v}}(\Gamma) - W_{\mathrm{v}}(\underline{k}_{\mathrm{mv}})]_{\mathrm{ETB}} \tag{8.15}$$

indicates that the branch points of these semiconductors lie 5% below the middle of the energy gap at the mean-value k-point k_{mv}. Table 8.1 displays the calculated p-type branch-point energies of the Group IV elemental semiconductors, of SiC, of III–V and II–VI compound semiconductors and of some I–III–VI_2 chalcopyrites.

Table 8.1 Optical dielectric constants, widths of the dielectric band gap, and branch-point energies of diamond-, zincblende, and chalcopyrite-structure semiconductors. (After [8.26, 29, 30])

Semiconductor	ε_{∞}	W_{dg} (eV)	$\Phi^{\mathrm{p}}_{\mathrm{bp}}$ (eV)

$AgInSe_2$	7.20	5.60	1.11[b]

* $\varepsilon_{\infty} = n^2$, [a] [8.26], [b] [8.29]

A simple phenomenological model of Schottky contacts with a continuum of interface states and a constant density of states D_{is} across the semiconductor band gap yields the slope parameter [8.31, 32]

$$S_{\mathrm{X}} = \frac{A_{\mathrm{X}}}{\left(1 + \frac{e_0^2}{\varepsilon_{\mathrm{i}}\varepsilon_0} D_{\mathrm{is}}\delta_{\mathrm{is}}\right)} \,, \tag{8.16}$$

where ε_{i} is an interface dielectric constant. The parameter A_{X} depends on the electronegativity scale chosen and amounts to 0.86 eV/Miedema-unit and 1.79 eV/Pauling-unit. For $D_{\mathrm{is}} \to 0$, relation (8.16) yields $S_{\mathrm{X}} \to A_{\mathrm{X}}$ or, in other words, if no IFIGS were present at the metal–semiconductor interfaces one would obtain the Schottky–Mott rule. The extension δ_{is} of the interface states may be approximated by their charge decay

length $1/2q_{is}$. *Mönch* [8.32] used theoretical D_{gs}^{mi} and q_{gs}^{mi} data for metal-induced gap states (MIGS), as the IFIGS in Schottky contacts are traditionally called, and plotted the $(e_0^2/\varepsilon_0)D_{gs}^{mi}/(2q_{gs}^{mi})$ values versus the optical susceptibility $\varepsilon_\infty - 1$. The linear least-squares fit to the data points yielded [8.32]

$$\frac{A_X}{S_X} - 1 = 0.1(\varepsilon_\infty - 1)^2 \,, \tag{8.17}$$

where the reasonable assumption $\varepsilon_i \approx 3$ was made.

To a first approximation, the slope parameter D_X of heterostructure band offsets may be equated with the slope parameter S_X of Schottky contacts, since the IFIGS determine the intrinsic electric-dipole contributions to both the valence-band offsets and the barrier heights.

In early *Gedanken experiments*, Schottky contacts and semiconductor heterostructures were assembled by gradually approaching the respective two solids in vacuum [8.3, 33]. As long as a vacuum gap exists between the two surfaces facing each other, the vacuum level W_{vac} is the appropriate reference and, for example, the work function $W_{vac} - W_F$ of the metal and the electron affinity $W_{vac} - W_c$ or the ionization energy $W_{vac} - W_v$ of the semiconductor may be used to describe the charge distribution and the energy-band alignment in such a metal–vacuum–semiconductor array. As the vacuum gap is closed, that is, an intimate Schottky contact is made, chemical bonds between metal and semiconductor atoms will have formed at the now intimate metal–semiconductor interface. Hence, the work function of the metal as well as the electron affinity or the ionization energy of the semiconductor are inappropriate reference properties, but instead the electronegativities of the metal and the semiconductor may be used to describe the electric dipole layer at Schottky contacts [8.34]. The same arguments also hold for semiconductor heterostructures.

8.3 Comparison of Experiment and Theory

8.3.1 Barrier Heights of Schottky Contacts

Experimental barrier heights of intimate, abrupt, clean, and (above all) laterally homogeneous Schottky contacts on n-Si, n-GaAs, n-GaN, and SiO_2, as an example for insulators, are plotted in Figs. 8.10 and 8.11 versus the difference in the Miedema electronegativities of the metals and the semiconductors. *Miedema*'s electronegativities [8.35] are preferred since they were derived from properties of metal alloys and intermetallic compounds, while *Pauling* [8.8] considered covalent bonds in small molecules. The p- and n-type branch-point energies, $\Phi_{bp}^{p} = W_{bp} - W_v(\Gamma)$ and $\Phi_{bp}^{n} = W_c - W_{bp}$, respectively, add up to the fundamental band-gap energy $W_g = W_c - W_v(\Gamma)$. Hence, the barrier heights of n-type Schottky contacts are

$$\Phi_{Bn}^{hom} = \Phi_{bp}^{n} + S_X(X_m - X_s) \,. \tag{8.18}$$

The electronegativity of a compound is taken as the geometric mean of the electronegativities of its constituent atoms.

First, the experimental data plotted in Figs. 8.10 and 8.11 clearly confirm that the different experimental techniques, I/V, C/V, BEEM, IPEYS, and PES, yield barrier heights of laterally homogeneous Schottky contacts which agree within the margins of experimental error.

Second, the experimental Si, GaAs, and GaN data are quantitatively explained by the branch-point energies (8.15) and the slope parameters (8.17) of the IFIGS-and-electronegativity theory. As was already mentioned in Sect. 8.1.1, the stacking fault, which is part of the interfacial Si(111)-$(7\times7)^i$ reconstruction [8.15], causes an *extrinsic* electric dipole in addition to the *intrinsic* IFIGS electric dipole. The latter one is present irrespective of whether the interface structure is reconstructed or $(1\times1)^i$-unreconstructed. The extrinsic stacking fault-induced electric dipole quantitatively explains the experimentally observed barrier-height lowering of 76 ± 2 meV [8.10].

Third, the IFIGS line in Fig. 8.11a was drawn using the branch-point energy calculated for *cubic* 3*C*-GaN since relation (8.15) was derived for zincblende-structure compounds only. However, the Schottky contacts were prepared on hexagonal *wurtzite-structure* 2*H*-GaN. The good agreement between the experimental data and the IFIGS line indicates that the p-type branch-point energy seems to be rather insensitive to the specific bulk lattice structure of the semiconductor. This conclusion is further justified by the barrier heights of laterally homogeneous Schottky contacts on cubic 3*C*-SiC and its hexagonal polytypes 4*H* and 6*H* [8.13] as well as by the experimentally observed band-edge discontinuities of semiconductor heterostructures, which will be discussed in Sect. 8.3.2.

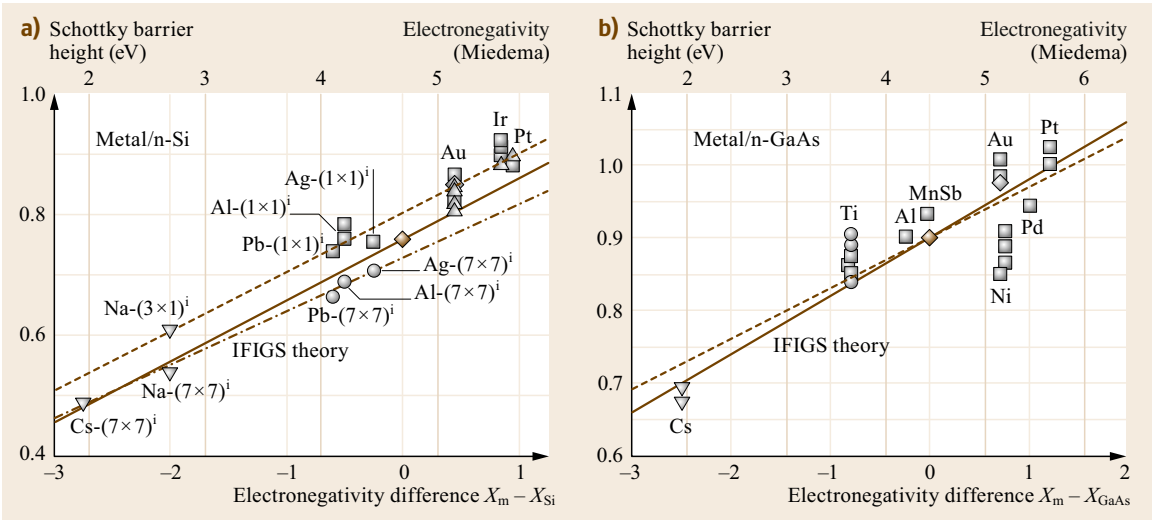

Fig. 8.10a,b Barrier heights of laterally homogeneous n-type silicon **(a)** and GaAs Schottky contacts **(b)** versus the difference in the Miedema electronegativities of the metals and the semiconductors. The □ and ○, △, ◇, and ▽ *symbols* differentiate the data from I/V, BEEM, IPEYS, and PES measurements, respectively. The *dashed* and the *dash-dotted lines* are the linear least-squares fits to the respective experimental data. The *solid* IFIGS *lines* are drawn with $S_X = 0.101\,\text{eV/Miedema-unit}$ and $\Phi_{bp}^{p} = 0.36\,\text{eV}$ for silicon **(a)** and with $S_X = 0.08\,\text{eV/Miedema-unit}$ and $\Phi_{bp}^{p} = 0.5\,\text{eV}$ for GaAs **(b)**. (After [8.13])

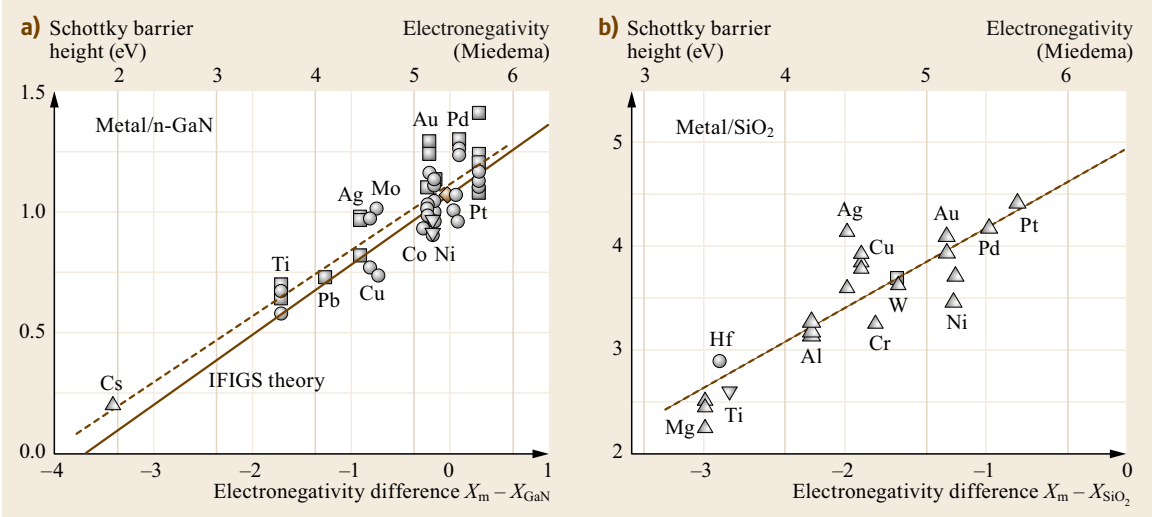

Fig. 8.11a,b Barrier heights of laterally homogeneous n-GaN(0001) **(a)** and SiO_2 Schottky contacts **(b)** versus the difference in the Miedema electronegativities of the metals and the semiconductors. **(a)** The *solid* IFIGS *line* is drawn with $S_X = 0.29\,\text{eV/Miedema-unit}$ and $\Phi_{bp}^{p} = 2.37\,\text{eV}$. **(a,b)** The □, ○, △, and ▽ *symbols* differentiate the data from I/V, C/V, IPEYS, and PES measurements. The *dashed lines* are the linear least-squares fits to the respective data. (After [8.13, 36])

8.3.2 Band Offsets of Semiconductor Heterostructures

In the bulk and at interfaces of sp^3-coordinated semiconductors, the chemical bonds are covalent. The simplest semiconductor–semiconductor interfaces are *lattice-matched* heterostructures. However, if the bond lengths of the two semiconductors differ, then the interface will respond with tetragonal lattice distortions. Such *pseudomorphic* interfaces are under tensile or

compressive stress. If the strain energy becomes too large, then it is energetically more favorable to release the stress by the formation of misfit dislocations. Such *metamorphic* interfaces are almost relaxed.

In contrast to isovalent heterostructures, the chemical bonds at heterovalent interfaces require special attention, since interfacial donor- and acceptor-type bonds may cause interfacial electric dipoles [8.37]. No such extrinsic electric dipoles will exist normal to nonpolar (110) interfaces. However, polar (001) interfaces behave quite differently. Acceptor bonds or donor bonds normal to the interface would exist at abrupt heterostructures. But, for reasons of charge neutrality, they have to be compensated by a corresponding density of donor bonds and acceptor bonds, respectively. This may be achieved by an intermixing at the interface which, on the other hand, causes extrinsic electric dipoles. Their components normal to the interface will add an extrinsic electric-dipole contribution to the valence-band offset.

The valence-band offsets at nonpolar heterostructures of compound semiconductors should equal the difference in the branch-point energies of the two semiconductors in contact provided the intrinsic IFIGS electric-dipole contribution can be neglected, see relation (8.13). This assumption is justified for heterostructures among the elemental Group IV semiconductors Ge and Si, SiC, and the III–V and II–VI compounds – with the nitrides and the oxides being excepted – because the elements that constitute these semiconductors are all placed in the middle of the Periodic Table so that their electronegativities only differ slightly. Figure 8.12a displays respective experimental results for diamond- and zincblende-structure semiconductors as a function of the difference in the calculated branch-point energies given in Table 8.1. The dashed line clearly demonstrates that the experimental data are excellently explained by the theoretical branch-point energies or, in other words, by the IFIGS theory.

As an example of lattice-matched and isovalent heterostructures, Fig. 8.13 shows valence-band offsets of $Al_{1-x}Ga_xAs/GaAs$ heterostructures as a function of the alloy composition x. The IFIGS branch-point energies of the alloys were calculated assuming virtual cations [8.30] and were found to vary linearly as a function of composition between the values of AlAs and GaAs. More refined first-principles calculations yielded identical results [8.38–40]. Figure 8.13 reveals that the theoretical IFIGS valence-band offsets excellently fit the experimental data.

Figure 8.12b displays valence-band offsets of metamorphic heterostructures versus the difference in the branch-point energies of the two semiconductors. The dashed line indicates that the experimental results are again excellently described by the theoretical IFIGS

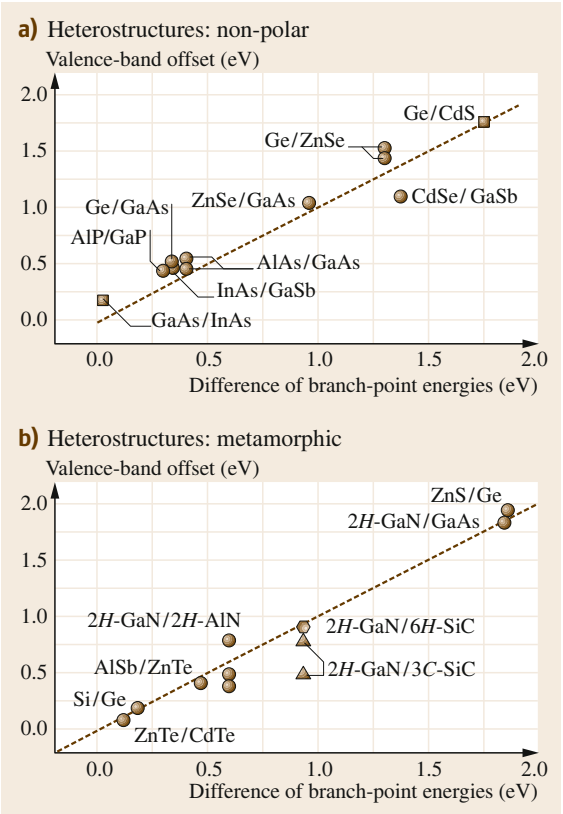

Fig. 8.12a,b Valence-band offsets at nonpolar (110)-oriented **(a)** and metamorphic semiconductor heterostructures **(b)** versus the difference between the p-type branch-point energies of the semiconductors in contact. (After [8.13])

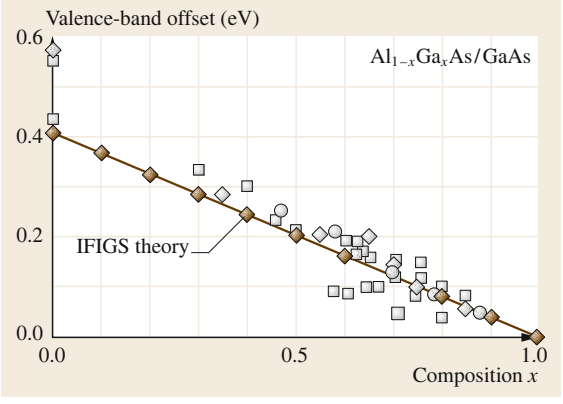

Fig. 8.13 Valence-band offsets of lattice-matched and isovalent heterostructures as a function of alloy composition x. (After [8.13])

data. This is true not only for heterostructures between cubic (C) zincblende- and hexagonal (H) wurtzite-

structure compounds but also for wurtzite-structure Group III nitrides grown on both cubic 3*C*- and hexagonal 6*H*-SiC substrates. These observations suggest the following conclusions. First, all of the heterostructures considered in Fig. 8.12b are only slightly (if at all) strained, although their lattice parameters differ by up to 19.8%. First-principles calculations [8.41] revealed that misfit dislocations change the valence-band offsets of metamorphic heterostructures by less than 0.1 eV only. Second, the calculations of the IFIGS branch-point energies assumed zincblende-structure semiconductors. These values, on the other hand, reproduce the experimental valence-band offsets irrespective of whether the semiconductors have zincblende, wurtzite, or, as in the case of 6*H*-SiC, another hexagonal-polytype structure. These findings again support the conclusion drawn from the GaN Schottky barrier heights in the previous section that the IFIGS branch-point energies are rather insensitive to the specific semiconductor bulk lattice structure.

Quite generally, the contribution of the IFIGS electric-dipole term $S_X(X_{sl} - X_{sr})$ to the valence-band offset ΔW_v of heterostructures may not be neglected. A simple rearrangement of terms in relation (8.13) gives

$$\Delta W_v - S_X(X_{sr} - X_{sl}) = \Phi^p_{bpr} - \Phi^p_{bpl} \,. \qquad (8.19)$$

For heterostructres of one and the same semiconductor, the valence-band offsets less the IFIGS-related electric-dipole contributions thus vary as the p-type branch-point energies of the respective other semiconductors. Figure 8.14 displays experimental valence-band offsets of SiO_2 heterostructures minus the respective electric-dipole contributions as a function of the calculated branch-point energies of the respective other semiconductors [8.26, 30] (Table 8.1); the S_X value of SiO_2 was adopted from Fig. 8.11b. The linear least-squares fit has a slope parameter of 0.94 ± 0.07 which value is close to 1 as is to be expected from (8.19), and its intercept on the ordinate gives the empirical p-type branch-point energy of SiO_2 as 3.73 ± 0.07 eV.

Figures 8.15 and 8.16 display experimental $\Delta W_v - S_X(X_{semi} - X_{Si,Ge,GaN})$ data of Si, Ge, and GaN heterostructures as a function of the branch-point energies of the other semiconductors and insulators involved. For the semiconductors, the calculated values [8.26, 30] were taken again while for the insulators empirical values [8.42–44] were considered. Again, the slope parameters of the linear least-squares fits (0.97 ± 0.03, 0.90 ± 0.04, and 0.87 ± 0.04) are close to 1, the value expected from (8.19). The empirical p-type branch-point energies result as 0.30 ± 0.09 eV for Si, 2.34 ± 0.4 eV for GaN, and 0.08 ± 0.10 eV for Ge. Within the margins of experimental error, these empirical values excellently agree with the calculated ones (Table 8.1).

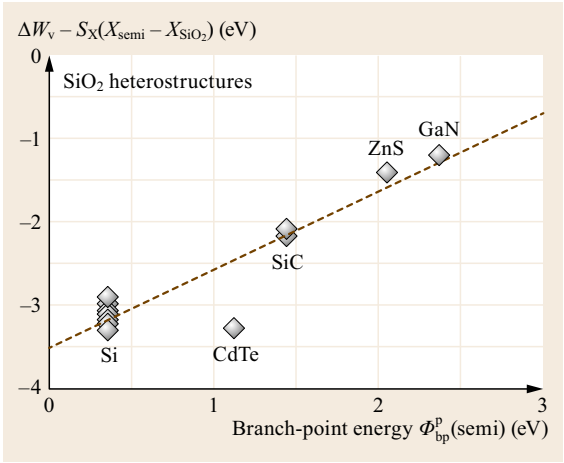

Fig. 8.14 Experimental valence-band offsets of SiO_2 heterostructures minus the respective IFIGS electric-dipole contributions as a function of the calculated p-type branch-point energies of the respective other semiconductors. The *dashed line* is the linear least-squares fit to the data points. (After [8.42])

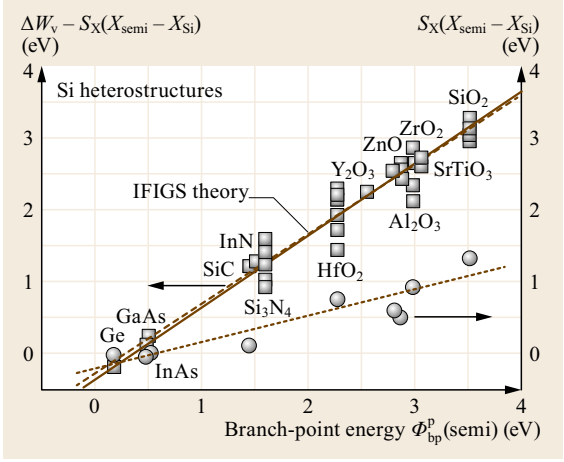

Fig. 8.15 Experimental valence-band offsets of Si heterostructures minus the respective IFIGS electric-dipole contributions (□) and the IFIGS electric-dipole contributions (○) as a function of calculated and empirical p-type branch-point energies of the respective other semiconductors and insulators, respectively. The *dashed* and *dash-dotted lines* are the linear least-squares fits to the data points. (After [8.43])

Figure 8.15 also displays some of the IFIGS electric-dipole contributions $S_X(X_{semi} - X_{Si})$ in Si heterostructures. The example of SiO_2/Si heterostructures demonstrates that this intrinsic dipole term measures 1.3 eV and this large value thus amounts to approximately 30% of the total valence-band offset.

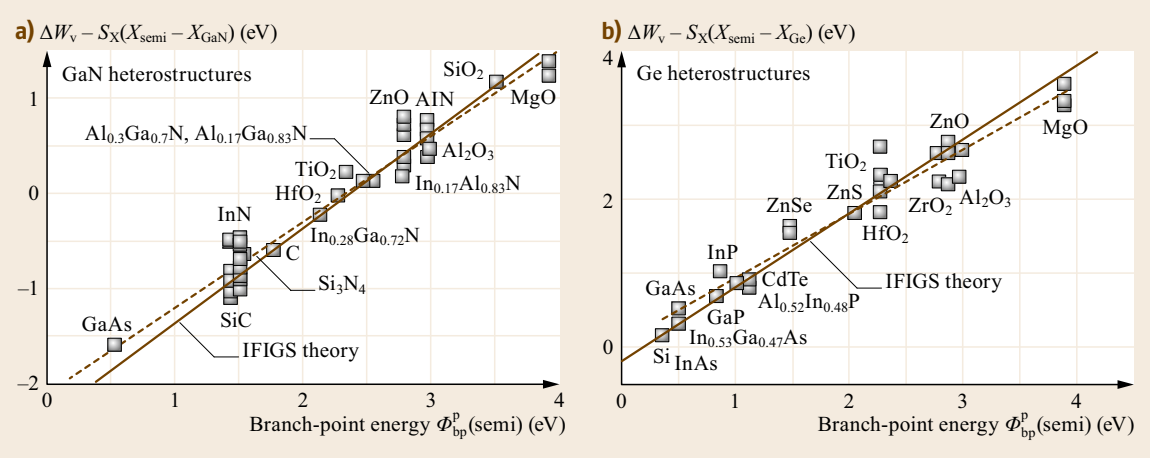

Fig. 8.16a,b Experimental valence-band offsets of GaN **(a)** and Ge heterostructures **(b)** minus the respective IFIGS electric-dipole contributions as a function of the calculated and empirical p-type branch-point energies of the respective other semiconductors and insulators, respectively. The *dashed lines* are the linear least-squares fits to the data points. (After [8.43])

Table 8.2 Fundamental band gaps W_g and empirical branch-point energies Φ_{bp}^{n} and Φ_{bp}^{p} as obtained from barrier heights of Schottky contacts and valence-band offsets of heterostructures, respectively [8.13, 36, 42–46]

Semiconductor	W_g (eV)	Φ_{bp}^{n} (eV)	Φ_{bp}^{p} (eV)	$\Phi_{bp}^{n} + \Phi_{bp}^{p}$ (eV)
Si	1.12	0.80 ± 0.01	0.30 ± 0.09	1.10
Ge	0.66	0.59 ± 0.01	0.08 ± 0.10	0.67
GaN	3.39	1.12 ± 0.03	2.34 ± 0.09	3.46
GaAs	1.42	0.90 ± 0.01	0.68 ± 0.11	1.58
InP	1.34	0.50 ± 0.02	0.86 ± 0.11	1.36
SiO_2	8.7–8.9	4.95 ± 0.19	3.73 ± 0.07	8.68
TiO_2	3.3–3.5	$1.13\ (\pm 0)$	2.34 ± 0.36	3.47
HfO_2	5.7–6.0	4.01 ± 0.19	2.27 ± 0.14	6.28
Al_2O_3	6.7–7.0	4.38 ± 0.34	2.98 ± 0.26	7.36
Ga_2O_3	4.9	1.34 ± 0.08	3.57 ± 0.50	4.91

As was already mentioned, the p- and n-type branch-point energies, $\Phi_{bp}^{p} = W_{bp} - W_v(\Gamma)$ and $\Phi_{bp}^{n} = W_c - W_{bp}$, respectively, add up to the fundamental band-gap energy $W_g = W_c - W_v(\Gamma)$. Table 8.2 shows empirical Φ_{bp}^{n} and Φ_{bp}^{p} values that were obtained from experimental barrier heights of n-type Schottky contacts and valence-band offsets of heterostructures, respectively; see, for example, Figs. 8.10, 8.11, 8.14–8.16, 8.19. Within the margins of experimental error, the empirical p- and n-type branch-point energies of these semiconductors and insulators indeed add up to the widths of their fundamental band gaps. These findings again strongly support the IFIGS-and-electronegativity concept of the band-structure alignment at semiconductor interfaces. The empirical Φ_{bp}^{n} values are of special importance since they were evaluated from experimental barrier heights with no other input than the metal and semiconductor electronegativities.

8.4 Modifications of Schottky Contacts

8.4.1 Nonalloyed Ohmic Contacts or MUTIS Schottky Contacts

Ideal metal–semiconductor or Schottky contacts are generally rectifying while genuine low-resistance or ohmic contacts are obtained with p-type Ge and GaSb and n-type InN, InAs, and InSb only because their IFIGS branch points are close to their valence-band maxima and above their conduction-band minima, respectively (Table 8.1). Recently, *Connelly* et al. [8.47, 48] studied a new path towards Ohmic contacts. They avoided alloying and demonstrated that the resistance of

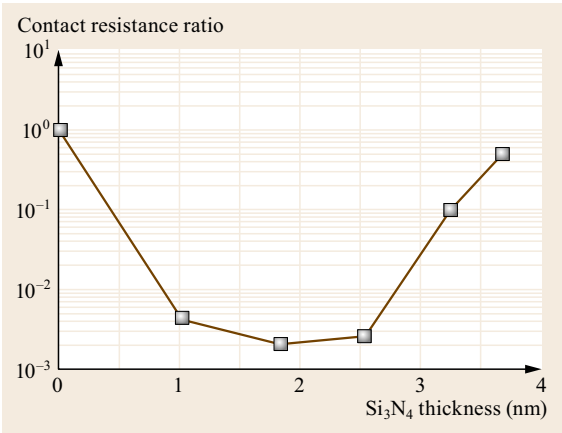

Fig. 8.17 Contact resistance ratio of Al/Si_3N_4/n-GaAs Schottky contacts versus the thickness of the Si_3N_4 interlayer. (After [8.49])

Si Schottky contacts is considerably lowered by ultrathin Si_3N_4 layers placed between the metal and silicon. As a typical example, Fig. 8.17 displays the contact resistance of Al/Si_3N_4/n-GaAs Schottky contacts normalized to the value of the intimate Al/n-GaAs contact in dependence on the insulator thickness [8.49]. The initial dramatic decrease of the contact resistance is accompanied by a gradual reduction of the Schottky barrier heights to a then constant value while the subsequent rise is easily attributed to the increasing tunnel resistance through the then thicker insulator interlayers.

Figure 8.18 schematically shows the energy-band diagram of ideal metal-ultrathin insulator–semiconductor or MUTIS structures resulting from the IFIGS-and-electronegativity concept. It is assumed that the electronegativity of the insulator is intermediate between the values of the metal and the semiconductor. In order to avoid that the IFIGS of the metal–insulator and the insulator–semiconductor interface overlap the thickness of the insulator has to be larger than four to five times the decay length at the IFIGS branch point of the insulator. Theoretical calculations found these dacay lengths to range between 0.09 and 0.28 nm [8.50]. The pronounced minimum value of the contact resistance ratio displayed in Fig. 8.17 is compatible with this estimate. Considering (8.12) and (8.13), one obtains

$$W_F - W_v^i = \Phi_{bp}^{pi} - S_X^i(X_m - X_i) \tag{8.20}$$

at the metal–insulator interface and

$$\begin{aligned} W_F - W_v^i &= \Delta W_v + W_g^s - \Phi_{Bn}^s \\ &= \Phi_{bp}^{pi} - \Phi_{bp}^{ps} + S_X^i(X_s - X_i) + W_g^s - \Phi_{Bn}^s \end{aligned} \tag{8.21}$$

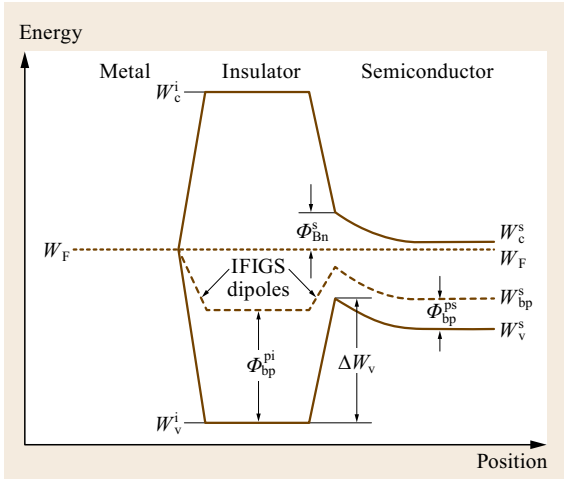

Fig. 8.18 Band-structure lineup at metal-ultrathin insulator–semiconductor (MUTIS) structures (schematically) with the assumption $X_m < X_i > X_s$. On the semiconductor side the extension of the band-bending regime is not drawn to scale. (After [8.50])

at the insulator–semiconductor interface where the sub- and superscripts m, i, and s indicate metals, insulators, and semiconductors, respectively. W_g^s designates the width of the fundamental band gap of the semiconductor. A rearrangement of (8.20) and (8.21) then gives the effective n-type barrier heights of the MUTIS structures as

$$\begin{aligned} \Phi_{Bn}^s &= W_g^s - \Phi_{bp}^{ps} + S_X^i(X_m - X_s) \\ &= \Phi_{bp}^{ns} + S_X^i(X_m - X_s) \end{aligned} \tag{8.22}$$

The effective n-type barrier height of an ideal n-type MUTIS structure is thus determined by the n-type branch-point energy Φ_{bp}^{ns} of the semiconductor and the slope parameter S_X^i of the insulator. The optical dielectric constant ε_∞ of Si_3N_4, and the same holds for other insulators such as Al_2O_3, Ge_3N_4, and MgO, is considerably smaller than the respective values of semiconductors as, for example, Ge, Si, and GaAs and, hence, (8.17) gives $S_X^i > S_X^s$ for the slope parameters. The insertion of the ultrathin insulators in MUTIS contacts thus alleviates the pinning of the Fermi level in comparison with the respective intimate MS contacts. Furthermore, (8.22) reveals that Ohmic rather than rectifying n-type MUTIS contacts will be obtained provided metals are chosen such that their electronegativities are sufficiently smaller than the values of the respective semiconductors.

Experimental barrier heights of Si_3N_4/n-Si and intimate n-Si Schottky contacts are plotted versus the electronegativity difference $X_m - X_{Si}$ in Fig. 8.19. The

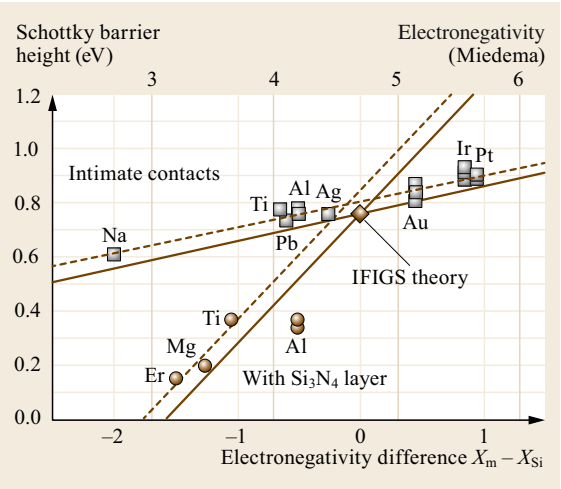

Fig. 8.19 Schottky barrier heights of intimate metal/n-Si (from Fig. 8.10a) and metal/Si_3N_4/n-Si versus the difference $X_m - X_{Si}$ of the metal and the Si electronegativities. The *full* and the *dashed lines* are the predictions of the IFIGS theory and the linear-least squares fits to the experimental data, respectively. (After [8.50])

thickness of the Si_3N_4 layers measured approximately 1 nm and is thus sufficiently larger than the estimated decay length of the IFIGS at their branch point. Within the margins of experimental error, the experimental barrier heights of the metal/Si_3N_4/n-Si junctions clearly confirm prediction (8.22) of the IFIGS-and-electronegativity concept in that the MUTIS barrier heights are determined by the branch-point energy of the semiconductor and the slope parameter of the insulator. This observation most directly demonstrates the alleviation of the Fermi-level pinning in MUTIS structures in comparison with intimate MS interfaces.

8.4.2 Atomic Interlayers

The barrier heights of metal–semiconductor contacts may also be modified by atomic interlayers. Figure 8.20 displays barrier heights of p-type silicon and diamond Schottky contacts without and with hydrogen interlayers [8.48, 50, 51]. Irrespective of the metals used, the H-induced modifications amount to -1.4 eV for p-diamond(001) but to $+0.3$ eV for p-Si(111) and to $+0.16$ eV for p-Si(001) Schottky contacts. In contrast to the insertion of ultrathin insulators, the H-interlayers do not alter the slope parameters S_X.

The metal-independent H-induced modifications of the Schottky barrier heights were explained by the partial ionic character of the covalent bonds between the H atoms and the interface atoms of the substrates [8.52]. The electronegativity of hydrogen ranges between the values of silicon and carbon, that is, $X_{Si} < X_H < X_C$ [8.8]. Hence, the partial ionic character of covalent Si–H and C–H bonds differs in sign, and $H^{-\Delta q}$-$Si^{+\Delta q}$ but $H^{+\Delta q}$-$C^{-\Delta q}$ bonds will exist at silicon and diamond interfaces, respectively. The opposite directions of the H-induced interface dipoles easily explain why the H-induced variations of the barrier

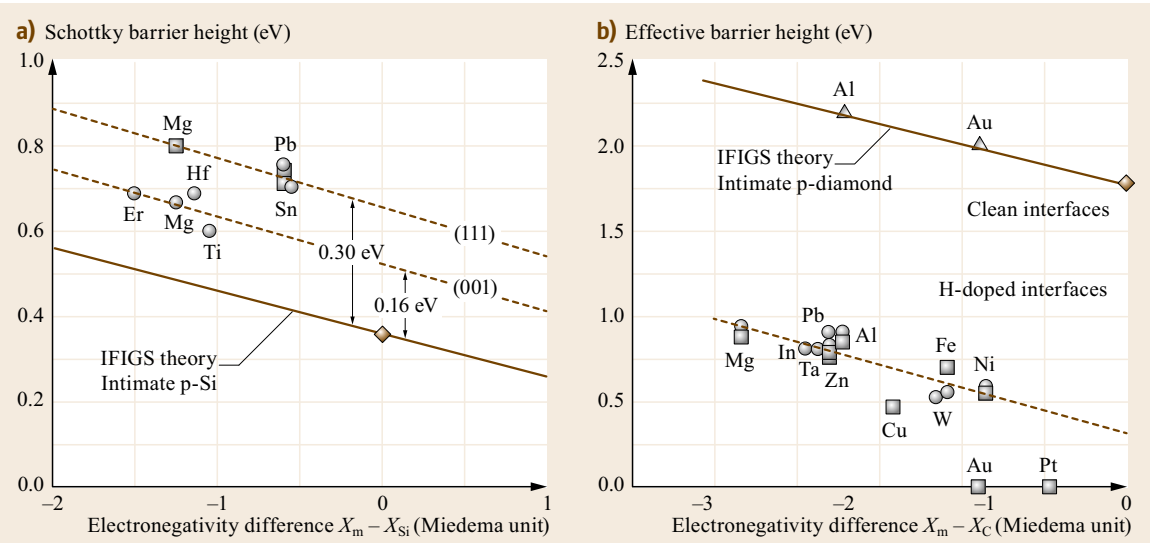

Fig. 8.20a,b Barrier heights of p-Si **(a)** and p-diamond Schottky contacts **(b)** with and without H-interlayers. The *full* and the *dashed lines* are the predictions of the IFIGS theory and the linear least-squares fits to the experimental data, respectively. (After [8.50])

height exhibit different signs with p-Si and p-diamond Schottky contacts.

These early conclusions were excellently confirmed by the recent observation that F-interlayers reduce the barrier heights of n-Ge Schottky contacts and do not change the slope parameter S_X [8.53]. The electronegativity of F is larger than the one of Ge so that $F^{-\Delta q}$-$Ge^{+\Delta q}$ dipoles are to be expected at F-doped Ge interfaces. These dipoles will reduce the barrier heights of metal/F:n-Ge Schottky contacts while, as with H:p-Si contacts, an increase would be observed with metal/F:p-Ge interfaces. The reduction of the barrier height observed with Fe/S:n-Ge contacts [8.54] is easily explained along the same lines.

The experimental data presented in Fig. 8.20 and [8.53] clearly demonstrate that atomic interlayers in Schottky contacts cause no depinning of the Fermi level and no alleviation of the Fermi-level pinning either.

8.5 Graphene Schottky Contacts

Graphene (Gr) is a single layer of sp^2-bonded carbon atoms arranged in a hexagonal crystal lattice. The remaining $2p_z$ orbitals are perpendicular to the graphene plane and form contiguous π and π^* bands so that graphene may be described as a zero-overlap semimetal. As the *conventional* metal-semiconductor contacts discussed in the preceding chapters graphene-semiconductor contacts indeed exhibit rectifying properties. However, *conventional* and Gr Schottky contacts differ in that the bonds between the metal and the semiconductor atoms are covalent while the bonds between graphene and semiconductor substrates are of van der Waals type. *Mönch* [8.55] verified that the experimental barrier heights of intimate Gr contacts on *conventional* n-type semiconductors as well as on layered n-MoS_2 agree with the values predicted by (8.17) and (8.18) but do not follow the Schottky–Mott rule. Hence, electric dipoles exist at Gr-semiconductor interfaces because graphene has a larger electronegativity than the semiconductors, with SiO_2 being the only exemption. The respective electronic charge transfer from the semiconductors towards the more electronegative Gr layer was also confirmed by theoretical calculations (see Refs. cited in [8.55]). The barrier heights of graphene Schottky contacts are thus explained by the π and π^* wave-function tails of the graphene across the interface in the energy range where the π–π^* bands of the graphene overlap the band gap of the semiconductor. The IFIGS-and-electronegativity concept thus also explains the band structure lineup at graphene-semiconductor interfaces rather than the Schottky–Mott rule as assumed in almost all the articles reporting barrier heights of such contacts.

8.6 Final Remarks

The local density approximation to density functional theory (LDA-DFT) is the most powerful and widely used tool in theoretical studies of the ground-state properties of solids. However, excitation energies such as the width of the energy gaps between the valence and conduction bands of semiconductors cannot be correctly obtained from such calculations. The fundamental band gaps of the elemental semiconductors C, Si, and Ge as well as of the III–V and II–VI compounds are notoriously underestimated by 25−50%. However, it became possible to compute quasi-particle energies and band gaps of semiconductors from first principles using the so-called GW approximation for the electron self-energy [8.56, 57]. The resulting band-gap energies agree to within 0.1−0.3 eV with experimental values.

For some specific metal–semiconductor contacts, the band-structure lineup was also studied by state-of-the-art ab-initio LDA-DFT calculations. The resulting LDA-DFT barrier heights were then subjected to a-posteriori corrections, which consider quasi-particle effects and, if necessary, spin–orbit interactions and semicore-orbital effects. However, comparison of the theoretical results with experimental data gives an inconsistent picture. The *mean* values of the barrier heights of Al- and Zn/p-ZnSe contacts, which were calculated for different interface configurations using ab-initio LDA-DF theory and a-posteriori spin–orbit and quasi-particle corrections [8.58, 59], agree with the experimental data to within the margins of experimental error. The same conclusion was reached for Al/$Al_xGa_{1-x}As$ Schottky contacts [8.60]. However, ab-initio LDA-DFT barrier heights of Al-, Ag-, and Au/p-GaN contacts [8.61, 62], as well as of Al– and Ti/3*C*-SiC(001) interfaces [8.63, 64], strongly deviate from the experimental results.

As already mentioned, ab-initio LDF-DFT valence-band offsets of heterostructures [8.39–41] reproduce the experimental results well. The same holds for *mean* values of LDF-DFT valence-band offsets computed for different interface configurations of GaN- and AlN/SiC-heterostructures [8.65–69].

The main difficulty, which the otherwise extremely successful ab-initio LDF-DFT calculations encounter when describing semiconductor interfaces, is not the precise exchange-correlation potential, which may be estimated in the GW approximation, but their remarkable sensitivity to the geometrical and compositional structure right at the interface. This aspect is more serious at metal–semiconductor interfaces than at heterostructures between two sp^3-bonded semiconductors. The more conceptual IFIGS-and-electronegativity theory, on the other hand, quantitatively explains not only the barrier heights of ideal Schottky contacts but also the valence-band offsets of semiconductor heterostructures. Here again, the Schottky contacts are the more important case, since their zero-charge-transfer barrier heights equal the branch-point energies of the semiconductors, while the valence-band offsets are determined by the differences in the branch-point energies of the semiconductors in contact.

9. Charge Transport in Disordered Materials

Sergei Baranovskii, Oleg Rubel

This chapter surveys general theoretical concepts developed to qualitatively understand and to quantitatively describe the electrical conduction properties of disordered organic and inorganic materials. In particular, these concepts are applied to describe charge transport in amorphous and microcrystalline semiconductors and in conjugated and molecularly doped polymers. Electrical conduction in such systems is achieved through incoherent transitions of charge carriers between spatially localized states. Basic theoretical ideas developed to describe this type of electrical conduction are considered in detail. Particular attention is given to the way the kinetic coefficients depend on temperature, the concentration of localized states, the strength of the applied electric field, and the charge carrier localization length. Charge transport via delocalized states in disordered systems and the relationships between kinetic coefficients under the nonequilibrium conditions are also briefly reviewed.

Many characteristics of charge transport in disordered materials differ markedly from those in perfect crystalline systems. The term *disordered materials* usually refers to noncrystalline solid materials without perfect order in the spatial arrangement of atoms. One should distinguish between disordered materials with ionic conduction and those with electronic conduction. Disordered materials with ionic conduction include various glasses consisting of a *network-formers* such as SiO_2, B_2O_3 and Al_2O_3, and of *network-modifiers* such as Na_2O, K_2O and Li_2O. When an external voltage is applied, ions can drift by hopping over potential barriers in the glass matrix, contributing to the electrical conduction of the material. Several fascinating effects have been observed for this kind of electrical conduction. One is the extremely nonlinear dependence of the conductivity on the concentration of ions in the material. Another beautiful phenomenon is the so-called *mixed alkali effect*: mixing two different modifiers in one glass leads to an enormous drop in the conductivity in comparison to that of a single modifier with the same total concentration of ions. A comprehensive description of these effects can be found in the review article of *Bunde* et al. [9.1]. Although these effects sometimes appear puzzling, they can be naturally and rather trivially explained using routine classical percolation theory [9.2]. The description of ionic conduction in glasses is much simplified by the inability of ions to tunnel over large distances in the glass matrix in single transitions. Every transition occurs over a rather small interatomic distance, and it is relatively easy to describe such electrical conductivity theoretically [9.2]. On the other hand, disordered systems with electronic conduction have a much more complicated theoretical description. Transition probabilities of electrons between spatially different regions in the material significantly depend not only on the energy parameters (as in the case of ions), but also on spatial factors such as the tunnelling distance, which can be rather large. The interplay between the energy and spatial fac-

tors in the transition probabilities of electrons makes the development of a theory of electronic conduction in disordered systems challenging. Since the description of electronic conduction is less clear than that of ionic conduction, and since disordered electronic materials are widely used for various device applications, in this chapter we concentrate on disordered materials with the electronic type of electrical conduction.

Semiconductor glasses form one class of such materials. This class includes amorphous selenium, a-Se and other chalcogenide glasses, such as a-As_2Se_3. These materials are usually obtained by quenching from the melt. Another broad class of disordered materials, inorganic amorphous semiconductors, includes amorphous silicon a-Si, amorphous germanium a-Ge, and their alloys. These materials are usually prepared as thin films by the deposition of atomic or molecular species. Hydrogenated amorphous silicon, a-Si:H, has attracted much attention from researchers, since incorporation of hydrogen significantly improves conduction, making it favorable for use in amorphous semiconductor devices. Many other disordered materials, such as hydrogenated amorphous carbon (a-C:H) and its alloys, polycrystalline and microcrystalline silicon are similar to a-Si:H in terms of their charge transport properties. Some crystalline materials can also be considered to be disordered systems. This is the case for doped crystals if transport phenomena within them are determined by randomly distributed impurities, and for mixed crystals with disordered arrangements of various types of atoms in the crystalline lattice. In recent years much research has also been devoted to the study of organic disordered materials, such as conjugated and molecularly doped polymers and organic glasses, since these systems have been shown to possess electronic properties similar to those of inorganic disordered materials, while they are easier to manufacture than the latter systems.

There are two reasons for the great interest of researchers in the conducting properties of disordered materials. On the one hand, disordered systems represent a challenging field in a purely academic sense. For many years the theory of how semiconductors perform charge transport was mostly confined to crystalline systems where the constituent atoms are in regular arrays. The discovery of how to make solid amorphous materials and alloys led to an explosion in measurements of the electronic properties of these new materials. However, the concepts often used in textbooks to describe charge carrier transport in crystalline semiconductors are based on an assumption of long-range order, and so they cannot be applied to electronic transport in disordered materials. It was (and still is) a highly challenging task to develop a consistent theory of charge transport in such systems. On the other hand, the explosion in research into charge transport in disordered materials is related to the various current and potential device applications of such systems. These include the application of disordered inorganic and organic materials in photovoltaics (the functioning material in solar cells), in electrophotography, in large-area displays (they are used in thin film transistors), in electrical switching threshold and memory devices, in light-emitting diodes, in linear image sensors, and in optical recording devices. Readers interested in the device applications of disordered materials should be aware that there are numerous monographs on this topic: the literature on this field is very rich. Several books are recommended [9.3–12], as are numerous review articles referred to in these books.

In this chapter we focus on disordered semiconductor materials, ignoring the broad class of disordered metals. In order to describe electronic transport in disordered metals, one can more or less successfully apply extended and modified conventional theoretical concepts developed for electron transport in ordered crystalline materials, such as the Boltzmann kinetic equation. Therefore, we do not describe electronic transport in disordered metals here. We can recommend a comprehensive monograph to interested readers [9.13], in which modern concepts about conduction in disordered metals are presented beautifully.

Several nice monographs on charge transport in disordered semiconductors are also available. Although many of them were published several years ago (some even decades ago), we can recommend them to the interested reader as a source of information on important experimental results. These results have permitted researchers the present level of understanding of transport phenomena in disordered inorganic and organic materials. A comprehensive collection of experimental data for noncrystalline materials from the books specified above would allow one to obtain a picture of the modern state of experimental research in the field.

We will focus in this chapter on the theoretical description of charge transport in disordered materials, introducing some basic concepts developed to describe electrical conduction. Several excellent books already exist in which a theoretical description of charge transport in disordered materials is the main topic. Among others we can recommend the books of *Shklovskii* and *Efros* [9.14], *Zvyagin* [9.15], *Böttger* and *Bryksin* [9.16], and *Overhof* and *Thomas* [9.17]. There appears to be a time gap in which comprehensive monographs on the theoretical description of electrical conduction in disordered materials were not published. During this period some new and rather powerful theoretical concepts were developed. We present these concepts below, along with some more traditional ones.

9.1 General Remarks on Charge Transport in Disordered Materials

Although the literature on transport phenomena in disordered materials is enormously rich, there are still many open questions in this field due to various problems specific to such materials. In contrast to ordered crystalline semiconductors with well-defined electronic energy structures consisting of energy bands and energy gaps, the electronic energy spectra of disordered materials can be treated as quasi-continuous. Instead of bands and gaps, one can distinguish between extended and localized states in disordered materials. In an extended state, the charge carrier wavefunction is spread over the whole volume of a sample, while the wavefunction of a charge carrier is localized in a spatially restricted region in a localized state, and a charge carrier present in such a state cannot spread out in a plane wave as in ordered materials. Actually, localized electron states are known in ordered systems too. Electrons and holes can be spatially localized when they occupy donors or acceptors or some other impurity states or structural defects in ordered crystalline materials. However, the localized states usually appear as δ-like discrete energy levels in the energy spectra of such materials. In disordered semiconductors, on the other hand, energy levels related to spatially localized states usually fill the energy spectrum continuously. The energy that separates the extended states from the localized ones in disordered materials is called the mobility edge. To be precise, we will mostly consider the energy states for electrons in the following. In this case, the states above the mobility edge are extended and the states below the edge are localized. The localized states lie energetically above the extended states for holes. The energy region between the mobility edges for holes and electrons is called the mobility gap. The latter is analogous to the band gap in ordered systems, although the mobility gap contains energy states, namely the spatially localized states. Since the density of states (DOS), defined as the number of states per unit energy per unit volume, usually decreases when the energy moves from the mobility edges toward the center of the mobility gap, the energy regions of localized states in the vicinity of the mobility edges are called band tails. We would like to emphasize that the charge transport properties depend significantly on the energy spectrum in the vicinity and below the mobility edge (in the band tails). Unfortunately this energy spectrum is not known for almost all disordered materials. A whole variety of optical and electrical investigation techniques have proven unable to determine this spectrum. Since the experimental information on this spectrum is rather vague, it is difficult to develop a consistent theoretical description for charge transport ab initio. The absence of reliable information on the energy spectrum and on the structures of the wavefunctions in the vicinity and below the mobility edges can be considered to be the main problem for researchers attempting to quantitatively describe the charge transport properties of disordered materials.

An overview of the energy spectrum in a disordered semiconductor is shown in Fig. 9.1. The energy levels ε_v and ε_c denote the mobility edges for the valence and conduction bands, respectively. Electron states in the mobility gap between these energies are spatially localized. The states below ε_v and above ε_c can be occupied by delocalized holes and electrons. Some peaks in the DOS are shown in the mobility gap, which can be created by some defects with particularly high concentrations. Although there is a consensus between researchers on the general view of the DOS in disordered materials, the particular structure of the energy spectrum is not known for most disordered systems. From a theoretical point of view, it is enormously difficult to calculate this spectrum.

There are several additional problems that make the study of charge transport in disordered materials more difficult than in ordered crystalline semiconductors. The particular spatial arrangements of atoms and molecules in different samples with the same chemical composition can differ from each other depending on the preparation conditions. Hence, when discussing electrical conduction in disordered materials one often should specify the preparation conditions. Another problem is related to the long-time relaxation processes in disordered systems. Usually these systems are not in thermodynamic equilibrium and the slow relaxation of the atoms toward the equilibrium arrangement can lead to some changes in electrical conduction proper-

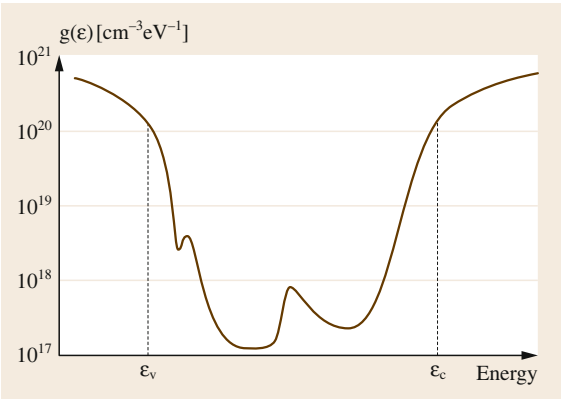

Fig. 9.1 Density of states of a noncrystalline semiconductor (schematic); ε_v and ε_c correspond to mobility edges in the conduction band and the valence band, respectively

ties. In some disordered materials a long-time electronic relaxation can affect the charge transport properties too, particularly at low temperatures, when electronic spatial rearrangements can be very slow. At low temperatures, when tunneling electron transitions between localized states dominate electrical conduction, this long-time electron relaxation can significantly affect the charge transport properties.

It is fortunate that, despite these problems, some general transport properties of disordered semiconductors have been established. Particular attention is usually paid to the temperature dependence of the electrical conductivity, since this dependence can indicate the underlying transport mechanism. Over a broad temperature range, the direct current (DC) conductivity in disordered materials takes the form

$$\sigma = \sigma_0 \exp\left[-\left(\frac{\Delta(T)}{k_B T}\right)^{\beta}\right], \tag{9.1}$$

where the pre-exponential factor σ_0 depends on the underlying system and the power exponent β depends on the material and also sometimes on the temperature range over which the conductivity is studied; $\Delta(T)$ is the activation energy. In many disordered materials, like vitreous and amorphous semiconductors, σ_0 is of the order of 10^2–$10^4\,\Omega^{-1}\,\mathrm{cm}^{-1}$. In such materials the power exponent β is close to unity at temperatures close to and higher than the room temperature, while at lower temperatures β can be significantly smaller than unity. In organic disordered materials, values of β that are larger than unity also have been reported. For such systems the value $\beta \approx 2$ is usually considered to be appropriate [9.18].

Another important characteristic of the electrical properties of a disordered material is its alternating current (AC) conductivity measured when an external alternating electric field with some frequency ω is applied. It has been established in numerous experimental studies that the real part of the AC conductivity in most disordered semiconductors depends on the frequency according to the power law

$$\mathrm{Re}\,\sigma(\omega) = C\omega^s\,, \tag{9.2}$$

where C is constant and the power s is usually smaller than unity. This power law has been observed in numerous materials at different temperatures over a wide frequency range. This frequency dependence differs drastically from that predicted by the standard kinetic theory developed for quasi-free charge carriers in crystalline systems. In the latter case, the real part of the AC conductivity has the frequency dependence

$$\mathrm{Re}\,\sigma(\omega) = \frac{ne^2}{m}\frac{\tau}{1+\omega^2\tau^2}\,, \tag{9.3}$$

where n is the concentration of charge carriers, e is the elementary charge, m is the effective mass and τ is the momentum relaxation time. Since the band electrons in crystalline semiconductors usually have rather short momentum relaxation times, $\tau \approx 10^{-14}$ s, the contribution of charge carriers in delocalized states to the AC conductivity usually does not depend on frequency at $\omega \ll \tau^{-1}$. Therefore, the observed frequency dependence described by (9.2) should be ascribed to the contribution of charge carriers in localized states.

One of the most powerful tools used to study the concentrations of charge carriers and their mobilities in crystalline semiconductors is the provided by measurements of the Hall constant, R_H. Such measurements also provide direct and reliable information about the sign of the charge carriers in crystalline materials. Unfortunately, this is not the case for disordered materials. Moreover, several anomalies have been established for Hall measurements in the latter systems. For example, the sign of the Hall constant in disordered materials sometimes differs from that of the thermoelectric power, α. This anomaly has not been observed in crystalline materials. The anomaly has been observed in liquid and solid noncrystalline semiconductors. Also, in some materials, like amorphous arsenic, a-As, $R_H > 0$, $\alpha < 0$, while in many other materials other combinations with different signs of R_H and α have been experimentally established.

In order to develop a theoretical picture of the transport properties of any material, the first issues to clarify are the spectrum of the energy states for charge carriers and the spatial structure of such states. Since these two central issues are yet to be answered properly for noncrystalline materials, the theory of charge transport in disordered systems should be considered to be still in its embryonic stage.

The problem of deducing electron properties in a random field is very complicated, and the solutions obtained so far only apply to some very simple models. One of them is the famous Anderson model that illustrates the localization phenomenon caused by random disorder [9.19]. In this model, one considers a regular system of rectangular potential wells with randomly varying depths, as shown schematically in Fig. 9.2. The ground state energies of the wells are assumed to be randomly distributed over the range with a width of W. First, one considers the ordered version of the model, with W equal to zero. According to conventional band theory, a narrow band arises in the ordered system where the energy width depends on the overlap integral I between the electron wavefunctions in the adjusting wells. The eigenstates in such a model are delocalized with wavefunctions of the Bloch type. This is trivial. The problem is to find the solution for a finite

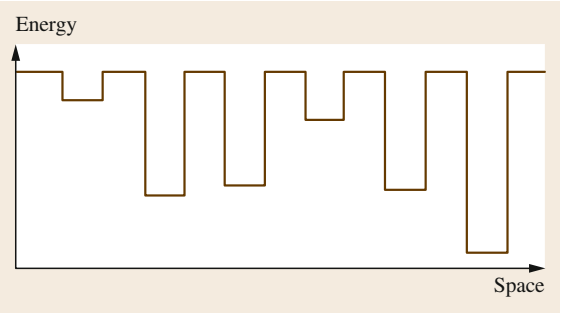

Fig. 9.2 Anderson model of disorder potential

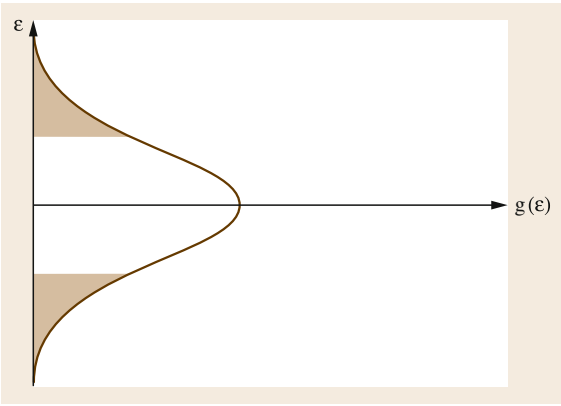

Fig. 9.3 Density of states in the Anderson model. *Hatched regions* in the tails correspond to spatially localized states

degree of disorder ($W \neq 0$). The result from the Anderson model for such a case is described as follows. At some particular value for the ratio $W/(zI)$, where z is the coordination number of the lattice, all electron states of the system are spatially localized. At smaller values of $W/(zI)$ some states in the outer regions of the DOS are localized and other states in the middle of the DOS energy distribution are spatially extended, as shown schematically in Fig. 9.3. This is one of the most famous results in the transport theory of disordered systems. When considering this result, one should note the following points. (i) It was obtained using a single-electron picture without taking into account long-range many-particle interactions. However, in disordered systems with localized electrons such interactions can lead to the localization of charge carriers and they often drastically influence the energy spectrum [9.14]. Therefore the applicability of the single-electron Anderson result to real systems is questionable. (ii) Furthermore, the energy structure of the Anderson model shown in Fig. 9.3 strongly contradicts that observed in real disordered materials. In real systems, the mobility gap is located between the mobility edges, as shown in Fig. 9.1, while in the Anderson model the energy region between the mobility edges is filled with delocalized states. Moreover, in one-dimensional and in some two-dimensional systems, the Anderson model predicts that all states are localized at any amount of disorder. These results are of little help when attempting to interpret the DOS scheme in Fig. 9.1.

A different approach to the localization problem is to try to impose a random potential $V(x)$ onto the band structure obtained in the frame of a traditional band theory. Assuming a classical smoothly varying (in space) potential $V(x)$ with a Gaussian distribution function

$$F(V) = \frac{1}{\varepsilon_0\sqrt{2\pi}} \exp\left(-\frac{V^2}{2\varepsilon_0^2}\right), \tag{9.4}$$

one can solve the localization problem using the classical percolation theory illustrated in Fig. 9.4. In Fig. 9.4a, an example of a disorder potential experienced by electrons is shown schematically. In Fig. 9.4b and Fig. 9.4c the regions below a given energy level E_c are colored black. In Fig. 9.4b this level is positioned very low, so that regions with energies below E_c do not provide a connected path through the system. In Fig. 9.4c an infinite percolation cluster consisting only of black regions exists. The E_c that corresponds to the first appearance of such a connected path is called the classical percolation level [9.14]. Mathematically soluing the percolation problem shows that the mobility edge identified with the classical percolation level in the potential $V(x)$ is shifted with respect to the band edge of the ordered system by an amount $\xi\varepsilon_0$, where $\xi \approx 0.96$ towards the center of the bandgap [9.15]. A similar result, though with a different constant ξ, can be obtained via a quantum-mechanical treatment of a short-range potential $V(x)$ of white-noise type [9.20]. As the amplitude ε_0 of the random potential increases the band gap narrows, while the conduction and valence bands become broader. Although this result is provided by both limiting models – by the classical one with a long-range smoothly varying potential $V(x)$ and by the quantum-mechanical one with a short-range white-noise potential $V(x)$ – none of the existing theories can reliably describe the energy spectrum of a disordered material and the properties of the charge carrier wavefunctions in the vicinity of the mobility edges, in other words in the energy range which is most important for charge transport.

The DC conductivity can generally be represented in the form

$$\sigma = e \int \mu(\varepsilon) n(\varepsilon) \mathrm{d}\varepsilon \,, \tag{9.5}$$

where e is the elementary charge, $n(\varepsilon)\mathrm{d}\varepsilon$ is the concentration of electrons in the energy range between ε and $\varepsilon + \mathrm{d}\varepsilon$ and $\mu(\varepsilon)$ is the mobility of these electrons.

Fig. 9.4a–c Disorder potential landscape experienced by a charge carrier **(a)**. Regions with energies below some given energy level E_c are *colored black*. In **(b)** this level is very low and there is no connected path through the system via *black regions*. In **(c)** the level E_c corresponds to the classical percolation level

The integration is carried out over all energies ε. Under equilibrium conditions, the concentration of electrons $n(\varepsilon)\mathrm{d}\varepsilon$ is determined by the density of states $g(\varepsilon)$ and the Fermi function $f(\varepsilon)$, which depends on the position of the Fermi energy ε_F (or a quasi-Fermi energy in the case of the stationary excitation of electrons)

$$n(\varepsilon) = g(\varepsilon) f(\varepsilon)\,, \tag{9.6}$$

where

$$f(\varepsilon) = \frac{1}{1+\exp\left(\frac{\varepsilon-\varepsilon_F}{k_B T}\right)}\,. \tag{9.7}$$

Here T is the temperature and k_B is the Boltzmann constant.

The Fermi level in almost all known disordered semiconductors under real conditions is situated in the mobility gap – in the energy range which corresponds to spatially localized electron states. The charge carrier mobility $\mu(\varepsilon)$ in the localized states below the mobility edge is much less than that in the extended states above the mobility edge. Therefore, at high temperatures, when a considerable fraction of electrons can be found in the delocalized states above the mobility edge, these states dominate the electrical conductivity of the system. The corresponding transport mechanism under such conditions is similar to that in ordered crystalline semiconductors. Electrons in the states within the energy range of the width, of the order $k_B T$ above the mobility edge, dominate the conductivity. In such a case the conductivity can be estimated as

$$\sigma \approx e\mu_c n(\varepsilon_c) k_B T\,, \tag{9.8}$$

where μ_c is the electron mobility in the states above the mobility edge ε_c, and $n(\varepsilon_c)k_B T$ is their concentration. This equation is valid under the assumption that the typical energy scale of the DOS function $g(\varepsilon)$ above the mobility edge is larger than $k_B T$. The position of the Fermi level in disordered materials usually depends on temperature only slightly. Combining (9.6)–(9.8), one obtains the temperature dependence of the DC conductivity in the form

$$\sigma = \sigma_0 \exp\left(-\frac{\Delta}{k_B T}\right), \tag{9.9}$$

described by (9.1) with $\beta = 1$ and constant activation energy, which is observed in most disordered semiconductors at high temperatures.

In order to obtain the numerical value of the conductivity in this high-temperature regime, one needs to know the density of states in the vicinity of the mobility edge $g(\varepsilon_c)$, and also the magnitude of the electron mobility μ_c in the delocalized states above ε_c. While the magnitude of $g(\varepsilon_c)$ is usually believed to be close to the DOS value in the vicinity of the band edge in crystalline semiconductors, there is no consensus among researchers on the magnitude of μ_c. In amorphous semiconductors μ_c is usually estimated to be in the range of $1-10\,\mathrm{cm}^2/(\mathrm{V\,s})$. Unfortunately, there are no reliable theoretical calculations of this quantity for most disordered materials. The only exception is provided by so-called mixed crystals, which are also sometimes called crystalline solid solutions. In the next section we describe the theoretical method which allows one to estimate μ_c in such systems. This method can be extended to other disordered materials, provided the statistical properties of the disorder potential, essential for electron scattering, are known.

9.2 Charge Transport in Disordered Materials via Extended States

The states with energies below ε_v and above ε_c in disordered materials are believed to possess similar properties to those of extended states in crystals. Various experimental data suggest that these states in disordered materials are delocalized states. However, traditional band theory is largely dependent upon the system having translational symmetry. It is the periodic atomic structure of crystals that allows one to describe

electrons and holes within such a theory as quasi-particles that exhibit behavior similar to that of free particles in vacuum, albeit with a renormalized mass (the so-called *effective mass*). The energy states of such quasi-particles can be described by their momentum values. The wavefunctions of electrons in these states (the so-called Bloch functions) are delocalized. This means that the probability of finding an electron with a given momentum is equal at corresponding points of all elementary cells of the crystal, independent on the distance between the cells.

Strictly speaking, the traditional band theory fails in the absence of translational symmetry – for disordered systems. Nevertheless, one still assumes that the charge carriers present in delocalized states in disordered materials can be approximately described by wavefunctions with a spatially homogeneous probability of finding a charge carrier with a given quasi-momentum. As for crystals, one starts from the quasi-free particle picture and considers the scattering effects in a perturbation approach following the Boltzmann kinetic description. This description is valid if the de Broglie wavelength of the charge carrier $\lambda = \hbar/p$ is much less than the mean free path $l = v\tau$, where τ is the momentum relaxation time and p and v are the characteristic values of the momentum and velocity, respectively. This validity condition for the description based on the kinetic Boltzmann equation can also be expressed as $\hbar/\tau \ll \varepsilon$, where ε is the characteristic kinetic energy of the charge carriers, which is equal to $k_B T$ for a nondegenerate electron gas and to the Fermi energy in the degenerate case. While this description seems valid for delocalized states far from the mobility edges, it fails for energy states in the vicinity of the mobility edges. So far, there has been no consensus between the theorists on how to describe charge carrier transport in the latter states. Moreover, it is not clear whether the energy at which the carrier mobility drops coincides with the mobility edge or whether it is located above the edge in the extended states. Numerous discussions of this question, mostly based on the scaling theory of localization, can be found in special review papers. For the rest of this section, we skip this rather complicated subject and instead we focus on the description of charge carrier transport in a semiconductor with a short-range random disorder potential of white-noise type. This seems to be the only disordered system where a reliable theory exists for charge carrier mobility via extended states above the mobility edge. Semiconductor solid solutions provide an example of a system with this kind of random disorder [9.20–25].

Semiconductor solid solutions A_xB_{1-x} (mixed crystals) are crystalline semiconductors in which the sites of the crystalline sublattice can be occupied by atoms of two different types, A and B. Each site can be occupied by either an A or a B atom with some given probability x between zero and unity. The value x is often called the composition of the material. Due to the random spatial distributions of the A and B atoms, local statistical fluctuations in the composition inside the sample are unavoidable, meaning that mixed crystals are disordered systems. Since the position of the band edge depends on the composition x, these fluctuations in local x values lead to the disorder potential for electrons and holes within the crystal. To be precise, we will consider the influence of the random potential on a conduction band electron. Let $E_c(x)$ be the conduction band minimum for a crystal with composition x. In Fig. 9.5 a possible schematic dependence $E_c(x)$ is shown. If the average composition for the whole sample is x_0, the local positions of the band edge $E_c(x)$ fluctuate around the average value $E_c(x_0)$ according to the fluctuations of the composition x around x_0. For small deviations in composition Δx from the average value, one can use the linear relation

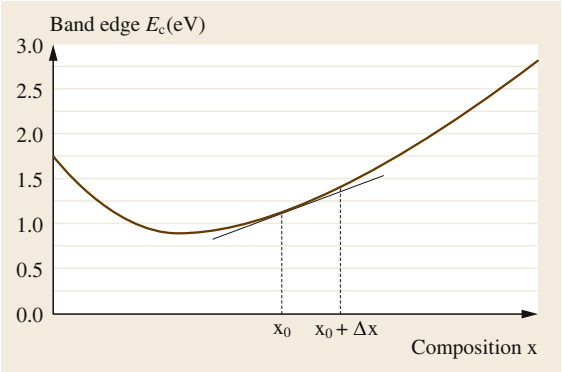

Fig. 9.5 Schematic dependence of the conduction band edge ε_c on composition x in a mixed crystal A_xB_{1-x}

$$E_c(x_0 + \Delta x) = E_c(x_0) + \alpha \Delta x \,, \tag{9.10}$$

where

$$\alpha = \left.\frac{dE_c(x)}{dx}\right|_{x=x_0} . \tag{9.11}$$

If the deviation of the concentration of A atoms from its mean value in some region of a sample is $\xi(r)$ and the total concentration of (sub)lattice sites is N, the deviation of the composition in this region is $\Delta x = \xi(r)/N$, and the potential energy of an electron at the bottom of the conduction band is

$$V(r) = \alpha \frac{\xi(r)}{N} . \tag{9.12}$$

Although one calls the disorder in such systems a *short-range* disorder, it should be noted that the consideration

is valid only for fluctuations that are much larger than the lattice constant of the material. The term *short-range* is due to the assumption that the statistical properties of the disorder are absolutely uncorrelated. This means that potential amplitudes in the adjusting spatial points are completely uncorrelated to each other. Indeed, it is usually assumed that the correlation function of the disorder in mixed crystals can be approximated by a white-noise correlation function of the form

$$\left\langle \xi(r)\xi(r')\right\rangle = x(1-x)N\delta(r-r') \,. \tag{9.13}$$

The random potential caused by such compositional fluctuations is then described by the correlation function [9.20]

$$\left\langle V(r)V(r')\right\rangle = \gamma\delta(r-r') \tag{9.14}$$

with

$$\gamma = \frac{\alpha^2}{N}x(1-x) \,. \tag{9.15}$$

Charge carriers in mixed crystals are scattered by compositional fluctuations. As is usual in kinetic descriptions of free electrons, the fluctuations on the spatial scale of the order of the electron wavelength are most efficient. Following *Shlimak* et al. [9.23], consider an isotropic quadratic energy spectrum

$$\varepsilon_p = \frac{p^2}{2m} \,, \tag{9.16}$$

where p and m are the quasi-momentum and the effective mass of an electron, respectively. The scattering rate for such an electron is

$$\nu_p = \frac{2\pi}{\hbar}\sum_q \left\langle \left|V_q\right|^2\right\rangle \left(1-\cos\vartheta_q\right)\delta\left(\varepsilon_p-\varepsilon_{p-q}\right) \,, \tag{9.17}$$

where ϑ_q is the scattering angle and

$$\left\langle \left|V_q\right|^2\right\rangle = \frac{1}{\Omega}\int \mathrm{d}^3 r \exp\left(\mathrm{i}qr\right)\left\langle V(r)V(0)\right\rangle \,. \tag{9.18}$$

The quantity Ω in this formula is the normalization volume. Using the correlation function (9.14), one obtains the relation

$$\left\langle \left|V_q\right|^2\right\rangle = \frac{\alpha^2 x(1-x)}{\Omega N} \,, \tag{9.19}$$

which shows that the scattering by compositional fluctuations is equivalent to that by a short-range potential [9.23]. Substituting (9.19) into (9.17) one obtains the following expression for the scattering rate [9.20]

$$\nu_p = \frac{\alpha^2 x(1-x)mp}{\pi\hbar^4 N} \,. \tag{9.20}$$

This formula leads to an electron mobility of the following form in the framework of the standard Drude approach [9.20, 23]

$$\mu_\mathrm{C} = \frac{\pi^{3/2}}{2\sqrt{2}}\frac{e\hbar^4 N}{\alpha^2 x(1-x)m^{5/2}(k_\mathrm{B}T)^{1/2}} \,. \tag{9.21}$$

Very similar formulae can be found in many recent publications (see for example *Fahy* and *O'Reily* [9.26]). It has also been modified and applied to two-dimensional systems [9.27] and to disordered diluted magnetic semiconductors [9.28].

It would not be difficult to apply this theoretical description to other disordered systems, provided the correlation function of the disorder potential takes the form of (9.14) with known amplitude γ. However, it is worth emphasizing that the short-range disorder of white-noise type considered here is a rather simple model that cannot be applied to most disordered materials. Therefore, we can conclude that the problem of theoretically describing charge carrier mobility via delocalized states in disordered materials is still waiting to be solved.

In the following section we present the general concepts developed to describe electrical conduction in disordered solids at temperatures where tunneling transitions of electrons between localized states significantly contribute to charge transport.

9.3 Hopping Charge Transport in Disordered Materials via Localized States

Electron transport via delocalized states above the mobility edge dominates the electrical conduction of disordered materials only at temperatures high enough to cause a significant fraction of the charge carriers fill these states. As the temperature decreases, the concentration of the electrons described by (9.9) decreases exponentially and so their contribution to electrical conductivity diminishes. Under these circumstances, tunneling transitions of electrons between localized states in the band tails dominate the charge transport in dis-

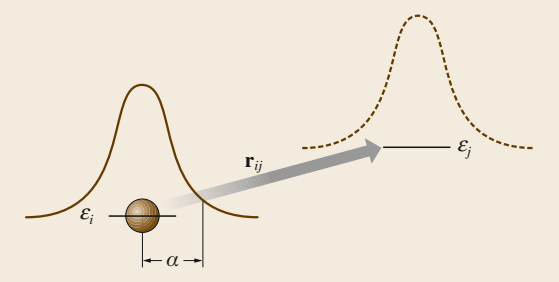

Fig. 9.6 Hopping transition between two localized states i and j with energies of ε_i and ε_j, respectively. The *solid* and *dashed lines* depict the carrier wavefunctions at sites i and j, respectively; α is the localization radius

ordered semiconductors. This transport regime is called hopping conduction, since the incoherent sequence of tunneling transitions of charge carriers resembles a series of their hops between randomly distributed sites. Each site in this picture provides a spatially localized electron state with some energy ε. In the following we will assume that the localized states for electrons (concentration N_0) are randomly distributed in space and their energy distribution is described by the DOS function $g(\varepsilon)$

$$g(\varepsilon) = \frac{N_0}{\varepsilon_0} G\left(\frac{\varepsilon}{\varepsilon_0}\right), \tag{9.22}$$

where ε_0 is the energy scale of the DOS distribution.

The tunneling transition probability of an electron from a localized state i to a localized state j that is lower in energy depends on the spatial separation r_{ij} between the sites i and j as

$$\nu_{ij}(r) = \nu_0 \exp\left(-\frac{2r_{ij}}{\alpha}\right), \tag{9.23}$$

where α is the localization length, which we assume to be equal for sites i and j. This length determines the exponential decay of the electron wavefunction in the localized states, as shown in Fig. 9.6. The pre-exponential factor ν_0 in (9.23) depends on the electron interaction mechanism that causes the transition. Usually it is assumed that electron transitions contributing to charge transport in disordered materials are caused by interactions of electrons with phonons. Often the coefficient ν_0 is simply assumed to be of the order of the phonon frequency ($\approx 10^{13}\,\mathrm{s}^{-1}$), although a more rigorous approach is in fact necessary to determine ν_0. This should take into account the particular structure of the electron localized states and also the details of the interaction mechanism [9.29, 30].

When an electron transits from a localized state i to a localized state j that is higher in energy, the transition rate depends on the energy difference between the states. This difference is compensated for by absorbing a phonon with the corresponding energy [9.31]

$$\nu_{ij}(r, \varepsilon_i, \varepsilon_j) = \nu_0 \exp\left(-\frac{2r_{ij}}{a}\right) \times \exp\left(-\frac{\varepsilon_j - \varepsilon_i + |\varepsilon_j - \varepsilon_i|}{2k_\mathrm{B}T}\right). \tag{9.24}$$

Equations (9.23) and (9.24) were written for the case in which the electron occupies site i whereas site j is empty. If the system is in thermal equilibrium, the occupation probabilities of sites with different energies are determined by Fermi statistics. This effect can be taken into account by modifying (9.24) and adding terms that account for the relative energy positions of sites i and j with respect to the Fermi energy ε_F. Taking into account these occupation probabilities, one can write the transition rate between sites i and j in the form [9.31]

$$\nu_{ij} = \nu_0 \exp\left(-\frac{2r_{ij}}{a}\right) \times \exp\left(-\frac{|\varepsilon_i - \varepsilon_\mathrm{F}| + |\varepsilon_j - \varepsilon_\mathrm{F}| + |\varepsilon_j - \varepsilon_i|}{2k_\mathrm{B}T}\right). \tag{9.25}$$

Using these formulae, the theoretical description of hopping conduction is easily formulated. One has to calculate the conductivity provided by transition events (the rates of which are described by (9.25)) in the manifold of localized states (where the DOS is described by (9.22)).

9.3.1 Nearest-Neighbor Hopping

Before presenting the correct solution to the hopping problem we would like to emphasize the following. The style of the theory for electron transport in disordered materials via localized states significantly differs from that used for theories of electron transport in ordered crystalline materials. While the description is usually based on various averaging procedures in crystalline systems, in disordered systems these averaging procedures can lead to extremely erroneous results. We believe that it is instructive to analyze some of these approaches in order to illustrate the differences between the descriptions of charge transport in ordered and disordered materials. To treat the scattering rates of electrons in ordered crystalline materials, one usually proceeds by averaging the scattering rates over the ensemble of scattering events. A similar procedure is often attempted for disordered systems too, although

various textbooks (see, for instance, *Shklovskii* and *Efros* [9.14]) illustrate how erroneous such an approach can be in the case of disordered materials.

Let us consider the simplest example of hopping processes, namely the hopping of an electron through a system of isoenergetic sites randomly distributed in space with some concentration N_0. It will be always assumed in this chapter that electron states are strongly localized and the strong inequality $N_0\alpha^3 \ll 1$ is fulfilled. In such a case the electrons prefer to hop between the spatially nearest sites and therefore this transport regime is often called nearest-neighbor hopping (NNH). This type of hopping transport takes place in many real systems at temperatures where the thermal energy k_BT is larger than the energy scale of the DOS. In such situations the energy-dependent terms in (9.24) and (9.25) do not play any significant role and the hopping rates are determined solely by the spatial terms. The rate of transition of an electron between two sites i and j is described in this case by (9.23). The average transition rate is usually obtained by weighting this expression with the probability of finding the nearest neighbor at some particular distance r_{ij}, and by integrating over all possible distances

$$\begin{aligned}\langle\nu\rangle &= \int_0^\infty \mathrm{d}r\nu_0 \\ &\quad\times \exp\left(-\frac{2r}{\alpha}\right) 4\pi r^2 N_0 \exp\left(-\frac{4\pi}{3}r^3 N_0\right) \\ &\approx \pi\nu_0 N_0\alpha^3 \,.\end{aligned} \tag{9.26}$$

Assuming that this average hopping rate describes the mobility, diffusivity and conductivity of charge carriers, one apparently comes to the conclusion that these quantities are linearly proportional to the density of localized states N_0. However, experiments evidence an exponential dependence of the transport coefficients on N_0.

Let us look therefore at the correct solution to the problem. This solution is provided in the case considered here, $N_0\alpha^3 \ll 1$, by percolation theory (see, for instance, *Shklovskii* and *Efros* [9.14]). In order to find the transport path, one connects each pair of sites if the relative separation between the sites is smaller than some given distance R, and checks whether there is a continuous path through the system via such sites. If such a path is absent, the magnitude of R is increased and the procedure is repeated. At some particular value $R = R_c$, a continuous path through the infinite system via sites with relative separations $R < R_c$ arises. Various mathematical considerations give the following relation

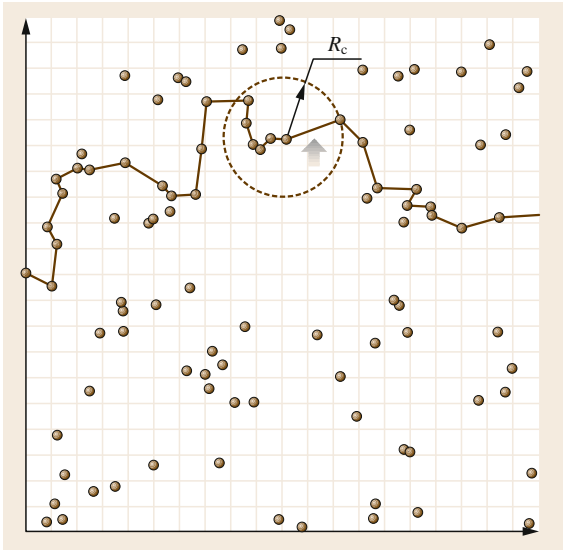

Fig. 9.7 A typical transport path with the lowest resistance. *Circles* depict localized states. The *arrow* points out the most *difficult* transition, with length R_c

for R_c [9.14]

$$\frac{4\pi}{3}N_0R_c^3 = B_c \,, \tag{9.27}$$

where $B_c = 2.7 \pm 0.1$ is the average number of neighboring sites available within a distance of less than R_c. The corresponding value of R_c should be inserted into (9.23) in order to determine kinetic coefficients such as the mobility, diffusivity and conductivity. The idea behind this procedure is as follows. Due to the exponential dependence of the transition rates on the distances between the sites, the rates for electron transitions over distances $r < R_c$ are much larger than those over distances R_c. Such fast transitions do not play any significant role as a limiting factor in electron transport and so they can be neglected in calculations of the resistivity of the system. Transitions over distances R_c are the slowest among those that are necessary for DC transport and hence such transitions determine the conductivity. The structure of the percolation cluster responsible for charge transport is shown schematically in Fig. 9.7. The transport path consists of quasi-one-dimensional segments, each containing a *difficult* transition over the distance $\approx R_c$. Using (9.23) and (9.27), one obtains the dependence of the conductivity on the concentration of localization sites in the form

$$\sigma = \sigma_0 \exp\left(-\frac{\gamma}{\alpha N_0^{1/3}}\right), \tag{9.28}$$

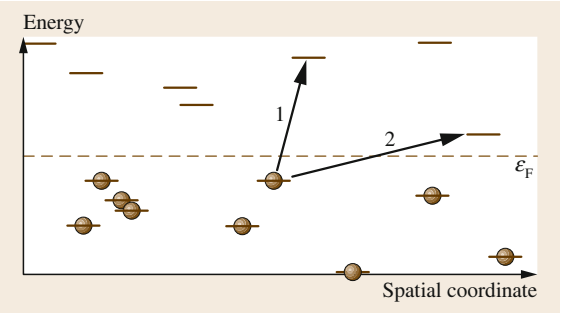

Fig. 9.8 Two alternative hopping transitions between occupied states (*filled circles*) and unoccupied states. The *dashed line* depicts the position of the Fermi level. Transitions (1) and (2) correspond to nearest-neighbor hopping and variable-range hopping regimes, respectively

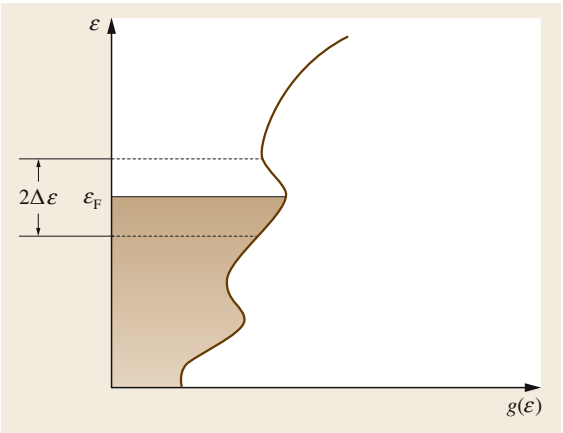

Fig. 9.9 Effective region in the vicinity of the Fermi level where charge transport takes place at low temperatures

where σ_0 is the concentration-independent pre-exponential factor and $\gamma = 1.73 \pm 0.03$. Such arguments do not allow one to determine the exponent in the kinetic coefficients with an accuracy better than a number of the order of unity [9.14]. One should note that the quantity in the exponent in (9.28) is much larger than unity for a system with strongly localized states when the inequality $N_0\alpha^3 \ll 1$ is valid. This inequality justifies the above derivation. The dependence described by (9.28) has been confirmed in numerous experimental studies of the hopping conductivity via randomly placed impurity atoms in doped crystalline semiconductors [9.14]. The drastic difference between this correct result and the erroneous one based on (9.26) is apparent. Unfortunately, the belief of many researchers in the validity of the procedure based on the averaging of hopping rates is so strong that the agreement between (9.28) and experimental data is often called occasional. We would like to emphasize once more that the ensemble averaging of hopping rates leads to erroneous results. The magnitude of the average rate in (9.26) is dominated by rare configurations of very close pairs of sites with separations of the order of the localization length α. Of course, such pairs allow very fast electron transitions, but electrons cannot move over considerable distances using only these close pairs. Therefore the magnitude of the average transition rate is irrelevant for calculations of the hopping conductivity. The correct concentration dependence of the conductivity is given by (9.28). This result was obtained under the assumption that only spatial factors determine transition rates of electrons via localized states. This regime is valid at reasonably high temperatures.

If the temperature is not as high and the thermal energy k_BT is smaller than the energy spread of the localized states involved in the charge transport process, the problem of calculating the hopping conductivity becomes much more complicated. In this case, the interplay between the energy-dependent and the distance-dependent terms in (9.24) and (9.25) determines the conductivity. The lower the temperature, the more important the energy-dependent terms in the expressions for transition probabilities of electrons in (9.24) and (9.25) become. If the spatially nearest-neighboring sites have very different energies, as shown in Fig. 9.8, the probability of an upward electron transition between these sites can be so low that it would be more favorable for this electron to hop to a more distant site at a closer energy. Hence the typical lengths of electron transitions increase with decreasing temperature. This transport regime was termed *variable-range hopping*. Next we describe several useful concepts developed to describe this transport regime.

9.3.2 Variable-Range Hopping

The concept of variable-range hopping (VRH) was put forward by Mott (see *Mott* and *Davis* [9.32]) who considered electron transport via a system of randomly distributed localized states at low temperatures. We start by presenting Mott's arguments. At low temperatures, electron transitions between states with energies in the vicinity of the Fermi level are most efficient for transport since filled and empty states with close energies can only be found in this energy range. Consider the hopping conductivity resulting from energy levels within a narrow energy strip with width $2\Delta\varepsilon$ symmetric to the Fermi level shown in Fig. 9.9. The energy width of the strip useful for electron transport can be determined from the relation

$$g(\varepsilon_F)\Delta\varepsilon r^3(\Delta\varepsilon) \approx 1 \,. \qquad (9.29)$$

This criterion is similar to that used in (9.27), although we do not care about numerical coefficients here. Here we have to consider the percolation problem in four-dimensional space since in addition to the spatial terms considered in Sect. 9.3.1 we now have to consider the energy too. The corresponding percolation problem for the transition rates described by (9.25) has not yet been solved precisely. In (9.29) it is assumed that the energy width $2\Delta\varepsilon$ is rather small and that the DOS function $g(\varepsilon)$ is almost constant in the range $\varepsilon_F \pm \Delta\varepsilon$. One can obtain the typical hopping distance from (9.29) as a function of the energy width $\Delta\varepsilon$ in the form

$$r(\Delta\varepsilon) \approx [g(\varepsilon_F)\Delta\varepsilon]^{-1/3} , \tag{9.30}$$

and substitute it into (9.24) in order to express the typical hopping rate

$$\nu = \nu_0 \exp\left(-\frac{2[g(\varepsilon_F)\Delta\varepsilon]^{-1/3}}{\alpha} - \frac{\Delta\varepsilon}{k_B T}\right) . \tag{9.31}$$

The optimal energy width $\Delta\varepsilon$ that provides the maximum hopping rate can be determined from the condition $d\nu/d\Delta\varepsilon = 0$. The result reads

$$\Delta\varepsilon = \left(\frac{2k_B T}{3g^{1/3}(\varepsilon_F)}\right)^{3/4} . \tag{9.32}$$

After substitution of (9.32) into (9.31) one obtains Mott's famous formula for temperature-dependent conductivity in the VRH regime

$$\sigma = \sigma_0 \exp\left[-\left(\frac{T_0}{T}\right)^{1/4}\right] , \tag{9.33}$$

where T_0 is the characteristic temperature

$$T_0 = \frac{\beta}{k_B g(\varepsilon_F)\alpha^3} . \tag{9.34}$$

Mott gave only a semi-quantitative derivation of (9.33), from which the exact value of the numerical constant β cannot be determined. Various theoretical studies in thee-dimensional (3-D) systems suggest values for β in the range $\beta = 10.0$ to $\beta = 37.8$. According to our computer simulations, the appropriate value is close to $\beta = 17.6$.

Mott's law implies that the density of states in the vicinity of the Fermi level is energy-independent. However, it is known that long-range electron–electron interactions in a system of localized electrons cause a gap (the so-called Coulomb gap) in the DOS in the vicinity of the Fermi energy [9.33, 34]. The gap is shown schematically in Fig. 9.10. Using simple semiquantitative arguments, *Efros* and *Shklovskii* [9.33] suggested a parabolic shape for the DOS function

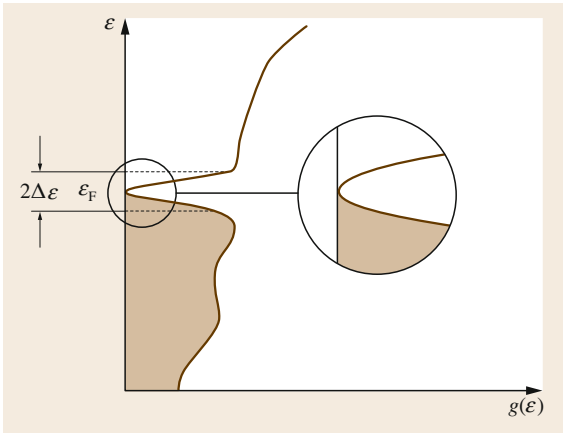

Fig. 9.10 Schematic view of the Coulomb gap. The *insert* shows the parabolic shape of the DOS near the Fermi level

$$g(\varepsilon) = \frac{\eta\,\kappa^3}{e^6}(\varepsilon - \varepsilon_F)^2 , \tag{9.35}$$

where κ is the dielectric constant, e is the elementary charge and η is a numerical coefficient. This result was later confirmed by numerous computer simulations (see, for example, *Baranovskii* et al. [9.35]). At low temperatures, the density of states near the Fermi level has a parabolic shape, and it vanishes exactly at the Fermi energy. As the temperature rises, the gap disappears (see, for example, *Shlimak* et al. [9.36]).

As we have seen above, localized states in the vicinity of the Fermi energy are the most useful for transport at low temperatures. Therefore the Coulomb gap essentially modifies the temperature dependence of the hopping conductivity in the VRH regime at low temperatures. The formal analysis of the T-dependence of the conductivity in the presence of the Coulomb gap is similar to that for the Mott's law discussed above. Using the parabolic energy dependence of the DOS function, one arrives at the result

$$\sigma = \sigma_0 \exp\left[-\left(\frac{\tilde{T}_0}{T}\right)^{1/2}\right] \tag{9.36}$$

with $\tilde{T}_0 = \tilde{\beta}e^2/(\kappa\alpha k_B)$, where $\tilde{\beta}$ is a numerical coefficient.

Equations (9.33) and (9.36) belong to the most famous theoretical results in the field of variable-range hopping conduction. However these formulae are usually of little help to researchers working with essentially

noncrystalline materials, such as amorphous, vitreous or organic semiconductors. The reason is as follows. The above formulae were derived for the cases of either constant DOS (9.33) or a parabolic DOS (9.36) in the energy range associated with hopping conduction. These conditions can usually be met in the impurity band of a lightly doped crystalline semiconductor. In the most disordered materials, however, the energy distribution of the localized states is described by a DOS function that is very strongly energy-dependent. In amorphous, vitreous and microcrystalline semiconductors, the energy dependence of the DOS function is believed to be exponential, while in organic materials it is usually assumed to be Gaussian. In these cases, new concepts are needed in order to describe the hopping conduction. In the next section we present these new concepts and calculate the way the conductivity depends on temperature and on the concentration of localized states in various significantly noncrystalline materials.

9.3.3 Description of Charge-Carrier Energy Relaxation and Hopping Conduction in Inorganic Noncrystalline Materials

In most inorganic noncrystalline materials, such as vitreous, amorphous and polycrystalline semiconductors, the localized states for electrons are distributed over a rather broad energy range with a width of the order of an electronvolt. The DOS function that describes this energy distribution in such systems is believed to have a purely exponential shape

$$g(\varepsilon) = \frac{N_0}{\varepsilon_0} \exp\left(-\frac{\varepsilon}{\varepsilon_0}\right), \tag{9.37}$$

where the energy ε is counted positive from the mobility edge towards the center of the mobility gap, N_0 is the total concentration of localized states in the band tail, and ε_0 determines the energy scale of the tail. To be precise, we consider that electrons are the charge carriers here. The result for holes can be obtained in an analogous way. Values of ε_0 in inorganic noncrystalline materials are believed to vary between 0.025 and 0.05 eV, depending on the system under consideration.

It is worth noting that arguments in favor of a purely exponential shape for the DOS in the band tails of inorganic noncrystalline materials described by (9.37) cannot be considered to be well justified. They are usually based on a rather ambiguous interpretation of experimental data. One of the strongest arguments in favor of (9.37) is the experimental observation of the exponential decay of the light absorption coefficient for photons with an energy deficit ε with respect to the energy width of the mobility gap (see, for example, *Mott* and *Davis* [9.32]). One should mention that this argument is valid only under the assumption that the energy dependence of the absorption coefficient is determined solely by the energy dependence of the DOS. However, in many cases the matrix element for electron excitation by a photon in noncrystalline materials also strongly depends on energy [9.14, 37]. Hence any argument for the shape of the DOS based on the energy dependence of the light absorption coefficient should be taken very cautiously. Another argument in favor of (9.37) comes from the measurements of dispersive transport in time-of-flight experiments. In order to interpret the observed time dependence of the mobility of charge carriers, one usually assumes that the DOS for the band tail takes the form of (9.37) (see, for example, *Orenstein* and *Kastner* [9.38]). One of the main reasons for such an assumption is probably the ability to solve the problem analytically without elaborate computer work.

In the following we start our consideration of the problem by also assuming that the DOS in a band tail of a noncrystalline material has an energy dependence that is described by (9.37). This simple function will allow us to introduce some valuable concepts that have been developed to describe dynamic effects in noncrystalline materials in the most transparent analytical form. We first present the concept of the so-called transport energy, which, in our view, provides the most transparent description of the charge transport and energy relaxation of electrons in noncrystalline materials.

The Concept of the Transport Energy

The crucial role of a particular energy level in the hopping transport of electrons via localized band-tail states with the DOS described by (9.37) was first recognized by *Grünewald* and *Thomas* [9.39] in their numerical analysis of equilibrium variable-range hopping conductivity. This problem was later considered by *Shapiro* and *Adler* [9.40], who came to the same conclusion as Grünewald and Thomas, namely that the vicinity of one particular energy level dominates the hopping transport of electrons in the band tails. In addition, they achieved an analytical formula for this level and showed that its position does not depend on the Fermi energy.

Independently, the rather different problem of nonequilibrium energy relaxation of electrons by hopping through the band tail with the DOS described by (9.37) was solved at the same time by *Monroe* [9.41]. He showed that, starting from the mobility edge, an electron most likely makes a series of hops downward in energy. The manner of the relaxation process changes at some particular energy ε_t, which Monroe called the transport energy (TE). The hopping process near and below TE resembles a multiple-trapping type

of relaxation, with the TE playing a role similar to the mobility edge. In the multiple-trapping relaxation process [9.38], only electron transitions between delocalized states above the mobility edge and the localized band-tail states are allowed, while hopping transitions between the localized tail states are neglected. Hence, every second transition brings the electron to the mobility edge. The TE of *Monroe* [9.41] coincides exactly with the energy level discovered by *Grünewald* and *Thomas* [9.39] and by *Shapiro* and *Adler* [9.40] for equilibrium hopping transport.

Shklovskii et al. [9.42] have shown that the same energy level ε_t also determines the recombination and transport of electrons in the nonequilibrium steady state under continuous photogeneration in a system with the DOS described by (9.37).

It is clear, then, that the TE determines both equilibrium and nonequilibrium and both transient and steady-state transport phenomena. The question then arises as to why this energy level is so universal that electron hopping in its vicinity dominates all transport phenomena. Below we derive the TE by considering a single hopping event for an electron localized deep in the band tail. It is the transport energy that maximizes the hopping rate as a final electron energy in the hop, independent of its initial energy [9.43]. All derivations below are carried out for the case $k_BT < \varepsilon_0$.

Consider an electron in a tail state with energy ε_i. According to (9.24), the typical rate of downward hopping of such an electron to a neighboring localized state deeper in the tail with energy $\varepsilon_j \geq \varepsilon_i$ is

$$\nu_{\downarrow}(\varepsilon_i) = \nu_0 \exp\left(-\frac{2r(\varepsilon_i)}{\alpha}\right), \tag{9.38}$$

where

$$r(\varepsilon) \approx \left[\frac{4\pi}{3}\int_{\varepsilon_i}^{\infty} g(x)\mathrm{d}x\right]^{-1/3}. \tag{9.39}$$

The typical rate of upward hopping for such an electron to a state less deep in the tail with energy $\varepsilon_j \leq \varepsilon_i$ is

$$\nu_{\uparrow}(\varepsilon_i,\, \delta) = \nu_0 \exp\left[-\frac{2r(\varepsilon_i-\delta)}{\alpha} - \frac{\delta}{k_BT}\right], \tag{9.40}$$

where $\delta = \varepsilon_i - \varepsilon_j \geq 0$. This expression is not exact. The average nearest-neighbor distance, $r(\varepsilon_i - \delta)$, is based on all states deeper than $\varepsilon_i - \delta$. For the exponential tail, this is equivalent to considering a slice of energy with a width of the order ε_0. This works for a DOS that varies slowly compared with k_BT, but not in general. It is also assumed for simplicity that the localization length, α, does not depend on energy. The latter assumption can be easily jettisoned at the cost of somewhat more complicated forms of the following equations.

We will analyze these hopping rates at a given temperature T, and try to find the energy difference δ that provides the fastest typical hopping rate for an electron placed initially at energy ε_i. The corresponding energy difference δ is determined by the condition

$$\frac{\mathrm{d}\nu_{\uparrow}(\varepsilon_i, \delta)}{\mathrm{d}\delta} = 0\,. \tag{9.41}$$

Using (9.37), (9.39) and (9.40), we find that the hopping rate in (9.40) has its maximum at

$$\delta = \varepsilon_i - 3\varepsilon_0 \ln \frac{3\varepsilon_0(4\pi/3)^{1/3}N_0^{1/3}\alpha}{2k_BT}\,. \tag{9.42}$$

The second term in the right-hand side of (9.42) is called the transport energy ε_t after *Monroe* [9.41]

$$\varepsilon_t = 3\varepsilon_0 \ln \frac{3\varepsilon_0(4\pi/3)^{1/3}N_0^{1/3}\alpha}{2k_BT}\,. \tag{9.43}$$

We see from (9.42) that the fastest hop occurs to the state in the vicinity of the TE, independent of the initial energy ε_i, provided that ε_i is deeper in the tail than ε_t; in other words, if $\delta \geq 0$. This result coincides with that of *Monroe* [9.41]. At low temperatures, the TE ε_t is situated deep in the band tail, and as the temperature rises it moves upward towards the mobility edge. At some temperature T_c, the TE merges with the mobility edge. At higher temperatures, $T > T_c$, the hopping exchange of electrons between localized band tail states becomes inefficient and the dynamic behavior of electrons is described by the well-known multiple-trapping model (see, for instance, *Orenstein* and *Kastner* [9.38]). At low temperatures, $T < T_c$, the TE replaces the mobility edge in the multiple-trapping process [9.41], as shown in Fig. 9.11. The width, W, of the maximum of the hopping rate is determined by the requirement that near ε_t the hopping rate, $\nu_{\uparrow}(\varepsilon_i, \delta)$, differs by less than a factor of e from the value $\nu_{\uparrow}(\varepsilon_i, \varepsilon_i - \varepsilon_t)$. One finds [9.42]

$$W = \sqrt{6\varepsilon_0 k_BT}\,. \tag{9.44}$$

For shallow states with $\varepsilon_i \leq \varepsilon_t$, the fastest hop (on average) is a downward hop to the nearest spatially localized state in the band tail, with the rate determined by (9.38) and (9.39). We recall that the energies of electron states are counted positive downward from the mobility edge towards the center of the mobility gap. This means that electrons in the shallow states with $\varepsilon_i \leq \varepsilon_t$ normally hop

into deeper states with $\varepsilon > \varepsilon_i$, whereas electrons in the deep states with $\varepsilon_i > \varepsilon_t$ usually hop upward in energy into states near ε_t in the energy interval W, determined by (9.44).

This shows that ε_t must play a crucial role in those phenomena, which are determined by electron hopping in the band tails. This is indeed the case, as shown in numerous review articles where comprehensive theories based on the concept of the TE can be found (see, for instance, *Shklovskii* et al. [9.42]). We will consider only one phenomenon here for illustration, namely the hopping energy relaxation of electrons in a system with the DOS described by (9.37). This problem was studied initially by *Monroe* [9.41].

Consider an electron in some localized shallow energy state close to the mobility edge. Let the temperature be low, $T < T_c$, so that the TE, ε_t, lies well below the mobility edge, which has been chosen here as a reference energy, $\varepsilon = 0$. The aim is to find the typical energy, $\varepsilon_d(t)$, of our electron as a function of time, t. At early times, as long as $\varepsilon_d(t) < \varepsilon_t$, the relaxation is governed by (9.38) and (9.39). The depth $\varepsilon_d(t)$ of an electron in the band tail is determined by the condition

$$\nu_{\downarrow}\left[\varepsilon_d(t)\right] t \approx 1 \,. \tag{9.45}$$

This leads to the double logarithmical dependence $\varepsilon_d(t) \propto \varepsilon_0 \ln[\ln(\nu_0 t)] + C$, where constant C depends on $\varepsilon_0, N_0, \alpha$ in line with (9.38) and (9.39). Indeed, (9.38) and (9.45) prescribe the logarithmic form of the time dependence of the hopping distance, $r(t)$, and (9.37) and (9.39) then lead to another logarithmic dependence $\varepsilon_d\left[r(t)\right]$ [9.41]. At the time

$$t_C \approx \nu_0^{-1} \exp\left(\frac{3\varepsilon_0}{k_B T}\right) \tag{9.46}$$

the typical electron energy, $\varepsilon_d(t)$, approaches the TE ε_t, and the style of the relaxation process changes. At $t > t_c$, every second hop brings the electron into states in the vicinity of the TE ε_t from where it falls downward in energy to the nearest (in space) localization site. In the latter relaxation process, the typical electron energy is determined by the condition [9.41]

$$\nu_{\uparrow}\left[\varepsilon_d(t), \varepsilon_t\right] t \approx 1 \,, \tag{9.47}$$

where $\nu_{\uparrow}\left[\varepsilon_d(t), \varepsilon_t\right]$ is the typical rate of electron hopping upward in energy toward the TE [9.41]. This condition leads to a typical energy position of the relaxing electron at time t of

$$\varepsilon_d(t) \approx 3\varepsilon_0 \ln\left[\ln\left(\nu_0 t\right)\right] - \varepsilon_0 \frac{8}{N_0 \alpha^3} \,. \tag{9.48}$$

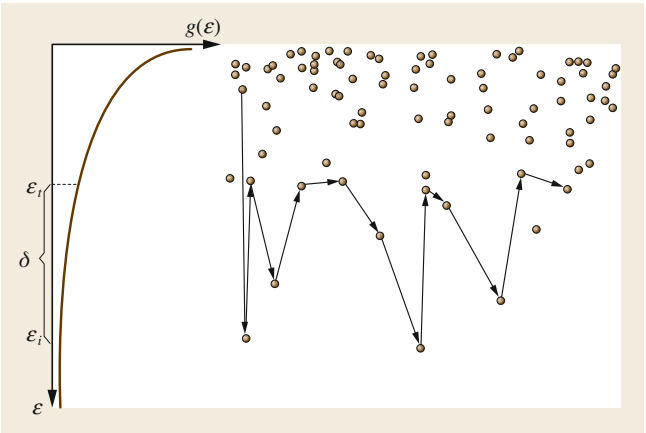

Fig. 9.11 Hopping path via the transport energy. On the *left*, the exponential DOS is shown schematically. The *right part* depicts the transport path constructed from upward and downward hops. The upward transitions bring the charge carrier to sites with energies close to the transport energy ε_t

This is a very important result, which shows that in a system where the DOS has a pure exponential energy dependence, described by (9.37), the typical energy of a set of independently relaxing electrons would drop deeper and deeper into the mobility gap with time. This result is valid as long as the electrons do not interact with each other, meaning that the occupation probabilities of the electron energy levels are not taken into account. This condition is usually met in experimental studies of transient processes, in which electrons are excited by short (in time) pulses, which are typical of time-of-flight studies of the electron mobility in various disordered materials. In this case, only a small number of electrons are present in the band tail states. Taking into account the huge number of localized band tail states in most disordered materials, one can assume that most of the states are empty and so the above formulae for the hopping rates and electron energies can be used. In this case the electron mobility is a time-dependent quantity [9.41]. A transport regime in which mobility of charge carriers is time-dependent is usually called dispersive transport (see, for example, *Mott* and *Davis* [9.32], *Orenstein* and *Kastner* [9.38], *Monroe* [9.41]). Hence we have to conclude that the transient electron mobility in inorganic noncrystalline materials with the DOS in the band tails as described by (9.37) is a time-dependent quantity and the transient electrical conductivity has dispersive character. This is due to the nonequilibrium behavior of the charge carriers. They continuously drop in energy during the course of the relaxation process.

In some theoretical studies based on the Fokker–Planck equation it has been claimed that the maximum

of the energy distribution of electrons coincides with the TE ε_t and hence it is independent of time. This statement contradicts the above result where the maximum of the distribution is at energy $\varepsilon_d(t)$, given by (9.48). The Fokker–Planck approach presumes the diffusion of charge carriers over energy. Hence it is invalid for describing the energy relaxation in the exponential tails, in which electron can move over the full energy width of the DOS (from a very deep energy state toward the TE) in a single hopping event.

In the equilibrium conditions, when electrons in the band tail states are provided by thermal excitation from the Fermi energy, a description of the electrical conductivity can easily be derived using (9.5)–(9.7) [9.39]. The maximal contribution to the integral in (9.5) comes from the electrons with energies in the vicinity of the TE ε_t, in an energy range with a width, W, described by (9.44). Neglecting the temperature dependence of the pre-exponential factor, σ_0, one arrives at the temperature dependence of the conductivity

$$\sigma \approx \sigma_0 \exp\left(-\frac{2r(\varepsilon_t)}{B_c^{-1/3}\alpha} - \frac{\varepsilon_F - \varepsilon_t}{k_B T}\right), \tag{9.49}$$

where coefficient $B_c \approx 2.7$ is inserted in order to take into account the need for a charge carrier to move over macroscopic percolation distances in order to provide low-frequency charge transport.

A very similar theory is valid for charge transport in noncrystalline materials under stationary excitation of electrons (for example by light) [9.42]. In such a case, one first needs to develop a theory for the steady state of the system under stationary excitation. This theory takes into account various recombination processes for charge carriers and provides their stationary concentration along with the position of the quasi-Fermi energy. After solving this recombination problem, one can follow the track of the theory of charge transport in quasi-thermal equilibrium [9.39] and obtain the conductivity in a form similar to (9.49), where ε_F is the position of the quasi-Fermi level. We skip the corresponding (rather sophisticated) formulae here. Interested readers can find a comprehensive description of this sort of theory for electrical conductivity in the literature (see, for instance, *Shklovskii* et al. [9.42]).

Instead, in the next section we will consider a very interesting problem related to the nonequilibrium energy relaxation of charge carriers in the band tail states. It is well known that at low temperatures, $T \leq 50$ K, the photoconductivities of various inorganic noncrystalline materials, such as amorphous and microcrystalline semiconductors, do not depend on temperature [9.44–46]. At low temperatures, the TE ε_t lies very deep in the band tail and most electrons hop downward in energy, as described by (9.38) and (9.39). In such a regime, the photoconductivity is a temperature-independent quantity determined by the loss of energy during the hopping of electrons via the band-tail states [9.47]. During this hopping relaxation, neither the diffusion coefficient D nor the mobility of the carriers μ depend on temperature, and the conventional form of Einstein's relationship $\mu = eD/(k_B T)$ cannot be valid. The question then arises as to what the relation between μ and D is for hopping relaxation. We answer this question in the following section.

Einstein's Relationship for Hopping Electrons

Let us start by considering a system of nonequilibrium electrons in the band tail states at $T = 0$. The only process that can happen with an electron is its hop downward in energy (upward hops are not possible at $T = 0$) to the nearest localized state in the tail. Such a process is described by (9.37)–(9.39). If the spatial distribution of localized tail states is isotropic, the probability of finding the nearest neighbor is also isotropic in the absence of the external electric field. In this case, the process of the hopping relaxation of electrons resembles diffusion in space. However, the median length of a hop (the distance r to the nearest available neighbor), as well as the median time, $\tau = \nu_\downarrow^{-1}(r)$, of a hop (see (9.38)) increases during the course of relaxation, since the hopping process brings electrons deeper into the tail. Nevertheless, one can ascribe a diffusion coefficient to such a process [9.42]

$$D(r) = \frac{1}{6}\nu_\downarrow(r) r^2 . \tag{9.50}$$

Here $\nu_\downarrow(r)r^2$ replaces the product of the *mean free path* r and the *velocity* $r\nu_\downarrow(r)$, and the coefficient $1/6$ accounts for the spatial symmetry of the problem. According to (9.37)–(9.39) and (9.50), this diffusion coefficient decreases exponentially with increasing r and hence with the number of successive electron hops in the relaxation process.

In order to calculate the mobility of electrons during hopping relaxation under the influence of the electric field, one should take into account the spatial asymmetry of the hopping process due to the field [9.47, 48]. Let us consider an electron in a localized state at energy ε. If an external electric field with a strength F is applied along direction x, the concentration of tail states available to this hopping electron at $T = 0$ (in other words those that have energies deeper in the tail than ε) is [9.47]

$$N(\varepsilon, x) = N(\varepsilon)\left(1 + \frac{eFx}{\varepsilon_0}\right), \tag{9.51}$$

where

$$N(\varepsilon) = \int_{\varepsilon}^{\infty} g(\varepsilon)\mathrm{d}\varepsilon = N_0 \exp\left(-\frac{\varepsilon}{\varepsilon_0}\right). \tag{9.52}$$

It was assumed in the derivation of (9.51) that $eFx \ll \varepsilon_0$.

Due to the exponential dependence of the hopping rate on the hopping length r, the electron predominantly hops to the nearest tail state among the available states if $r \gg \alpha$, which we assume to be valid. Let us calculate the average projection $\langle x\rangle$ on the field direction of the vector $\boldsymbol{r}$ from the initial states at energy ε to the nearest available neighbor among sites with a concentration $N(\varepsilon, x)$ determined by (9.51). Introducing spherical coordinates with the angle θ between r and the x-axis, we obtain [9.48]

$$\begin{aligned}\langle x\rangle = &\int_0^{2\pi} \mathrm{d}\phi \int_0^{\pi} \mathrm{d}\theta \sin\theta \\ &\times \int_0^{\infty} [\mathrm{d}r\, r^3 \cos(\theta)\, N(\varepsilon, r\cos\theta)] \\ &\times \exp\left[-\int_0^{2\pi} \mathrm{d}\phi \int_0^{\pi} \mathrm{d}\theta \sin\theta \right. \\ &\left. \times \int_0^{r} \mathrm{d}r' r'^{2N}(\varepsilon, r'\cos\theta)\right].\end{aligned} \tag{9.53}$$

Substituting (9.51) for $N(\varepsilon, r\cos\theta)$, calculating the integrals in (9.53) and omitting the second-order terms

$$\left(\frac{eN^{-1/3}(\varepsilon)F}{\varepsilon_0}\right)^2 \ll 1\,, \tag{9.54}$$

we obtain

$$\langle x\rangle = \frac{eFN^{-2/3}(\varepsilon)}{3\varepsilon_0}\frac{\Gamma(5/3)}{(4\pi/3)^{2/3}}\,, \tag{9.55}$$

where Γ is the gamma-function and $N(\varepsilon)$ is determined by (9.52). Equation (9.55) gives the average displacement in the field direction of an electron that hops downward from a state at energy ε to the nearest available neighbor in the band tail. The average length $\langle r\rangle$ of such a hop is

$$\begin{aligned}\langle r\rangle &= \int_0^{\infty} \mathrm{d}r 4\pi r^3 N(\varepsilon) \exp\left[-\frac{4\pi}{3}N(\varepsilon)r^3\right] \\ &= \left(\frac{4\pi N(\varepsilon)}{3}\right)^{-1/3} \Gamma\left(\frac{4}{3}\right).\end{aligned} \tag{9.56}$$

One can ascribe to the hopping process a mobility

$$\begin{aligned}\mu &= \frac{v}{F} = \frac{\langle x\rangle\, \nu\, (\langle r\rangle)}{F} \\ &= \frac{eN^{-2/3}(\varepsilon)\, \nu\, (\langle r\rangle)}{3\varepsilon_0}\frac{\Gamma(5/3)}{(4\pi/3)^{2/3}}\end{aligned} \tag{9.57}$$

and a diffusion coefficient

$$\begin{aligned}D &= \frac{1}{6}\langle r\rangle^2\, \nu\, (\langle r\rangle) \\ &= \frac{1}{6}N^{-2/3}(\varepsilon)\, \nu\, (\langle r\rangle)\, \frac{\Gamma^2(4/3)}{(4\pi/3)^{2/3}}\,.\end{aligned} \tag{9.58}$$

Expressions (9.57) and (9.58) lead to a relationship between μ and D of the form

$$\mu = \frac{2\Gamma(5/3)}{\Gamma^2(4/3)}\frac{e}{\varepsilon_0}D \approx 2.3\frac{e}{\varepsilon_0}D\,. \tag{9.59}$$

This formula replaces the Einstein's relationship $\mu = eD/(k_{\mathrm{B}}T)$ for electron hopping relaxation in the exponential band tail. Several points should be noted about this result. First of all, one should clearly realize that (9.59) is valid for nonequilibrium energy-loss relaxation in which only downward (in energy) transitions between localized states can occur. This regime is valid only at low temperatures when the TE ε_{t} is very deep in the band tail. As the temperature increases, the upward hops become more and more efficient for electron relaxation. Under these circumstances, the relation between μ and D evolves gradually with rising temperature from its temperature-independent form at $T = 0$ to the conventional Einstein's relationship, $\mu = eD/(k_{\mathrm{B}}T)$ [9.49, 50]. Secondly, one should realize that (9.59) was derived in the linear regime with respect to the applied field under the assumption that $eFx \ll \varepsilon_0$. According to (9.55), the quantity $\langle x\rangle$ is proportional to $N^{-2/3}(\varepsilon) = N_0^{-2/3}\exp[2\varepsilon/(3\varepsilon_0)]$, in other words it increases exponentially during the course of the relaxation toward larger localization energies ε. This means that for deep localized states in the band tail, the condition $eFx \ll \varepsilon_0$ breaks down. The boundary energy for application of the linear theory depends on the strength of the electric field, F. As F decreases, this boundary energy drops

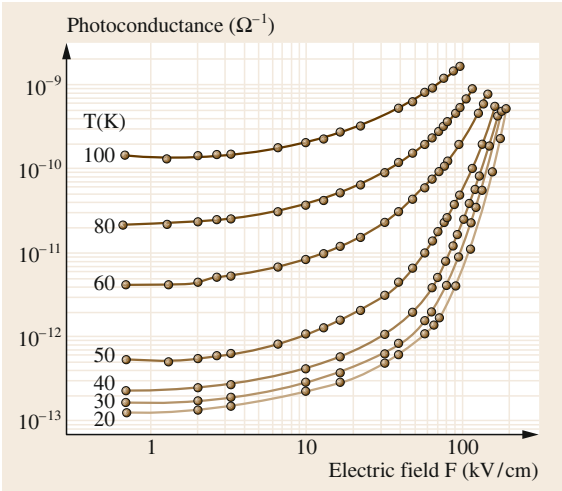

Fig. 9.12 Dependence of the photoconductivity in a-Si:H on the electric field at different temperatures. (After [9.53])

deeper into the tail. However, for any F, there is always a boundary energy in the tail below which the condition $eFx \ll \varepsilon_0$ cannot be fulfilled and where nonlinear effects play the decisive role in the hopping conduction of charge carriers. In the next section we show how one can describe these nonlinear effects with respect to the applied electric field.

Nonlinear Effects in Hopping Conduction

Transport phenomena in inorganic noncrystalline materials, such as amorphous semiconductors, under the influence of high electric fields are the foci for intensive experimental and theoretical study. This is due to observations of strong nonlinearities in the dependencies of the dark conductivity [9.11, 51, 52], the photoconductivity [9.53] and the charge carrier drift mobility [9.54–56] on the field for high electric fields. These effects are most pronounced at low temperatures, when charge transport is determined by electron hopping via localized band tail states (Fig. 9.12).

Whereas the field-dependent hopping conductivity at low temperatures has always been a challenge to describe theoretically, theories for the temperature dependence of the hopping conductivity in low electric fields have been successfully developed for all of the transport regimes discussed: for the dark conductivity [9.39], for the drift mobility [9.41], and for the photoconductivity [9.42]. In all of these theories, hopping transitions of electrons between localized states in the exponential band tails play a decisive role, as described above in (9.37)–(9.59).

Shklovskii [9.57] was the first to recognize that a strong electric field plays a similar role to that of temperature in hopping conduction. In order to obtain the field dependence of the conductivity $\sigma(F)$ at high fields, *Shklovskii* [9.57] replaced the temperature T in the well-known dependence $\sigma(T)$ for low fields by a function $T_{\text{eff}}(F)$ of the form

$$T_{\text{eff}} = \frac{eF\alpha}{2k_{\text{B}}} , \tag{9.60}$$

where e is the elementary charge, k_{B} is the Boltzmann constant, and α is the localization length of electrons in the band tail states. A very similar result was obtained later by *Grünewald* and *Movaghar* [9.58] in their study of the hopping energy relaxation of electrons through band tails at very low temperatures and high electric fields. The same idea was also used by *Shklovskii* et al. [9.42], who suggested that, at $T = 0$, one can calculate the field dependence of the stationary photoconductivity in amorphous semiconductors by replacing the laboratory temperature T in the formulae of the low-field finite-temperature theory by an effective temperature $T_{\text{eff}}(F)$ given by (9.60).

It is easy to understand why the electric field plays a role similar to that of temperature in the energy relaxation of electrons. Indeed, in the presence of the field, the number of sites available at $T = 0$ is significantly enhanced in the field direction, as shown in Fig. 9.13. Hence electrons can relax faster at higher fields. From the figure it is apparent that an electron can increase its energy with respect to the mobility edge by an amount $\varepsilon = eFx$ in a hopping event over a distance x in the direction prescribed by the electric field. The process is reminiscent of thermal activation. The analogy becomes tighter when we express the transition rate for this hop as

$$\begin{aligned} \nu &= \nu_0 \exp\left(-\frac{2x}{\alpha}\right) = \nu_0 \exp\left(-\frac{2\varepsilon}{eF\alpha}\right) \\ &= \nu_0 \exp\left(-\frac{\varepsilon}{k_{\text{B}} T_{\text{eff}}(F)}\right) , \end{aligned} \tag{9.61}$$

where $T_{\text{eff}}(F)$ is provided by (9.60).

This electric field-induced activation at $T = 0$ produces a Boltzmann tail to the energy distribution function of electrons in localized states as shown by numerical calculations [9.59, 60]. In Fig. 9.12, the field-dependent photoconductivity in a-Si:H is shown for several temperatures [9.53]. If we compare the photoconductivity at the lowest measured temperature, $T = 20\,\text{K}$ in Fig. 9.12, with the low-field photoconductivity at $T = T_{\text{eff}} = eF\alpha/(2k_{\text{B}})$ as measured by *Hoheisel* et al. [9.44] and by *Stradins* and *Fritzsche* [9.45], we come to the conclusion that the data agree quantitatively if one assumes that the localization length $\alpha = 1.05\,\text{nm}$ [9.42], which is very close to the value

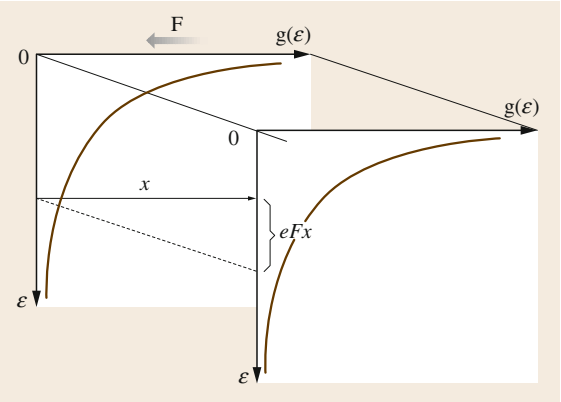

Fig. 9.13 Tunneling transition of a charge carrier in the band tail that is affected by a strong electric field. Upon traveling the distance x, the carrier acquires the energy eFx, where F is the strength of the electric field, and e is the elementary charge

$\alpha \approx 1.0\,\text{nm}$ found for a-Si:H from independent estimates [9.11]. This comparison shows that the concept of the effective temperature based on (9.60) provides a powerful tool for estimating transport coefficient nonlinearity with respect to the electric field using the low-field results for the temperature dependencies of such coefficients.

However, experiments are usually carried out not at $T = 0$ but at finite temperatures, and so the question of how to describe transport phenomena in the presence of both factors, finite T and high F, arises. By studying the steady state energy distribution of electrons in numerical calculations and computer simulations [9.59, 60], as well as straightforward computer simulations of the steady-state hopping conductivity and the transient energy relaxation of electrons [9.61], the following result was found. The whole set of transport coefficients can be represented by a function with a single parameter $T_{\text{eff}}(F, T)$

$$T_{\text{eff}}(F,T) = \left[T^{\beta} + \left(\gamma \frac{eF\alpha}{k_{\text{B}}} \right)^{\beta} \right]^{1/\beta} , \qquad (9.62)$$

where $\beta \approx 2$ and γ is between 0.5 and 0.9 depending on which transport coefficient is considered [9.61]. We are aware of no analytical theory that can support this numerical result.

To wrap up this section we would like to make the following remark. It is commonly claimed in the scientific literature that transport coefficients in the hopping regime should have a purely exponential dependence on the applied electric field. The idea behind such statements seems rather transparent. Electric field diminishes potential barriers between localized states by an amount $\Delta\varepsilon = eFx$, where x is the projection of the hopping radius on the field direction. The field should therefore diminish the activation energies in (9.24) and (9.25) by this amount, leading to the term $\exp(eFx/(k_{\text{B}}T))$ in the expressions for the charge carrier mobility, diffusivity and conductivity. One should, however, take into account that hopping transport in all real materials is essentially described by the variable-range hopping process. In such a process, as discussed above, the interplay between spatial and energy-dependent terms in the exponents of the transition probabilities determine the conduction path. Therefore it is not enough to solely take into account the influence of the strong electric field on the activation energies of single hopping transitions. One should consider the modification of the whole transport path due to the effect of the strong field. It is this VRH nature of the hopping process that leads to a more complicated field dependence for the transport coefficients expressed by (9.60)–(9.62).

We have now completed our description of electron transport in inorganic disordered materials with exponential DOS in the band tails. In the next section we tackle the problem of charge transport in organic disordered materials.

9.3.4 Description of Charge-Carrier Energy Relaxation and Hopping Conduction in Organic Noncrystalline Materials

Electron transport and energy relaxation in disordered organic solids, such as molecularly doped polymers, conjugated polymers and organic glasses, has been the subject of intensive experimental and theoretical study for more than 20 years. Although there is a wide array of different disordered organic solids, the charge transport process is similar in most of these materials. Even at the beginning of the 1980s it was well understood that the main transport mechanism in disordered organic media is the hopping of charge carriers via spatially randomly distributed localized states. Binary systems like doped polymeric matrices provide canonical examples of disordered organic materials that exhibit the hopping transport mechanism. Examples include polyvinylcarbazole (PVK) or bis-polycarbonate (Lexan) doped with either strong electron acceptors such as trinitrofluorenone acting as an electron transporting agent, or strong electron donors such as derivatives of tryphenylamine of triphenylmethane for hole transport [9.62, 63]. To avoid the need to specify whether transport is carried by electrons or holes each time, we will use a general notation of *charge carrier* below. The results are valid for both

types of carrier – electrons or holes. Charge carriers in disordered organic materials are believed to be strongly localized [9.18, 62–64]. The localization centers are molecules or molecular subunits, henceforth called sites. These sites are located in statistically different environments. As a consequence, the site energies, which are to great extent determined by electronic polarization, fluctuate from site to site. The fluctuations are typically on the order of 0.1 eV [9.65]. This is about one order of magnitude larger than the corresponding transfer integrals [9.65]. Therefore carrier wavefunctions can be considered to be strongly localized [9.65].

As discussed above, the crucial problem when developing a theoretical picture for hopping transport is the structure of the energy spectrum of localized states, DOS. It is believed that, unlike inorganic noncrystalline materials where the DOS is believed exponential, the energy dependence of the DOS in organic disordered solids is Gaussian (see *Bässler* [9.18] and references therein),

$$g(\varepsilon) = \frac{N_0}{\varepsilon_0\sqrt{2\pi}} \exp\left(-\frac{\varepsilon^2}{2\varepsilon_0^2}\right), \tag{9.63}$$

where N_0 is the total concentration of states and ε_0 is the energy scale of the DOS. The strongest evidence in favor of such an energy spectrum in disordered organic materials is the ability to reproduce the observed experimentally temperature dependence of the carrier mobility and that of hopping conductivity assuming the Gaussian DOS in computer simulations [9.18, 66]. It has been observed in numerous experimental studies [9.67–73] that the temperature dependence of the drift mobility of charge carriers in disordered organic solids takes the form

$$\mu \propto \exp\left[-\left(\frac{T_0}{T}\right)^2\right] \tag{9.64}$$

with a characteristic temperature T_0, as shown in Fig. 9.14a. Computer simulations and theoretical calculations [9.65, 66, 74, 75] with the Gaussian DOS described by (9.63) give a dependence of the form

$$\mu \propto \exp\left[-\left(C\frac{\varepsilon_0}{k_\mathrm{B}T}\right)^2\right], \tag{9.65}$$

where C is a numerical coefficient. Computer simulations [9.65, 66] give a value $C \approx 0.69$ for this coefficient, and analytical calculations [9.74, 75] predict a similar value of $C \approx 0.64$. Equation (9.65) is often used to determine the parameter ε_0 of the DOS from experimental measurements of the $\ln(\mu)$ versus $(1/T)^2$ dependences (see, for example, *Ochse* et al. [9.71]).

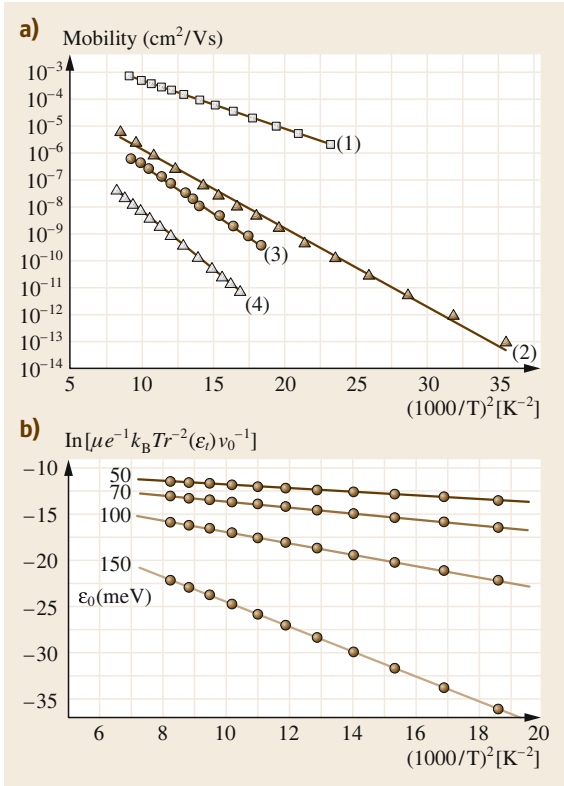

Fig. 9.14a,b Temperature dependence of the zero-field mobility in organic semiconductors. Experimental data **(a)**: (1) di-*p*-tolylphenylamine containing 1-phenyl-3-*p*-diethylaminostyryl-5-*p*-diethylamino-phenylpyrazoline (DEASP)-traps [9.69]; (2) butadiene (BD)-doped polycarbonate [9.70]; (3) naphthalenetetracarboxylic diimide (NTDI)-doped poly(styrene) [9.68]; (4) (BD)-doped TTA/polycarbonate [9.72]. Theoretical results **(b)** were obtained via (9.73)

One may wonder whether the theoretical description of hopping conduction and carrier energy relaxation in a system with a Gaussian DOS (9.63) should differ significantly from the theory described above for disordered systems with a purely exponential DOS (9.37). The answer to this question is yes. The reason becomes clear if one considers the behavior of a single charge carrier in an empty system. In an empty system with an exponential DOS, a charge carrier always (on average) falls downward in energy if $k_\mathrm{B}T < \varepsilon_0$ (see (9.45)–(9.48)), and its mobility continuously decreases with time; however, in a system with a Gaussian DOS, a particular energy level ε_∞ determines the equilibrium energy position of a charge carrier. When it is located at some site with high energy in the Gaussian DOS, the charge carrier first hops via localized states so that its average energy $\varepsilon_\mathrm{d}(t)$

decreases until it achieves the energy level ε_∞ after some typical time period τ_{rel}. At times $t < \tau_{rel}$ the behavior of the carrier qualitatively resembles that seen for the purely exponential DOS. The downward hops are then replaced by relaxation hops that send the carrier upward to the transport energy, and the carrier mobility at $t < \tau_{rel}$ decreases with time. However, in contrast with the case for the exponential DOS, in a Gaussian DOS the carrier mobility becomes time-independent after a time τ_{rel}, when the average carrier energy reaches the level ε_∞. At $t > \tau_{rel}$, the dispersive transport regime with time-dependent carrier mobility is replaced by a quasi-equilibrium so-called *Gaussian transport* regime, in which the spatial spreading of the carrier packet with time can be described by the traditional diffusion picture with a time-independent diffusion coefficient.

The peculiarity of the hopping energy relaxation of charge carriers in a system with a Gaussian DOS described above makes it easier to describe charge transport at times $t > \tau_{rel}$ than in the case of the exponential DOS. In the latter case, only the presence of a significant number of carriers in a quasi Fermi level can make kinetic coefficients such as mobility, diffusivity and conductivity time-independent and hence conventionally measurable and discussible quantities. In the case of the Gaussian DOS, these kinetic coefficients are not time-dependent at times $t > \tau_{rel}$. Moreover, in diluted systems one can calculate these coefficients by considering the behavior of a single charge carrier. This makes theoretical considerations of electrical conductivity in organic disordered solids with a Gaussian DOS much easier than when considering inorganic noncrystalline materials with an exponential DOS. Let us now calculate ε_∞, τ_{rel} and μ in disordered organic solids with a Gaussian DOS.

Computer simulations [9.66] and analytical calculations [9.74, 75] show that the mean energy of the independently hopping carriers, initially distributed randomly over all states in the Gaussian DOS, decreases with time until it approaches the thermal equilibrium value

$$\varepsilon_\infty = \frac{\left[\int_{-\infty}^{\infty} \varepsilon \exp\left(-\frac{\varepsilon}{k_B T}\right) g(\varepsilon) \mathrm{d}\varepsilon\right]}{\left[\int_{-\infty}^{\infty} \exp\left(-\frac{\varepsilon}{k_B T}\right) g(\varepsilon) \mathrm{d}\varepsilon\right]} = -\frac{\varepsilon_0^2}{k_B T} \,. \tag{9.66}$$

The time τ_{rel} required to reach this equilibrium is of key importance in the analysis of experimental data [9.65], since at $t < \tau_{rel}$ the carrier mobility decreases with time (dispersive transport) until it reaches its equilibrium, time-independent value at $t \approx \tau_{rel}$. It has been established by computer simulations that τ_{rel} strongly depends on temperature [9.18]

$$\tau_{rel} \propto \exp\left[\left(B\frac{\varepsilon_0}{k_B T}\right)^2\right] \tag{9.67}$$

with $B \approx 1.07$. Given that the same hopping processes determine both μ and τ_{rel}, researchers were puzzled for many years by the fact that they had different coefficients B and C (in other words they have different temperature dependencies) [9.65]. Below we show how to calculate both quantities – μ and τ_{rel} – easily, and we explain their temperature dependencies (obtained experimentally and by computer simulations as expressed by (9.64), (9.65) and (9.67)).

Our theoretical approach is based on the concept of transport energy (TE), introduced in Sect. 9.3.3, where it was calculated for the exponential DOS given by (9.37). Literally repeating these calculations with the Gaussian DOS, given by (9.63), we obtain the equation [9.76, 77]

$$\exp\left(\frac{x^2}{2}\right)\left[\int_{-\infty}^{\frac{x}{\sqrt{2}}} \exp(-t^2)\mathrm{d}t\right]^{4/3} = \left[9(2\pi)^{1/2} N_0 \alpha^3\right]^{-1/3} \frac{k_B T}{\varepsilon_0} \,. \tag{9.68}$$

If we denote the solution of (9.68) as $X_t(N_0\alpha^3, k_B T/\varepsilon_0)$, then the transport energy in the Gaussian DOS is equal to

$$\varepsilon_t = \varepsilon_0 X_t\left(N_0\alpha^3, \frac{k_B T}{\varepsilon_0}\right) . \tag{9.69}$$

Charge carriers perform thermally activated transitions from states with energies below the TE, ε_t, to the states with energies close to that of the TE [9.76]. Charge carriers hop downward in energy from states with energies above the TE to the spatially nearest sites with rates determined by (9.38) and (9.39).

Now that we have clarified the relaxation kinetics of charge carriers in the Gaussian DOS, it is easy to calculate the relaxation time τ_{rel} and the drift mobility μ. We consider the case $\varepsilon_\infty < \varepsilon_t < 0$, which corresponds to all reasonable values of material parameters $N_0\alpha^3$ and $k_B T/\varepsilon_0$ [9.76]. The energy relaxation of most carriers with energies ε in the interval $\varepsilon_\infty < \varepsilon < \varepsilon_t$ occurs via a multiple trapping-like process, well described in the literature (see, for example, *Orenstein* and *Kastner* [9.38] or *Marschall* [9.78]). Below ε_t the average energy of the carriers $\varepsilon(t)$ moves logarithmically downward with time t. States above $\varepsilon(t)$ achieve

thermal equilibrium with states at ε_t at time t, while states below $\varepsilon(t)$ have no chance at time t to exchange carriers with states in the vicinity of ε_t. Hence the occupation of those deep states does not correspond to the equilibrium one, being determined solely by the DOS of the deep states. The system reaches thermal equilibrium when the time-dependent average energy $\varepsilon(t)$ achieves the equilibrium level ε_∞, determined by (9.66). This happens at $t = \tau_{rel}$. Since the relaxation of carriers occurs via thermal activation to the level ε_t, the relaxation time τ_{rel} is determined by the time required for activated transitions from the equilibrium level ε_∞ to the transport energy ε_t. Hence, according to (9.40) and (9.47), τ_{rel} is determined by the expression

$$\tau_{rel} = \nu_0^{-1} \exp\left[\frac{2r(\varepsilon_t)}{\alpha} + \frac{\varepsilon_t - \varepsilon_\infty}{k_B T}\right]. \qquad (9.70)$$

From (9.68)–(9.70) it is obvious that the activation energy of the relaxation time depends on the parameters $N_0\alpha^3$ and k_BT/ε_0. Hence, generally speaking, this dependence cannot be represented by (9.67) and, if at all, the coefficient B should depend on the magnitude of the parameter $N_0\alpha^3$. However, numerically solving (9.68)–(9.70) using the value $N_0\alpha^3 = 0.001$, which was also used in computer simulations by *Bässler* [9.18, 65], confirms the validity of (9.67) with $B \approx 1.0$. This result is in agreement with the value $B \approx 1.07$ obtained from computer simulations [9.18, 65]. A way to describe the temperature dependence of the relaxation time τ_{rel} by (9.67) is provided by the strong temperature dependence of ε_∞ in the exponent in (9.70), while the temperature dependencies of the quantities ε_t and $r(\varepsilon_t)$ in (9.70) are weaker and they almost cancel each other out. However, if $N_0\alpha^3 = 0.02$, the relaxation time is described by (9.67) with $B \approx 0.9$. This shows that (9.67) can only be considered to be a good approximation.

Now we turn to the calculation of the carrier drift mobility μ. We assume that the transition time t_{tr} necessary for a carrier to travel through a sample is longer than τ_{rel}, and hence the charge transport takes place under equilibrium conditions. As described above, every second jump brings the carrier upward in energy to the vicinity of ε_t, and is then followed by a jump to the spatially nearest site with deeper energy, determined solely by the DOS. Therefore, in order to calculate the drift mobility μ, we must average the hopping transition times over energy states below ε_t, since only these states are essential to charge transport in thermal equilibrium [9.77, 79]. Hops downward in energy from the level ε_t occur exponentially faster than upward hops to-

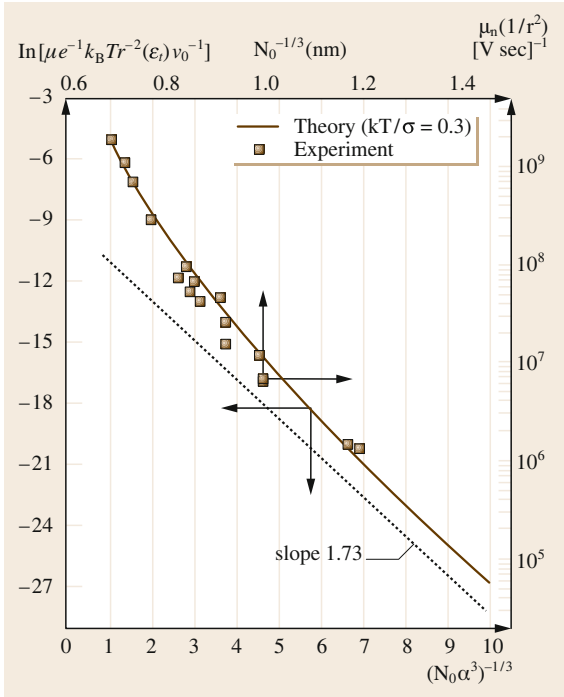

Fig. 9.15 Concentration dependence of the drift mobility evaluated from (9.73) (*solid line*), and the dependence observed experimentally (*circles*) for trinitrofluorenone with polyvinylcarbazole (TNF/PVK). (After [9.63])

wards ε_t. This means that one can neglect the former in the calculation of the average time $\langle t \rangle$. The carrier drift mobility can be evaluated as

$$\mu \approx \frac{e}{k_B T} \frac{r^2(\varepsilon_t)}{\langle t \rangle}, \qquad (9.71)$$

where $r(\varepsilon_t)$ is determined via (9.39), (9.63), (9.68) and (9.69). The average hopping time takes the form [9.79]

$$\langle t \rangle = \left[\int_{-\infty}^{\varepsilon_t} g(\varepsilon)\mathrm{d}\varepsilon\right]^{-1} \times \int_{-\infty}^{\varepsilon_t} \nu_0^{-1} g(\varepsilon) \times \exp\left(\frac{2r(\varepsilon_t)B_c^{1/3}}{a} + \frac{\varepsilon_t - \varepsilon}{k_B T}\right) \mathrm{d}\varepsilon, \qquad (9.72)$$

where $B_c \approx 2.7$ is the percolation parameter. This numerical coefficient is introduced into (9.72) in order to warrant the existence of an infinite percolation path over the states with energies below ε_t. Using (9.63), (9.68), (9.69), (9.71) and (9.72), one obtains the following relation for the exponential terms in the expression for the

carrier drift mobility

$$\ln\left[\frac{\mu}{\left(\frac{er^2(\varepsilon_t)\nu_0}{k_BT}\right)}\right] = -2\left[\frac{4\sqrt{\pi}}{3B_c}N_0\alpha^3\int_{-\infty}^{X_t/\sqrt{\pi}}\exp(-t^2)\mathrm{d}t\right]^{-1/3} - \frac{X_t\varepsilon_0}{k_BT} - \frac{1}{2}\left(\frac{\varepsilon_0}{k_BT}\right)^2 . \tag{9.73}$$

It is (9.73) that determines the dependence of the carrier drift mobility on the parameters $N_0\alpha^3$ and k_BT/ε_0.

In Fig. 9.14b, the dependence of the drift mobility on the temperature at $N_0\alpha^3 = 0.01$ is depicted for several values of ε_0. The sensitivity of the mobility to temperature is clear from this picture. Comparison of these dependencies with experimental measurements of $\ln(\mu)$ versus $(1/T)^2$ (some are shown in Fig. 9.14a) provides information on the energy scale, ε_0, of the DOS (see, for example, *Bässler* [9.18] and *Ochse* et al. [9.71]).

In Fig. 9.15, the dependence of the drift mobility on $N_0\alpha^3$ is shown for $k_BT/\varepsilon_0 = 0.3$. Experimental data from *Gill* [9.80] are also shown in the figure. It is clear that the slope of the mobility exponent as a function of $(N_0\alpha^3)^{-1/3}$ given by the theory described above agrees with the experimental data. At a very low concentration of localized states, N_0, when the probability of carrier tunneling in space dominates the transition rate in (9.24), charge carriers hop preferentially to the nearest spatial sites. In this regime of nearest-neighbor hopping, the concentration dependence of the drift mobility is described by (9.28), as illustrated by the dashed line in Fig. 9.15.

So far we have discussed the drift mobility of charge carriers under the assumption that the concentration of charge carriers is much less than that of the localized states in the energy range relevant to hopping transport. In such a case one can assume that the carriers perform independent hopping motion and so the conductivity can be calculated as the product

$$\sigma = en\mu , \tag{9.74}$$

where n is the concentration of charge carriers in the material and μ is their drift mobility. If, however, the concentration n is so large that the Fermi energy at thermal equilibrium or the quasi-Fermi energy at stationary excitation is located significantly higher (energetically) than the equilibrium energy ε_∞, a more sophisticated theory based on the percolation approach is required [9.81]. The result obtained is similar to that given by (9.49).

9.4 Concluding Remarks

Beautiful effects have been observed experimentally by studying the charge transport in disordered organic and inorganic materials. Among these, the transport coefficients in the hopping regime show enormously strong dependencies on material parameters. The dependence of the charge carrier mobility on the concentration of localized states N_0 (Fig. 9.15) spreads over many orders of magnitude, as does its dependence on the temperature T (Fig. 9.14) and on the (high) electric field strength F (Fig. 9.12). Such strong variations in physical quantities are typical, say, in astrophysics, but they are not usual in solid state physics. This makes the study of the charge transport in disordered materials absolutely fascinating. The strong dependencies of kinetic coefficients (like drift mobility, diffusivity and conductivity) in disordered materials on various material parameters makes these systems very attractive for various device applications. Since they are relatively inexpensive to manufacture too, it is then easy to understand why disordered organic and inorganic materials are of enormous interest for various technical applications.

These materials also provide a purely academic challenge with respect to their transport phenomena. While traditional kinetic theories developed for crystalline materials are largely dependent on the systems having translational symmetry, there is no such symmetry in disordered materials. However, we have shown in this chapter that it is still possible to develop a reliable theoretical approach to transport phenomena in disordered materials. Particularly interesting is the hopping transport regime. In this regime, charge carriers perform incoherent tunneling jumps between localized states distributed in space and energy. The enormously strong (exponential) dependence of the transition rates on the distances between the sites and their energies call for a completely new set of ideas compared to those for crystalline solids. Conventional transport theories based on the averaging of transition rates lead to absurd results if applied to hopping transport in disordered materials.

One can use ideas from percolation theory instead to adequately describe charge transport. One of the most important ideas in this field is so-called variable-range hopping (VRH) conduction. Although the rate of transitions between two localized states is a product of exponential terms that are separately dependent on the concentration of localized states N_0, the temperature of the system T, and also on the field strength F (for high field strengths), it is generally wrong to assume that the carrier drift mobility, diffusivity or conductivity can also be represented as the product of three functions that are separately dependent on N_0, T and F. Instead one should search for a percolation path that takes into account the exponential dependences of the hopping rates on all of these parameters simultaneously. Such a procedure, based on strong interplay between the important parameters in the exponents of the transition rates, leads to very interesting and (in some cases) unexpected results, some of which were described in this chapter. For example, it was shown that the effect of a strong electric field on transport coefficients can be accounted for by renormalizing the temperature. Most of the ideas discussed in this chapter were discussed in the early works of Mott and his coauthors (see, for example, *Mott* and *Davis* [9.32]). Unfortunately, these ideas are not yet known to the majority of researchers working in the field of disordered materials. Moreover, it is often believed that transport phenomena in different disordered materials need to be described using different ideas. Mott based his ideas, in particular the VRH, mostly on inorganic glassy semiconductors. Most of the researchers that are studying amorphous inorganic semiconductors (like a-Si:H) are aware of these ideas. However, new researchers that are working on more modern disordered materials, such as organic disordered solids and dye-sensitized materials, are often not aware of these very useful and powerful ideas developed by Mott and his followers that can be used to describe charge transport in inorganic disordered systems. In this chapter we have shown that the most pronounced charge transport effects in inorganic and organic disordered materials can be successfully described in a general manner using these ideas.

Although we have presented some useful ideas for describing charge transport in disordered systems above, it is clear that the theoretical side of this field is still embyonic. There are still no reliable theories for charge transport via extended states in disordered materials. Nor are there any reliable theoretical descriptions for the spatial structure of the localized states (DOS) in organic and inorganic noncrystalline materials. All of the theoretical concepts presented in this chapter were developed using very simple models of localization centers with a given energy spectrum that are randomly distributed in space. No correlations between the spatial positions of the sites and the energies of the electronic states at these sites were considered here. Some theoretical attempts to account for such correlations can be found in the literature, although the correlations have not been calculated ab initio: instead they are inserted into a framework of model assumptions. This shows how far the field of charge transport in disordered materials is from a desirable state. Since these materials are already widely used in various technical applications, such as field transistor manufacture, light-emitting diodes and solar cells, and since the sphere of such applications is increasing, the authors are optimistic about the future of research in this field. The study of fundamental charge transport properties in disordered materials should develop, leading us to a better understanding of the fundamental charge transport mechanisms in such systems.

Acknowledgments. The authors are indebted to numerous colleagues for stimulating and enlightening discussions. Among those are Boris Shklovski (University of Minnesota), Alexei Efros and Michael Raikh (Utah University), Hellmut Fritzsche (Chicago University), Peter Thomas, Walther Fuhs and Heinz Bässler (Philipps-University Marburg), Igor Zvyagin (Moscow State University) and many other colleagues. 10. Dielectric Response

Leonard Dissado

Nearly all materials are dielectrics, and the measurement of their dielectric response is a very common technique for their characterisation. This chapter is intended to guide scientists and engineers through the subject to the point where they can interpret their data in terms of the microscopic and atomistic dynamics responsible for the dielectric response, and hence derive useful information appropriate to their particular needs. The focus is on the physical concepts underlying the observed behaviour and is developed from material understandable by an undergraduate student. Emphasis is placed on the information content in the data, and the limits to be placed on its interpretation are clearly identified.

Generic forms of behaviour are identified using examples typical of different classes of material, rather than an exhaustive review of the literature. Limited-range charge transport is included as a special item. The theoretical concepts are developed from a basic level up to the ideas current in the field, and the points where these are controversial have been noted so that the readers can choose for themselves how far to rely on them.

Nearly all materials are dielectrics, that is they do not exhibit a direct-current (DC) conductivity on the macroscopic scale, but instead act as an electrical capacitance i. e., they store charge. The measurement of the dielectric response is noninvasive and has been used for material characterisation throughout most of the 20th century, and consequently a number of books already exist that cover the technique from various points of view. Those that have stood the test of time are *Debye* [10.1], *Smyth* [10.2], *McCrum* et al. [10.3], *Daniels* [10.4], *Bottcher* and *Bordewijk* [10.5], and *Jonscher* [10.6]. These texts cover the subject in terms of the basic physics [10.1, 5], the material properties [10.2–4], and the electrical features [10.6]. An introduction to the wide range of dielectric response measurements that are undertaken can be obtained by referring to the proceedings publication of the International Discussion Meeting on Relaxations in Complex Systems [10.7]. In view of the enormous range of properties and materials covered by the topic it is not feasible or desirable to attempt to review the whole field in a chapter such as this. Instead the topic is approached from the viewpoint of a researcher who, having measured the dielectric *spectrum* (i. e., frequency-dependent complex permittivity) of a material sample, wishes to know what information can be taken from the measurements. Along the way the limits on the information content and the problems (and controversies) associated with the microscopic and molecular-scale interpretation will be identified. Emphasis will be placed on the physical concepts involved, but inevitably there will be some mathematical expressions whose features I aim to place in as simple a physical context as possible.

10.1 Definition of Dielectric Response

10.1.1 Relationship to Capacitance

Stated simply the dielectric response of a material is its response to an electric field within it. Let us start in the simplest way with some basic macroscopic definitions. Imagine that we have a flat slab of our material of thickness d with electrodes of area A on each opposing surface, and we apply a potential difference between opposing sides (Fig. 10.1). Since the material is a dielectric our system is a capacitor and electric charges $\pm Q$ will be stored on the surfaces between which the potential difference V is applied with Q given by

$$Q = CV\,, \tag{10.1}$$

where C is the capacitance of the system. For the sample geometry considered C is given by the expression

$$C = \frac{\varepsilon_0 \varepsilon_r A}{d}\,. \tag{10.2}$$

Here the factor ε_0 is a fundamental constant termed the permittivity of free space ($\varepsilon_0 = 8.854 \times 10^{-12}\,\mathrm{F\,m^{-1}}$) and ε_r is the permittivity of the material relative to that of free space and hence is termed the relative permittivity. Of course it is a pure number, which is a material property that contains information about the way the material responds to the application of the potential difference. Since however, the replacement of our sample by a vacuum yields a capacitance given by

$$C = \frac{\varepsilon_0 A}{d}\,, \tag{10.3}$$

i. e., $\varepsilon_r = 1$, the information about the response of the material to the electric field is contained in a factor χ,

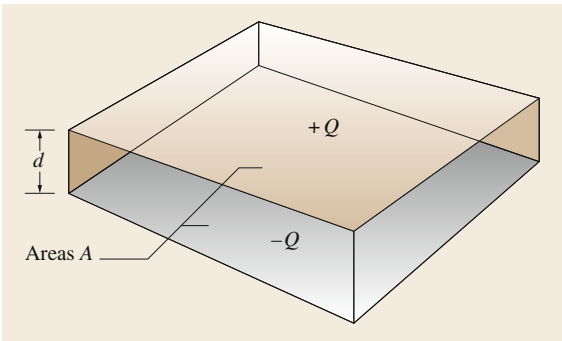

Fig. 10.1 A schematic representation of a dielectric in the form of a parallel-sided slab of surface area A and thickness d that has acquired surface charges $+Q$ and $-Q$ as a result of a potential difference applied across it. (After [10.8])

which is called the susceptibility of the material and is given by

$$\chi = \varepsilon_0(\varepsilon_r - 1)\,. \tag{10.4}$$

Noting that the electric field for the parallel electrode geometry described is given by $E = V/d$ and that the electrostatic flux density (electric displacement field) D within the material is $D = Q/A$, allows (10.1) and (10.2) to be transformed into the familiar constitutive relationship,

$$D = \varepsilon_0 \varepsilon_r E = \varepsilon_0 E + \chi E \tag{10.5}$$

which is valid irrespective of the geometry. Here the response of the material has been explicitly separated out in the form of an additive term that is called the electric polarisation P, which has dimensions of charge/area or more familiarly electric dipole moment density (electric dipole moment/volume), and is given by

$$P = \chi E\,. \tag{10.6}$$

It can be seen from (10.5) and (10.6) that the charges that correspond to P are the *additional* charges (Q_i) that are induced on the electrodes when a dielectric material replaces a vacuum with the same field applied.

An electric dipole occurs when electric charges of opposite polarity are separated in space and the magnitude of the dipole moment is given by $\boldsymbol{\mu} = \boldsymbol{r}\delta$, where δ is the magnitude of the charge and $\boldsymbol{r}$ is the separation vector. The connection between P as defined above and the dipole moment density can be easily seen once it is recognised that the separation of the charges $\pm Q_i$ by the inter-electrode separation d constitutes a macroscopic dipole moment of magnitude $Q_i d$ contained within the volume Ad. The definition of the polarisation as the dipole moment density makes it clear that the dielectric response to an electric field relates to the generation of a net dipole per unit volume in the material. In most cases the dielectric has a zero net dipole moment in the absence of an applied electric field and the action of the electric field is to produce one. Some materials such as electrets [10.9] and ferroelectrics lack a centre of symmetry, however, and possess a nonzero polarisation in the absence of an electric field. Therefore the definition of the polarisation P in (10.6) that is applicable to all cases is that P is the *change in net dipole moment density* produced by the applied field.

10.1.2 Frequency-Dependent Susceptibility

The outline given above has been written as if the electric field within the material was a static field ($f = 0$)

but (10.6) is equally valid if the field oscillates with an angular frequency ω ($\omega = 2\pi f$, where f is the frequency in Hz). In this case (10.6) becomes

$$P(\omega) = \chi(\omega)E(\omega)\,, \tag{10.7}$$

where $E(\omega) = E_0 \exp(\mathrm{i}\omega t)$.

The fundamental reason for the dependence of $P(\omega)$ upon the frequency of the alternating-current (AC) field, as in (10.7), can be envisaged by constructing a general picture of the way that a material responds to an electric field. Let us imagine that we have our material in thermal equilibrium in the absence of an electric field and we switch on a constant field at a specified time. The presence of the electric field causes the generation of a net dipole moment density (or change in one already existing). This alteration in the internal arrangement of positive and negative charges will not be instantaneous. Instead it will develop according to some equation of motion appropriate to the type of charges and dipole moments that are present. Consequently some time will be required before the system can come into equilibrium with the applied field. Formally this time will be infinity (equivalent to an AC frequency of zero), but to all intents and purposes we can regard the system as coming into equilibrium fairly rapidly after some relevant time scale, τ, with the polarisation approaching the static value $P = P(0)$ for $t \gg \tau$. If now we think of the electric field as reversing sign before equilibrium is reached, such reversal being the case for an AC field at a time $t = 1/(2f)$ after it is switched on, it is clear that the polarisation will not have reached its equilibrium value before the field is reversed and hence that $P(\omega) \lesssim P(0)$, and $\chi(\omega) \lesssim \chi(0)$. The frequency dependence of the dielectric susceptibility $\chi(\omega)$ is therefore determined by the equation of motion governing the evolution of the ensemble of electric dipole moments following excitation.

In general $\chi(\omega)$ will be a complex function with a real component $\chi'(\omega)$ defining the component of $P(\omega)$ that is in phase with the applied AC field $E(\omega) = \mathrm{Re}[E_0 \exp(\mathrm{i}\omega t)] = E_0 \cos(\omega t)$, and $\chi''(\omega)$ defining the component that is 90° out of phase. The conventional form is given by

$$\chi(\omega) = \chi'(\omega) - \mathrm{i}\chi''(\omega) \left[\mathrm{i} = \sqrt{-1}\right]\,. \tag{10.8}$$

It is easy to see that $\chi'(\omega)$ determines the net separation of charge with the dielectric in the form of a macroscopic capacitor, but the nature of $\chi''(\omega)$ is not so obvious. The answer lies in considering the *rate of change of polarisation*, $\mathrm{d}[P(\omega)]/\mathrm{d}t$. This has the dimensions of a current density (current/area), is sometimes termed the polarisation current density, and is given by,

$$\begin{aligned}\mathrm{d}[P(\omega)]/\mathrm{d}t &= \left[\chi'(\omega) - \mathrm{i}\chi''(\omega)\right]\mathrm{d}[E(\omega)]/\mathrm{d}t \\ &= [\chi'(\omega) - \mathrm{i}\chi''(\omega)]\mathrm{i}\omega[\cos(\omega t) \\ &\quad + \mathrm{i}\sin(\omega t)]E_0\,.\end{aligned} \tag{10.9}$$

Thus $\chi''(\omega)$ determines the real component of the polarisation current density that is in phase with the electric field, i. e., $J_{\mathrm{pol}}(\omega)$ given by

$$\begin{aligned}J_{\mathrm{pol}}(\omega) &= \chi''(\omega)\omega E_0 \cos(\omega t) \\ &= \sigma_{\mathrm{AC}}(\omega)E_0 \cos(\omega t)\,.\end{aligned} \tag{10.10}$$

Here $\chi''(\omega)\omega = \sigma_{\mathrm{AC}}(\omega)$ is the contribution to the AC conductivity due to the polarisation response to the electric field. If we remember Joule's Law for the power dissipated thermally by an electric current, i. e., power lost $= IV$, then we can see that $\chi''(\omega)\omega(E_0)^2$ is the power dissipated per unit volume resulting from the generation of a net polarisation by the electric field, i. e., the power dissipation density. The imaginary susceptibility $\chi''(\omega)$ is often termed the power dissipation component. It arises because the electric field has to carry out work on the dielectric in order to produce a net dipole moment density. Some of this energy is stored in the charge separations and is recoverable in an equivalent way to the elastic energy stored in a spring. The rest of the energy is used to overcome the friction opposing the establishment of the net dipole density. This energy is transferred to the dielectric in an unrecoverable way, i. e., it is dissipated within the dielectric. It can be seen that $\chi''(\omega)$ is dependent upon the form of the equations of motion governing the evolution of the net dipole moment density under the action of an electric field.

10.1.3 Relationship to Refractive Index

Equation (10.7) can be regarded as relating to the polarisation response purely to an oscillating electric field, but of course all electromagnetic waves contain such a field. In general the topic of dielectric response includes the response of the material to the electric field component of an electromagnetic field, i. e., the electromagnetic spectrum of a material is a form of dielectric response. This form of response is generally characterised by a complex frequency-dependent refractive index $n^*(f)$, with

$$n^*(f) = n(f) - \mathrm{i}\kappa(f)\,, \tag{10.11}$$

where n is the real refractive index expressing the velocity of light in the material, v, as $v = c/n$, and κ

is the absorption coefficient, which defines the reduction of intensity of light of frequency f as it passes through the medium due to absorption of the photons by the medium, i. e., it relates to energy dissipated from the electromagnetic wave. The absorption coefficient can be determined from the Beer–Lambert law, which defines the reduction in intensity as the wave travels a distance z

$$I = I_0 \exp\left(-\frac{4\pi\kappa f z}{c}\right). \tag{10.12}$$

For nonmagnetic materials an equivalence can be established between n^* and the relative permittivity (see [10.10] for example). If we think of two slabs of dielectric material placed in contact with an electromagnetic wave passing through them, the component of the field D perpendicular to the boundary is unchanged as the wave passes from one medium to another. Essentially the same electrostatic flux passes through the same perpendicular area. Equation (10.5) gives the ratio of the electric fields in the two dielectric media as the inverse of the ratio of their relative permittivities. A comparison with Snell's law [10.10, 11] then yields

$$\varepsilon_r = [n^*(f)]^2 . \tag{10.13}$$

Measurement of the dielectric response of a material involves the determination of the polarisation and its frequency dependence in some form or other. This can be carried out in a large number of ways such as the absorption spectra of electromagnetic radiation as has been described above as well as the application of an AC electric field across a sample of defined dimensions. Those readers interested in the technical details of the measurement systems are referred to the general literature, which has an enormous number of works on these experimental techniques (see for example [10.12] for bridge techniques and [10.13] for recent microwave techniques, and [10.14] for broadband dielectric spectroscopy). This chapter will have a different focus. It will in essence be a discussion of the microscopic origins of the polarisation $P(\omega)$ and the physical reasons for its variation in frequency so that data obtained from such measurements can be used to gain information relevant to the nature of the material to be studied.

10.2 Frequency-Dependent Linear Responses

In this context a linear response is one in which $P(\omega)$ is only dependent upon the first power of the electric field, i. e., $\chi(\omega)$ is independent of the electric field. The general form of frequency dependence expected for $\varepsilon(\omega) = \varepsilon_0 + \chi(\omega)$ is shown schematically in (Fig. 10.2), where it can be seen that two basic types of response can be distinguished: a resonance response at high frequencies in the quantum region, and what is termed a relaxation response at lower frequencies.

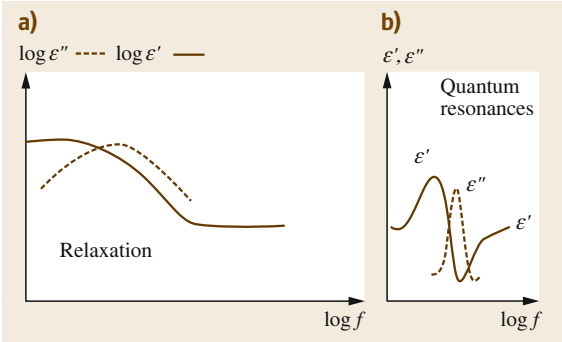

Fig. 10.2a,b Schematic representation of the frequency dependence of **(a)** relaxation and **(b)** resonance responses

10.2.1 Resonance Response

Although our main topic in this chapter will be the relaxation behaviour I will start with the resonance response as this has been dealt with extensively [10.15] from the spectroscopic viewpoint. Here we shall approach it from the perspective of its identity as a dielectric response with the intention of identifying basic features that also occur in relaxation responses. The equation of motion is familiar: this form of response relates to a *net* electric dipole moment, ϕ, that undergoes damped simple harmonic oscillation at a natural oscillation frequency $\Omega = 2\pi\nu$ in the absence of an electric field,

$$\frac{d^2\phi}{dt^2} + \frac{\gamma d\phi}{dt} + \Omega^2\phi = 0 . \tag{10.14}$$

The interpretation of (10.14) is not as obvious as it seems. We have to remember that we are always dealing with a sample of material that contains an enormous number of molecules or molecular moieties. Two types of situation may lead to this form of equation of motion. In one case a fluctuation in the positions of *groups* of positive and negative charges may form an oscillating

net dipole moment. Plasma oscillations, found in metals [10.16], are an example of this type of behaviour. In the other case, individual molecules may possess identical dipoles oscillating independently at a frequency Ω. Equation (10.14) then describes the behaviour of a *net* dipole moment produced by a fluctuation in the system of molecules independent of an applied electric field. Such fluctuations are deviations from the average equilibrium state produced by random impulses that act only for an infinitesimal time at $t = 0$, and (10.14) describes the subsequent evolution of the fluctuation. In both cases the damping (friction) term $\gamma \mathrm{d}\phi/\mathrm{d}t$, where γ is the damping factor, expresses the way in which the fluctuation dies away in the absence of an applied electric field and the net dipole moment density of the system returns to zero.

The situation applying in the case of most spectroscopic responses relates to dipole density fluctuations in which individual molecules contribute oscillating dipoles, and it is this form of behaviour that will be used to illustrate the resonance form of response. The first thing we have to do is to ask what kinds of dipole moments oscillate in our material at frequencies in the range $\nu \geq 5 \times 10^{10}$ Hz where most resonance responses are found. The answer to this question lies in the electronic structure of the atoms, ions and molecules that make up our material. The uncertainty principle states the energy of a system cannot be specified at any precise instant of time. This means that the electronic structure of atoms and molecules is allowed to continuously fluctuate between quantum states as long as the average energy over a period of time remains constant. The averaging time is determined by the uncertainty relationship between energy and time. The molecule is thus continuously moving back and forth between ground state and its excited states. These quantum fluctuations (between ground and excited states) displace the negative charge of the electron cloud with respect to the positive charge of the nucleus, and produce oscillating dipoles, termed transition dipoles (Fig. 10.3a). Their oscillation frequencies have specific values depending upon the energy difference between excited and ground quantum states of the species concerned, typically in the range $\nu \geq 4 \times 10^{14}$ Hz [10.16, 17]. These oscillating dipolar fluctuations give no net contribution to the dipole moment of the molecule or atom, i. e., no permanent dipole moment. The uncertainty principle similarly allows the nuclei of molecules, and the molecules themselves to vibrate and fluctuate between different vibration states. In many cases these nuclear fluctuations produce dipole moments [10.10, 17, 18] (Fig. 10.3b), which typically oscillate in the frequency range 4×10^{14} Hz $\geq \nu \geq 5 \times 10^{10}$ Hz. As with the electronic transition dipoles, these vibration fluctuations do not contribute to the permanent dipole moment of the molecule or system of molecules.

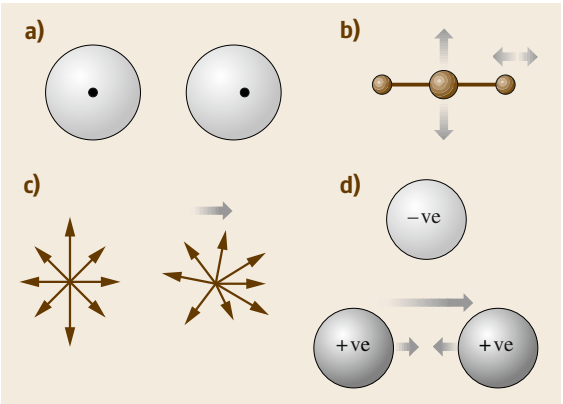

Fig. 10.3a–d Schematic representation of the various forms of dipole fluctuations: **(a)** atomic dipole, **(b)** dipoles formed by bending and stretching motion of a tri-atomic molecule of the form A–B–A, **(c)** net dipole fluctuation produced in a system of permanent dipoles, **(d)** reorienting dipole formed by transfer of an ion between two different centres of vibration. In all cases the *light arrow* shows the net dipole

When an AC electric field, such as that provided by an electromagnetic wave, is applied to the material, it couples to the transition dipoles to give a force that drives the system. As a result the population of dipoles is altered such that there is now a *net* average density of transition dipole moments. This oscillates with the frequency of the *field*, i. e., the system is polarised as defined by (10.7). Since transition dipoles do not contribute to a permanent dipole moment of a molecule, the net dipole moment density produced by the electric field is referred to as an induced dipole moment density. The response of the system to an electric field oscillating at a frequency ω is essentially obtained by adding the driving force to (10.14) and determining the solution for ϕ that oscillates with the same frequency, i. e., $\phi(t) \propto \mathrm{e}^{\mathrm{i}\omega t}$. The components of the frequency-dependent relative susceptibility, $\chi_\mathrm{r}(\omega) = \chi(\omega)/\varepsilon_0$, then take the form

$$\chi'_\mathrm{r}(\omega) = \frac{\chi_0 \Omega^2 \left(\Omega^2 - \omega^2\right)}{\left(\Omega^2 - \omega^2\right)^2 + \omega^2 \gamma^2} , \tag{10.15}$$

$$\chi''_\mathrm{r}(\omega) = \frac{\chi_0 \Omega^2 \omega \gamma}{\left(\Omega^2 - \omega^2\right)^2 + \omega^2 \gamma^2} . \tag{10.16}$$

These equations exhibit the typical signature of a resonance response such as shown in Fig. 10.2. The imaginary component $\chi''_\mathrm{r}(\omega)$ goes through a peak at $\omega = \Omega$ (the resonance frequency). The real component $\chi'_\mathrm{r}(\omega)$ exhibits a rise in positive value as the driving frequency

Ω approaches the natural frequency Ω from below, passes through zero when ω and Ω are equal, and rises towards zero from a negative value when $\omega \gg \Omega$. In some cases the exact frequency dependence of the relative susceptibility can be slightly different from that given above. The width of the peak in $\chi_r''(\omega)$ is determined by the damping constant γ. In addition the peak in $\chi_r''(\omega)$ may be broadened due to the possibility that either the resonance frequencies of different transitions of the same molecule can be close together and their responses can overlap, or that local electrical interactions between molecules cause the transition energies of individual molecules to be slightly shifted in energy giving a continuum of transitions around an average value.

As long as the transition energies are sufficiently far apart to be resolved experimental data of the resonance type will yield three pieces of information, which can be related to the electronic (or vibration) structure of the molecules. These are:

1. The natural oscillation frequency Ω
2. The damping constant γ
3. The amplitude factor χ_0.

The natural frequency ν is equal to the energy difference of the electronic states between which the fluctuation occurs, ξ, divided by Planck's constant i. e., $\nu = \xi/h$, and so provides information about the different quantum states in relation to one another. The amplitude factor χ_0 is proportional to the square of the transition dipole and therefore yields information on the relative rearrangement of positive and negative charges within the molecule by the transition fluctuation. Damping in these types of systems arises from the sharing of the transition energy between many energy states of the molecule and its vibrations. It removes energy from the specific oscillating dipoles for which the field produces a net dipole moment density. It may act through a delay in returning energy to the electromagnetic wave, i. e., incoherent reradiation, or by transferring it to other energy states where it cannot be reradiated. The damping therefore expresses the way that the energy transferred from the electromagnetic field to the molecule is absorbed and dissipated in the system. The damping factor γ often will have a complicated form. There is of course one other piece of information that is implied by data that fit (10.15)–(10.16) and that is that the equation of motion for the natural oscillating dipole moments is given by (10.14). In some cases, however, the damping factor may be frequency dependent as a result of changes in the interaction between different energy states of the system that occur on the same time scale as the relaxation time, $1/\gamma$. The equation of motion will now have a different and more complicated form than that of (10.14).

The above outline of spectroscopic responses is of necessity very sketchy as it is not the main theme of this chapter, and is dealt with in detail in many standard textbooks, for example *Heitler* [10.15]. There are however, a number of general features that can be used as a guide to what happens in the *linear* relaxation response. In the first place the dipoles involved are properties of natural fluctuations of the system, in this case quantum fluctuations in molecules. They are not produced by the electric field. In the absence of an electric field the fluctuating dipoles do not contribute to the net dipole moment of the system, in this case individual molecules. The action of the electric field in linear responses is solely to alter the population of the fluctuations such that a net dipole moment density is produced. This is achieved in the resonance cases considered above by the production of a net density of molecules in an excited state proportional to $\chi_0 E_0$. The irreversible transfer of energy from the electric field to the system relates to the sharing of this energy between the oscillating dipoles coupled to the electric field, and many equi-energetic states of the system that do not couple directly to the electric field. The energy shared in this way is dissipated among the many connected states. Dissipation is an essential consequence of natural fluctuations in an ensemble [10.19] and expresses the requirement that the fluctuation die away to zero at long times. The function $\phi(t)$ must therefore approach zero as t tends to infinity. In the absence of an electric field dipole density fluctuations utilise energy gained transiently from the ensemble and return that energy via the dissipation mechanism. When however an electric field is present, the relative number of fluctuations with dipole moments in different directions is altered and the dissipation term irreversibly transfers energy from the electric field to the ensemble.

10.2.2 Relaxation Response

We turn now to the relaxation response. The simplest way to view this behaviour is as an overdamped oscillation of the net dipole moment density, i. e., one for which $\gamma^2 > 4\Omega^2$. There are a number of ways of addressing this situation and below I shall develop the description starting from the simplest model whose behaviour is rarely found in condensed matter.

The Debye Response

In this case we can neglect the force constant term in (10.14), i. e., the term $\Omega^2\phi$. This leads to an equation of motion with the form

$$\frac{d\phi}{dt} + \gamma\phi = 0\,. \tag{10.17}$$

The solution to this equation is the very familiar exponential form, $\phi(t) \propto \mathrm{e}^{-t/\tau}$. Equation (10.17) can be interpreted by taking on board the lessons from the resonance response. As before we have to view it as describing the behaviour of a natural fluctuation in our system that produces a net dipole moment density as the result of a random impulse at $t = 0$. Now however, there is no evidence for dipole oscillation, so we are not looking at the quantum fluctuations of electronic charge clouds and nuclei positions of molecules. In this case the response originates with the permanent dipoles that many molecules possess due to the asymmetry of their atomic construction. We should also remember that, though atoms do not possess a permanent dipole moment, ion pairs in a material will act as dipoles. Such systems contain a large number (ensemble) of permanent dipoles and this ensemble will obey the laws of thermodynamics. Therefore, with the exception of such materials as electrets and ferroelectrics the orientation of the permanent dipoles will be random in the absence of an electric field, i. e., the *average* net dipole moment of the system will be zero. Thermodynamic ensembles are however described by distributions that allow for fluctuations about the defined average values, thus for example canonical ensembles allow for fluctuations in energy about a defined average energy content, and grand canonical ensembles allow for fluctuations in the number of effective units (e.g., net dipole moments) as well. In the case of dipole responses we are looking at fluctuations that involve the orientations of the permanent dipoles and hence create a net dipole density (Fig. 10.3c,d). Such fluctuations are natural to the ensemble, but are transient, i. e., as in Sect. 10.2.1 $\phi(t) \to 0$ as $t \to \infty$. Equation (10.17) describes the way in which such a local fluctuation in the dipole moment density decays (regresses) to zero, i. e., the ensemble relaxes. An applied electric field couples with the permanent dipoles to produce a torque that attempts to align the dipole with the electric field vector where its energy is lowest. Consequently the linear response of the system to the application of an electric field is an increase in the population of the permanent dipole fluctuations with a component oriented in the field direction as compared to those which have components oriented in the reverse direction. This relative change in the populations of the natural fluctuations of the system gives a net dipole moment density that is driven at the frequency of the electric field as in (10.7) [10.20].

As in the resonance case the polarisation can be obtained by adding the AC driving force oscillating at frequency ω to (10.17) and determining the solution for ϕ oscillating with the same frequency. The corresponding relative susceptibility components have the form

$$\chi'_{\mathrm{r}}(\omega) = \frac{\chi_0}{1+\omega^2/\gamma^2}\,, \tag{10.18}$$

$$\chi''_{\mathrm{r}}(\omega) = \frac{\chi_0\omega/\gamma}{1+\omega^2/\gamma^2}\,. \tag{10.19}$$

These functions show a peak in the imaginary susceptibility component, $\chi''_{\mathrm{r}}(\omega)$, at a frequency $\Omega = \gamma$, which is sometimes called the loss peak frequency since $\chi''_{\mathrm{r}}(\omega)$ is associated with the dissipation of energy, or equivalently the loss of energy from the driving electric field. The real component of the susceptibility, $\chi'_{\mathrm{r}}(\omega)$, changes monotonically from zero at high frequencies to a limiting low-frequency value of χ_0. This is termed the dielectric dispersion.

Equations (10.17)–(10.19) define what has come to be known as the Debye response after *P. Debye* who first addressed the nature of relaxation dielectric responses [10.1]. It is characterised by two pieces of information: the magnitude of the dispersion χ_0 and the damping factor γ, more usually defined via the relaxation time $\tau = 1/\gamma$ of the dipole density fluctuations. The dispersion magnitude χ_0 is a measure of the net change in dipole density fluctuations that can be produced by a unit field (i. e., $E_0 = 1\,\mathrm{V\,m^{-1}}$), and is proportional to the square of the individual permanent dipole moments. An exact fit between the relaxation response data and (10.18), (10.19) implies a specific form for the equation of motion of the dipole density fluctuations of the permanent dipole ensemble, i. e., that of (10.17) in the same way that a fit to (10.15)–(10.16) implies a fit to the damped oscillator equation of motion (10.14) in the resonance response.

Frequency-Dependent Dielectric Response in Condensed Matter

In practice the Debye response is rarely observed outside of the gas phase. Instead the experimental data can usually be characterised through fractional power laws in the frequency dependence of $\chi''_{\mathrm{r}}(\omega)$ [10.6, 8, 21] in the regions away from the peak (Fig. 10.4), i. e., for $\omega \gg \gamma$, and $\omega \ll \gamma$, giving

$$\chi'_{\mathrm{r}}(\omega) \propto \chi''_{\mathrm{r}}(\omega) \propto \omega^{n-1}, \omega \gg \gamma\,, \tag{10.20}$$

$$\chi'_{\mathrm{r}}(0) - \chi'_{\mathrm{r}}(\omega) \propto \chi''_{\mathrm{r}}(\omega) \propto \omega^{m}, \omega \ll \gamma\,. \tag{10.21}$$

Here n, and m are fractional exponents, i. e., $0 < n, m < 1$. This general form was first defined empirically as the *Havriliak–Negami* function [10.22, 23]. A number of special cases have been identified [10.5, 8]. Thus for example the Cole–Cole function is given by $n + m = 1$. When $m = 1$, and $0 < n < 1$, the Cole–Davidson form is produced, which obeys (10.20) and

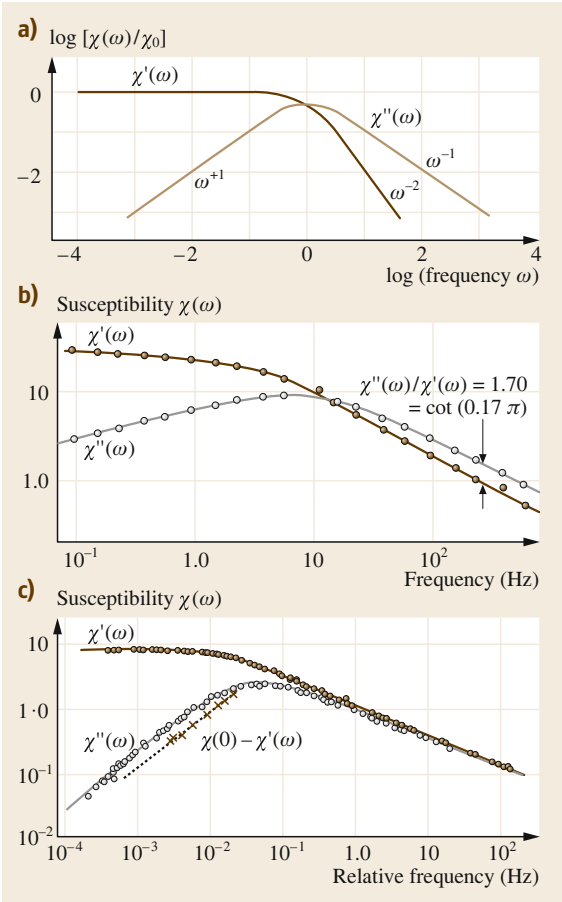

Fig. 10.4 **(a)** Schematic drawing of the Debye response. **(b)**, **(c)** examples of measured data fitted to the response function $\chi(\omega)/\chi(0) \propto [(1+\mathrm{i}\omega\tau)^{n-1}\,{}_2F_1(1-n;1-m;2-n;(1+\mathrm{i}\omega\tau)^{-1})]$ resulting from the response function $\phi(t)$ of (10.22). The function ${}_2F_1(,;;)$ is the Gaussian hypergeometric function (After [10.24]). *Plot* **(b)** data from irradiated tri-glycine sulphate (TGS); *Plot* **(c)** data from polyvinylacetate. (After [10.25])

follows $\chi''_{\mathrm{r}}(\omega) \propto \omega^m$ $(m=1)$ for $\omega \ll \gamma$ but without $\chi''_{\mathrm{r}}(\omega)$ being proportional to $\chi'_{\mathrm{r}}(0)-\chi'_{\mathrm{r}}(\omega)$ as in (10.21).

The physical theory of *Dissado* and *Hill* [10.26, 27] yields analytical expressions for $\chi'_{\mathrm{r}}(\omega)$ and $\chi''_{\mathrm{r}}(\omega)$ that contain both the Debye and Cole–Davidson functions as *exact* limiting cases, and the Cole–Cole and Havriliak–Negami functions as approximations with only minor differences in the curvature in the region of the peak in $\chi''_{\mathrm{r}}(\omega)$. The frequency-dependent susceptibility given by this theory has come to be known as the Dissado–Hill function and is defined in terms of a hypergeometric function [10.24], which is an infinite series with similarities to that of the exponential function. The reader is referred to [10.26, 27] for details.

Unlike the empirical functions the Dissado–Hill dielectric response function has a clearly defined equation of motion for $\phi(t)$ [10.27],

$$\frac{\mathrm{d}^2\phi}{\mathrm{d}t^2} + \frac{\left[2+n+\left(\frac{t}{\tau}\right)\right]}{t}\frac{\mathrm{d}\phi}{\mathrm{d}t} + \frac{\left[n+\left(\frac{t}{\tau}\right)(1+m)\right]}{t^2}\phi = 0\,. \tag{10.22}$$

This equation has an analytical solution for $\phi(t)$ in terms of a confluent hypergeometric function [10.24], which has the limiting behaviour $\phi(t) \propto t^{-n}$ at times $t < \tau = 1/\gamma$ and $\phi(t) \propto t^{-(1+m)}$ when $t > \tau = 1/\gamma$. When $m=1$ the solution is $\phi(t) \propto t^{-n}\exp(-t/\tau)$ giving the Cole–Davidson susceptibility function, and the Debye response function $\phi(t) \propto \exp(-t/\tau)$ is obtained when $n=0$ and $m=1$. The general analytical function for $\phi(t)$ was first derived in [10.28] and later re-derived and its equation of motion discussed in [10.26, 27] to which the reader is referred for details. The form of (10.22) illustrates clearly the development of the relaxation response from short-time high-frequency damped harmonic oscillations, characterised by (10.14), as a consequence of time-dependent damping functions and oscillation frequencies. More specifically the damping function approaches a constant value $1/\tau$ (equivalent to γ) at long times, while the oscillation frequency approaches zero. In contrast the Debye model assumes that the dipole motions are overdamped motions with no time-dependent transition from the damped oscillations occurring at short times. Of course there are many ways that time-dependent damping functions and oscillation frequencies may be introduced, most of which involve making similar approximations to that of Debye as regards the ensemble forces that control these factors, but only the specific forms of (10.22) give the power-law frequency dependencies observed in the susceptibility (10.20), (10.21). These forms are produced because the dipole density fluctuations retain some memory of the restoring and damping forces that act on it over very long periods of time, i. e., these forces are not random impulses. The reader is referred to [10.27] for more detail. An alternative equation of motion for the polarisation has been obtained in terms of a fractional time derivative [10.29–31], which is a differ-integral operator involving a memory kernel with the form of a decaying fractional time power law [10.29]. Although this form of equation of motion cannot be related directly to an oscillator equation, the fractional time power law of the memory kernel must have time reversal symmetry at short time [10.19] and hence it should develop from coupled oscillators as in [10.26, 27].

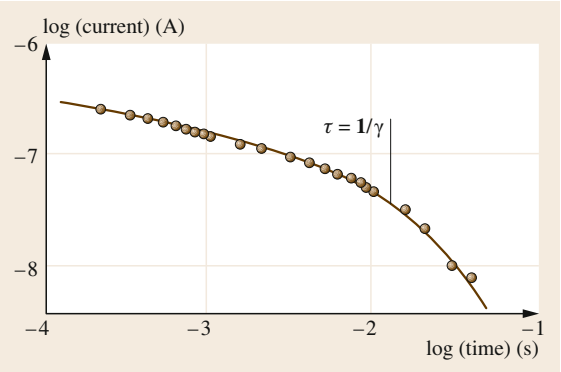

Fig. 10.5 The fit between the response function $\phi(t)/\phi(0) \propto (t/\tau)^{-n} e^{-t/\tau}\, {}_1F_1(1-m; 2-n; t/\tau)$ from (10.22) (where ${}_1F_1(;;)$ is the confluent hypergeometric function [10.24]), and experimental data for amorphous gallium arsenide. (After [10.27])

The Response Function

A different approach may be taken to deriving the frequency-dependent susceptibility of linear responses. Returning to (10.14), (10.17), (10.22) it can be seen that the solutions for $\phi(t)$ in the absence of a driving field give the time evolution of the dipole density fluctuation caused by a dipole generating impulse at $t = 0$, i. e., the natural motions of the system. The resulting expression for $\phi(t)$ is called the response function [10.20], and the complex susceptibility is obtained through (10.23)

$$\chi_r(\omega) = \chi'_r(\omega) - i\chi''_r(\omega) = \mathrm{Lt}_{\varepsilon\to 0}\left[\int_0^\infty \phi(t) e^{-i\omega t-\varepsilon t} dt\right]. \qquad (10.23)$$

Here ε is an infinitesimal quantity that is taken to zero after the integral has been carried out. This equation is valid for all linear dielectric responses. The requirement that $\phi(t) \to 0$ as $t \to \infty$ for natural fluctuations ensures that $\chi'_r(\omega)$ and $\chi''_r(\omega)$ remain finite. The equations of motion, (10.14), (10.17), and (10.22) have solutions for $\phi(t)$ that can be transformed in this way to yield analytical expressions for the frequency-dependent susceptibility. An important consequence of (10.23) is that the frequency dependencies of $\chi'_r(\omega)$ and $\chi''_r(\omega)$ contain the same information since they are Laplace transforms of the same time-dependent function. This also means that a frequency-dependent conductivity $\sigma(\omega) \equiv [\omega\chi''_r(\omega)]$ contains no more information than the equivalent dielectric dispersion $\chi'_r(\omega)$. In fact the linear susceptibility components $\chi'_r(\omega)$ and $\chi''_r(\omega)$ are related to one another through the Kramers–Kronig relationships (KKR) [10.5, 6]

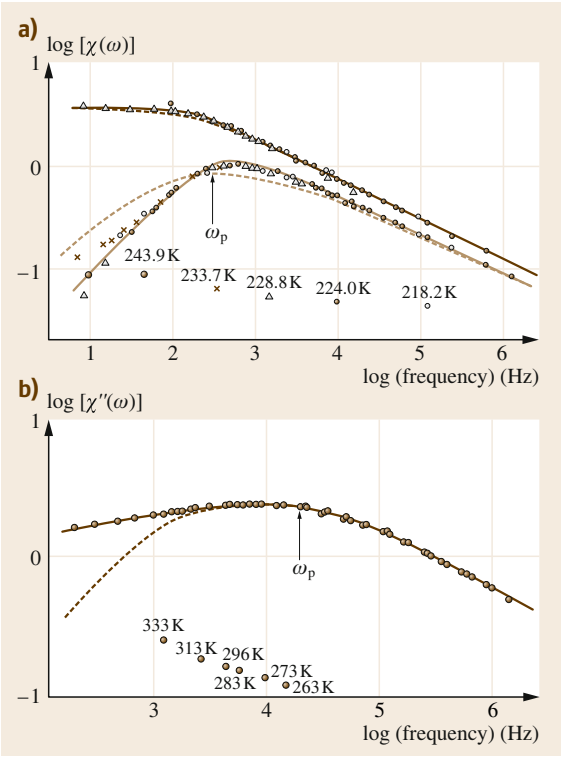

Fig. 10.6a,b Two examples of the fit between the susceptibility functions resulting from the response function $\phi(t)$ of (10.22) (*continuous line*) and (10.26) (*broken line*) and experimental master curves: **(a)** nematic form of N-(2-hydroxy-4-methoxybenzylidene)-pn-butylaniline (OHMBBA), and **(b)** polyallylbenzene. The shift of the representative point required to construct the master curve is marked on the plot. (After [10.27])

$$\chi'_r(\omega) = \frac{2}{\pi}\int_0^\infty \frac{x\chi''_r(x)}{x^2-\omega^2} dx\,, \qquad (10.24)$$

$$\chi''_r(\omega) = -\frac{2\omega}{\pi}\int_0^\infty \frac{\chi'_r(x)}{x^2-\omega^2} dx\,. \qquad (10.25)$$

The imaginary contribution from the pole at $x = \omega$ is excluded from these integrals. Although formally values of $\chi'_r(\omega)$ and $\chi''_r(\omega)$ are required over the frequency range from zero to infinity, the reciprocal relationships are adequately reproduced as long as the major part of the dispersion from any specific relaxation process is used.

Equation (10.23) means that linear dielectric responses are characterised through the time dependence of $\phi(t)$. This led *Williams* and *Watts* [10.32] to approach

the description of the frequency dependence commonly observed by proposing that the exponential behaviour of $\phi(t)$ resulting from the Debye model, (10.17), should be generalised to the form

$$\phi(t) \propto (t/\tau)^{-n} \exp\left[-(t/\tau)^{1-n}\right] . \qquad (10.26)$$

This expression is sometimes called the expanded exponential function or the Kohlrausch–Williams–Watt function, as it was later found that it was first proposed in [10.33] for mechanical responses. It is not known to possess a simple equation of motion such as (10.14), (10.17), and (10.22) but its relaxation function $\Phi(t)$, defined by $\Phi(t) = \int_t^\infty \phi(t)\mathrm{d}t$ [10.20] obeys a relaxation equation of the form of (10.17) with a time-dependent damping factor $\gamma(t) \propto t^{-n}$. The corresponding frequency-dependent susceptibility has the same power-law form as (10.20) for $\omega \gg \gamma = 1/\tau$, but exhibits a slowly varying increase of slope in a $\log[\chi_\mathrm{r}''(\omega)]$–$\log(\omega)$ plot as the frequency progressively reduces below γ that, with suitable choices for the value n, can approximate a power law for $\chi_\mathrm{r}''(\omega)$ such as is defined in (10.21). The relationship between experimental data for $\phi(t)$ and that derived in the Dissado–Hill cluster model, i. e., the solution to (10.22), is shown in Fig. 10.5. It can be seen that the data and the function for $\phi(t)$ approaches zero as t tends to infinity, with the time power law $t^{-(1+m)}$, but accurate experimental data for times several decades beyond τ is required if this behaviour is to be distinguished from that of (10.26). A better means of distinguishing the two results can often be had by recourse to their appropriate frequency-dependent susceptibilities, Fig. 10.6.

10.3 Information Contained in the Relaxation Response

As described in Sect. 10.2.2 relaxation responses contain three pieces of information. The strength of the coupling of dipole density fluctuations to the electric field characterised by χ_0, a characteristic relaxation frequency $\gamma = 1/\tau$, where τ is the characteristic relaxation time, and the relaxation dynamics characterised by the frequency dependence of $\chi_\mathrm{r}'(\omega)$ and $\chi_\mathrm{r}''(\omega)$. This latter feature is open to different interpretations, as will be discussed later.

10.3.1 The Dielectric Increment for a Linear Response χ_0

The dielectric increment is proportional to the square of the permanent dipole moments that give rise to the dipole density fluctuation. It is a feature of the dielectric response that does not usually receive the most attention, mainly because a quantitative relationship to the molecular physics of the relaxation process is often difficult to achieve. Nevertheless it has been used to determine the dipole moments of polar molecules using measurement in the gas phase or if necessary dilute solutions in a nonpolar solvent. In these cases the permanent molecular dipoles, μ, can be assumed to have the same magnitude everywhere, to be independent of one another, and to be able to adopt all orientations with equal probability in the absence of an electric field, i. e., all dipole moment orientations are at the same energy. This section starts by outlining the derivation of χ_0 for this situation even though this is not the topic area of this book and chapter. The aim is to demonstrate the procedure and bring out the assumptions involved so that the more complicated nature of dipole density fluctuations in condensed-state materials can be better appreciated.

Independent Free Dipoles

In an electric field a dipole that is at an angle θ to the field direction is at the energy $-\mu E\cos\theta$. Those molecules aligned with the electric field are therefore at the lowest energy. The thermal motions of the molecules will however tend to randomise the dipole orientations and the probability of finding a dipole with an orientation angle θ becomes $\exp(\mu E\cos\theta/k_\mathrm{B}T)$. The average value of $\mu\cos\theta$ is given by

$$M = \langle\mu\cos\theta\rangle = \frac{\int_0^\pi \mu\cos\theta\exp(\mu E\cos\theta/k_\mathrm{B}T)\sin\theta\mathrm{d}\theta}{\int_0^\pi \exp(\mu E\cos\theta/k_\mathrm{B}T)\sin\theta\mathrm{d}\theta} , \qquad (10.27)$$

and the contribution to the static polarisation is given by $N\mu < \cos\theta >$, where N is the number of permanent dipoles per unit volume. The term independent of the electric field is zero because all orientations are equally probable in the absence of the field. Equation (10.27) results in a nonlinear function in the electric field E for M, which is called the Langevin function, $L(\mu E/k_\mathrm{B}T)$, with,

$$L\left(\frac{\mu E}{k_\mathrm{B}T}\right) = \coth\left(\frac{\mu E}{k_\mathrm{B}T}\right) - \left(\frac{k_\mathrm{B}T}{\mu E}\right) . \qquad (10.28)$$

This function saturates at unity for very high values of $\mu E/k_\mathrm{B}T$, reflecting the total alignment of all the perma-

nent dipoles in the electric field. At low fields defined by $\mu E/k_B T \ll 1$, $L(\mu E/k_B T)$ is a linear function of E that gives the linear polarisation $P = N\mu < \cos\theta >$. Using $P = \varepsilon_0 \chi_r E$ gives the linear dielectric increment in χ_r as,

$$\chi_0 = \left(\frac{N}{\varepsilon_0}\right)\left(\frac{\mu^2}{3k_B T}\right) \tag{10.29}$$

Dipoles in Condensed Matter

In condensed-phase systems, particularly solids, the approximations that lead to the Langevin function and (10.29) no longer apply, and hence these expressions no longer hold. In the first place the dipoles are constrained by the local structure and in general will not be able to assume all orientations with equal probability in the absence of an electric field. In the second place we cannot assume that the dipoles are independent of one another. This dependence may arise in more than one way. For example there may be electrostatic interactions between the dipoles, such as would be responsible for the formation of ferroelectric and anti-ferroelectric states. However when the dipoles concerned are of a low concentration such as those that originate with impurities, lattice defects, interstitial ions etc. these dipole–dipole interactions may be weak. The dipoles concerned may also be arranged in such a way that even though they can adopt one or more alternative orientations their dipole–dipole interactions essentially cancel, such as might be expected in dipole glasses [10.34]. The common way to deal with this situation is to assume that a dipole representative of the average dipole in the ensemble experiences the average electric field of all the other dipoles. This is called the *mean-field* approach [10.35]. Since the mean field will be a function of the average dipole moment due to the applied electric field it is usually possible to construct an equation that can be solved to yield M and hence χ_0. Another way in which the dipoles can interact arises because permanent dipoles are part of the lattice structure of the material. Those permanent dipoles that lead to a polarisation in the presence of an electric field must have two or more local orientations available to them, i. e., they must be able to adopt a different orientation that in the presence of an electric field has a lower energy. Any such change will inevitably alter the local atomic and molecular interactions around the dipole that has moved. This effect will travel through the structure and influence other permanent dipoles through changes in atomic and molecular positions in its environment [10.36]. The strength of such interactions will vary depending on the type of dipole and the way that it is connected to the structure. For example reorientable dipoles formed by small interstitial (or substitution) ions may not interact very strongly with the surrounding lattice, whereas polar groups attached to a polymer chain will in many cases interact very strongly when they adopt a different orientation. Similarly the reorientation of polar molecules in liquids may be expected to distort their surrounding solvent cage and create a disturbance that will be transmitted to other polar molecules. The special feature of this form of interaction is that it is transmitted along specific directions depending upon the lattice structure and hence is nonisotropic.

Order–Disorder Ferroelectrics

These are materials in which the permanent dipoles possess two or a limited number of possible orientations. At high temperatures the dipoles are randomly distributed between the alternative orientations in the absence of an electric field. As the temperature is lowered the electrostatic field of the dipoles acts on any one dipole to make one of the orientations more preferable than the others. This causes the permanent dipole system to adopt a specific orientation at the Curie temperature T_c. The mean-field approach results in an expression for χ_0 that diverges at T_c, i. e.,

$$\chi_0 \propto \frac{\mu^2}{|T - T_c|} \,. \tag{10.30}$$

This expression is so common to us that it is easy to overlook the physical meaning that it contains, which is much better expressed in the renormalisation group approach [10.37]. Essentially the interactions between the dipoles cause their orientation and dynamics to become correlated to some extent. As T_c is approached from above, the dipole fluctuations in the system are correlated over increasingly long distances and involve increasingly larger groups of individual dipole moments μ. The dielectric increment increases in proportion to a power of the correlation length $\xi \propto |(T - T_c)^{-\delta}|$ and a more exact form for χ_0 is

$$\chi_0 \propto \frac{\mu^2}{|T - T_c|^{\alpha}} \,. \tag{10.31}$$

At temperatures below T_c the material will possess domains in which all the dipoles are aligned together. Dipole fluctuations in this state have the opposite orientation to that of the polarity of the domain dipole that is they are *changes in net dipole moment density*, Sect. 10.1.1. These dipole fluctuations also produce an electrostatic field that causes them to be correlated. As the temperature reduces their correlation length reduces and hence so does χ_0. These materials show that the responding dipole in condensed-phase materials will not always be that of individual molecular or ionic components of the system, they may in fact be groups of

individual dipoles that respond as a single unit. In fact the susceptibility increment may be written in terms of an effective dipole moment that is also a power of the correlation length, i. e., $\mu_{\text{eff}} \propto (\xi)^{\alpha/2\delta}$.

Kirkwood Correlation Factor

The particular feature of the ferroelectric order–disorder transition is that the correlation between dipoles in the dipole fluctuations is temperature dependent. In general this will not be the case; instead we can expect the correlation to be dependent upon the lattice structure of the material, and hence independent of temperature except for discrete step changes when the material undergoes a phase transition. One way of allowing for these correlations is to introduce a factor g, termed the *Kirkwood* factor [10.10, 38], into the expression for χ_0 such that it becomes

$$\chi_0 \propto Ng\mu^2 \,. \tag{10.32}$$

Here a value of $g = 1$ defines a system in which the dipoles are uncorrelated, i. e., they are independent of one another. Values of $g > 1$ indicate positive correlation i. e., the dipoles align in the same direction as in the ferroelectric case where g diverges as discussed. Values of $g < 1$ indicate dipoles that are anticorrelated i. e., pairs of dipoles tend to align in opposite directions. Both kinds of behaviour are known to occur.

General Features of the Temperature Dependence of the Dielectric Increment

Section 10.3.1 gives examples of behaviour in which an electric field imposes order, in terms of the polarity of the net dipole density fluctuations, upon an ensemble where the temperature acts as a disordering factor. In the case of independent free dipoles it is the applied field that attempts to align dipoles and for order–disorder ferroelectrics it is the electrostatic field of the other dipoles. It might therefore be expected that the temperature is always a factor that attempts to oppose the field and that the dielectric increment will decrease at high temperatures, but this is not always the case. For example, in situations where the dipole can adopt one of two orientations one of which is favoured by the local lattice structure, the equilibrium population will be heavily weighted towards the favoured orientation. The equilibrium value of M in such a region can be expressed as,

$$M = \mu \tanh\left(\frac{\Delta_\chi}{k_\mathrm{B}T}\right) \,, \tag{10.33}$$

where $2\Delta_\chi$ is the energy difference between the alternative orientations produced by the local structure. Here μ is the reorientable component of the dipole moment, Fig. 10.7. An applied electric field that will favour the one orientation over the other will change the energy difference between alternative orientations from $2\Delta_\chi$ to $2(\Delta_\chi - \mu E)$. Differentiation with respect to E then gives the susceptibility increment as $\chi_0 \propto (\mu^2/k_\mathrm{B}T)\cosh^{-2}(\Delta_\chi/k_\mathrm{B}T)$, with the approximately activated form

$$\chi_0 \propto \left(\frac{\mu^2}{k_\mathrm{B}T}\right)\exp\left(-\frac{2\Delta_\chi}{k_\mathrm{B}T}\right) \,, \tag{10.34}$$

holding when $\Delta_\chi/k_\mathrm{B}T \gg 1$. Although (10.33) implies that regions exist where dipoles are aligned by the structure this does not necessarily mean that the material has a net dipole in the absence of an electric field. Such regions may be local and with dipole vectors randomly arranged by the structure. This behaviour has been found in ferroelectric ceramics [10.39, 40] in both the ferroelectric and paraelectric phases outside the transition region where T approaches T_c. Expression (10.34) indicates that in the appropriate temperature range the effect of the thermal fluctuations is effectively to increase the density of dipoles that can respond to the electric field, and that this overcomes any randomising behaviour. In contrast, at high temperatures ($\Delta_\chi/k_\mathrm{B}T \ll 1$) the distribution of dipoles between the alternative orientations becomes almost random and χ_0 approaches the free-dipole result (10.29).

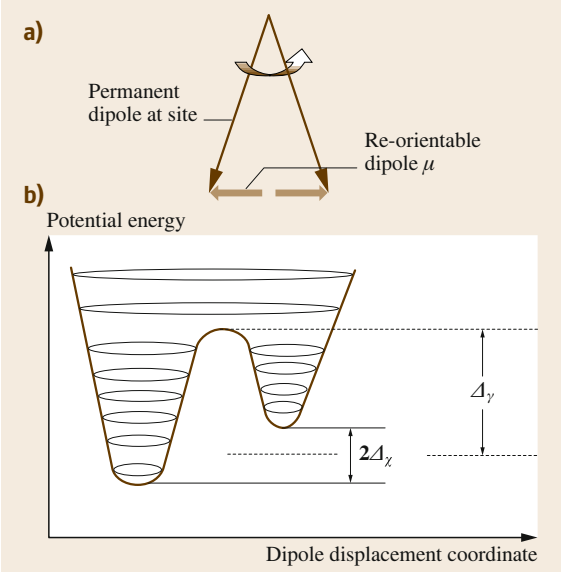

Fig. 10.7a,b Dipole reorientation between two potential wells: **(a)** shows the reorientable component of the dipole, **(b)** shows the potential-energy surface

In many experimental situations the value of the dielectric increment is essentially independent of temperature. It is difficult to see how this can occur in an ensemble where the dipole density fluctuations are produced by fluctuations in thermal energy about the average value, which couple to the electric field via changes in the heat content as in (10.27). However it may be possible to conceive of this behaviour as due to fluctuations in the configuration entropy of the molecular system, of which the dipole is a part, that take place without any change in the heat content. The effect of the field would be to change the configuration entropy S rather than the heat content H. As a result the susceptibility would be independent of temperature. This picture implies that we must think of the dipoles in this case not as local elements embedded within the material matrix moving in a fixed local potential, but as an integral part of the matrix whose dynamics is described by fluctuations in the Gibbs free energy $G = H - TS$ of the whole ensemble. In this case correlations between dipoles would be expected to occur mainly via the indirect route through their interaction with their local environment, rather than their direct electrostatic interactions.

Equation (10.31) describes the behaviour of a system undergoing an order–disorder transition *among the permanent dipole orientations*. A similar behaviour will be found for the relaxation response of a first-order ferroelectric or dipole alignment transition [10.41]. In general phase transitions will not give rise to a divergence in χ_0, which occurs because the phase transition in these cases is defined through the dipole, i. e., the dipole orientation is the order parameter. In other types of phase transition the dipoles are not the primary cause and what can be expected is an abrupt change of χ_0 as the dipoles find themselves embedded into a different lattice structure with different local potentials and orientation positions, different ensemble energies, and different correlations with one another and the material matrix.

The Information Content of the Dielectric Increment

As is clear from the above discussion it is not easy to make definite quantitative statements about the dipole system based on the dielectric increment. The basic reason for this situation is that the measurements are made on a macroscopic sample that contains an ensemble of an enormous number of dipoles, up to $\approx 10^{28}\,\mathrm{m}^{-3}$. The description of such systems can be carried through if the elements, here electric dipoles, are independent and their orientation is defined by a static local potential; as discussed above this will not be the case in general. More typically the dipoles will be correlated with the matrix in which they are embedded and/or one another. This means that the dipoles that are involved in the dipole density fluctuations are not site dipoles but groups of molecules/ions including dipoles, i. e., the responding features have a size intermediate between that of the molecule/unit cell and that of the sample. Determination of the temperature dependence will give some clues as to how to regard the dipole system through the definition of an effective dipole. The way the effective dipole changes with temperature will allow some interpretation of the kind of system that is present. Variation with other control parameters will produce more information, and systematic variation of the structure, for example replacement of side groups in polymers by longer or different side groups, or substitution of impurity ions by similar ions of different oxidation state or ionic radius, will help to identify the local dipole moment contributing the dielectric increment. However, even if the form of the site dipole is known, the quantitative evaluation of a factor such as the Kirkwood factor g (10.32) is not trivial. In condensed matter, as can be seen from Fig. 10.7, only a component of the site dipole is likely to be involved in reorientation. Unless the local structure is very well known it will not be possible to determine the actual value of the reorientable component in order to obtain a quantitative estimate of g. What can be achieved is a fingerprint of the dipole fluctuations in the material that can be used to characterise it. However at best this will be a partial picture of the dipole fluctuations in the material and information gained from the relaxation time and the relaxation dynamics should be used to enhance it further. In this way a holistic view of the dipole fluctuation can be attempted. It is important to realise that the picture obtained from these three features must be complementary. It is not acceptable to regard them as three independent features, as in fact they just yield different facets of the same process.

10.3.2 The Characteristic Relaxation Time (Frequency)

Equations (10.14), (10.17), (10.22), and (10.23) define a characteristic relaxation rate γ or relaxation time $\tau = 1/\gamma$ for the dipole density fluctuations. In the case of the Debye response, whose susceptibility functions are given by (10.18) and (10.19), γ is the frequency at which the imaginary (dielectric loss) component $\chi_\mathrm{r}''(\omega)$ exhibits a peak. It has therefore become customary to determine the dependence of the relaxation time (rate) upon the control parameters (e.g., temperature, pressure, etc.) that are varied via that of the loss peak frequency. As long as the frequency dependence of $\chi_\mathrm{r}''(\omega)$ (i. e., the loss peak shape) remains unchanged

this procedure is valid because essentially the dielectric response investigated can be treated as a single composite process, even though it has a wider frequency dependence than that predicted for the independent free dipoles. Both the theoretical equation of motion (10.22) and response function (10.26) do in fact describe the response as a single composite process with a characteristic relaxation rate (time). However the frequency of the peak in $\chi_r''(\omega)$ (loss peak frequency) predicted from (10.22) is not γ but γ multiplied by a numerical factor depending upon the power-law exponents, n and m. In many cases the loss peak is very broad ($n \to 1, m \to 0$) and it is difficult to locate the peak precisely and to be sure that the point located is at the same position with respect to the functional dependence of $\chi_r''(\omega)$ upon ω. Under these circumstances a better procedure is to construct a master curve. This is done by first plotting $\chi_r''(\omega)$ as a function of ω in log–log coordinates for each of the values of the control parameters (e.g., temperature, pressure, etc.) used in measurement, and then translating the data sets along the $\log(\omega)$ and $\log[\chi_r''(\omega)]$ axes. This will bring the data into coincidence if the susceptibility frequency dependence is unchanged. The translation required to achieve coincidence gives the dependence of the susceptibility increment ($\log(\chi'')$-axis) and characteristic relaxation frequency ($\log(\omega)$-axis) on the controlled variable. For example it gives the ratios $\gamma(T_1)/\gamma(T_2)$ (or $\chi_0(T_1)/\chi_0(T_2)$) for the temperature change T_1 to T_2 when temperature is the controlled variable. This technique also has the advantage of illustrating clearly whether or not the frequency dependence is independent of the variation in temperature (or other parameter), i. e., whether or not the different sets of data can be brought into coincidence. It can also be used to determine any relationship between χ_0 and γ. This is done by selecting a reference point (e.g., the point $\chi_0 = A, \omega = B$) and marking the position on the master curve of this point from each data set after it has been translated to achieve coincidence. A trace is formed giving the dependence of $\log[(\chi_0)^{-1}]$ as a function of $\log(\gamma^{-1})$ as shown in Fig. 10.6 where $\omega_p = \gamma$.

The relaxation rate is the dielectric response feature that shows most dependence upon the variation in the control parameters and so is the feature that is most often studied. In the following sections I will outline some of the most common types of behaviour and discuss their implications for the physics of the relaxation process.

Site Dipole Reorientation

The simplest form of relaxation rate is that described by Debye for independent molecular dipoles suspended in a viscous continuum. As described in Sect. 10.3.1 these dipoles are regarded as free to adopt any orientation in the absence of an electric field. Relaxation of a dipole density fluctuation involves the rotation of the molecular dipoles in the fluctuation to a state in which the net dipole density is zero. In such a situation the rotation of each individual dipole occurs at the same speed determined by the viscosity, η, of the medium, and the relaxation time ($\tau = 1/\gamma$) of the dipole density fluctuation is governed by that speed. For a molecular dipole whose effective length is a the relaxation time has the form [10.10],

$$\tau \propto \frac{\eta a^3}{k_B T} \,. \tag{10.35}$$

The more viscous the medium, or the bigger the molecular dipole, the slower it rotates and the slower will be the relaxation of a fluctuation, giving a net dipole moment to the ensemble.

Of course the conditions for this behaviour to be exactly applicable cannot be met except in a gaseous medium. Condensed-phase materials are not continua. Even liquids possess a local structure and molecular dipoles will either be part of that structure if they are contributed by the medium, or will be surrounded by a solvent shell if they are dissolved in the medium. In solids the molecular (or ionic) dipole is of necessity part of the structural matrix, and even though this must be irregular enough to permit rotational displacement to at least one other orientation the matrix can be expected to maintain some structural correlation to distances well away from the site of a reorientable dipole. These are the conditions that must be included in any description of the relaxation frequency (time).

The first point of departure from the picture of a free dipole in a continuum is that the dipole will possess only a limited number of orientations that it can adopt. Consequently there will be a potential barrier between these alternative equilibrium orientations. The rate of transition between alternative orientations and hence the relaxation frequency will be determined by the rate at which a dipole or, to be more specific, the atoms or ions that form the local dipole can pass over the potential barrier to switch orientation, as shown for example in Fig. 10.7. In this case the relaxation frequency will possess an activated (Arrhenius) form where the activation energy Δ_γ is the mean potential barrier height between the alternative orientations, i. e.,

$$\gamma = \frac{1}{\tau} = A \exp\left(-\frac{\Delta_\gamma}{k_B T}\right) \,. \tag{10.36}$$

The expression to be used for the pre-exponential factor A depends on the way in which the atoms/ions comprising the local dipole pass through the transition region

at the top of the barrier [10.42, 43]. In the schematic drawing of Fig. 10.7 the dipole is described as having an atom (ion) at its head that performs quantum oscillations in one of two potential wells. As long as it can be assumed that there is a thermal equilibrium between all the vibration states and that the dipole head passes into the alternative well in a single transit of the barrier region, then $A = \nu$, where ν is the frequency of the quantum vibrations at the bottom of the wells. This result continues to hold even if thermal equilibrium is established only for the states at the bottom of the well as long as the effective friction acting on the dipole head in the barrier region is weak. The type of potential surface with these properties is one that remains essentially rigid during the actual transit of the barrier region, which takes place in a time typically of $\approx 10^{-14}$ s. The activated factor in (10.36) expresses the thermal probability of finding a dipole in a quantum state at the top of the barrier. The other extreme situation occurs when the friction ς_d in the barrier region is high, for which $A \propto (1/\varsigma_d)$. This occurs when the transit of the barrier region is slow enough to allow interactions with neighbouring vibrating atoms to overdamp the motion. In this case the potential surface distorts during the transit of the barrier. Such situations can be expected when the barrier is broad and ill-defined, and correspond to local structures that are flexible, such as may be expected in viscoelastic materials. A general expression $A = \lambda_r(\nu/\nu_b)$ has been developed by *Grote* and *Hynes* [10.43] where λ_r is a function that describes the change from low to high friction and ν_b is the quantum frequency in the barrier region.

An interesting consequence of this type of potential surface is that, regardless of the magnitude of the barrier energy Δ_γ, a temperature should exist below which reorientation over the barrier would take so long that any dipole fluctuation would essentially remain unrelaxed, i. e., the dipole system becomes frozen. However when the moving atom in the permanent dipole is a hydrogen atom this is not the case; relaxation can occur by the tunnelling of the hydrogen atom through the barrier [10.44]. This has been demonstrated by experiments on deuterated oxidised polyethylene molecules at millikelvin temperatures [10.45, 46]. In this case the relaxation frequency is determined by the tunnelling probability of the deuterium/hydrogen atom through the barrier, which is dependent upon the atomic mass, the barrier width and height, but *not the temperature*, i. e., the relaxation frequency becomes temperature independent at temperatures below ≈ 100 mK.

Relaxation on a Free Energy Surface

The situation described in the previous section is one in which the dipole moves on a potential surface provided by the surrounding structural matrix. The only dynamic effect of the matrix is via elastic and inelastic interaction between the quantum vibrations of the dipole and the matrix. In many cases however, the atoms (ions) comprising the dipole will cause the displacement of the centres of motion of the surrounding atoms during its transit between alternative orientations. In this case the expression for the relaxation frequency has to refer to the group of atoms affected as a unit, and an appropriate form is that derived by *Eyring* [10.47] for chemical reactions

$$\gamma = \left(\frac{k_B T}{h}\right) \exp\left(-\frac{G^\#}{k_B T}\right) . \tag{10.37}$$

Here $G^\#$ is the change in Gibbs free energy on passing from the ground state to the transition state in the process of reorientation. The barrier is now a free energy rather than a potential barrier and reflects the need for the involvement of displacements in a number of atoms, ions or molecules in order to achieve the dipole reorientation. If we refer again to Fig. 10.7 the difference is that the normal coordinate of the quantum vibrations in the barrier region is a mixture of several different normal coordinates of the surrounding matrix as well as that of the dipole in the well. In general $G^\#$ will be composed of an activation entropy contribution $S^\#$ as well as an activation enthalpy contribution $H^\#$ with $G^\# = H^\# - TS^\#$, and both will be properties of the group of atoms/molecules involved and their structural relationship. The expression for γ therefore takes a form similar to that of (10.36)

$$\begin{aligned}\gamma &= \left[\left(\frac{k_B T}{h}\right) \exp\left(\frac{S^\#}{k}\right)\right] \exp\left(-\frac{H^\#}{k_B, T}\right) \\ &= A_{\text{eff}} \exp\left(-\frac{H^\#}{k_B T}\right) .\end{aligned} \tag{10.38}$$

The activation entropy $S^\#$ will reflect the configuration rearrangement required for the dipole to reorient. Thus for example, when reorientation requires the surrounding matrix to adopt a more irregular (disordered) arrangement so as to remove a steric hindrance to reorientation the transition region entropy will be greater than that of the dipole in the bottom of the well and $S^\#$ will be positive. Alternatively the transition region may require specific local arrangements in order that the dipole can avoid such hindrances. In this case the entropy of the transition state will be less than that of the dipole in the bottom of the well and $S^\#$ will be negative. A nonzero value of $S^\#$ will therefore lead to a relaxation frequency with an effective pre-exponential factor, A_{eff}, that is either greater or less than $k_B T/h$.

An interesting variation on this behaviour has been suggested by *Hill* and *Dissado* [10.46] who showed that several experimental relaxation frequencies could be described via what they termed an activated tunnelling expression. Here they allowed the possibility that the transfer between alternative orientations could take place by thermal activation to an energy state for which the tunnelling of hydrogen atoms through the barrier was feasible. An expression for the relaxation frequency was obtained by determining the optimum transfer rate, with all processes considered from that of an unactivated quantum tunnelling to activation over the top of the barrier. If the energy difference between the alternative orientations is zero the resulting relaxation frequency had the form

$$\gamma \propto \exp(BT)\,, \tag{10.39}$$

over a considerable temperature range, where B is a temperature-independent factor dependent upon the tunnelling distance, the barrier height and shape, and the mass of the tunnelling particle. If the *barrier* in this work is taken to be a free-energy barrier rather than a potential barrier, the analysis can be seen to be equivalent to a situation whereby the dipole relaxes by finding a route between the alternative orientations that allows for lower values of $H^{\#}$ at the expense of ordering the surrounding molecules/atoms, i. e., a negative $S^{\#}$. Routes with higher values of $H^{\#}$ require values of $S^{\#}$ that are less negative. In this case the optimum relaxation frequency will take a form such as (10.39) and only at very high temperatures will γ become purely activated with $S^{\#} \approx 0$. The picture of dielectric relaxation provided by this interpretation is consistent with the *defect diffusion* mechanism [10.48], in which defects diffusing in the structural matrix, such as a kink in a polymer chain or a dislocation in a crystal, lower or remove barriers when they reach a dipole, allowing it to take an alternative orientation of equal energy. When the defect moves on, the dipole is locked into the new position until another defect arrives.

The Glass Transition

A glass is essentially a material that has become macroscopically rigid without attaining its thermodynamically favoured crystalline state. The manner in which this occurs for a liquid or viscoelastic (rubbery) material that has been rapidly cooled has been the subject of intense investigation over a large number of years (see *Angell* [10.49]). A simple, some would say oversimple, view of the situation is to regard it as a concatenation of two effects. In the first place supercooling the liquid phase will at some temperature result in a situation where the liquid no longer possesses a heat content in excess of the crystal state at that temperature [10.50]. The liquid will be unstable with respect to a disordered solid possessing only local crystalline order. In the second place the lowering of the temperature during the supercooling will cause the lattice to contract thereby introducing and increasing barriers to local molecular/atomic motions. At some temperature the thermal fluctuations (described by the Boltzman factor in (10.36)–(10.37)) that are responsible for raising the site energy to that of the barrier become so rare that the time required for rearrangement becomes enormously long. At this temperature, termed T_g, the structure is essentially locked into a macroscopically rigid state, termed a glass. The glass transition cannot be regarded as a thermodynamic transition of state (unlike a melting/crystallisation temperature for example) and there are different ways of defining and determining T_g [10.49].

During the approach to the glass state the rate of reorientation of permanent dipoles will become slower and eventually reach zero as shown in Fig. 10.8. It is common to denote the response due to a set of dipoles that are frozen during glass formation as the α-response. A second response can be seen in the figure: termed the β-response. This is provided by dipoles that are able to reorient without requiring any substantial rearrangement of the surrounding structural matrix. It should not be expected however that this response is due just to a dipole reorientation with respect to the molecule it is attached to. In many cases the β-response involves the displacement of the molecule or part thereof as a whole [10.51]. In polymers this is a local displacement of small polymer chain sections with or without side groups (see polyethylene in [10.52] for

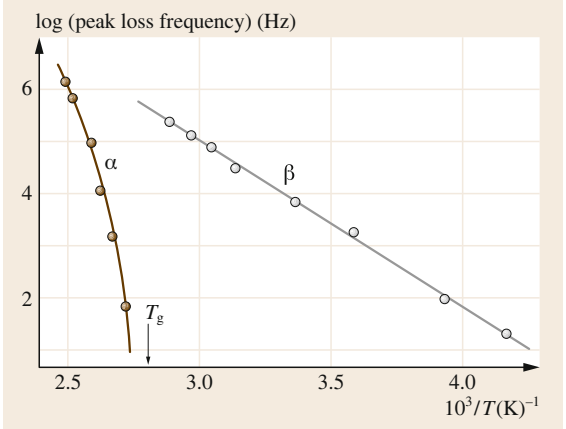

Fig. 10.8 The Arrhenius plot of the glass-forming polyvinylchloride system showing the slowing down of the α-response ($T > T_g$) as T_g is approached from above and the activated β-response. (After [10.8])

example), and either the free-energy expression (10.38) or the potential-energy expression (10.36) will apply, depending on whether the surrounding chains remain rigid during the relaxation or rearrange locally. These dipoles are active in the glass state and can be expected to have a relaxation rate of the form of (10.36), i. e., reorientation over a potential barrier. In the case of the α-response it is clear that the relaxations must involve displacements in a number of molecules/atoms other than just those comprising the permanent dipole, and hence it is instructive to discuss the behaviour in terms of the rate expression (10.37). What can be seen is that, as the temperature at which the system becomes rigid is approached from above the gradient in the Arrhenius plot gets steeper, and $H^{\#}$ therefore becomes larger. The non-thermally-activated pre-exponential factor, A_{eff}, in (10.36) is greater than $k_{\mathrm{B}}T/h$ and hence $S^{\#} > 0$. As the temperature approaches T_{g} there is an increase in A_{eff}, by many decades in frequency, which must be due to an increase in $S^{\#}$. These changes in $H^{\#}$ and $S^{\#}$ indicate that, as T_{g} is approached, dipole-orientation relaxation not only requires an increased amount of energy in order to enter the transition (barrier) region but also a larger amount of configuration disordering in the surrounding structure that makes up the molecular/atom group involved in relaxation. Although it is possible that such a situation may come about because reducing the temperature produces a local increase in density that increases steric hindrances for the same group of atoms and molecules, it is more likely that the number of molecules that are displaced in order to allow the dipole to pass through the transition region has increased. These considerations are consistent with a structure that is becoming either tangled or interlocked as the temperature decreases. Detailed expressions based on these concepts but involving macroscopic parameters have been attempted [10.30, 49, 53–56].

The glass formation discussed above has a structural basis and dipole–dipole interactions will play at most a minimal role. In some situations however, the glass is a disordered array of dipole orientations [10.34]. This sort of state is most likely to occur at very low temperatures in materials that possess dipoles occupying the sites of a regular lattice. At high temperatures the dipole orientations will be disordered but, as the temperature is reduced to low values, each individual dipole would be expected to adopt their lowest-energy orientation, resulting in a state of ordered dipole orientation. A *dipole glass* will result instead when the dipole–dipole interactions produce forces that generate barriers to the local reorientation and frustrate the ordering process at temperatures low enough that the barriers generated cannot be overcome in any conceivable time.

Ferroelectric Transition

The dielectric response of ferroelectrics at temperatures in the vicinity of their Curie (critical) temperature also exhibit relaxation frequencies that approach zero, while their dielectric increment approaches infinity (Fig. 10.9a,b) as discussed in Sect. 10.3.1. In this case both the dielectric increment and the relaxation frequency are functions of a hidden variable that characterises the system, the correlation length ξ of the dipole fluctuations. Just as the dielectric increment increases with a power of the correlation length, the relaxation frequency will decrease. Put simply the more

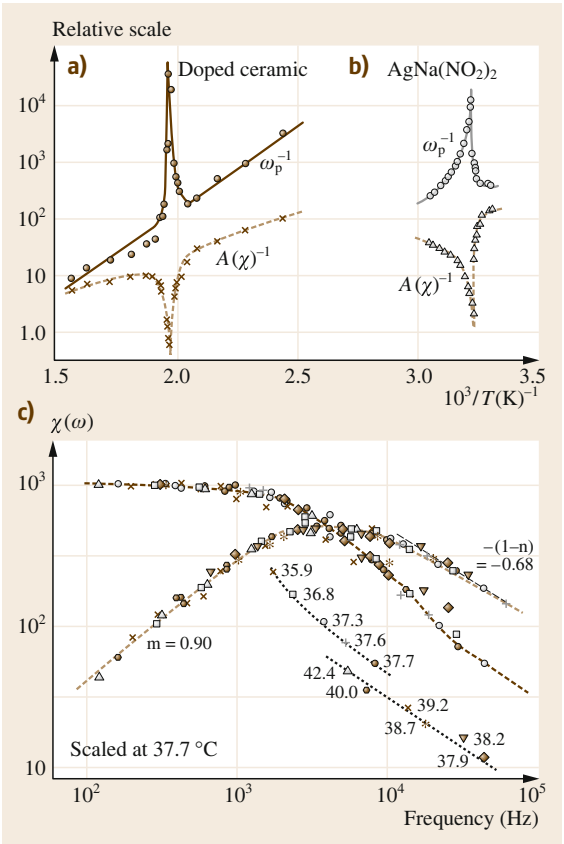

Fig. 10.9a–c An Arrhenius plot of the inverse of the susceptibility increment $A(\chi)(\equiv \chi_o)$ and loss peak frequency $\omega_{\mathrm{p}}(\equiv \gamma)$ is shown for **(a)** a ferroelectric ceramic and **(b)** the ferroelectric $AgNa(NO_2)_2$. The frequency-dependent susceptibility of $AgNa(NO_2)_2$ is shown in **(c)** (on log–log scales) together with the locus of the representative point as $T_{\mathrm{c}} = 37.8\,^{\circ}\mathrm{C}$ is approached from above and below. Note the power-law relationship between the dielectric increment and the relaxation frequency, and the parallelism between this locus and the frequency dependence for $\omega > \gamma$, demonstrating an identical power-law behaviour. (After [10.39])

dipoles are correlated in the fluctuation the longer the time that is required for its relaxation. Scaling theory [10.37] describes the system by a hierarchy of self-similar correlations. The strongest correlations are between the dipole and its nearest neighbours. This gives a local geometrical arrangement of correlations. The next-strongest correlations are between the same geometrical arrangement of groups of nearest neighbours, and the next strongest is between the same geometry of groups of groups. Eventually the whole system up to the correlation length is constructed in this way. Because the geometrical arrangement is preserved at each stage the properties for each stage have to be proportional to a power of the size. This gives

$$\gamma \propto |T - T_c|^{\beta} \propto \xi^{-\frac{\beta}{\delta}} , \tag{10.40}$$

and using (10.31) the relationship

$$\chi_0 \propto \gamma^{-\frac{\alpha}{\beta}} , \tag{10.41}$$

follows. But the theory can go further and predict the frequency dependence of $\chi_r''(\omega)$ and $\chi_r'(\omega)$ for $\omega > \gamma$. This follows because we can think of the response of the system to a field of frequency ω as being due to the correlation scale that can relax at the frequency ω, i. e., $\xi_\omega \propto \omega^{-\delta/\beta}$. The dielectric increment appropriate to this length scale can be obtained from (10.31) as $(\xi_\omega)^{\alpha/\delta}$ and hence,

$$\chi_r''(\omega) \propto \chi_r'(\omega) \propto (\xi_\omega)^{\frac{\alpha}{\delta}} \propto \omega^{-\frac{\alpha}{\beta}} = \omega^{n-1} , \tag{10.42}$$

with $n = 1 - \alpha/\beta$. These relationships describe what is called dynamic scaling. A detailed description of the derivation of the frequency dependence in (10.42) is given in [10.37] and the relationship of the power-law frequency dependence to self-similar relaxations is shown explicitly using scaled electrical circuits in [10.57]. Because of the small range of temperatures around T_c over which the power-law relationships (10.40)–(10.41) are expected to hold it is difficult to determine the exponents α and β with any accuracy, however the dynamic scaling law can be easily demonstrated by using the master-curve technique and determining the locus of the representative point (see the beginning of Sect. 10.3.2). An example is shown in Fig. 10.9c where it can be seen that the representative-point locus of χ_0 as a function of γ is a power law with the same exponent as that of the frequency dependence of $\chi_r''(\omega)$ and $\chi_r'(\omega)$ for $\omega > \gamma$.

The Information Content of the Relaxation Frequency (Time)

The typical starting point in investigating the relaxation frequency (time) is to make an Arrhenius plot, i. e., $\log(\gamma)$ is plotted as a function of $1/T$. A straight line is taken to indicate an activated process of the form of (10.36), with the gradient yielding the activation energy Δ_γ. However in most cases data is only available from a restricted temperature range and so the variation of $k_B T/h$ with temperature will be small. In this case the free energy expression (10.38) would give an equally good straight line. Since there are many situations in which the pre-exponential factor in (10.36) will be less than a quantum vibration frequency $10^{12}\,\text{Hz} \leq \nu \leq 3\times10^{13}\,\text{Hz}$, it is difficult to discriminate between the potential-barrier situation and the free-energy barrier in which $S^{\#} < 0$. Only when $A \gg 3\times10^{13}\,\text{Hz}$ will identification with relaxation via a free-energy barrier be certain. As can be seen from the foregoing it is difficult to obtain any definite information from the pre-exponential factor in an activated relaxation, except for the latter case where an evaluation of $S^{\#}$ is possible. Where $S^{\#}$ can be determined it gives us a qualitative picture of a relaxing dipole centre which has to be structurally distorted in order for the dipole to adopt a different orientation. The corresponding value of $H^{\#}$ gives the amount of energy that has to be supplied to the group in order for the reorientation to occur even allowing for the distortion. What cannot be determined from this information is the size of the group that is involved, though the behaviour and magnitude of χ_0 may give an idea as to the dipole magnitude and density. To give an idea of the difficulty of a molecular interpretation let us take the case of cyclo-hexanol [10.58]. This molecule forms a plastic crystal, i. e., the molecular centres are located on a crystal lattice but their orientations are disordered. The dipole moment is associated with the only strong polar feature, the alcohol (–OH) group, which can take one of two orientations with respect to the molecule. It would therefore be expected that the measured activation energy of $\approx 0.5\,\text{eV}$ would be the potential barrier to the transfer of the alcohol group between the two positions, with its contributions from the neighbouring molecular cage as well as the molecular energy change. However, the molecular structure of the cyclohexanol can itself exist in two conformations, the chair and the boat, and can rearrange its orientation in a lattice by passing through the alternative conformation as an intermediate. The free-energy barrier to this interconversion is also $\approx 0.5\,\text{eV}$. So we cannot decide from the relaxation frequency whether the relaxation involves just -OH group transfer or transfer via a boat-to-chair transition or a mixture of both. In this case the pre-exponential frequency $A_{\text{eff}} \approx 6\times10^{16}\,\text{Hz}$, so relaxation has to have a positive $S^{\#}$ and involve a number of atoms rather than a dipole reorienting on a rigid potential surface.

In the case of near-crystalline materials where the dipole is associated with defect centres we would expect the potential-barrier approach to be the best, but even here the fact that local reorientation is possible implies some sort of interaction between the surroundings and the moving dipole head. Calculations based on a rigid cage should [10.59] however be possible, and comparison with experiment can be expected to determine how well this represents the situation and to what extent the transit of the barrier is affected by the barrier friction. Information provided by the dielectric increment should be of help here. The calculation ought to be able to yield an estimate of the reorientable component of the dipole, and if as seems likely the alternative orientations are at different energies, the temperature dependence of χ_0 should follow (10.34).

Although it is conceptually simple to think of dipoles relaxing upon a potential surface that remains unchanged during the relaxation, this is likely to be only an approximation to reality. The fact that alternative orientations exist indicates that in most cases the surrounding structure must be modified to some extent to accommodate the change; at the very least we can expect the dipole to polarise its surroundings differently according to its orientation. The expressions in Sect. 10.3.2 for the relaxation frequency of dipoles relaxing on a free-energy surface and dipoles in ferroelectrics reflect this fact in different ways. The ferroelectric behaviour described in Sect. 10.3.2 shows that when the *dipoles* become extensively correlated the relaxation frequency reduces as an inverse power of the correlation length and the dielectric increment increases as a different power of the same correlation length. The self-similar scaling relates this behaviour to the frequency dependence of the susceptibility. The behaviour of the α-response of a glass-forming system involves dipole-structure interaction in a different way. The relaxation frequency approaches zero as T approaches T_g from above. Whatever the details of the glass-forming process this behaviour has to indicate a progressively increasing difficulty for the dipoles to reorient, which here is associated with structural ordering, densification, and atomic packing rather than long-range correlations as in ferroelectrics. This response is also one for which the dielectric increment is often insensitive to temperature. If we put the two dielectric response features together we come to a picture in which the electric field effectively modifies the configuration entropy of the system in generating a net dipole density fluctuation. The net dipole density produced is essentially the same at different temperatures, so the change in configuration density generated by the electric field does not vary, but the relaxation time increases as the activation enthalpy $H^{\#}$ and entropy $S^{\#}$ increases. Put together with the fact that in structural glass formation small local regions are attempting to adopt a crystalline structure, this data indicates that there are *local* values of ground-state configuration entropy that reduce as T_g is approached, with a transition state involving a disordering of the local regions to free the dipole enough to allow it to adopt an alternative orientation in an equally ordered but different configuration. The dipole density fluctuations that couple to the electric field seem to involve reorganisations of the structure that can occur without a change in the value of the heat content H, i. e., they are essentially configuration entropy fluctuations rather than thermal fluctuations. In contrast to the ferroelectric situation the slowing down of the relaxation is not caused by longer-range correlations but by the increasingly larger numbers of molecular adjustments required to achieve a dipole reorientation.

The message of this section is that in most cases a detailed molecular description of the dipole motions is generally not accessible just from an analysis of the dielectric response. The reason is that, in general, dipole reorientations involve adjustments in the surrounding molecules/atoms that are not easy to define in molecular terms. However by putting together the behaviour of the dielectric increment and relaxation frequency it should be possible to obtain some general idea as to the extent of the connection of the reorientation to the molecular environment and the way in which it takes place.

10.3.3 The Relaxation Peak Shape

The explanation of the frequency dependence of the susceptibility is currently the most contentious of the features of the dielectric response. Many workers are content with just defining the shape by one or other of the empirical functions mentioned in Sect. 10.2.2, or through the power-law exponents of (10.20)–(10.21). This gives a fingerprint of the dipole dynamics but no more. In particular it does not provide a description of the equation of motion of the dipole density fluctuation. Others determine what is termed a *distribution of relaxation times* for the loss peak in $\chi_r''(\omega)$. Essentially this approach is predicated on the assumption that the broadening of the loss peak compared to that of the Debye response (10.19) is the result of dipoles of the same type and dipole moment that each relax according to the Debye equation of motion (10.17) but possess different relaxation times with a distribution denoted by $g(\tau)$, which is defined via (10.43)

$$\chi_r''(\omega) = \int_0^\infty \frac{g(\tau)\chi_0\omega\tau}{1+\omega^2\tau^2}\mathrm{d}\tau\,. \tag{10.43}$$

This construction is still no more than a fingerprint unless a physical reason for the distribution $g(\tau)$ can be found. Usually this is ascribed to a distribution of local activation energies associated with dipoles that each move on their own potential surface independent of one another. The system usually quoted as an example is that of the β-response in the rigid glassy phase, which typically has a very broad loss peak. In this case it is assumed that each dipole that can reorient to contribute to the β-response is essentially trapped in a local potential surface that is held rigid in the glass state. Of course the potential surface is not truly rigid, molecular/atomic vibrations must take place, but it is assumed that their effect on the potential averages out during the relaxation and their only effect is to raise the energy state of the reorienting dipole head to the state at the top of the barrier. One problem associated with this explanation of the origin of $g(\tau)$ is that, if the *function* $g(\tau)$ is independent of temperature the values of exponents n and m (10.20), (10.21) will be temperature dependent. This does not seem to be the case in general, with these exponents usually either constant or changing at the most slowly or discretely at a transition of state [10.8, 60], but there is no real agreement on this point. Of course a temperature-dependent distribution function $g(\tau)$ may be assumed, but then the question arises as to why it *is* temperature dependent in a system that is presumed to be macroscopically rigid. Another facet of the problem associated with non-Debye loss peaks that does not seem to have received any consideration is the possibility that the magnitude of the reorientable dipole moment associated with each site of a given activation energy is also distributed. It is clear that this is highly likely even if the dipole moment that changes direction is the same everywhere, as illustrated in Fig. 10.7. Also, as described in Sects. 10.2 and 10.3, the local dipole may be correlated with other dipoles or its surroundings, and in this case we can expect the Debye rate equation not to hold. The ferroelectric result (Sect. 10.3.2) already shows that this is the case when the dipoles motions are correlated giving the system a scale relationship in its dynamics, and even correlation between the dipole and its surroundings, for which there is considerable evidence (Sects. 10.2 and 10.3) can be expected to alter the form of the equation of motion from (10.17), by for example anharmonic coupling between the various modes. Even if we assume that all the criteria for the application of (10.43) are met, the $g(\tau)$ that are required to fit the experimental form of response defined by (10.20), (10.21) (and its corresponding theoretical response function, (10.22)) have unique features that require a physical justification, i. e., there is a cusp or sharp peak at the value of τ corresponding to the characteristic frequency ($\tau_c = 1/\gamma$), and power-law wings to either side whose power exponents are $1-n$ [$g(\tau) \propto \tau^{1-n}$] for $\tau < \tau_c$, and $-m$ [$g(\tau) \propto \tau^{-m}$] for $\tau > \tau_c$. In the Debye case the distribution becomes a delta function at the characteristic relaxation time. Essentially the *distribution of relaxation times* approach is convenient but it is not as easy to justify as would seem at first sight.

The *Williams* and *Watts* response function [10.32] started life as a heuristic suggestion but has received some later theoretical support [10.61–66]. The dynamic scaling behaviour appropriate to ferroelectrics gives a clue as to the way in which a frequency-dependent susceptibility of the form of (10.20) can come about, which results from both the equation of motion (10.22) and the response function (10.26). Essentially there has to be a self-similarity (or scaling) between the relaxation frequency of subcomponents of the system and their contribution to the dielectric increment (as illustrated in the circuit model of [10.57]). The theory proposed by *Palmer* et al. [10.64] refers this scaling to the removal of a hierarchy of constraints, thus for example we may imagine that close neighbours move quickest and remove the constraints imposed on larger groups of molecules and so on. This picture would be appropriate to a system such as a glass-forming material. The assumption however is that the motions are overdamped at all levels of the hierarchy, and hence no bridge is provided to the oscillatory motions known to occur at times close to quantum vibrations. A rather different stochastic approach has been taken by *Weron* and *Jurlewicz* [10.65, 66] who assumed that the system relaxation followed a path in which the fastest dipoles out of a distribution relaxed first and then the fastest out of the residual distribution and so on. The key feature is that the relaxing dipole is the extreme fastest from the distribution existing at the time. It was argued that the extreme-value statistical distribution function then led automatically to the response function of (10.26). The choice of appropriate extreme-value distribution was made on the grounds that the relaxation time was a positive definite variable. However this is not a sufficient criterion [10.67]. In order for (10.26) to apply the continuous distribution density of relaxation times (i. e., the distribution the system would have if it were of infinite size) has to be stable to scale changes [10.68] and thus has to approach the extreme of long times as an inverse power law, otherwise a different extreme value statistic or *none at all* applies. The required form of distribution from which an extreme selection has to be made is one that applies to the size distribution of scaling systems [10.69] such as percolation clusters [10.70] for example. So even with this stochastic approach we are led back to a system for which the dynamics scale in some way.

The *Dissado–Hill* function [10.26, 27] for which the response function obeys (10.22) also has scaling features as its basis, however unlike the other approaches it starts with the vibration dynamics of the system. It is assumed that a dipole that can reorient couples local vibration modes to itself. These are no longer extended normal modes but modes centred on the dipole that reduce in frequency according to the molecular mass involved. Their frequencies lie in the region between optical modes and the relaxation frequency and have a scaling relationship one to another. In the theory of *Nigmatullin* and *Le Mehaute* [10.71, 72], the modes are impulses that are involved in the dipole relaxation process whose time of action is scaled, i. e., these are fractal time processes such that the longer the time of action the more correlated they are to the dipole motion. In general these modes are local versions of coupled optical and acoustic modes and it is not surprising that they extend to such low frequencies as those involved in relaxation, as acoustic modes essentially extend to zero frequency. Their coupling with the dipole leads to the high-frequency power law of (10.20), where n expresses the extent to which the dipole reorientation couples to the surroundings, i. e., $n = 0$ corresponds to no coupling and the dipole moves independently of its surroundings, and $n = 1$ corresponds to full coupling in which the dipole motion is just part of the local mode. In a sense the short-time development of the response function of (10.22) is that of the changes in the configuration entropy as various amounts of different local modes are progressively coupled into the dipole motion [10.26]. In this case there is no necessity for n to be temperature dependent. However the Dissado-Hill approach to the derivation of the fractional power laws of (10.20)–(10.21) can be regarded as equivalent to the development of the self-energy of a particle (the reorienting dipole) as it binds itself to the self-similar hierarchy of local modes of the medium in which it moves [10.26, 27]. Recently this parallelism between the fractional power laws and energy scaling in the coupling constant defining the self-energy of a reorienting dipole has been exploited [10.73] to derive the temperature dependence of n for aluminium oxide. At the characteristic relaxation frequency, the *characteristic* dipole group relaxes and transfers energy to the heat bath. The low-frequency behaviour of (10.21) is the result of a distribution in the ensemble of locally coupled dipole motions. This occurs because the motions of local dipole centres may be weakly coupled to one another. As a result the relaxation of the centres proceeds in a scaled or self-similar manner. First the dipole in a local centre relaxes with respect to its own environment, this leaves each dipole centre unrelaxed with respect to one another. Next groups of dipole centres, with some arrangement depending upon the specific structure involved, relax as a group. Then groups of groups relax and so on. Each level of inter-group complexity essentially has a time scale associated with its relaxation that cannot be reached until the preceding level has been completed. This is rather similar to the constraint relaxation concept of *Palmer* et al. [10.64]. The power-law exponent m expresses the way that this hierarchy of relaxing groups is scaled, by defining the power-law tail of the distribution of inter-group relaxation times in the ensemble [10.74]. A value of $m = 1$ corresponds to a sequence of inter-group relaxations with a relaxation time that is proportional to the number of groups involved in the sequence [10.74]. This implies that the sequential events are uncorrelated, i. e., the long-time relaxation is a white-noise (random) process [10.26]. When combined together with $n = 0$ the Debye response is recovered. On the other hand a value of m approaching zero corresponds to relaxation times that are a very high power of the number of groups involved [10.74] and indicates a very strong connection between groups at all levels of the hierarchy. This will spread the response to very low frequencies, as observed. Essentially m is a measure of the extent to which energy is transferred to the heat bath (dissipated) at each level of the hierarchy compared to being stored in the inter-group interactions of the next level. This scaling has also been used to derive the temperature dependence of m in the case of aluminium oxide [10.73] by means of a similar self-energy approach such as was used for n. Scaling has also been shown to yield the Cole–Cole response (Sect. 10.2.2) through a fractional Fokker–Planck equation resulting from anomalous sub-diffusion [10.75] (i. e., the compact exploration of a matrix, fractal or non-fractal) and has been demonstrated recently [10.76] to apply to the relaxation of water in porous silica glasses.

The common feature of all theories other than the *distribution of relaxation times* approach is that self-similar scaling is at the basis of the fractional power law responses. The Dissado-Hill theory differs from the others in that there are two different ways in which scaling can be involved. This theory is not generally accepted. The controversial parts of the theory are firstly the coupling of the dipole motions with vibration modes, which modifies the oscillator behaviour towards an overdamped form, and secondly the hierarchy of relaxations whereby energy is transferred to the heat bath. However it should be noted that the susceptibility function that results has a general form that agrees well with experiment. In addition the concepts are reasonable given the complexity that is likely to occur in the internal motions once an ideal crystalline regularity is ruled out by the possibility of dipole reorientation. Thus

for example this concept would apply to the dipoles involved in the β-response of the glass state as well as correlated motions of dipoles over long distances, since even in a macroscopically rigid material local vibrations take place. In fact the limited regions of local order in a glass phase can be expected to favour such local modes and increase the coupling of the dipole motions with them, as observed.

The Information Content of the Loss Peak Shape

It is clear from the foregoing discussion that for all theoretical models of the loss peak shape the characteristic or loss peak frequency is but the culmination of a process in which subsections of the dipole and environment (with or without dipoles) are mixed into the motion of the dipole centre. In these models the dipole is not an independent entity, but rather an entity that is connected to its surroundings to some extent over a region that may be small or large. This implies that the dipole is not a particle that relaxes on a rigid potential surface independently of its environment. Only the *distribution of relaxation times* approach preserves the latter concept. If the theoretical models are correct they reflect the fact that we are looking at entities that are not truly of molecular scale but are of a mesoscopic nature. The correlations noted to occur in χ_0 and the need to use free energy rather than potential surfaces in describing the relaxation frequency support this view. The local entities involved are however not rigid features like permanent dipoles, and for this reason we should expect there to be weak connections between them that can be expected to relate to the way in which the relaxation of the whole system takes place. That is, not all entities relax at the characteristic time. As one entity relaxes its neighbours have to come into equilibrium with its new orientation and the system approaches equilibrium more slowly (i. e., as the time power law $t^{-(1+m)}$) than the exponential behaviour of the Debye response function or the expanded exponential function. The information contained in the loss peak shape indicates the way in which a dipole density fluctuation evolves from its state when initially created to an ensemble of mesoscopic dipole centres. The broadening of the peak from that of a Debye peak indicates the involvement of faster and slower processes as part of the overall mechanism, whatever their detailed origin, and in particular processes that have a scale relationship to one another. This must apply even to a distribution of relaxation times because of the unique form required for that distribution. Equation (10.22) implies an equivalent description that refers the overall relaxation process to a conversion of the vibration oscillation at short times to an overdamped motion as the dipole density fluctuation dissipates its energy irreversibly. In this sense evaluation of the shape parameters n and m give a means of describing this conversion process. At the very least they give a sense of the scaling involved in spreading the relaxation process around the characteristic relaxation frequency or equivalently the characteristic relaxation time.

10.4 Charge Transport

All dielectrics possess a constant (DC) conductivity (σ_{DC}), although usually it is very weak. Since $\chi''(\omega) = \sigma(\omega)/\omega$ as demonstrated in Sect. 10.1 (10.10), it would be expected that a dielectric response at low frequencies ($f \lesssim 10^{-2}$ Hz) would take a form in which $\chi''(\omega) = \sigma_{DC}/\omega$ and χ' is independent of frequency. In many cases however the conduction process is blocked at the electrodes or internal interfaces. In this case the DC conduction charges the interface, which behaves as a capacitor, and the whole system behaves as a single dipole. As long as the interface does not possess relaxation dynamics of its own, the response that would be observed is that given by the Debye response of (10.18)–(10.19), with $\tau = 1/\gamma = RC_i$, where R is the resistance of the body of the material and C_i is the capacitance of the interface. The measured dielectric increment $\chi_0 = dC_i/A$, where A is the electrode area and d is the sample thickness, and can be very large depending upon the ratio of the sample thickness to that of the interface. The situation where the interface has a frequency-dependent capacitance has been thoroughly discussed by *Jonscher* [10.6] who has shown that $\chi'_r(\omega)$ is modified from $\chi'_r(\omega) \propto \omega^{-2}$ $(\omega > \gamma)$ to $\chi'_r(\omega) \propto \omega^{-q}$, while $\chi''_r(\omega) \propto (1/\omega)$ $(\omega > \gamma)$ as in (10.19). The value of q lies in the range $1 < q < 2$ with its value depending upon the frequency dependence of the interface capacitance.

The bulk DC conductance arises from charged particles whose movements are not bound to a charge of the opposite polarity as in dipoles but are free to move independently of their countercharge, resulting in a net charge displacement in the same way that a liquid flows. However the transport of charged particles within the body of the sample can give rise to a very different form of response when their movement lies along defined paths such that the longer the displacement of the charge the lower the number of paths or equivalently the more difficult the transport becomes. This behaviour was called low-frequency dispersion by *Jonscher* [10.6,

21] and quasi-DC conduction (q-DC) in the theoretical model of *Dissado* and *Hill* [10.77] who wished to distinguish it from low-frequency dipole responses. At frequencies below some characteristic value ω_c this form of response takes the form,

$$\sigma(\omega) \propto \omega^{1-p}$$
$$[\text{i.e., } \chi_r''(\omega) \propto \chi_r'(\omega) \propto \omega^{-p}], \quad \omega < \omega_c, \quad (10.44)$$

and at frequencies above ω_c,

$$\sigma(\omega) \propto \omega^{n}$$
$$[\text{i.e., } \chi_r''(\omega) \propto \chi_r'(\omega) \propto \omega^{n-1}], \quad \omega > \omega_c. \quad (10.45)$$

The power-law exponents p in (10.44) and n in (10.45) have positive fractional values near to unity. It is obviously difficult to identify a value of p close to unity from measurements of $\chi_r''(\omega)$ (or equivalently $\sigma(\omega)$) and in many cases it is assumed that the measured behaviour shows a static (DC) conductivity. It is then common to subtract its supposed value from the measured data for $\sigma(\omega)$ to obtain an expression for the dipole relaxation response supposedly responsible for the behaviour at $\omega > \omega_c$. The values obtained in this way for $\chi_r''(\omega)$ at frequencies $\omega < \omega_c$ will not be zero as $\sigma(\omega)$ is not in fact constant, instead they will reduce as the frequency is reduced. This procedure yields a spurious loss peak in $\chi_r''(\omega)$ if the response is actually due to a q-DC mechanism since the high-frequency behaviour is an essential component of the whole and can never be resolved as a separate peak in $\chi_r''(\omega)$. The way to be certain that the response is really of the q-DC form is to measure the frequency response for $\chi_r'(\omega)$ and show that it takes the same frequency dependence. A convenient check is to determine the ratio of $\chi_r''(\omega)$ to $\chi_r'(\omega)$ (i.e., $\tan\delta$) which will have a constant value [10.6, 21] given by

$$\frac{\chi_r''(\omega)}{\chi_r'(\omega)} = \tan\delta = \cot\left[\frac{(1-p)\,\pi}{2}\right]. \quad (10.46)$$

Here $\tan\delta$ is called the loss tangent and δ is the phase angle between the real and imaginary components of the susceptibility. This relationship holds for pairs of values of $\chi_r'(\omega)$ and $\chi_r''(\omega)$ at the same frequency even if the measurements are noisy and so make it difficult to determine accurately the value of p from the frequency dependence. Another situation where it is difficult to detect the q-DC behaviour occurs in heterogeneous materials when one component has a low DC conductivity. This will add to the AC component, (10.44) and obscure the q-DC behaviour. In this case the DC conductivity can be eliminated from the data, if it is available over a large enough frequency range, by applying the Kramers–Kronig transform of (10.25) to obtain the function $\chi_r''(\omega)$ without the DC component (σ_{DC}/ω). The validity of the procedure can be checked by applying the inverse transform (10.24) to the measured data for $\chi_r''(\omega)$. This should yield the measured $\chi_r'(\omega)$ since the DC conductivity does not contribute to the real component of the susceptibility.

The q-DC behaviour, (Fig. 10.10a), is most often found in materials that are heterogeneous on a mesoscopic scale such as ceramics [10.79], rocks [10.80], porous structures [10.81], and biological systems [10.82]. In these materials charged particles are transported via structured paths over some finite range. The transported charge and its countercharge give rise to an effective dipole with a large dipole moment. However the q-DC behaviour rarely appears as an isolated response. Because of the heterogeneous nature of the materials it is usually found to be electrically in series with other dielectric response elements such as interface capacitances, and electrically in parallel with a ca-

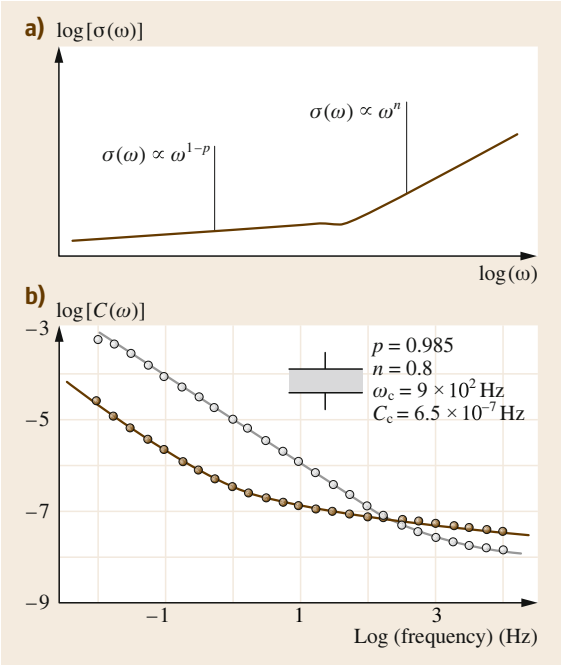

Fig. 10.10 **(a)** A schematic representation of the frequency dependence of $\sigma(\omega)$ for the q-DC process, **(b)** the equivalent q-DC susceptibility function $\chi(\omega)/\chi_c \propto (1 + i\omega\tau)^{n-1}\,{}_2F_1[1-n; 1+p; 2-n; (1+i\omega\tau)^{-1}]$ derived from the response function of (10.47) fitted to data from the leaf of *Nicotania* (Solanaceae), the *inset* gives the fitting parameters, with $\omega_c \equiv 1/\tau$, and $C_c \equiv \chi_c$. This data was chosen as it exhibits an isolated q-DC process. As before ${}_2F_1(,;;)$ is the Gaussian hypergeometric function. (After [10.24, 78])

pacitive circuit element. In this case the impedances of the series components ($Z(\omega) = [i\omega C(\omega)]^{-1}$) are added together, inverted to obtain the equivalent capacitance, and added to any capacitances in parallel. As a result identifying the response that can be assigned to any particular process requires the use of an appropriate equivalent circuit. In contrast, materials where the responses arise from different permanent dipoles embedded in the same structure but with different relaxation timescales give capacitance contributions in parallel that are simply added to yield the total capacitance, and hence are easy to separate. The reader is referred to [10.6] for examples of how to identify and separate the various processes in each situation.

The origin of the q-DC behaviour lies in a hidden scale relationship, with the dipole contribution to the susceptibility increment and its relaxation time both being a power of the length over which the transport takes place. The circuit models of *Dissado* and *Hill* et al. [10.57, 83] show how this behaviour can be produced when the system is represented by a geometrically self-similar arrangement of transport paths and blocking capacitive regions. Such geometrical regularity is not essential however [10.84]; a random arrangement of conductors (transport paths) in a dielectric (i. e., residual set of capacitances) will also result in the q-DC behaviour emerging as the total number of components increases. It is clear that this construction yields percolation clusters below the size necessary to span the material, and these sub-percolation clusters will of necessity possess scaling relationships dependent on their size and the number of paths within them, and between clusters of different sizes. Such percolation systems also show q-DC behaviour when below their critical limit [10.85]. Self-similarity in transport processes giving what has been termed a *fractal* current has also been used recently [10.86] to derive a generalised version of the low frequency power law of (10.44) and verify it for some electrode polarization processes, but it should be noted that many examples of q-DC behaviour have been demonstrated to be bulk processes [10.87, 88]. The theory proposed in [10.77] described the q-DC mechanism in similar terms to that used in percolation theory. At high frequencies they assumed that the charged particles had a short range of motion restricted to local clusters in which they were bound to their countercharges. The power-law exponent n reflected the extent of binding of the motions of the charges in the cluster and the local motions in the same way as for the dipole motions. Its value close to one indicates that the binding is strong and that the polarisation of the local clusters increases only to a small extent as the frequency is lowered, i. e., the net displacement of positive and negative charge is local and small. At the characteristic frequency the charged particles become free of their locality and are able to move over much longer distances. This frequency can be expected to correlate with the Debye screening length or an equivalent feature in the heterogeneous medium. The transport range allowed by the AC frequency increases as the frequency reduces, but the number of effective routes decreases as the distance becomes longer and hence the current becomes smaller. This leads to the weak dependence of the conductivity upon the AC frequency defined in (10.44). In the zero-frequency limit $\sigma(\omega) = 0$, which means that there are no paths across a system of infinite length, i. e., the system is formally below the percolation limit. Of course in reality the sample is of finite size and some routes may cross the sample, leading to a termination of the q-DC behaviour at low frequencies, either by a blocking capacitance at the electrodes or a weak DC current [10.89]. The theory leads to an analytical expression for the q-DC susceptibility in terms of a confluent hypergeometric function [10.24] (see [10.77] for the detailed expression), which is obtained from a response function that obeys an equation of motion similar to that of the permanent dipoles

$$\frac{d^2\phi}{dt^2} + \frac{\left(2+n+\frac{t}{\tau}\right)}{t}\frac{d\phi}{dt} + \frac{\left[n+\left(\frac{t}{\tau}\right)(1-p)\right]}{t^2}\phi = 0\,. \tag{10.47}$$

At times $t < \tau = 1/\omega_c$ the behaviour of the dipole density fluctuation is the same as that appropriate for permanent dipoles (10.22) with the same limiting solution, i. e., $\phi(t) \propto t^{-n}$ at $t < \tau$. At long times $t > \tau = 1/\omega_c$, however, it takes a different form in which the dipolar fluctuation relaxation has only a weak dependence on t, i. e., $\phi(t) \propto t^{p-1}$ at $t > \tau$. An example of the q-DC behaviour in frequency is given in Fig. 10.10b. The reader is referred to [10.78, 82, 87] for other examples.

In the limit of $p = 1$ ($\sigma(\omega) = \text{constant}; \omega < \omega_c$), the last term of (10.47) is zero in the limit $t > \tau$ at which time the decay of ϕ is governed by the first two terms. The solution for $\phi(t)$ now takes the form

$$\begin{aligned} &\phi(t) \propto t^{-n},\ t < \tau\,, \\ &\phi(t) \propto \exp\left(-\frac{t}{\tau}\right),\ t > \tau\,. \end{aligned} \tag{10.48}$$

In this case we can see that the dipole density fluctuations are produced within the local clusters and that they relax by freeing the charges to move independently at $t = \tau$. At this time there is a density of completely free charged particles with charge and countercharge cancelling throughout the system giving a net dipole of zero as in a true DC-conduction process.

10.5 Data Presentation

Throughout this chapter the dielectric data has been given in the log-log representation of a Bode plot. The reason has been to emphasise the power law wings of the dielectric loss peaks and thus demonstrate the non-exponential time dependence of the response function. There are many different representations that can be used (the reader is referred to [10.6] for details). Each of these representations contain the same information but emphasise different features of the response, thereby allowing them to be more accurately and easily evaluated. Researchers will of course use a representation that emphasises the features of most importance for their own work, but they should be aware that each representation may obscure other features to the detriment of a full interpretation of the data. Even if a computer fitting to an equivalent circuit containing frequency dependent components is used, the fitting can be misleading if the representation chosen obscures some of the components. A definite description can only be obtained if the same fitted components can reproduce the data in a number of different representations. A case in point is the use of the complex dielectric modulus

$$M^*(\omega) = \frac{1}{C^*(\omega)} = M'(\omega) - \mathrm{i}M''(\omega)\,.$$

This representation will emphasise weak loss peaks in $\chi_\mathrm{r}''(\omega)$ and allow a better identification of the loss peak frequency. It will also convert the q-DC response of Fig. 10.10b to a form in which $M''(\omega)$ has a peak at $\omega \approx \omega_\mathrm{c}$, which has been interpreted as the frequency at which ion hopping between local sites goes over to ion transport. However unless a Bode plot has been previously obtained showing clearly that a q-DC process is present rather than a DC conductivity in parallel with a constant capacitance the modulus plot is fraught with ambiguity because the modulus plot will show a peak in $M''(\omega)$ and an associated increase in $M'(\omega)$ from low frequencies that is very similar in shape and magnitude in both cases. Although an increase of several orders of magnitude in $M'(\omega)$ and $M''(\omega)$ as the frequency is raised from low values is indicative of either a parallel conductance or a q-DC process it is also possible that the peak may be confused with that arising from a dipole relaxation process if the measured frequency range does not extend very far towards low frequencies. The difficulty in ascertaining the nature of the processes is exacerbated if $M''(\omega)$ is plotted on its own as then the power law dependence of $M'(\omega)$ at low frequency cannot be easily shown to be the same as that of $M''(\omega)$ in the case of a q-DC process.

In order to avoid ambiguity it is therefore necessary to make a Bode-plot and other representations first and identify the various contributing processes, before making use of the modulus representation to emphasise the characteristic frequencies in order to evaluate them more accurately for use in analysis.

10.6 A Few Final Comments

The basic difficulty associated with the interpretation of dielectric responses is that they are of necessity macroscopic measurements made on samples that contain enormous numbers of atoms and molecules. In condensed-phase materials it is not possible to consider these systems as made up of local entities each moving independently of one another. All entities that contribute a permanent dipole are part of the condensed-phase structure, and even though they have a degree of freedom associated with the possibility of dipole reorientation, they will have motions that are correlated or connected to some extent to the molecules/atoms in their environment. This means that dipole reorientation is not that of a bare entity; instead it involves to some extent a local region. These regions will behave differently in different kinds of material and their definition and the way of describing their behaviour has not yet been established with any sort of rigour. Since we are dealing with a macroscopic measurement, there will of necessity be an ensemble of the local entities. This will result in a distribution of entities, but since these are part of the structure there will be some sort of connection between them unless the structure itself is disconnected dynamically. This means that fluctuations will take place among our entities, and perhaps even dissociation and amalgamation of the dynamically connected groups [10.90]. These effects will also have an influence on the relaxation dynamics. In the foregoing I have tried to give some simple pictures as to what is happening and to do so in a holistic way by correlating information from different facets of the measurement. What is abundantly clear is that the dynamics of such systems are very complicated in detail, but I hope that I have done enough to convince you that there are some basic features of the relaxation process that are common to all systems of this type, even though a full understanding of their nature does not yet exist.

11. Ionic Conduction and Applications

Harry Tuller

Solid state ionic conductors are crucial to a number of major technological developments, notably in the domains of energy storage and conversion and in environmental monitoring (such as battery, fuel cell and sensor technologies). Solid state ionic membranes based on *fast ion conductors* potentially provide important advantages over liquid electrolytes, including the elimination of sealing problems improved stability and the ability to miniaturize electrochemical devices using thin films. This chapter reviews methods of optimizing ionic conduction in solids and controlling the ratio of ionic to electronic conductivity in mixed conductors. Materials are distinguished based on whether they are characterized by intrinsic versus extrinsic disorder, amorphous versus crystalline structure, bulk versus interfacial control, cation versus anion conduction and ionic versus mixed ionic–electronic conduction. Data for representative conductors are tabulated.

A number of applications that rely on solid state electrolytes and/or mixed ionic–electronic conductors are considered, and the criteria used to choose such materials are reviewed. Emphasis is placed on fuel cells, sensors and batteries, where there is strong scientific and technological interest. The chapter concludes by considering how solid state ionic materials are likely to be used in the future, particularly in light of the trend for miniaturizing sensors and power sources and the interest in alternative memory devices based on memristors.

The ionic bonding of many refractory compounds allows for ionic diffusion and correspondingly, under the influence of an electric field, ionic conduction. This contribution to electrical conduction, for many years, was ignored as being inconsequential. However, over the past three to four decades, an increasing number of solids that support anomalously high levels of ionic conductivity have been identified. Indeed, some solids exhibit levels of ionic conductivity comparable to those of liquids. Such materials are termed *fast ion conductors*. Like solid state electronics, progress in *solid state ionics* has been driven by major technological developments, notably in the domains of energy storage and conversion and environmental monitoring, based on ongoing developments in battery, fuel cell and sensor technologies. More recently, this is being expanded to the memory device sphere as well. Some of the most important applications of solid state electronics and solid state ionics, and their categorization by type and magnitude of conductivity (such as dielectric, semiconducting, metallic and superconducting), are illustrated in Fig. 11.1 [11.1]. This figure also emphasizes that solids need not be strictly ionic or electronic, but may and often do exhibit mixed ionic–electronic conductivity. These *mixed conductors* play a critical role – particularly as electrodes – in solid state ionics, and

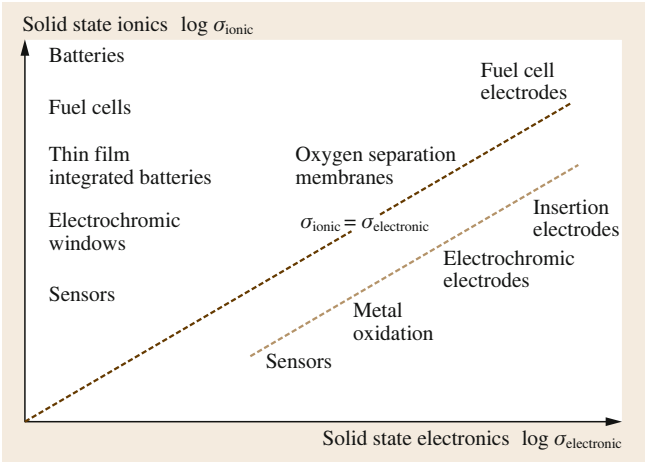

Fig. 11.1 Illustration of typical applications of ionic and electronic conductors as a function of the magnitude of electrical conductivity. Applications requiring mixed ionic electronic conductivity fall within the quadrant bounded by the two axes. (After [11.1])

are receiving comparable if not more attention than solid electrolytes at the present. Such solids which rely for their development on the intersection of a number of related fields including *solid state ionics*, *solid state electronics* and *solid state electrochemistry*, have grown in importance as our society has become more acutely concerned with efficient and environmentally clean methods for energy conversion, conservation and storage [11.2].

Solid state ionic membranes provide important potential advantages over liquids. The most important of these include:

1. Elimination of sealing problems associated with chemically reactive liquid or molten electrolytes
2. Minimization of discharge under open circuit conditions
3. Improved chemical stability under highly reactive conditions
4. The ability to miniaturize electrochemical devices through the use of thin films.

In the following, we begin by discussing methods of optimizing ionic conduction in solids and controlling the ratio of ionic to electronic conductivity. We then consider a number of applications that rely on solid state electrolytes and/or mixed ionic–electronic conductors and the criteria that should be used when selecting materials. We conclude by considering how solid state ionic materials are likely to be used in the future, particularly in light of trends related to the miniaturization of sensors, memory devices and power sources.

11.1 Conduction in Ionic Solids

The electrical conductivity, σ, the proportionality constant between the current density j and the electric field E, is given by

$$\frac{j}{E} = \sigma = \sum_i c_i Z_i q \mu_i \,, \tag{11.1}$$

where c_i is the carrier density (number/cm^3), μ_i the mobility (cm^2/Vs), and $Z_i q$ the charge ($q = 1.6 \times 10^{-19}$ C) of the ith charge carrier. The huge (many orders of magnitude) differences in σ between metals, semiconductors and insulators generally result from differences in c rather then μ. On the other hand, the higher conductivities of electronic versus ionic conductors are generally due to the much higher mobilities of electronic versus ionic species [11.3].

Optimized ionic conduction is a well-known characteristic of molten salts and aqueous electrolytes wherein all ions move with little hindrance within their surroundings. This leads to ionic conductivities as high as 10^{-1}–10^{1} S/cm in molten salts at temperatures of 400–900 °C [11.4]. Typical ionic solids, in contrast, possess limited numbers of mobile ions, hindered in their motion by virtue of being trapped in relatively stable potential wells. Ionic conduction in such solids easily falls below 10^{-10} S/cm for temperatures between room temperature and 200 °C. In the following sections, we examine the circumstances under which the magnitude of ionic conduction in solids approaches or even surpasses that found in liquid electrolytes.

The motion of ions is described by an activated jump process, for which the diffusion coefficient is given by [11.5]

$$\begin{aligned} D &= D_0 \exp\left(\frac{-\Delta G}{k_B T}\right) \\ &= \gamma(1-c) Z a^2 \nu_0 \exp\left(\frac{\Delta S}{k_B}\right) \exp\left(\frac{-E_m}{k_B T}\right), \end{aligned} \tag{11.2}$$

where a is the jump distance, ν_0 the attempt frequency, and E_m the migration energy. The factor $(1-c)Z$ defines the number of neighboring unoccupied sites, while

γ includes geometric and correlation factors. Note that the fractional occupation c here should not be confused with c_i, the charge carrier concentration, nor should the number of nearest neighbors Z be confused with Z_i, the number of charges per carrier defined in (11.1). Since the ion mobility is defined by $\mu_i = Z_i q D_i / k_B T$, where D_i and k_B are the diffusivity and Boltzmann constant respectively, and the density of carriers of charge $Z_i q$ is Nc, where N is the density of ion sites in the sublattice of interest, the ionic conductivity becomes

$$\begin{aligned}\sigma_{\text{ion}} &= \gamma \left[\frac{N(Z_i q)^2}{k_B T}\right] c(1-c) Z a^2 \nu_0 \\ &\quad \times \exp\left(\frac{\Delta S}{k_B}\right) \exp\left(\frac{-E_m}{k_B T}\right) \\ &= \left(\frac{\sigma_0}{T}\right) \exp\left(\frac{-E}{k_B T}\right) \end{aligned} \tag{11.3}$$

or

$$\begin{aligned}\sigma_{\text{ion}} &= \gamma N (Z_i q)^2 c(1-c) \frac{Z a^2 \gamma_0}{k_B T} \\ &\quad \times \exp\left(\frac{\Delta S}{k_B}\right) \exp\left(\frac{-E_m}{k_B T}\right). \end{aligned} \tag{11.4}$$

This expression shows that σ_{ion} is nonzero only when the product $c(1-c)$ is nonzero. Since all normal sites are fully occupied ($c = 1$) and all interstitial sites are empty ($c = 0$) in a perfect classical crystal, this is expected to lead to highly insulating characteristics. The classical theory of ionic conduction in solids is thus described in terms of the creation and motion of atomic defects, notably vacancies and interstitials.

Three mechanisms for ionic defect formation in oxides should be considered. These are:

1. Thermally induced intrinsic ionic disorder (such as Schottky and Frenkel defect pairs)
2. Redox-induced defects
3. Impurity-induced defects.

The first two categories of defects are predicted from statistical thermodynamics [11.6], and the latter form to satisfy electroneutrality. Examples of typical defect reactions in the three categories, representative of an ionically bonded binary metal oxide, are given in Table 11.1, in which the $K_i(T)$s represent the respective equilibrium constant and $a_{N_2O_3}$ the activity of the dopant oxide N_2O_3 added to the host oxide MO_2. Schottky and Frenkel disorder (1, 2) leave the stoichiometric balance intact. Reduction–oxidation behavior, as represented by (3), results in an imbalance in the ideal cation-to-anion ratio and thus leads to *nonstoichiometry*. Note that equilibration with the gas phase,

Table 11.1 Typical defect reaction

Defect reactions	Mass action relations	
$MO \leftrightarrow V''_M + V^{\cdot\cdot}_O$	$[V''_M][V^{\cdot\cdot}_O] = K_S(T)$	(1)
$O_O \leftrightarrow V^{\cdot\cdot}_O + O''_i$	$[V^{\cdot\cdot}_O][O''_i] = K_F(T)$	(2)
$O_O \leftrightarrow V^{\cdot\cdot}_O + 2e' + \frac{1}{2}O_2$	$[V^{\cdot\cdot}_O] n^2 = K_R(T) P_{O_2}^{-1/2}$	(3)
$O \leftrightarrow e' + h^{\cdot}$	$np = K_e(T)$	(4)
$N_2O_3(MO_2) \leftrightarrow 2N'_M + 3O_O + V^{\cdot\cdot}_O$	$[N'_M]^2 \cdot [V^{\cdot\cdot}_O] / a_{N_2O_3} = K_N(T)$	(5)

by the exchange of oxygen between the crystal lattice and the gas phase, generally results in the simultaneous generation of both ionic and electronic carriers. For completeness, the equilibrium between electrons and holes, via excitation across the band gap, is given in (4).

Altervalent impurities (for example N^{3+} substituted for the host cation M^{4+} – see (5)) also contribute to the generation of ionic carriers, commonly more than intrinsic levels do. This follows from the considerably reduced ionization energies required to dissociate impurity-defect pairs as compared to intrinsic defect generation. For example, E_A might correspond to the energy required to dissociate an acceptor–anion vacancy pair or E_D to the energy needed to dissociate a donor–anion interstitial pair. Such dissociative effects have been extensively reported in both the halide and oxide literature [11.7]. A more detailed discussion is provided below in the context of achieving high oxygen ion conductivity in solid oxide electrolytes.

The oxygen ion conductivity σ_i is given by the sum of the oxygen vacancy and interstitial partial conductivities. In all oxygen ion electrolytes of interest (in some mixed ionic conductors, such as La_2NiO_4 of interest as solid oxide fel cell cathodes, ionic conduction is largely via oxygen interstitials [11.8]), the interstitial does not appear to make significant contributions to the ionic conductivity, and so it is the product of the oxygen vacancy concentration $\left[V^{\cdot\cdot}_0\right]$, the charge $2q$, and the mobility (μ_v)

$$\sigma_i \approx \left[V^{\cdot\cdot}_0\right] 2q\mu_v \tag{11.5}$$

Optimized levels of σ_i obviously require a combination of high charge carrier density and mobility. Classically, high charge carrier densities have been induced in solids by substituting lower valent cations for the host cations [11.2]. Implicit in the requirement for high carrier densities are:

1. High solid solubility of the substituent with the lower valency
2. Low association energies between the oxygen vacancy and dopant
3. No long-range ordering of defects.

Additives which induce minimal strain tend to exhibit higher levels of solubility. The fluorite structure is the most well-known of these structures, with stabilized zirconia the best-known example. In this case, Y^{3+} substitutes for approximately 10% of Zr in $Zr_{1-x}Y_xO_{2-x/2}$, leading to $\sigma_i \approx 10^{-1}$ S/cm at 1000 °C and an activation energy of ≈ 1 eV. Other examples include CeO_2 [11.9], other fluorite-related structures such as the pyrochlores $A_2B_2O_7$ [11.10], and perovskites such as $La_{1-x}Sr_xGa_{1-y}Mg_yO_{3-\delta}$ (LSGM) [11.11].

Since the dopant and vacancy are of opposite charge (for example, Y'_{Zr} and $V_0^{\cdot\cdot}$), they tend to associate. With cations being much less mobile than oxygen ions, this serves to trap the charge carrier. It is of interest to examine how the concentration of *free* mobile carriers depends on the dopant concentration and the association energy. Consider the neutrality relation representing vacancy compensation of acceptor impurities by

$$N_V = \beta N_I \,, \tag{11.6}$$

where N_V and N_I are the vacancy and impurity densities while β reflects the relative charges of the two species and normally takes on values of 1 (for A''_M) and $\frac{1}{2}$ (for A'_M). The association reaction is given by

$$(I-V)^{x-y} \Leftrightarrow I^x + V^y \,, \quad \left(\beta = \frac{x}{y}\right), \tag{11.7}$$

where x and y are the relative charges of the impurity and vacancy, respectively. The corresponding mass action relation is then

$$\frac{N_I N_V}{N_{Dim}} = K_A^\circ \exp\left(\frac{-\Delta H_A}{k_B T}\right), \tag{11.8}$$

where N_{Dim} is the concentration of dimers and N_I and N_V are the corresponding defects remaining outside the complexes. It is straightforward to show that for weak dissociation (low temperatures or high association energies) one obtains the following solutions

$$\beta = 1: \quad N_V = \left(N_I K_A^0\right)^{\frac{1}{2}} \exp\left(\frac{-\Delta H_A}{2k_B T}\right), \tag{11.9}$$

$$\beta < 1: \quad N_V = \left(\frac{1-\beta}{\beta}\right) K_A^0 \exp\left(\frac{-\Delta H_A}{k_B T}\right). \tag{11.10}$$

The solution for condition $\beta = 1$ is the more familiar one. As in semiconductor physics [11.12], the number of free electrons or holes is proportional to the square root of the dopant density at reduced temperature, and it exhibits an Arrhenius dependence with activation energy that is equal to one half of the association or ionization energy. The solution for condition $\beta < 1$ is more unusual. Here one predicts that N_V is independent of dopant density! Also, the activation energy is predicted to be equal to the association energy.

At sufficiently high temperatures or low association energies, essentially all of the dimers are dissociated and

$$N_V = \beta N_I = \beta N_I(\text{total}) \,. \tag{11.11}$$

In general, therefore, two energies contribute to ionic conduction: a defect energy, E_D (which may either be related to the Frenkel or Schottky formation energy, or to a dissociation energy), and a migration energy E_m. The value of E in (11.3) therefore takes on different values in three characteristic temperature regimes. These include:

1. $E = E_m + E_A/2$: extrinsic associated regime at low T
2. $E = E_m$: extrinsic fully dissociated regime at intermediate T
3. $E = E_m + E_s/2$: intrinsic defect regime at elevated T (for instance, for Schottky equilibrium).

Such phenomena are clearly illustrated in recent publications dealing with donor and acceptor doping of TlBr, a gamma ray detector candidate material [11.13, 14]. By application of the appropriate defect model, values for $E_S = 0.91 \pm 0.03$ eV, $E_m(\text{Br}) = 0.28 \pm 0.05$ eV, $E_m(\text{Tl}) = 0.51 \pm 0.03$ eV and $E_A = 0.42 \pm 0.07$ eV ($Se'_{Br} - V^{\cdot}_{Br}$ associate) were extracted from the ionic conductivity data.

For optimized ionic conduction to exist, two criteria must be satisfied simultaneously. First the term c in (11.3) must approach 1/2. This corresponds to nearly all of the ions on a given sublattice being mobile. Second, the crystal structure must be arranged so as to enable easy motion of ions from one equivalent site to the next. This is reflected in exceptionally low values for the migration energy E_m. In the next section we discuss the conditions under which these criteria are satisfied.

11.2 Fast Ion Conduction

A number of routes leading to exceptionally high ion carrier densities in solids have been identified over the last few decades. These are subdivided into two major categories below (structurally disordered solids and highly defective solids). An important new development in recent years is the focus on the role of interfaces in creating ionic disorder localized in the vicinity of the boundaries. For nanosized structures, these disordered regimes may represent a large fraction of the overall volume of the material. Whatever the source of the enhanced ionic conductivity, such solids are commonly designated as *fast ion conductors* (FIC).

11.2.1 Structurally Disordered Crystalline Solids

In contrast to the idealized picture of crystal structures, many solids exist in which a sublattice of sites is only partially occupied. *Strock* [11.15, 16] already came to this conclusion in the 1930s in relation to the Ag sublattice in the high-temperature form (α-phase) of AgI. More recent neutron diffraction studies [11.17] differ with regard to the number of equivalent Ag sites. The special feature of partial occupancy of sites is nevertheless sustained.

Other notable systems characterized by sublattice disorder include Nasicon ($Na_3Zr_2PSi_2O_{12}$), sodium beta alumina (1.2 Na_2O–0.11 Al_2O_3) and $LiAlSiO_4$, which exhibit fast ion transport in three, two and one dimensions, respectively. Hundreds of other structurally disordered conductors may be found listed in review articles on the subject [11.2, 18–20]. Figure 11.2 illustrates the $\log \sigma - 1/T$ relations for representative FICs, while Table 11.2 summarizes data on representative materials in tabular form.

The rapid growth in the lithium battery industry has understandardly focused a great deal of attention on lithium ion solid electrolytes, given potentially lower capacity loss, improved cycle life, broader operation temperatures, enhanced safety and reliability, simplicity of design, and absence of leakage compared to liquid electrolytes [11.5]. The key factor limiting the application of lithium solid electrolytes has been their relatively low room temperature lithium ion conductivity. In recent years, new material compositions have been identified that exhibit much improved conductivities. A number of these are included in Fig. 11.3 along with representative organic liquid, ionic liquid and gel electrolytes. The thio-LISICON material $Li_{10}GeP_2S_{12}$ achieves a room temperature conductivity of 1.2×10^{-2} S/cm, surpassing the conductivity of many of the liquid and gel electrolytes. Several others are listed in Table 11.2.

Similarities between FICs and liquid electrolytes are often noted; the most important of these is that the disordered sublattice in the solid resembles the disordered nature of ions in a liquid. For this reason one often hears the term *lattice melting* used to describe phase transitions in solids which relate to the conversion of a conventional ionic conductor to a FIC (such as β to α transition in AgI at approximately 150 °C). Nevertheless, most investigators now believe that transport in FICs occurs via correlated jumps between well-defined sites rather than the liquid-like motion characteristic of aqueous or molten salt electrolytes.

The major structural characteristics of FICs include: (a) highly ordered, immobile or framework sublattice providing continuous open channels for ion transport, and (b) a mobile carrier sublattice which supports a random distribution of carriers over an excess number of equipotential sites. FICs exhibit framework sublattices that minimize strain, electrostatic and polarization contributions to the migration energy while offering high carrier concentrations within the mobile carrier sublattice. Given the high concentration of carriers, correlation effects between carriers must be taken into account. Calculations by *Wang* et al. [11.37], for ex-

Table 11.2 Representative solid electrolytes and mixed conductors: mobile ions, electrical properties and apllications

Material	Mobile	Properties	Remarks and applications
$Zr_{0.85}Y_{0.15}O_{2-x}$ [11.21]	O^{2-}	$\sigma_{O^{2-}}$ (1000 °C) = 0.12 S/cm E = 0.8 eV	Material of choice in auto exhaust sensors; prime solid electrolyte candidate for solid oxide fuel cells (SOFCs)
$Ce_{0.95}Y_{0.05}O_{2-x}$ [11.22] $Ce_{0.1}Gd_{0.9}O_{2-x}$ [11.23, 24]	O^{2-}	$\sigma_{O^{2-}}$ (1000 °C) = 0.15 S/cm E = 0.76 eV $\sigma_{O^{2-}}$ (800 °C) = 0.10 S/cm E = 0.56 eV	Semiconducting at low PO_2; prime candidate solid electrolyte for intermediate temperature SOFCs
$La_{0.8}Sr_{0.2}Ga_{0.8}Mg_{0.2}O_{3-x}$ [11.25]	O^{2-}	$\sigma_{O^{2-}}$ (750 °C) = 0.35 S/cm E = 0.55 eV	Readily converts to mixed conductor by addition of transition metals; candidate solid electrolyte for intermediate temperature SOFCs
$Gd_{1.8}Ca_{1.2}Ti_2O_{7-x}$ [11.26]	O^{2-}	$\sigma_{O^{2-}}$ (1000 °C) = 0.05 S/cm E = 0.67 eV	The related pyrochlore, $Gd_2Zr_2O_7$, is an intrinsic FIC
$Bi_2V_{0.9}Cu_{0.1}O_{5.5-x}$ [11.27]	O^{2-}	$\sigma_{O^{2-}}$ (700 °C) = 0.15 S/cm E = 0.47 eV	Mixed ionic–electronic conductor, $t_{O^{2-}} \approx 0.9$ at 900 K; of interest as a permeation membrane
$La_{0.8}Sr_{0.2}MnO_{3+x}$ [11.28]	O^{2-}	$\sigma_{O^{2-}}$ (1000 °C) $\approx 3\times10^{-7}$ S/cm E = 2.81 eV	This material is largely an electronic conductor with σ_e (1000 °C) ≈ 100 S/cm; as a cathode in prime candidate SOFC
$BaCe_{0.85}Yb_{0.15}O_{3-x}$ [11.29]	H^+	σ_{H^+} (300 °C) = 7×10^{-4} S/cm E = 0.54 eV	Of interest in SOFC based on protonic conduction
Nafion [11.30]	H^+	σ_{H^+} (75 °C) $\approx 10^{-2}$ S/cm (at 20% relative humidity)	Organic; prime candidate for low-temperature solid state fuel cell based on protonic conduction
α-AgI [11.31]	Ag^+	σ_{Ag^+} (200 °C) = 1.6 S/cm E = 0.1 eV	Phase transition at 146 °C; first recognized fast ion conductor
$RbAg_4I_5$ [11.31]	Ag^+	σ_{Ag^+} (30 °C) = 0.3 S/cm E = 0.09 eV	One of the most conductive ionic conductors at room temperature
α-CuI [11.32]	Cu^+	σ_{Cu^+} (450 °C) = 10^{-1} S/cm E = 0.15 eV	Phase transition at 407 °C
Na β-alumina [11.33]	Na^+	σ_{Na^+} (300 °C) = 0.13 S/cm $E \approx$ 0.3 ev	Stoichiometry varies between Al_2O_3/Na_2O = 5.3–8.5
$60Li_2S$-$40SiS_2$ [11.34]	Li^+	σ_{Li^+} (25 °C) = 5×10^{-4} S/cm E = 0.25 eV	Amorphous
Poly(vinylidene fluoride) (PVdF) – Propylene carbonate (PC) – Li salt (LiX=$LiSO_3CF_3$ $LiPF_6$ or $LiN(SO_2CF_3)_2$ [11.35]	Li^+	σ_{Li^+} (20 °C) $\approx 10^{-3}$ S/cm	Organic conductor; of interest for lithium batteries
$Li_{10}GeP_2S_{12}$-*thio-LISICON*	Li^+	σ_{Li^+} (25 °C) = 1.2×10^{-2} S/cm E = 0.25 eV	Promising for lithium batteries; more conductive than Li ion liquid electrolytes
$Li_{3x}La_{(2/3)-x}TiO_3$ (x = 0.11)-perovskite	Li^+	σ_{Li^+} (25 °C) = 1×10^{-3} S/cm	Promising for lithium batteries; Stable to > 8 V but not in contact with Li metal
β-PbF_2 [11.36]	F^-	σ_{F^-} (100 °C) = 10^{-4} S/cm E = 0.48 eV	Basis of a variety of gas sensors

ample, have demonstrated that cooperative motions of ions can lead to significantly lower calculated migration energies than those based on consideration of isolated jumps alone. Although no precise criterion now exists for categorizing FICs, they normally exhibit unusually high ionic conductivities ($\sigma > 10^{-2}$ S/cm), well below their melting points, and generally low activation energies (commonly $E \approx 0.05$–0.5 eV, but they can be as high as ≈ 1.0 eV).

Few intrinsically disordered oxygen ion conducting FICs are known. The pyrochlores, with general formula $A_2^{3+}B_2^{4+}O_7$, represent a particularly interesting system, given that the degree of disorder can be varied almost continuously from low to high values within select solid-solution systems. The pyrochlore crystal structure is a superstructure of the defect fluorite lattice with twice the lattice parameter and one out of eight oxygens missing. This can be viewed as resulting from the need

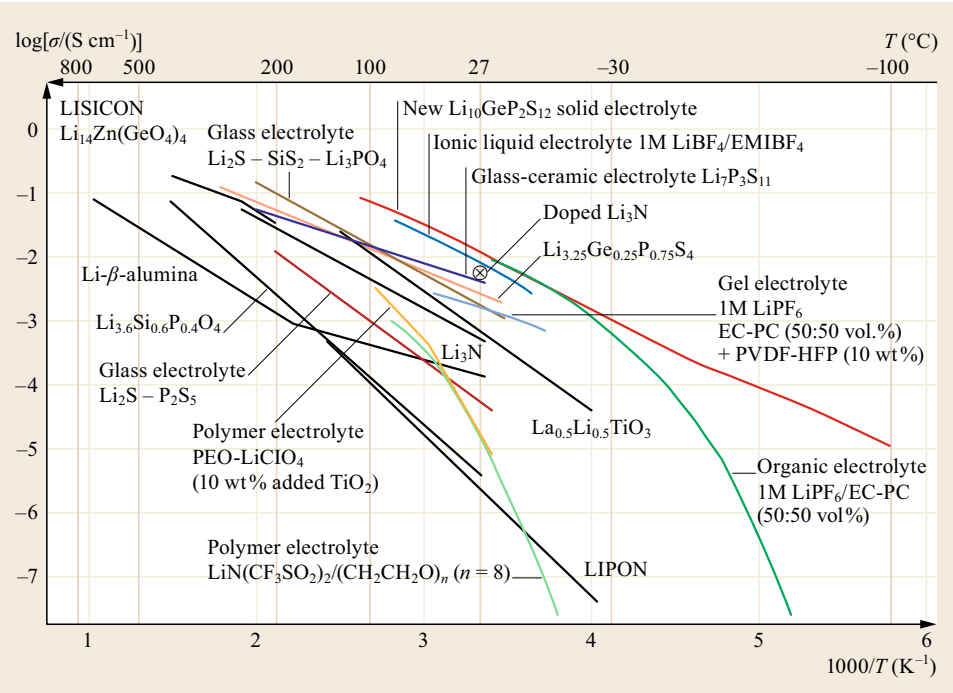

Fig. 11.3 The temperature dependences solid lithium ion conductors, together with representative organic liquid, ionic liquid and get electrolytes. (After [11.19])

to maintain charge neutrality after substituting trivalent ions for 50% of the quadravalent ions in the fluorite structure, as in $Gd_2Zr_2O_7$. Although oxygen vacancies occur at random throughout the anion sublattice in an ideal defect fluorite (such as yttria-stabilized zirconia – YSZ; Table 11.2), they are ordered onto particular sites in the pyrochlore structure. Thus, one properly views these as empty interstitial oxygen sites rather than oxygen vacancies. As a consequence, nearly ideal pyrochlore oxides, such as $Gd_2Ti_2O_7$, are ionic insulators [11.26]. Figure 11.4 illustrates the large increases in ionic conductivity induced by systematically substituting zirconium for titanium. *Moon* and *Tuller* [11.38] explain this on the basis of increased A and B cation antisite disorder as the radius of the B ion approaches that of the A ion. Thus, as the cation environments of the oxygen ions becoming more homogeneous, exchange between regular and interstitial sites also becomes more favorable, leading to increased Frenkel disorder. This interpretation has been confirmed by neutron diffraction studies on a closely related system [11.39].

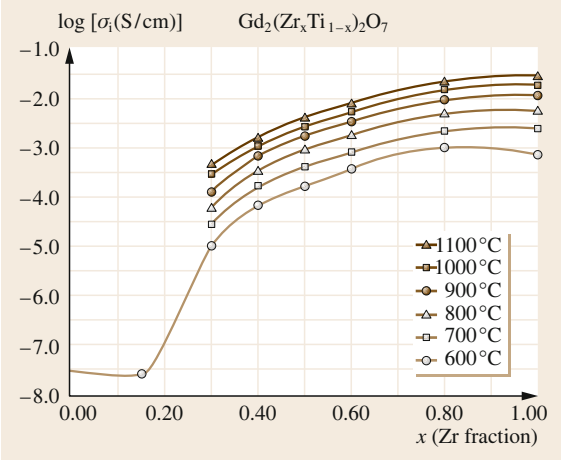

Fig. 11.4 Log ionic conductivity versus mole fraction Zr in $Gd_2(Zr_xTi_{1-x})_2O_7$ at a series of temperatures. (After [11.38])

Other important intrinsically disordered oxygen ion conductors are based on Bi_2O_3. At 730 °C [11.40], the low-temperature semiconducting modification transforms to the δ phase, which is accompanied by an oxide-ion conductivity jump of nearly three orders of magnitude. This is tied to the highly disordered fluorite-type structure, where a quarter of the oxygen sites are intrinsically empty, and to the high polarizability of the bismuth cation. *Takahashi* and *Iwahara* [11.41] succeeded in stabilizing the high-temperature δ phase to well below the transition temperature by doping with various oxides, including rare-earth oxides such as Y_2O_3. High oxide ion conductivity was also discovered above 570 °C in the Aurivillius-type γ phase of $Bi_4V_2O_{11}$ [11.42, 43], where one quarter of the oxygen sites coordinating V^{5+} are empty. Partial substitution of vanadium by lower valence cations, such as cop-

per, nickel or cobalt, led to a new family of so-called BIMEVOX compounds [11.44], with a remarkably high oxygen ion conductivity at moderate temperatures. The copper-substituted compound has an oxide ion conductivity above 200 °C which is ≈ 2 orders of magnitude higher than other oxide ion conductors. The bismuth-based electrolytes unfortunately suffer from instability under reducing conditions, which is a limitation for some applications, such as in the solid oxide fuel cells discussed below. However, *Wachsman* and *Lee* [11.45] demonstrate the ability to utilize the exceptional oxygen ion conductivity of bismuth oxide by pairing it with Gd doped ceria to form a bi-layer solid electrolyte in which the ceria exposed to the fuel environment protects the bismuth oxide from being too heavily reduced. Going one step further, *Sanna* et al. [11.46] report the ability to stabilize the δ-Bi_2O_3 phase to room temperature under both oxidizing and reducing conditions by creating layered superlattices with nano-dimensioned alternating layers of $Ce_{0.8}Gd_{0.2}O_{2-\delta}$ (gadolinium-doped ceria; CGO) and $Er_{0.4}Bi_{1.6}O_3$ (erbia-stabilized bismuth; ESB) on MgO single crystals. Interface and nanostructure effects are discussed in more detail below.

11.2.2 Amorphous Solids

One of the oft-mentioned criteria for FIC in solids (see before) is the existence of a highly ordered framework which provides channels for the ready motion of ions in the complementary, disordered sublattice. Reports of FIC in inorganic glasses [11.47] raised serious doubts concerning the relevance of this feature. The amorphous state, viewed as being liquid-like, is known to lack long-range order, with short-range order typically extending to, at most, a few atom spacings. Although highly oriented channels may be helpful in FIC, they are not essential, as demonstrated by the existence of FIC in glasses.

Fast ionic conductivity is observed in many glasses containing smaller cations with mole fractions greater than about 0.20, such as silver, copper, lithium and sodium [11.38, 47]. These glasses typically contain one or more network formers (such as SiO_2, B_2O_3, P_2O_5 or GeS_2), network modifiers (such as Ag_2O, Li_2O, Cu_2O or Ag_2S), and dopant compounds, largely halides (such as AgI, CuI and LiCl). The network structure and therefore its physical and chemical properties can be substantially modified by addition of the modifier. Dopant salts, on the other hand, do not strongly interact with the network, but *dissolve* into the interstices of the glass structure. A number of phenomenological trends have been noted including, ion conduction increases:

1. In the order K, Na, Li, Ag
2. With increasing modifier concentration
3. With halide additions in the order Cl, Br, I
4. In sulfide versus oxide glasses
5. In correlation with decreasing density and glass transition temperature.

Some authors speculate that ionic transport in glasses is enhanced upon addition of the halide anions by lowering the association energy between the mobile charge carriers and the network and thereby increasing the free carrier density [11.48]. An alternate model attributes the increased conductivity to major changes induced in the glass structure by the additives, as reflected in changes in glass transition temperature T_g and the density ρ. In this latter model, a large fraction of the carriers are already assumed to be unassociated and free to move, but with increased ionic mobility driven by structural changes. Here [11.49–52], the predominant influence of the halide addition is believed to impact the strain component of the migration energy.

Another important class of amorphous fast ion conductors is those based on organic or polymer electrolytes, which (analogous to the inorganic systems) are composed of a backbone polymer and a salt complex in which the counter-ion is covalently bound to the backbone. A classic example is the one based on polypropylene oxide $(CH_2CH(CH_3)O)_n$ (PPO) complexed with $LiCF_3SO_3$ to form $PPO_n \cdot LiCF_3SO_3$. Upon forming the complex, the Li ion conductivity increases by as much as a factor of $\approx 10^5$ [11.53]. In contrast to the inorganic glasses, which exhibit an Arrhenius temperature dependence, however, these polymers follow a curved dependence best expressed by

$$\sigma = \sigma_0 \exp\left(-\frac{B}{T - T_0}\right), \tag{11.12}$$

where T_0 is the glass transition temperature. This suggests a coupling between transport and network relaxation, a situation more closely coupled to transport in a liquid than in a solid, albeit a highly viscous liquid. Polymer electrolytes are now materials of choice for Li batteries and proton-based solid electrolytes given their attractive mechanical properties (ability to relax elastically upon stresses induced by volume changes related to charge–discharge of adjacent electrodes) and ease of processing [11.54].

11.2.3 Heavily Doped Defective Solids

Anomalously high concentrations of ionic carriers may also be induced in intrinsically insulating solids. In the following we briefly discuss two approaches for generating such *highly defective solids*.

We already know that ionic defect densities may be greatly enhanced above intrinsic levels by doping with altervalent impurities. However, the solubility limit of such impurities is often limited to only tens or hundreds of ppm. This corresponds to roughly $10^{17}-10^{18}$ defects/cm^3, a value 10^3-10^4 times smaller than in typical FICs. Compounds do exist, however, in which the solubility limit is extensive, reaching the 10–20% level even at reduced temperatures. Perhaps the most familiar example of such a system is stabilized zirconia, which due to its wide solid solubility with cations of lower valency such as Ca^{2+} and Y^{3+}, exhibits exceptionally high oxygen ion conductivity ($\sigma \approx 10^{-1}$ S/cm) at temperatures approaching 1000 °C.

As discussed above, high carrier densities must be coupled with high ion mobilities in order to attain high magnitudes of ionic conduction. The cubic fluorite structure, exhibited by stabilized zirconia (ZrO_2) and ceria (CeO_2), for example, supports high oxygen ion mobility due to the low four-fold coordination of cations around the oxygens, coupled with the interconnected nature of the face-shared polyhedra which surround the oxygen sites. Migration energies as low as ≈ 0.6 eV are reported for oxygen vacancy motion in ceria-based solid solutions [11.55]. High fluorine ion mobility is also observed in fluorite CaF_2 and related crystal systems.

More recently Ishihara demonstrated that very high oxygen conductivity can be achieved in the perovskite $LaGaO_3$ by accepter doping on both the La and Ga sites [11.11]. The solid solution $(La_{1-x}Sr_x)(Ga_{1-y}Mg_y)O_3$ exhibits ionic conductivity levels above that of ZrO_2 and CeO_2, for example 3×10^{-1} S/cm at 850 °C. Perovskites also support some of the highest proton conductivities at elevated temperatures. The most popular of these are ABO_3-type compounds with A = Ba, Sr, and B = Ce or Zr. Upon acceptor doping, as in $SrCe_{0.95}Yb_{0.05}O_3$, oxygen vacancies are generated as in the gallate above. However, in the presence of moisture, water is adsorbed and protons are generated [11.56]

$$H_2O + V_O^{\cdot\cdot} + O_O \Leftrightarrow 2OH^{\cdot} \,. \tag{11.13}$$

Given the high proton mobility, this is sufficient to induce large proton conductivity. Perovskite-related structures with the general formula $A_3B'B''O_9$ also exhibit high protonic conductivity [11.57]. Atomistic calculations simulating proton diffusion in numerous perovskite-type oxides are reported by the group of *Catlow* [11.58]. Ionic conductivities do not generally increase linearly with foreign atom additions. At the levels of defects being discussed here, defect–defect interactions become important, generally leading to defect ordering. This results in a maximum in ionic conductivity at some level of doping that depends on the particular system being investigated. *Nowick* et al. [11.55, 59] have demonstrated, in a series of studies, that the deviations from ideality are caused initially by composition-dependent activation energies rather than pre-exponentials (11.9), a feature also observed in a number of FIC glasses.

The formation of ionic defects that accompany excursions in composition away from stoichiometry due to redox reactions (Table 11.1, reaction 3) may also be large. CeO_2, for example, may be readily reduced to $CeO_{1.8}$ at 1000 °C and low PO_2s [11.60], resulting in oxygen vacancy concentrations of 5×10^{21} cm^{-3} ($c = 0.9$). It should be noted, however, that comparable concentrations of electrons are also formed during such stoichiometry excursions.

11.2.4 Interfacial Ionic Conduction and Nanostructural Effects

Interfaces can significantly modify the ionic conductivities of polycrystalline or composite materials and thin films. Modified levels of ionic conductivity near interfaces may result from space-charge regions formed near interfaces to compensate for charged defects and impurities segregated to surfaces, grain and phase boundaries. Grain boundaries, for example, serve as source and sink for impurities and point defects and thus often take on a net negative or positive charge relative to the grains. To maintain overall charge neutrality, a space charge of opposite charge forms in the grains adjacent to the grain boundaries with a width related to the Debye length L_D given by

$$L_D = \left(\frac{\varepsilon_r\varepsilon_0 k_B}{Tq^2 n_b}\right)^{\frac{1}{2}} \tag{11.14}$$

in which n_b is the majority charge carrier concentration within the grain, $\varepsilon_r\varepsilon_0$ the dielectric constant, k_B the Boltzmann constant, T the temperature and q is the electron charge. Depending on the sign of the charge at the interface, a depletion or accumulation of mobile ions in the vicinity of the boundary will form. Liang provided one of the first demonstrations of enhancement in the LiI : Al_2O_3 system [11.61].

The defect concentration profile in the space-charge region can be expressed as [11.62]

$$\frac{c_i}{c_i^\infty} = \exp\left[\frac{-q_i(\phi-\phi^\infty)}{k_B T}\right]. \tag{11.15}$$

The bulk concentration (c_i^∞) is a function of temperature, chemical potential and doping. The local concentration in the space-charge region (c_i) depends on

the difference between the bulk and the local electrical potential (ϕ^{∞} and ϕ). For positive values of ϕ, the concentrations of all negative defects are increased by the exponential factor, while those of the positive defects are decreased by the same factor and vice versa for negative values. When the mobile ion is depressed in vicinity of the grain boundary, this results in a reduction in ionic conductance due to blocking of ionic motion at the grain boundaries in polycrystalline specimens. This has been identified as a major obstacle in utilizing the perovskite based proton conductors described above in solid oxide fuel cells [11.63].

Films and/or polycrystalline materials with very small lateral dimensions can be expected to exhibit particularly strong space-charge effects on ionic conduction. This follows from the fact that the space-charge width approaches the dimensions of the film or grain. In this case, the space-charge regions overlap, and the defect densities no longer reach bulk values, even at the center of the particles [11.62]. In the limit of very small grains, local charge neutrality is not satisfied anywhere, and a full depletion (or accumulation) of charge carriers can occur with major consequences for ionic and electronic conductivity. Strong nanoscale effects on ionic and mixed ionic conductivity have been demonstrated for artificially modulated heterolayers of the solid ionic conductors CaF_2/BaF_2 [11.64] and nanocrystalline CeO_2 [11.65] and $Zr_{1-x}Y_xO_2/SrTiO_3$ superlattices [11.66] In the latter, as much as 8 orders of magnitude increase in the ionic conductivity of $Zr_{1-x}Y_xO_2$ was reported, although this interpretation has been questioned [11.67]. Figure 11.5 illustrates the orders of magnitude increase in fluorine ion conductivity possible with space-charge accumulation of mobile carriers in nanoscale CaF_2/BaF_2 multilayers.

In addition to the impact that interfaces may have on defect concentrations in their vicinity, others have investigated the potential role that interface-induced strain may have on defect mobility. In a series of studies by *Korte* et al. [11.67, 68], sandwiched $Zr_{1-x}Y_xO_2$ (YSZ) between insulating oxide layers with lattice mismatches with YSZ, thereby inducing both compressive and tensile stresses in the YSZ layers. As expected they found that dilatative strain increased the conductivity while compressive strain decreased the ionic conductivity, also consistent with a molecular dynamics study of YSZ that predicted considerably enhanced oxygen-ion diffusion for films subjected to dilatative strains [11.69]. These and other aspects of the roles of interfaces on impacting ionic conduction in heterostuctures are reviewed by *Fabbri* et al. [11.70]

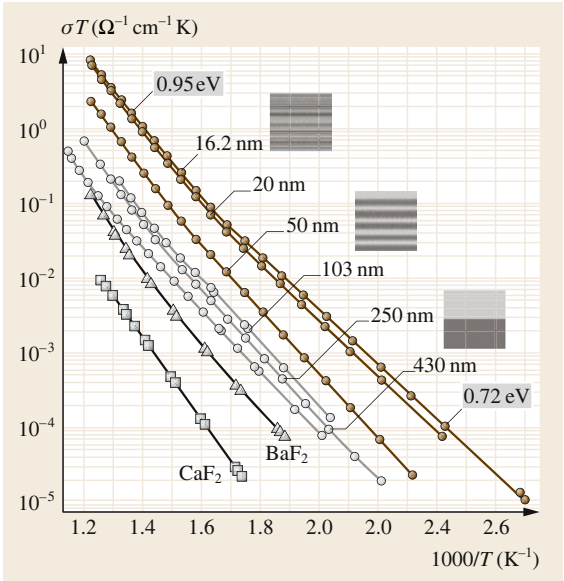

Fig. 11.5 Parallel ionic conductivity of CaF_2/BaF_2 nanometer-scale, artificially modulated heterolayers, with various periods and interfacial densities in the 430 to 16 nm range. (After [11.64])

11.3 Mixed Ionic–Electronic Conduction

11.3.1 Defect Equilibria

Deviations from stoichiometry in the direction of oxygen excess (MO_{1+x}) or deficiency (MO_{1-x}) form defect states that act identically in every way to impurity-related acceptor or donor states, respectively. In general, the electrical behavior of solids depends on defects formed in response to both impurities and deviations from stoichiometry. At or near stoichiometry, impurities predominate, while under strongly reducing or oxidizing conditions, defects associated with deviations from stoichiometry often take control. To characterize the electrical response of a metal oxide to temperature and atmosphere excursions, a series of simultaneous reactions of the form represented by (Table 11.1, reactions 1–5) must be considered. Furthermore, a representative electroneutrality equation for the case considered in Table11.1 would be

$$2\left[O_i''\right] + \left[N_M'\right] + n = 2\left[V_O^{\cdot\cdot}\right] + p\,. \qquad (11.16)$$

Note that: (1) intrinsic Frenkel disorder is assumed to predominate, so that (Table 11.1, reaction 1) may be ignored in subsequent discussions; (2) $a_{N_2O_3}$ is generally selected to be sufficiently low that all of N goes into solid solution. However, if exsolution of the dopant occurs e.g., upon cooling, it can also be treated in the framework of defect equilibria [11.14].

A piecewise solution to such problems is commonly attempted by sequentially choosing conditions for which only one term on either side of (11.16) need be considered. The region corresponding to mixed ionic conductivity is where the predominant charge carrier is an ion. In acceptor-doped material (A' being a generic acceptor), this corresponds to the condition (region II in Fig. 11.6) for which (11.16) may be simplified to read

$$[N'_M] = [A'_c] = 2[V^{\cdot\cdot}_O] \,. \tag{11.17}$$

Combining this with (Table 11.1, reaction 3) one obtains

$$n = \left[\frac{2K_R(T)}{[N'_M]}\right]^{\frac{1}{2}} P_{O_2}^{-\frac{1}{4}} \tag{11.18}$$

and from (Table 11.1, reactions 2 and 4),

$$p = K_e(T)\left(\frac{2K_R(T)}{[N'_M]}\right)^{-\frac{1}{2}} P_{O_2}^{\frac{1}{4}} \,, \tag{11.19}$$

$$[O''_i] = 2[A'_c]^{-1} K_F(T) \,. \tag{11.20}$$

Note that, in this defect regime, the ionic defects are pO_2-independent while the electronic species exhibit a $pO_2^{\pm 1/4}$ dependence. One obtains predictions for the corresponding dependencies of the partial conductivities of each of these charged species by multiplying carrier concentration by the respective charge and mobility. Experimentally, one normally observes the same pO_2 dependence of the partial conductivity as that predicted for the defect concentration, demonstrating that the mobility is pO_2-independent. One then uses the predicted pO_2 dependencies of the partial conductivities to deconvolute the ionic and electronic contributions to the electrical conductivity as discussed below.

The three other defect regimes most likely to occur, beginning at low P_{O_2} and moving on to increasing P_{O_2}, are depicted in Fig. 11.6 and include $n = 2[V^{\cdot\cdot}_O]$ (Region I), $p = [N'_M]$ (Region III) and $p = 2[O''_i]$ (Region IV).

In the case where μ_n, μ_p are sufficiently greater than $\mu(V^{\cdot\cdot}_O)$, then even in the defect regime where $V^{\cdot\cdot}_O$ is the predominant defect (so that $2[V^{\cdot\cdot}_O] = [N'_M]$), the total conductivity remains electronic. When the carrier mobility inequality is not nearly so pronounced, so that at the pO_2 at which electronic defects are at a minimum ($n = p$), conduction is predominantly ionic. Under these circumstances the oxide acts as a solid electrolyte, and in this regime of temperature and pO_2, one designates this as the *electrolytic domain*. Aside from the electrolytic domain, the neighboring zones on either side are designated as mixed zones within which both ionic and electronic conductivities are of comparable magnitude.

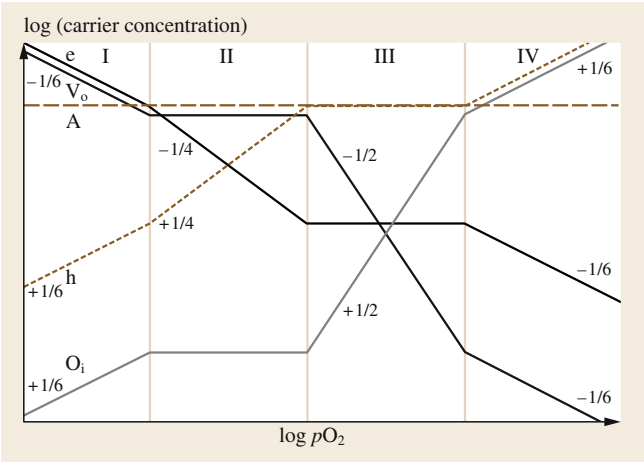

Fig. 11.6 Defect diagram for acceptor-doped oxide. (After [11.71])

11.3.2 Electrolytic Domain Boundaries

In applications where solid electrolytes are to be utilized, it is essential to know a priori under which conditions the material is likely to exhibit largely electrolytic characteristics. Expressions for the *electrolytic domain boundaries* can be obtained by first writing down general expressions for the partial conductivity (11.17)–(11.19)

$$\sigma_i = \sigma_i^\circ \exp\left(\frac{-E_i}{k_B T}\right), \tag{11.21}$$

$$\sigma_p = \sigma_p^\circ P_{o_2}^{+\frac{1}{4}} \exp\left(\frac{-E_p}{k_B T}\right), \tag{11.22}$$

$$\sigma_n = \sigma_n^\circ P_{o_2}^{-\frac{1}{4}} \exp\left(\frac{-E_n}{k_B T}\right). \tag{11.23}$$

One commonly defines the electrolytic domain boundary as that condition of T and pO_2 for which the ionic conductivity drops to 0.5 of the total conductivity. Under reducing conditions, this pO_2 is designated by P_n and under oxidizing conditions by P_p. Consequently,

one equates σ_i and σ_n or σ_i and σ_p to solve for P_n and P_p, respectively. These are given by

$$\ln P_n = \frac{-4(E_n - E_i)}{k_B}\frac{1}{T} + 4\ln\left(\frac{\sigma_n^0}{\sigma_i^0}\right), \quad (11.24)$$

$$\ln P_p = \frac{-4(E_i - E_p)}{k_B}\frac{1}{T} + 4\ln\left(\frac{\sigma_i^0}{\sigma_p^0}\right). \quad (11.25)$$

Note that since the mobilities of vacancies in such oxides have been found to be much greater than those of interstitials [11.38], we ignore the latter's contributions. The domain boundaries for stabilized zirconia are shown plotted in Fig. 11.7 [11.72]. Note that, as commonly observed, the electrolytic domain shrinks with increasing temperature due to the fact that E_n and E_p are typically greater in magnitude than E_i.

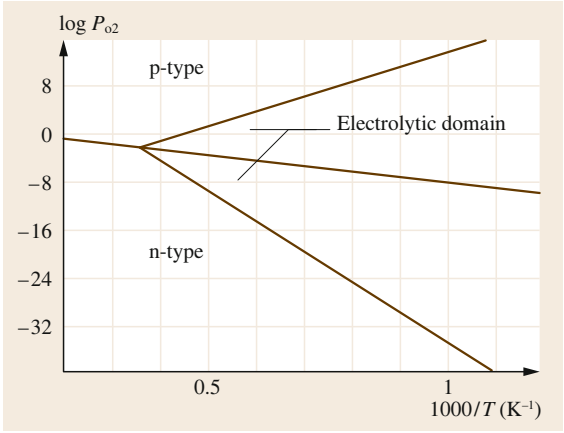

Fig. 11.7 Domain boundaries of stabilized zirconia as projected onto the log P_{o_2}–1000 T^{-1} plane. (After [11.72])

11.4 Applications

Fast ionic conducting ceramics and MIECs are finding extensive application in various solid state electrochemical devices. Some of these include fuel cells and electrolyzers [11.2, 45, 73–77] high energy density Li batteries [11.78–80], electrochromic windows [11.81] and auto exhaust sensors [11.82]. A very recent development is the proposed use of ionic or mixed ionic conductors as memory devices. These so call memristors can be switched from an insulating to a conductive state upon the application of a high electric field and switched back to the insulating state upon application of a suffiently high field of opposite polarity. The application of smaller fields are used to *read* the state of the memristor. Switching, whose speed can be below 10 ns, is believed to be driven by electromigration of either cations or anions. Such memristors are being designed to exceed 10^7 write cycles and retention times of > 10 yr [11.83].

11.4.1 Sensors

The monitoring of our environment has become essential for effective emissions control. Likewise, monitoring of chemical processes in real time enables closer quality control of products. Electrochemical sensors transform a chemical signal into an electrical signal, which is easy to measure, monitor and process [11.84]. Ionic and mixed conducting solids are basic materials for this development, because they can be easily miniaturized, for instance in thin film form, and they can often be operated at elevated temperatures or in an aggressive environment. The three major types of sensors utilizing ionic or mixed conducting materials are potentiometric amperometric and semiconducting, and are summarized below.

Potentiometric Sensors

In a potentiometric gas sensor, the concentration or partial pressure of a species is determined by measuring the emf of a solid electrolyte concentration cell. The most successful commercial sensor is the oxygen sensor [11.75], which uses stabilized zirconia as the solid oxygen ion electrolyte (Fig.11.8). The emf of the cell, $O_{2,ref}$, Pt/YSZ/Pt, O_2, can be written according to the Nernst equation

$$E = t_i\left(\frac{k_B T}{4q}\right)\ln\left[\frac{P(O_2)}{P(O_2)_{ref}}\right]. \quad (11.26)$$

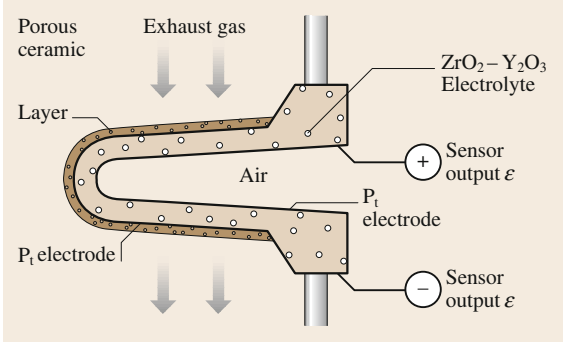

Fig. 11.8 Schematic of auto exhaust sensor based on the Nernst equation. (After [11.75])

$P(O_2)_{ref}$ is the oxygen partial pressure of the reference gas, generally air, and t_i is the ionic transference number. For proper operation, t_i needs to be kept very close to unity i. e., well within the electrolytic domain. All other terms have their common meanings.

The zirconia auto exhaust sensor monitors the air-to-fuel ratio, which is maintained within close limits for optimum operating efficiency of the three-way exhaust catalyst that serves to reduce the amount of pollutants, including unburned hydrocarbons, CO and NO_x. Such sensors are designed to provide response times on the order of tens of milliseconds. A voltage near to zero corresponds to an oxygen-rich *lean* mixture, and a voltage nearer to 1 V to an oxygen-poor *rich* mixture. The fuel injector of the engine is controlled via a closed-loop system. The zirconia oxygen sensor sees a wide range of exhaust temperatures, up to values as high as $\approx 900\,^{\circ}C$. Fortunately, the large step in voltage in going from lean to rich conditions can be easily detected by the on-board circuitry at all temperatures. The molecular mechanisms operating at the electrolyte/platinum interface have been examined in detail [11.85].

Another example of a potentiometric sensor is the one reported by *Maier* et al., of the type [11.86]

$$\mathrm{Au}, \mathrm{O_2}, \mathrm{CO_2}, \mathrm{Na_2CO_3}/\mathrm{Na^+}\text{-conductor}/\\ \mathrm{Na_2ZrO_3}, \mathrm{ZrO_2}, \mathrm{CO_2}, \mathrm{O_2}, \mathrm{Au}\,. \qquad (11.27)$$

This is used to monitor pCO_2; it eliminates the need for a gas-tight reference electrode. Here the two-phase reference electrode Na_2ZrO_3, ZrO_2, which fixes the Na activity on the right side of the cell, is insensitive to CO_2, while the change in Na activity in the Na_2CO_3 electrode on the left side can be sensed by the Na^+-conductor, typically NASICON or β-alumina. *Yamazoe* and *Miura* have reviewed the possible different types of potentiometric sensors by using single or multicomponent auxiliary phases [11.87].

Amperometric Sensors

By applying a voltage across an electrolyte, it is possible to electrochemically pump chemical species from one chamber to the other. Amperometric sensors rely on limiting current due to diffusion or interfacial phenomena at the electrode, which is linearly dependent on the partial pressure of the gas constituent [11.88, 89]. These become particularly important in so-called lean burn engines. Here the partial pressure of oxygen does not strongly vary with the air-to-fuel ratio, in contrast to engines operating at or near the stoichiometric air-to-fuel ratio. Under these circumstances, sensors are needed which have a stronger than logarithmic sensitivity to oxygen partial pressure variations. Sensors based on this principle are also being developed to detect other gases including NO_x.

Semiconducting Sensors

One can take advantage of the strong pO_2 dependence exhibited by n and p (see (11.22), (11.23)) in nonstoichiometric oxides as well to monitor the pO_2 in the surrounding gas phase by monitoring changes in their conductivity. Besides higher sensitivity, such resistive sensors offer low cost fabrication, potential for miniaturization and no need for seals and reference atmospheres, as required by zirconia-based sensors. A major limitation, however, is the significant cross sensitivity to temperature variations via the material's exponential dependence on temperature ((11.22), (11.23) large E_n and E_p). For $SrTiO_3$, $E_p = 1.3$ eV which would result in 2% change in resistance per degree Celsius, equivalent to an 8% change in pO_2 [11.90]. This temperature cross sensitivity renders $SrTiO_3$, and most other semiconducting oxides, unsuitable for this purpose. A solid solution between strontium titanate and ferrite, given by $Sr(Ti_{0.65}Fe_{0.35})O_{3-\delta}$ (STF35), on the other hand, has been found to exhibit a near zero temperature coefficient of resistance (ZTCR) [11.91]. This can be understood by examining the source of the temperature dependence of the electrical conductivity of metal oxide semiconductors given by

$$\sigma = \sigma_0 T^{(1.5-m)} \exp\left(\frac{-E_F}{k_B T}\right), \qquad (11.28)$$

where m reflects the power law dependence of mobility on temperature and E_F is the Fermi energy measured relative to the top of the valence band. Normally the first term in (11.28), which contributes to a positive coefficient of resistance PTCR, is overwhelmed by the second term, largely deriving from the exponential term, leading to a negative temperature coefficient of resistance (NTCR). However, with the reduced band gap resulting from the introduction of Fe and its lower lying 3d energy levels, the NTCR term becomes comparable to that of the PTCR term in (11.28), leading to a temperature insensitive oxygen sensor operation [11.91–93].

In addition to temperature sensitivity, for the oxygen sensor to be able to provide adequate feedback to the engine control unit, it must respond quickly (typically 10 ms) to changes in pO_2. For this to be possible, diffusion times given by $\tau_D \propto \ell^2/D$ must be exceptionally low, where D is the chemical diffusivity and ℓ the diffusion length which is the thickness for dense films and the grain radius for porous films. Screen printed STF35 thick film sensors are reported to satisfy these criteria, given the high oxygen diffusivity of this highly oxygen deficient material [11.94]. The response

time of thin films of STF, on the other hand, are limited instead by slow surface oxygen exchange kinetics. Controversy remains concerning the source(s) of this surface rate limiting step in mixed conducting oxides. For STF35, for example, surface chemistry, electronic structure and defect structure, all appear to play important roles [11.95].

11.4.2 Solid Oxide Fuel Cells (SOFC)

Solid oxide fuel cells (SOFC) provide many advantages over traditional energy conversion systems, including high energy conversion efficiency, fuel flexibility (due to internal reforming), low levels of NO_x and SO_x emissions, versatile plant size and long lifetimes [11.96]. Quiet, vibration-free operation also eliminates noise associated with conventional power-generation systems. However, operation at elevated temperature is necessary given relatively low ionic conductivities and slow electrode processes at temperatures below 800 °C. Recent progress with thinner electrolytes and advanced electrodes holds promise for reducting operating temperatures by as much as several hundred degrees.

The three major components of the elemental solid oxide fuel cell (SOFC) include the cathode, electrolyte and anode. While the solid electrolyte is selected so that it only conducts ions to ensure a Nernst open circuit potential that is as close to ideal as possible, the electrodes must support the reduction/oxidation reactions that occur at the electrolyte/electrode/gas interfaces. For example, when current is being drawn, the following reaction occurs at the cathode

$$\frac{1}{2}O_2 + 2e' + V_O^{\cdot\cdot} \Leftrightarrow O_O \,. \qquad (11.29)$$

This reaction is accelerated if the cathode can provide both electrons, as in a typical current collector, as well as oxygen vacancies. An example of such a mixed conducting cathode is $La_{1-x}Sr_xCoO_3$ (LSCO), which has an electronic conductivity of $> 100\,S/cm$ and an oxygen ion conductivity of $> 1\,S/cm$ at temperatures above 800 °C [11.97]. Given its importance to performance, modeling of the electrode processes has also received a great deal of attention recently [11.98, 99]. Unfortunately, while exhibiting highly attractive mixed conducting properties, LSCO is unstable in contact with yttria-stabilized zirconia, the electrolyte of choice.

In an attempt to take advantage of LSCO's attractive features, there is growing interest in marrying this electrode with doped ceria electrolytes, such as $Ce_{1-x}M_xO_2 : M = Gd$ or Sm, for operation at reduced temperatures of 550–750 °C, given ceria's higher ionic conductivity (albeit higher mixed ionic electronic conductivity at the anode) and stability in contact with LSCO. Electronic conduction degrades solid electrolyte performance in several ways. Because electronic conduction serves as an alternate path for charged species through the electrolyte, it decreases the power that can be dissipated through the load. Further, the short circuiting factor also serves to allow permeation of gaseous species through the electrolyte, even under open circuit conditions (see the section on membranes below). These primary figures of merit are summarized in the context of a solid oxide fuel cell (SOFC) in Fig. 11.9. E represents the potential induced across the cell under open circuit conditions for a given Po_2 gradient, t_i is the ionic transference number, E_N is the Nernst potential, R_{INT}, R_C, R_{SE} and R_A are the internal cell, cathode, solid electrolyte and anode resistances, respectively, Jo_2 is the oxygen permeation flux, and L the thickness across which the Po_2 gradient is imposed. All other terms have their normal meanings. Fortunately, the electronic conductivity in ceria electrolytes drops exponentially with decreasing temperature, and the overall power output exceeds that of zirconia-based systems at reduced temperatures, so it can be used with LSCO and other electrodes incompatible with YSZ.

The system $(La_{1-x}Sr_x)(Ga_{1-y}Mg_y)O_3$ (LSGM) was mentioned above as exhibiting one of the highest oxygen ion conductivities ($\approx 3\times10^{-1}\,S/cm$ at 850 °C) due to high levels of acceptor doping (Sr and Mg) on both the La and Ga sites. As a consequence, it is now being considered as one of several candidates for the electrolyte in solid oxide fuel cells. Experiments have shown that mixed ionic electronic conduction in a fuel cell electrode contributes to reduced overpotentials [11.74]. It has also been recognized that a single-phase *monolithic* fuel cell structure would benefit from the minimization of chemical

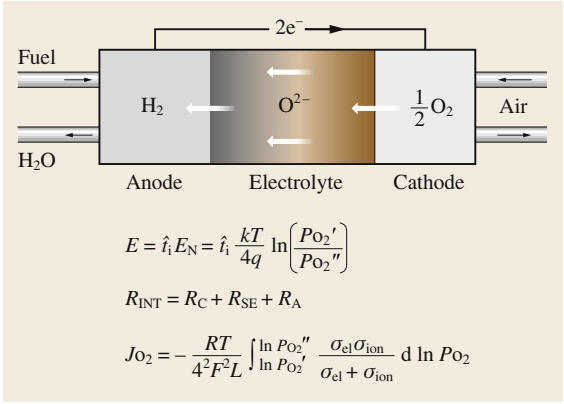

Fig. 11.9 Schematic of a solid oxide fuel cell and the primary figures of merit. (After [11.74])

and thermomechanical degradation [11.100]. Consequently, an electrode based on LSGM would satisfy all requirements. *Long* et al. proposed to add a transition metal in solution, which would introduce an additional 3d *conducting impurity* band within the wide band-gap of the initially electronically insulating gallate [11.101]. As expected, as the Ni content in the system $La_{0.9}Sr_{0.1}Ga_{1-x}Ni_xO_3$ (LSGN) increased, the electronic conductivity increased, finally reaching $\approx 50\,S/cm$ without decreasing the already high ionic conductivity. Improved electrode performance was indeed observed with the LSGM/LSGN interface [11.102]. Alternative options for a single-phase *monolithic* fuel cell structure could also, in principle, be based on fluorite structured ceria, with mixed conducting $Pr_xCe_{1-x}O_{2-\delta}$ cathode [11.103], the solid electrolyte $Gd_{0.2}Ce_{0.8}O_{1.9}$ and porous $Sm_{0.2}Ce_{0.8}O_{1.9}$ as the anode [11.104].

11.4.3 Membranes

Oxygen-permeable ceramic membranes are used for the separation of oxygen from air or for industrial-scale oxygen separation in the conversion of natural gas to syngas ($CO + H_2$) for example [11.105]. They are made from mixed conducting oxides in which ambipolar diffusion of ionic and electronic charge carriers in an oxygen potential gradient assures a high oxygen permeation flux through the membrane (Fig. 11.8 for an expression for the permeation current). High oxygen permeation rates were obtained with the system (La, Sr)$MO_{3-\delta}$ (M=Fe, Co, Cr) [11.97], but some deterioration over time was noticed. Research continues into this class of materials with regard to long-term ordering of defects, surface exchange kinetics, optimization of oxygen conduction and phase stability under steep oxygen activity gradients. One of the best materials developed to date is the BICUVOX compound, with composition $Bi_2V_{0.9}Cu_{0.1}O_{5.35}$, which shows a particularly large mixed conductivity that enables high oxygen permeation rates at moderate temperature, such as 700 K, at high and intermediate oxygen partial pressures [11.43]. Also receiving a great deal of attention is the perovskite $Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-\delta}$ (BSCF) given its exceptionally high permeation rates, albeit with concerns about phase stability and reactivity with CO_2 in the gas phase [11.106].

Mixed oxide ion and electronic conductivity is also observed in composites of a solid oxide ion electrolyte and a noble metal, if percolating pathways exist for each component. These mixed conducting oxide ceramic–metal composites (cermets), including Y-stabilized ZrO_2 with Pd [11.107], Sm-doped CeO_2 with Pd [11.108], and rare-earth doped Bi_2O_3 with Ag [11.109], have an appreciable oxygen permeation rate at elevated temperature without degradation and are considered attractive for industrial applications, although they are relatively expensive. Recent work by *Takamura* et al. [11.110] shows promising results based on ceramic/ceramic composites.

11.4.4 Batteries

Power storage requires high energy density batteries. The highest possible energy density is achieved using reactants with high free energies of reaction and low mass, such as lithium or sodium reacting with elements high up in column 6 and 7 of the periodic table. This also requires that the solid electrolyte remains stable under highly reducing or highly oxidizing conditions. Major advantages of solid electrolytes over liquid electrolytes are the absence of leakage and container problems, better chemical stability, improved safety and the possibility of miniaturization; for example using thin solid films.

There is an increasing demand for microbatteries compatible with microelectronics technology, related to the development of laptop computers or portable cell phones. This led to the development of high energy density and long life-cycle rechargeable lithium batteries, initially based on metallic lithium anodes. However, systems based on metallic lithium suffered from problems due to metal oxidation and poor rechargeability due to the formation of metallic dendrites. The alternative *rocking chair* concept, proposed in 1980 [11.111], based on two lithium insertion compounds Li_xWO_3 and Li_yTiS_2, replaced the unstable lithium electrode, but was unable to provide sufficiently high energy densities. Improved rechargeable lithium ion batteries based instead on nongraphitic *hard* carbons as the lithium insertion anodes have since been developed [11.112]. This was followed by the successful association of hard carbon insertion anodes with the high-voltage $LiCoO_2$ insertion cathode. Due to the relatively high cost of Co, alternative systems based on other cathode materials, such as $LiNiO_2$ or $LiMn_2O_4$, are currently under investigation [11.113]. Polymer (rather than inorganic) electrolytes are used in these applications (see above). An overview of lithium batteries and polymer electrolytes can be found in books by *Julien* and *Nazri* [11.78] and *Gray* [11.114] and several more recent reviews [11.79, 80].

11.4.5 Electrochromic Windows

Electrochromic light transmission modulators – so-called *smart windows* that use solid ionic conductors –

may play a significant role in energy-saving by regulating thermal insulation. In such a system, the window is maintained transparent in the visible and reflecting in the IR during the winter, allowing penetration of sunshine but blocking loss of interior heat. On the other hand, the window is rendered partially opaque during hot summer days, reducing the amount of radiation entering the building. The electrochromic elements [11.115], which color or bleach upon insertion–deinsertion of lithium or hydrogen ions, are sandwiched between two transparent thin-film electrodes and are separated by a solid electrolyte. The transparent electrodes are generally indium tin oxide (ITO). Glass electrolytes appear to be promising choices. Research and development on tungsten trioxide-based electrochromic materials started in the 1970s. Ions fill empty tetrahedral sites in the WO_3 structure [11.116]

$$x\mathrm{Li}^+ + \mathrm{WO}_3 + x\mathrm{e}^- \rightarrow \mathrm{Li}_x\mathrm{WO}_3 \,. \tag{11.30}$$

Key requirements include:

1. Compatible electrochromic and solid electrolyte thin film materials
2. The ability to operate near ambient temperature, in the range −40 to +120 °C
3. Cycle reversibly many thousands of times a year for a lifetime of 20 yr
4. Exhibit significant shifts in reflectivity with the degree of insertion–deinsertion.

11.5 Future Trends

A rapidly converging interest in thin film oxides has been developing in the microelectronics and solid state ionics communities. In the solid state ionics arena, the desire to reduce the operating temperature of solid oxide fuel cells (SOFC) has been stimulating a shift in emphasis from bulk to thin film electrolytes. Likewise, the trend in recent years has shifted away from bulk ceramics towards miniaturized smart sensor systems in which the sensor elements are integrated with electronics and various MEMS-based components, including microheaters, valves and membranes. Considering the continued drive towards ever smaller submicron lateral dimensions in MOSFET technology, it is likely that future efforts will be directed towards the construction of micro- and nanoscale ionic devices.

Specifically, one can envision the embedding of miniaturized thin film or SOFC structures as sensors or power sources together with microelectromechanical (MEM) components and other active electronics in the same silicon wafer. By applying standard Si technology, such as thin film deposition and photolithography, one accesses methods for tailoring electrolyte and electrode geometry (thickness, active electrode area and triple phase boundary length) with exceptionally high dimensional reproducibility, while retaining the ability to scale to larger dimensions. Already mentioned, is the potential for widespread use of memristors as alternative nonvolatile memory devices which benefit from nanoscale dimensions, simple geometries, high switching speeds, low power requirements, long retention time and competitive switching cyles. Attention will need to be focused on the special challenges that the marriage between solid state ionics and electronics implies, including semiconductor-compatible processing, rapid temperature excursions, stress-induced property modifications and interfacial stability.

One will also need to consider how the defect and transport properties of thin films may differ from their bulk counterparts, and how silicon and other materials platform provides opportunities to examine such properties in an in situ manner, and thereby identify novel or distinctive properties associated with low-dimensional structures. Good progress along these lines have been made in recent years. For example, the multibeam optical stress sensor (MOSS) is used to measure stress, with high precision, induced in films, in situ, during growth, or subsequently by changes in temperature or pO_2, by optically determining the curvature of the support wafer. Stoichiometry changes in the films lead to stress given constraints imposed by the underlying substrates. Cyclic expansion–contraction experiments conducted on $TiO_{2-\delta}$ films grown on Si using an in situ MOSS system could be correlated with grain size demonstrating that grain boundaries are associated with significantly higher defect concentrations [11.117]. Chemical capacitance, derived from complex impedance spectroscopy, has recently been demonstrated to enable the nonstoichiometry of thin film $Pr_{0.1}Ce_{0.9}O_{2-\delta}$ to be measured with high precision and over an extensive range of temperature and pO_2. The authors found the thin film to have a lower enthalpy of reduction than the bulk counterpart leading to a greater loss of oxygen per unit volume in the film under the same operating conditions [11.118]. The same authors demonstrated an in situ optical absorption technique also capable of monitoring changes in stoichiometry in $Pr_{0.1}Ce_{0.9}O_{2-\delta}$ thin films and were

able to confirm that the chemical capacitance and optical absorption methods provide self-consistent results [11.119].

Materials, like those used in solid state batteries, fuel cells and permeation membranes often suffer large changes in stoichiometry. This is inevitable, for example, in the lithim battery cathode, such as Li_xCoO_2 in which Li is inserted and extracted during the charging and discharging of the battery. Such changes in stoichiometry carry along with them often large changes in lattice parameter and consequently large dimensional changes. These in turn create stresses that can lead to fracture. Alternatively, the induced strains can lead to changes in defect formation and mobility, stabilization of alternate phases, and modified surface chemistries. These phenomena are now being studied under the category of electro-chemo-mechanical phenomena that have recently been reviewed and categorized [11.120].

Acknowledgments. Support from the Department of Energy, Basic Energy Science (Award No. DE-SC0002633), the National Science Foundation (Award No. DMR-1507047) and the Skoltech-MIT Center for Electrochemical Energy Storage for topics related to this work are highly appreciated. In assembling this work, I drew on earlier journal and proceedings articles published by myself or in in conjunction with colleagues. In particular, I wish to particularly acknowledge joint publications with Prof. P. Knauth of the Aix Marseille Université, France and Dr. S.R. Bishop of MIT. Thanks also go to the International Institute of Carbon Neutral Energy Research (I2CNER), Kyushu University, for its hospitality and support.

12. Bulk Crystal Growth: Methods and Materials

Peter Capper

This chapter covers the field of bulk single crystals of materials used in electronics and optoelectronics. These crystals are used in both active and passive modes, that is, to produce devices directly in/on bulk-grown slices of material, or as substrates in epitaxial growth, respectively. Single-crystal material usually provides superior properties to polycrystalline or amorphous equivalents. The various bulk growth techniques are outlined, together with specific critical features, and examples are given of the types of materials, and their current typical sizes, grown by these techniques. Materials covered range from group IVs (Si, Ge, SiGe, diamond, SiC), group III–Vs (e.g., such as GaAs, InP, nitrides, etc.) group II–IVs (e.g., CdTe, ZnSe, HgCdTe (MCT), etc.) through to a wide range of oxide/halide/phosphate/borate/tungstate materials. This chapter is to be treated as a snapshot only; the interested reader is referred to the remainder of the chapters in this handbook for more specific growth and characterization details on the various materials outlined in this chapter. Neither does this chapter cover the more fundamental aspects of the growth of the particular materials covered; again the reader is referred to relevant chapters within the handbook, or to other sources of information in the general literature.

12.1 Background

Despite the widespread progress in several epitaxial growth techniques for producing electronic and optoelectronic device-quality material, various bulk growth methods are still used to produce tens of thousands of tons of such materials each year. These crystals are used in both active and passive modes; i. e., to produce devices directly in/on bulk-grown slices of material, or used as substrates in epitaxial growth, respectively.

This chapter covers the field of bulk single crystals of materials used in electronics and optoelectronics. Single-crystal material usually provides superior properties to polycrystalline or amorphous equivalents. The various bulk growth techniques are outlined, together with the specific critical features, and examples are given of the types of materials, and their typical current sizes, grown by these techniques. Materials covered range from group IVs (Si, Ge, SiGe, diamond, SiC), group III–Vs (e.g., GaAs, InP, InSb, GaSb, nitrides, etc.) group II–IVs (e.g., CdTe, ZnSe, HgCdTe (MCT), ZnO, etc.) through to a wide range of oxide/halide/phosphate/borate/tungstate materials. This chapter is to be treated as a snapshot only; the interested reader is referred to the remainder of the chapters in this

handbook for more specific growth and characterization details on the various materials outlined in this chapter. Many of the crystals grown at a small size mainly for R&D purposes, particularly in Universities, are not discussed, and neither, in general, are organic materials. Neither does this chapter cover the more fundamental aspects of the growth of the particular materials covered; again the reader is referred to the relevant chapters within this book, or to other sources of information in the general literature.

12.2 History

Several very useful studies on the history of crystal growth in general can be found in the literature [12.1–9]. There were many significant contributions made to the fundamentals of crystal growth during the 18th and 19th centuries, including the development of thermodynamics, undercooling, and supersaturation [12.6, 7]. In terms of crystal growth techniques, it is accepted that the first to produce usable crystals on a large scale was that of flame fusion by *Verneuil* [12.10].

Before World War II, synthetic crystals (other than ruby) were mainly used in scientific instruments. However, between 1900 and 1940 there were enormous advances in both the theoretical aspects and in producing samples for scientific study. The diffusion boundary layer was applied by *Nernst* [12.11], while ideas on the growth of perfect crystals were proposed by *Volmer* [12.12], *Kossel* [12.13], and *Stranski* [12.14]. Also during this period many of the growth techniques now used were also initially developed. The flame fusion of *Verneuil* [12.10] was followed by hydrothermal growth [12.15, 16], crystal pulling [12.17], *Kyropoulos* [12.18], *Bridgman* growth [12.19–22], and vertical gradient freeze (VGF) [12.23].

During World War II, synthetic crystals were used as piezoelectric transducers (in sonar) as resonant devices (in radar) and as infrared detectors. However, it was the invention of the transistor (announced in 1948) that heralded the modern era of crystal growth for practical purposes rather than for pure scientific interest. *Teal* and *Little* developed crystal pulling of Ge in 1950 [12.24] and *Dash* [12.25] improved this with the *necking* technique to produce dislocation-free material. A key aspect at this stage was that of impurity levels and means to measure them. The semiconductors that were used for such solid-state devices as transistors work because they have desired dopants incorporated selectively in them. Techniques were developed at this time to improve the purity of materials, for example, zone refining [12.26] and float-zone (FZ) refining [12.27, 28]. Theoretical aspects developed in this period include the role of screw dislocations in growth [12.29] and the generalized theory of *Burton* et al. [12.30]. Reducing melt inclusions in crystals was discussed by *Ivantsov* [12.31, 32] in terms of diffusional undercooling, and by *Tiller* et al. [12.33] in terms of constitutional supercooling. Similar work was carried out in solution growth by *Carlson* [12.34], who studied flow effects across crystal faces, and *Scheel* and *Elwell* [12.35], who derived the maximum stable growth rate and optimized supersaturation to produce inclusion-free crystals. Seg-

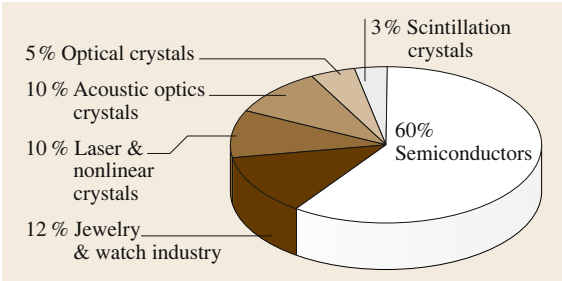

Fig. 12.1 Estimated share of the world production of 20 000 t of bulk crystals. (After [12.1], copyright Elsevier Science, used with permission)

Table 12.1 Estimated worldwide annual production rates of crystals (as at 1986, [12.5]). Some materials are mainly used for non-(electronic/optoelectronic) purposes, for example, cubic zirconia and much of the ruby are used in jewelry, watches, etc. (Items in *brackets* are small in volume but high in value)

Crystal	Rate (t/yr)	Growth methods
Silicon	4000	Czochralski, float-zone, (vapor phase epitaxy VPE)
Metals	4000	Bridgman, Strain anneal
Quartz	800	Hydrothermal
III–V compounds	600	Czochralski, Bridgman (VPE, liquid phase epitaxy LPE)
Alkali halides	500	Bridgman, Kyropoulos
Ruby	500	Verneuil
Germanium	400	Czochralski, Bridgman
Garnets	200	Czochralski
Lithium niobate	100	Czochralski
Phosphates	50	Low-temperature solution
Lithium tantalate	20	Czochralski
Cubic zirconia	15	Skull melting
TGS	10	Low-temperature solution
Diamond	10	High-temperature solution
II–VI compounds	5	Vapor, Bridgman

regation effects, which are related to mass and heat transfer, were studied by *Burton* et al. [12.36] for melt growth and by *van Erk* [12.37] for solution growth, while experimental conditions to produce striation-free material were established by *Rytz* and *Scheel* [12.38]. Forced convection in diffusion-limited growth was recognized as being beneficial for open systems with stirrers [12.39–42], while stirring in sealed containers was accomplished using the accelerated crucible rotation technique [12.43].

In 1986, *Brice* [12.5] estimated the annual production rates of crystals and Table 12.1 reproduces that data. Semiconductor materials clearly dominated at that stage, in particular silicon and III–V compounds. Later, *Scheel* [12.6] gave estimates of 5000 t in 1979, 11 000 t in 1986 (from [12.5]) and approximately 20 000 t in 1999 (Fig. 12.1), with a similar total quoted by *Scheel* in 2008 [12.8]. By 1999, the balance had shifted somewhat from the earlier estimates, but semiconductors continued to dominate, at ≈ 60%. There were roughly equal percentages of scintillator, optical, and acousto-optical crystals, at around 10–12%. The remainder was made up of laser and nonlinear optical crystals and crystals for jewelry and the watch industries.

A recent book edited by *Capper* [12.44] gives a comprehensive update on the bulk growth of many of the materials used in the electronic, optical and optoelectronic fields.

12.3 Techniques

12.3.1 Verneuil

This is the fastest growth method and was the first to be capable of controlling nucleation and thus producing large crystals of high melting point oxide crystals, for example, sapphire and ruby. Currently, a large number of high melting point materials have been grown by this technique, including ZrO_2 (2700 °C), SrO (2420 °C), Y_2O_3 (2420 °C), etc., but the largest use is still Al_2O_3 (often doped to produce ruby, sapphire, etc.). Figure 12.2 shows a schematic of the equipment used. Many different heat sources have been used, for example, solar furnace, glow discharge, plasma torch, arc image and radio frequency heating, but the original gas-flame technique is still the most popular. An oxy-hydrogen flame heats the seed crystal placed on a ceramic pedestal. Powder from a hopper is shaken through the flame and melts, forming a melt surface on the seed. During growth the seed is lowered, controlling the linear growth rate, while the volume growth rate is governed by the powder feed rate. The balance of these two rates controls the crystal diameter and the crystal is normally rotated slowly. Ruby crystals up to 200 mm diameter can be grown. Drawbacks of the technique include high dislocation densities and concentration variations.

12.3.2 Czochralski

Czochralski is a fast growth method and is widely used for both semiconductors and oxide/fluoride materials for optical applications. It also normally produces the most nearly perfect and homogeneous crystals. However, it is only really applicable to those materials that melt congruently or nearly congruently, that is, the solid and the melt compositions are the same at equilibrium. Normally a crucible material is needed that is compatible with the melt, however, the most common crucible material used for silicon, that is, silica, dissolves slowly in the melt and this raises certain process issues in the growth of this material. Capital costs for Czochralski pulling are higher than most other techniques, but it is used when the greatest perfection of grown material is required.

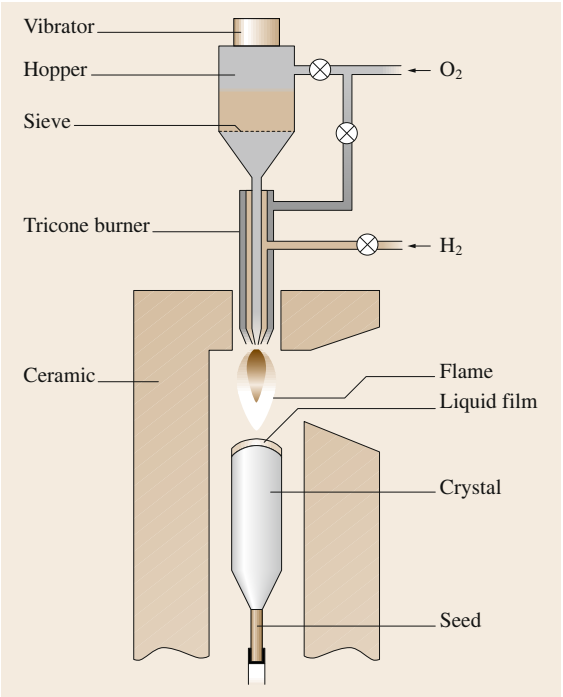

Fig. 12.2 Schematic of Verneuil growth equipment. (After [12.5])

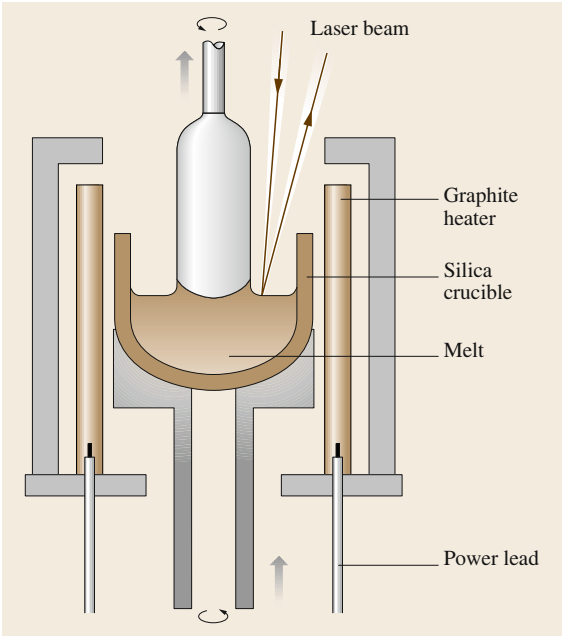

Fig. 12.3 Schematic of Czochralski growth equipment. (After [12.5])

The largest use is clearly for silicon, but probably ≈ 100 materials are commercially grown using this method, while many more are at the research stage. As the diameter of the crystal increases, in silicon for example from 200 to 300 mm, dislocation control becomes more difficult due to larger radial temperature gradients. Figure 12.3 shows a schematic of a Czochralski growth equipment. The basic method is relatively simple: The solid charge is placed in the crucible and heated to a temperature several degrees above the melting point. The seed crystal, rotating slowly, is lowered to contact the melt and the seed then slowly melts. After a short delay (a few minutes) pulling is commenced and new material (with slightly reduced diameter) begins to grow. A long narrow *neck* region is grown to reduce dislocations, then the melt temperature is reduced to increase the diameter. When the crystal attains full diameter growth is maintained until the desired length of crystal has grown, and growth is terminated by sharply increasing the pull rate or increasing the melt temperature so that the diameter reduces to zero.

A constant diameter is maintained by adjusting the power input to the melt. This is done automatically either by directly monitoring the diameter optically, that is, by observing the bright ring around the crystal periphery, or by indirectly measuring the diameter via weighing methods. Crucibles are normally round based for semiconductors but should be relatively flat for oxide/halide growth, that is, ionic materials.

Hurle [12.45] discusses the effects, in detail, of convection, flows in melts, heat transport, mass transport, solute segregation, use of magnetic fields, systems dynamics and automatic diameter control, morphological stability, and defect control. In general, as melt sizes have increased natural convective flows have increased, leading to turbulence, which causes growth rate fluctuations leading to dopant concentration variations (so-called striations).

For growth of III–V compounds, liquid encapsulated Czochralski (LEC) was pioneered by *Mullin* [12.46] for GaAs and GaP. Suppression of the volatility of As and P was crucial to the successful growth of these types of compounds. This technique involves the use of an inert layer of a transparent liquid, usually B_2O_3, which floats on the melt surface and acts as a liquid seal. Most importantly, the encapsulant should wet both the crucible and crystal so that a thin film adheres to the crystal as growth proceeds. The latter prevents dissociation of the hot crystal. Pyrolytic boron nitride (PBN) crucibles are now often used and either resistance or r.f. heating is employed. Semi-insulating GaAs is produced in a high-pressure puller (100–200 atm). The main advantage here is that elemental Ga and As can be used as the starting materials. Diameter is often control by crystal-weight measurements, rather than meniscus observation. Pull rates are typically < 1 cm/h. Axial or transverse magnetic fields can again be used to control melt turbulence and dopant segregation.

Precious metal (Pt, Ir) crucibles are used for oxide crystal growth as high temperatures are used. To prevent reduction of oxide melts, a partial pressure of oxygen is needed. Normally, the crucible is not rotated or translated and the growth rate is greater than the pulling rate as the melt height decreases. Growth rates are a few mm/h, at best, so growth times are normally > 1 week. Large temperature gradients can lead to melt turbulence, which in turn produces a banded structure of solute concentration and varying stoichiometry in the crystals. Control of convection in these systems is therefore of critical importance. *Rudolph* and *Kakimoto* [12.47] have outlined various means of controlling uniformity and stability of crystal growth from the melt by complementing internal parameters (e.g., temperature field, pressure, growth velocity, etc.) by external influences, for example, mechanical, electrical, and mechanical fields. Stirring during crystal growth can often be essential to enhance solute transport through the growth fluid, to homogenize the solute concentration in the fluid and solid, and to reduce the thickness of the solute diffusion boundary layer (in order to prevent constitutional supercooling and hence the morphological instability of the crystal). The question that obviously arises then is why are the properties of the crystal not

markedly affected by the periodic disturbances applied to growth fluids? The answer lies in a comparison of the time scales involved. Movement of solute species in melt growth is normally of the order of hundreds of cm/s. With growth rates in the region of 10^{-2} cm/s, and induced fluctuations in the region of cm/s solute movement dominates. In addition, if the characteristic ratio of D/δ^2 (with D the diffusion coefficient and δ the boundary layer thickness) is less than the frequency of any hydrodynamic changes and their related temperature oscillations then mass diffusivity cannot follow the thermal changes.

12.3.3 Kyropoulos

This simple technique is used where a large diameter is more important than length, for example, for windows, prisms, lenses and other optical components, and for scintillator materials. The set-up and method of growth are similar to those of Czochralski (Fig. 12.4) but after the seed is brought into contact with the melt it is not raised much during growth. As in Czochralski, a short necked region is still grown but then the seed removal is stopped and growth proceeds by reducing the input power to the melt. The resulting crystals normally have diameters of ≈ 80–90% of the crucible diameter. Although the control systems in these equipments are relatively simple, the temperature distribution over the crucible is critical. For alkali halides, the crystal density is greater than the melt density so the melt level decreases with growth and the desired temperature distribution is one of the increasing temperature as the base of the crucible is approached. Average linear growth rates are a few mm/h, corresponding to cooling rates of $< 1\,^{\circ}$C/h. The only other process parameter of concern is the seed rotation rate, which is normally low or zero.

While the method appears to be economically very attractive there are technical deficiencies. The isothermal surfaces are curved, resulting in high dislocation densities and the growth interface is composed of different crystal faces, with consequent inhomogeneities in impurities and vacancy concentrations. High levels of impurities result from the majority of the not well-stirred melt being consumed. Despite these drawbacks many tons of alkali halides for optical applications are grown each year by this technique.

12.3.4 Stepanov

In this technique, a crystal is pulled from a crucible containing a crystal-shaped aperture (Fig. 12.5). Crystals can be pulled vertically upward, downward, or even horizontally. Growth rates are below those of the normal Czochralski technique, but dislocation densities can be reasonably low.

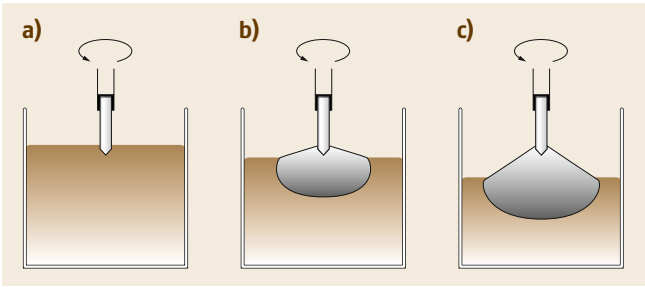

Fig. 12.4a–c Schematic of Kyropoulos growth equipment. **(a)** The seed crystal contacts the melt, a small amount melts, and then cooling is commenced to produce **(b)** and **(c)**. (After [12.5])

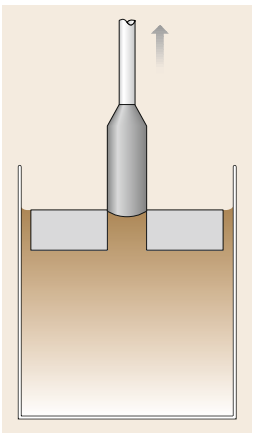

Fig. 12.5 Schematic of Stepanov growth equipment, in which a crystal is pulled through an aperture that defines its shape. (After [12.5])

12.3.5 Edge-Defined Film Growth

A die with a central capillary is placed on the surface of the melt (Fig. 12.6). Surface tension forces cause the melt to wet the die and be drawn up the capillary. A pointed seed crystal is lowered to contact this melt and then pulled upward. The melt is cooled slightly to increase the crystal diameter until it reaches the size of the die. Die can be designed to produce various shapes of crystals, for example, tubes, sheets, etc. Rapid growth is possible, but crystal quality normally suffers. One product is alumina tape (1 mm thick by several cm wide) used as a substrate for the production of high-frequency circuits. In this technique, however, purity can be limited.

12.3.6 Bridgman

In essence, this is a method of producing a crystal from a melt by progressively freezing it from one end to the other (Fig. 12.7). Crystals can be obtained with good

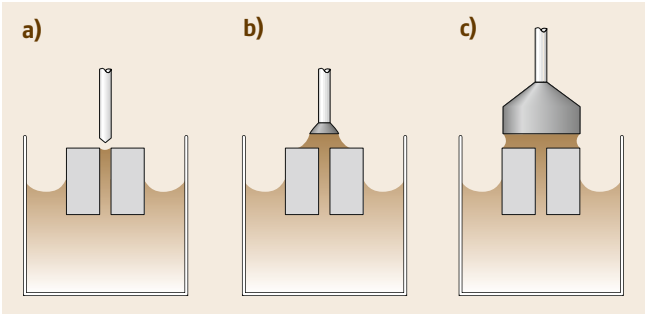

Fig. 12.6a–c Schematic of edge-defined film growth equipment. **(a)** The melt wets the die and is drawn up the capillary; **(b)** the seed is contacted to the melt and pulled up and cooling starts to increase the crystal size; **(c)** the crystal reaches the size of the die. (After [12.5])

dimensional control and the method uses relatively simple technology requiring little supervision. However, as the diameter increases, controlling heat flow becomes progressively more difficult. A wide range of materials have been produced by this technique, including sapphire at a melting point of $\approx 2370\,^{\circ}\mathrm{C}$. One major requirement is that neither the melt nor its vapor must attack the crucible material significantly. Dislocation densities can also be limited to $> 10^4\,\mathrm{cm}^{-2}$, and many materials contain low-angle grain boundaries.

Growth rates can be in the range $0.1{-}30\,\mathrm{mm\,h}^{-1}$. Either the crucible or the furnace can be moved to achieve movement of the freezing isotherm, and both vertical and horizontal orientations are used. Crucible materials include silica (for covalently bonded crystals), graphite, and some metals (e.g., Mo for sapphire growth). Traditionally, crucibles have tapered tips to try to restrict nucleation to one crystal, although seed crystals can also be used. If spurious nucleation occurs it usually forms at the crucible walls, but this can be suppressed by making the growth face concave into the melt. Baffles are often used to separate upper and lower parts of the furnace to ensure thermal isolation. A low radial temperature gradient is needed to reduce dislocation densities. Calculating the temperature distribution is possible [12.48]. The most obvious requirements are a large temperature gradient at the growth interface and low-temperature gradients in the radial direction.

Impurity distributions in crystals are, in general, governed by the type of mixing in the melt. In stirred melts, so-called normal freezing, the relevant equation is

$$C_\mathrm{s} = k_\mathrm{eff} C_0 (1-x) k_\mathrm{eff} - 1\,,$$

where C_s is the concentration in the solid, C_0 the initial concentration, k_eff is the effective distribution coefficient, and x is the fraction solidified. In unstirred melts,

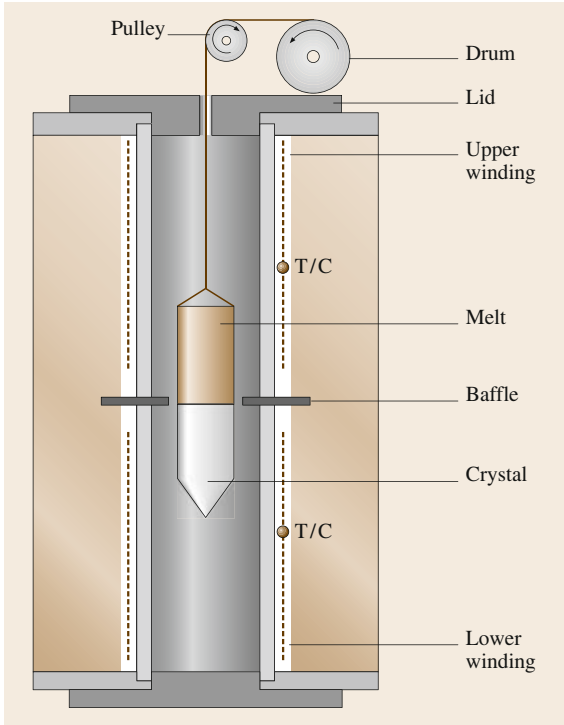

Fig. 12.7 Schematic of Bridgman growth equipment. (After [12.5])

the interface segregation coefficient k^* governs the segregation behavior

$$C_\mathrm{s} = k^* C_0 \left[1 - \frac{(1-k^*)}{k} \times \left(1 - \exp\left[-\frac{(1-k^*)k^* f_z}{D_\mathrm{L}}\right]\right)\right],$$

where f is the growth rate, z the axial distance, and D_L is the diffusion coefficient. For a molten zone of length L, the equation is

$$C_\mathrm{s} = C_0[1 + (k_\mathrm{eff} - 1)\exp(-k_\mathrm{eff}\, x)]\,.$$

For materials with a volatile component, there are several possible refinements of the basic process, for example, sealed ampoules, overpressure, and liquid encapsulation (e.g., using B_2O_3). Normally in sealed-ampoule growth there is a lack of control over stirring. For vertical systems, the accelerated crucible rotation technique (ACRT) can be used, and this author has developed this refinement for the growth of mercury cadmium telluride (MCT) up to 70 mm in diameter [12.49]. Faster stable growth rates are possible with ACRT [12.50], as are larger diameter crystals, improved uniformity and better crystallinity.

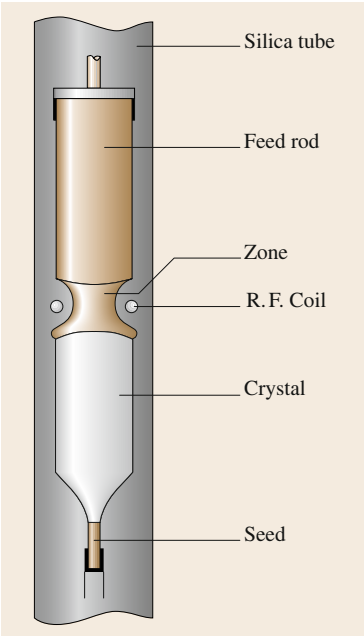

Fig. 12.8 Schematic of float-zone growth equipment. (After [12.5])

Zharikov [12.9, Chap. 3] discussed how axial vibrational control can be used to control the heat and mass transfer and growth kinetics during growth from liquids. Low-frequency, small-amplitude vibrations allow growth of high-quality crystals at high growth rates, and also provide control of stoichiometry and dopant distribution. This technique suppresses temperature oscillations at the interface and improves radial and axial distributions of impurities. It can also be used for non-electroconducting melts and liquids with high Prandtl numbers. Applications range from semiconductors to dielectrics produced from Bridgman, TSSG, Czochralski, and float-zone techniques.

12.3.7 Vertical Gradient Freeze

The vertical gradient freeze (VGF) technique involves the progressive freezing of the lower end of a melt upward. This freezing process can be controlled by moving the furnace past the melt or, preferable, by moving the temperature gradient in a furnace with several independently controlled zones. Low-temperature gradients are normally obtained, leading to reduced dislocation densities, and the crystal is of a defined shape and size. Difficulties include furnace design, the choice of boat material, and the issue of seeding.

The majority of melt-grown crystals are produced by the Bridgman and Czochralski techniques (and their variants). In general, if no suitable crucible can be found then other methods are required, for example, Verneuil.

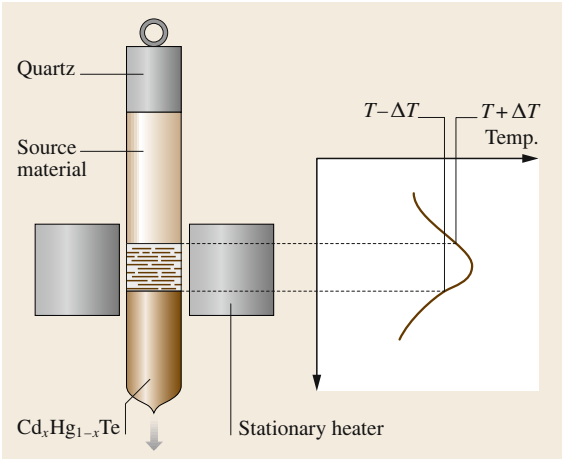

Fig. 12.9 Schematic of THM growth equipment. (After [12.5])

12.3.8 Float Zone

In this technique, a molten zone is maintained between two solid rods (Fig. 12.8). By moving the zone relative to the rods, one of them grows, and a single crystal can be grown if a seed is used. Silicon is the only material grown on a large scale by this technique. The only other use for it is in the small-scale growth of very pure crystals, as no crucible contact is involved. For silicon, r.f. heating is used, with frequencies of 2–3 MHz for diameters > 70 mm. There is a steep temperature gradient that induces flows in the molten zone, and if both the seed and feed rods are rotated then the shape of the solid/liquid interface can be controlled. The molten zone normally moves upward.

12.3.9 Traveling Heater Method

The traveling heater method (THM) technique was developed for II–VI alloy growth (Te-based) by *Triboulet* [12.51]. In this technique, a molten zone is made to migrate through a homogeneous solid source material. This is normally accomplished by slowly moving the ampoule relative to the heater (Fig. 12.9). The key requirement here is to obtain the appropriate temperature profile, also shown in Fig. 12.9. Matter transport is by convection and diffusion across the solvent zone under the influence of the temperature gradient resulting from the movement. For alloy growth, a steady state can be reached where the solvent dissolves a solid of composition C_0 at the upper growth interface and deposits, at near-equilibrium conditions, a material of the same composition at the lower growth interface. Growth occurs at a constant temperature below the solidus temperature and hence shows all the advantages

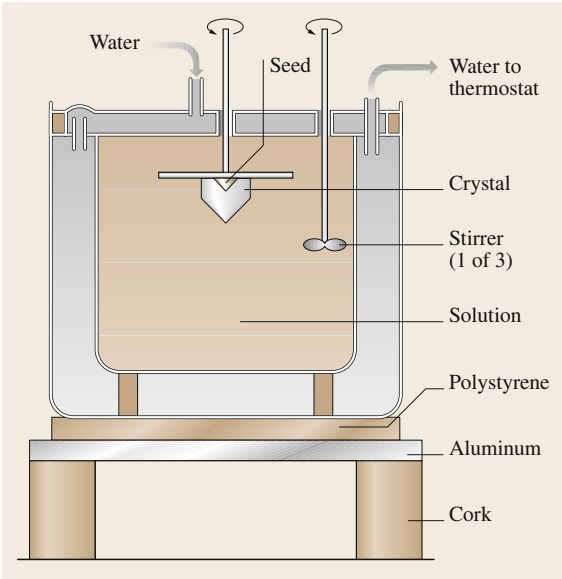

Fig. 12.10 Schematic of low-temperature solution growth equipment. (After [12.5])

of low-temperature growth. When tellurium was used as a molten zone there was a marked purification effect. Seeding was also found to be possible with the technique, as was growth of larger diameter material than with the other common melt techniques used for these compounds.

Problems with THM include the availability of suitable feed material with the required composition and dimensions, although several different routes have been used to overcome this problem. Natural convection is the dominant mechanism of material transport, which led to the addition of ACRT to the basic THM method for some of the ternary alloys.

By producing two bevelled cylinders of binary compounds graded-composition alloys were also produced. These were then used to assess the effects of composition on various electrical and optical properties in the given system. Other modifications to the basic process included the *cold THM* process, in which the relevant metallic elements were used as the source material. This produced a process that accomplished synthesis, growth, and purification at low temperature all in a single run. To avoid the problems resulting from solvent excess in the crystal *sublimation THM* was developed in which an empty space of the same dimension as the molten zone is used. This method was successfully applied to the growth of ZnSe. To improve the purification effect, repeated runs on the same material were used. A drawback of this is one of repeated handling, which in turn was solved by using the *multipass THM* technique, which can be thought of as a variety of the classical zone-melting method.

12.3.10 Low-Temperature Solution Growth

Most of the crystals grown by this technique are water soluble. This limits their use to applications in which moisture can be excluded. Growth rates are low (0.1−10 mm/d), as the growth faces are unstable. This is due to the concentration gradient near the growth face, in addition to which the crystal is normally totally immersed in the solution so that latent heat evolution increases the adverse supersaturation gradient (Fig. 12.10).

Water (both light and heavy) is used in ≈ 95% of the cases, and must be highly pure. All equipment must be carefully cleaned and protected from dust and the solutions must be stirred vigorously while being prepared. Both slow cooling and solvent evaporation techniques are used. Large volumes of solution (> 100 l) are needed for very large crystals of, e.g., KH_2PO_4 (KDP). These large volumes imply very long thermal time constants, which can be increased by adding thermal insulation, up to a limit. Large time constants make it easy to obtain good temperature control. The growth equipment is normally held in temperature-controlled rooms. Although temperature stability is key, other parameters, such as fluctuations in stirring, can lead to large changes in growth rate too.

Solvent evaporation simplifies the temperature control system and makes it more reliable. However, it is difficult to ensure a constant acceptable rate of loss of solvent. This can be approached by using a water-cooled condensation region. One drawback of this technique is that concentrations of impurities increase as the growth proceeds.

12.3.11 High-Temperature Solution Growth (Flux)

This method is used for those materials that melt incongruently; the solvent (flux) reduces the freezing point below the relevant temperature to produce the desired phase of the compound. Both liquid metals (Ga, In, Sn) used in semiconductors and oxides/halides (e.g., PbO, PbF_2) used for ionic materials are employed as solvents. Often, an excess of one of the components will be used (e.g., Ga for GaAs and GaP for instance) or a common ionic material (e.g., K_2CO_3 for $KTa_xNb_{1-x}O_3$). Alternatively, the solvents contain large atoms, such as Pb and Bi, which are too large to enter the lattice of the desired crystal. Mixed solvents, for example, alkali metal ions, break the chains that exist in B_2O_3, SiO_2, and

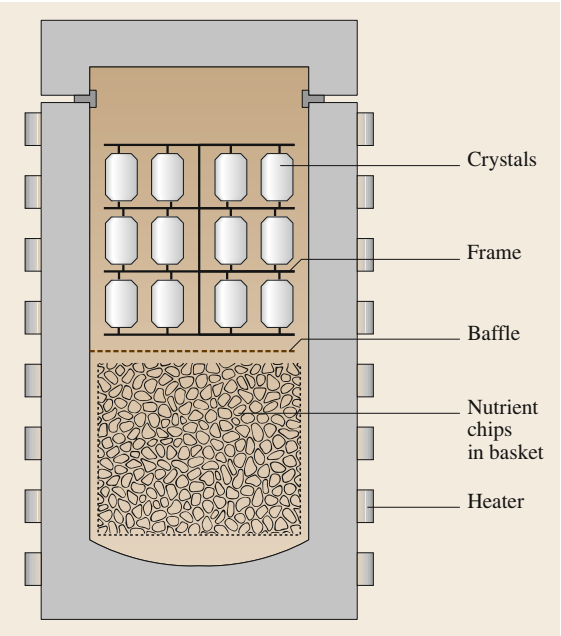

Fig. 12.11 Schematic of hydrothermal growth equipment. (After [12.5])

Bi_2O_3, lowering viscosities and surface tensions. The book by *Elwell* and *Scheel* [12.4] contains much useful information in this field.

Slow cooling of high-temperature solutions was used between 1950 and 1970 to produce hundreds of different materials. Small crystals were normally obtained but these were sufficient to obtain useful measurements of magnetic, optical, and dielectric properties. Later, seeded growth and stirring using ACRT led to much larger crystals. A Czochralski-type pulling technique can also be used in high-temperature solution growth to produce larger crystals.

12.3.12 Hydrothermal

This is growth from aqueous solution at high temperature and pressure. Most materials grown have low solubilities in pure water, so other materials (called mineralizers, for example, NaOH and Na_2CO_3) are added to increase the solubility. Quartz is the only material grown on a significant scale by this method, although ZnO is also produced commercially by this technique.

Natural quartz crystals are used as seeds, as they have lower dislocation densities. Growth proceeds in the temperature-gradient transfer mode. Nutrient is held in the lower part of the liquid in an autoclave. This region is held at between 5 and 50 °C above the upper portion of the autoclave. Convection carries the hot supersaturated liquid to the cooler upper regions, where deposition occurs on the seed crystals (Fig. 12.11). These autoclaves can be operated at up to 400 °C and 2000 atm pressure for ≈ 10 yr without degradation. Autoclaves can be up to 1 m in diameter and 2.5 m high for low-pressure growth from Na_2CO_3 solution, while 40 cm diameter and 8 m high autoclaves are typical for growth from NaOH.

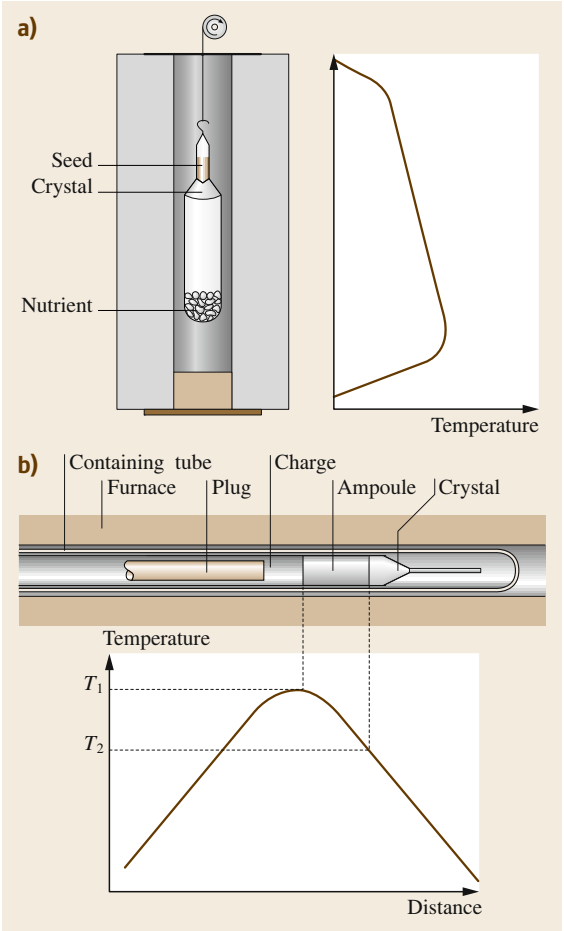

Fig. 12.12a,b Schematic of vapor growth equipment. **(a)** Seeded growth; **(b)** Piper–Polich set-up. (After [12.5])

Resistive heating elements are strapped to the outside of the autoclave and connected to two control systems, allowing independent control of the temperatures in the solution and growth zones. *Brice* [12.5] presents a table that shows some typical hydrothermal growth conditions for a wide range of materials.

The essential problem in the growth of quartz is to produce useful devices with reasonable yields with OH concentration (measured by IR absorption) of < 100 ppma. Several parameters restrict the maximum growth rate to ≈ 0.5 mm/d.

12.3.13 Growth from the Vapor

Vapor growth has some applications, particularly in high melting point materials and in II–VI compounds such as ZnSe and ZnS (Fig. 12.12). High-temperature vapor transport, or sublimation, of SiC has progressed recently to producing 1–2 in crystals. Growth proceeds by sublimation of a SiC source at 2000–2500 °C in near-vacuum conditions onto a seed held at ≈ 1000 °C lower than the source. 6H-polytype material oriented at ⟨0001⟩ is produced. Growth rates are ≈ 2 mm/h. Problems remaining include impurities (≈ 10^{16} cm^{-3}), voids, high dislocation densities, and mixed polymorphism.

12.3.14 Multicrystalline Si Growth for Solar Cells

Green [12.52] discusses the production of multicrystalline Si slices for photovoltaic applications and notes that in 2011 approximately 48% of the world production was based on this material. Advantages over the Czochralski process are noted as lower capital costs, higher throughput, and a higher tolerance to poor feedstock quality. Basically, the process involves the controlled solidification of molten silicon in a container to give silicon ingots with large columnar grains, normally propagating from the container base (Fig. 12.13a). These rectilinear ingots can be very large, up to 400–600 kg, and they are sawn into smaller more manageable sections, ≈ 150 mm in size (Fig. 12.13b), before being sliced into wafers by continuous wire sawing. This material is capable of producing solar cells with ≈ 90% of the performance of single-crystal Si, but due to the higher packing density possible due to the square geometry, this difference is masked at the module level where the overall performance is equivalent.

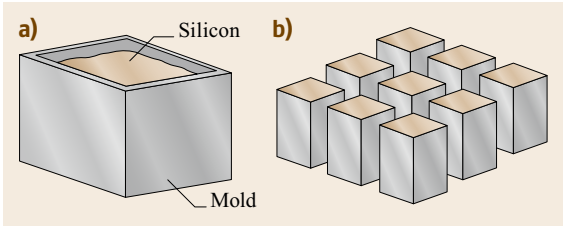

Fig. 12.13 (a) Direction solidification of silicon within a mold: (b) smaller sections are sawn from the main ingot. (After [12.52])

12.4 Materials Grown

This section summarizes the position regarding the wide range of materials used in electronics and optoelectronics. Again the reader is referred to the following relevant chapters for more in-depth coverage of a particular material. The section is subdivided roughly into group IV, group III–V, group II–VI, oxides, halides, and finally phosphates/borates.

12.4.1 Group IV

Silicon (Germanium)

The growth of silicon still dominates the electronics industry in terms of size of activity. *Hurle* [12.45] describes in detail the growth of silicon by the Czochralski method. In essence, a polysilicon charge is placed in a high-purity quartz crucible mounted in pre-baked graphite supports. Chains or cables are used in the pulling system, rather than rods, to limit the height of modern pullers. Both the crystal and the crucible can be rotated, although the details of this aspect vary from manufacturer to manufacturer and are proprietary. As the growth proceeds, the crucible is raised to maintain the position of the melt surface in the heater.

Silicon has two major advantages from a crystal growth perspective: a high thermal conductivity (which permits removal of latent heat of solidification) and a high critical resolved shear stress (which allows high thermal gradients without dislocation generation). These two factors enable high growth rates, leading to economic benefits. Heat is provided by *picket-fence*-type graphite heaters. Most commercial pullers are highly automated with full computer control. In most cases, diameter control is achieved via monitoring of the *bright ring* around the meniscus of the growing crystal. Oxygen is a particular problem and is introduced via erosion of the silica crucible by the melt. Convection moves the oxygen within the melt toward the crystal, where it is incorporated. A similar situation arises with carbon monoxide loss from the melt. Problems with convection have increased as the diameters of silicon crystals have increased over the past several decades. This convection controls concentrations and distributions of oxygen, carbon, and other unwanted impurities.

Although current production of large-diameter material is at the 300 mm level, there have been reports of 400 mm diameter material [12.53] and even 450 mm (≈ 450 kg) [12.8, Chap. 6]. In this case, it was necessary to grow a secondary neck below the Dash dislocation-reducing one as the thin Dash neck could not hold the

weight of the crystal. One report [12.54] shows how co-doping Si with B and Ge can obviate the need for this narrow-neck region, while maintaining dislocation-free growth. *Rudolph* and *Kakimoto* [12.47] report how the use of a 0.35 T magnetic field can reduce turbulence in such large melts.

The highest grade of silicon i. e., the highest purity, is probably still produced by the float-zone (FZ) method, rather than the Czochralski technique [12.55, 56]. The higher purity (particularly regarding carbon and oxygen) and better microdefect control result in higher solar cell efficiencies in FZ material. Faster growth rates and heating/cooling times together with the absence of crucibles and hot-zone consumables also give FZ material an economic advantage over Czochralski material.

Table 12.2 summarizes the present position on sizes of various crystals, including silicon and germanium and silicon/germanium. The author does not claim that this list is complete nor is it authoritative, it merely serves to show the range of crystals and sizes currently being grown by bulk growth techniques. The information is taken from a number of published conference proceedings [12.57–66] and other sources [12.8, 9, 44, 49, 67–69].

Silicon Carbide

The growth of SiC for semiconductor devices, as opposed to abrasive applications, became successful when substrates could be reproducibly grown up to large sizes [12.70–72]. Currently, substrates up to 50 mm diameter are commercially available and 100 mm diameter substrates have been reported by *Talalaev* et al. [12.9, Chap. 2]. The current method is that of seeded sublimation growth. A water-cooled quartz reactor enclosure surrounds a graphite crucible, which is heated by r.f. means. Crucible sizes are slightly larger than the required crystal size and SiC powder (particle size 20–200 μm) and/or sintered polysilicon is used as the source. Typically a distance of 1–20 mm between the seed and the source is used. At the high process temperatures of 1800–2400 °C, volatile species of Si_2C, SiC_2, and Si evaporate from the source and deposit on the seed. The source temperature determines the rate of evaporation, and the temperature difference between the source and the seed determines the diffusion transport rate; together these two temperatures govern the growth rate. The Si : C ratio is a key control parameter for proper growth of the desired material. Sublimation is normally performed in vacuum or inert gas, such as argon. The pressure of this gas also controls the growth rate to an extent. Growth rates can reach up to 0.5–1.0 mm/h, and crystal lengths of up to 20–40 mm are achieved. Doping can be accomplished via nitrogen and aluminum addition for n- and p-type material, respectively.

Polytype control is obtained by carefully choosing the seed orientation, with growth on the (0001) Si face giving 6H material, while 4H material grows on the $(000\bar{1})$ face. Both growth temperature and pressure and intentional/unintentional impurities can also affect the polytype obtained. One remaining problem is that of micropipes within the material. These are hollow core defects of 1–10 μm diameter, although their density has been reduced from 1000 to 1 cm^{-2} in the best samples. Maintaining good control over the nucleation conditions can reduce micropipe density.

Diamond

High-pressure diamond is produced under conditions where it is thermodynamically more stable than graphite [12.73]. However, very high temperatures and pressures are required for growth, unless catalysts are also employed. Clearly a detailed knowledge of the diamond–graphite pressure–temperature phase diagram is a prerequisite for successful growth. For example, in static compression, 8–20 GPa of pressure and temperatures of 1000–3000 °C are needed. Carbon sources include graphite, amorphous carbon, glassy carbon, and C_{60}. Dynamic compression techniques employ pressures of 7–150 GPa. A wide variety of catalysts have been used ranging from conventional ones, for example, transition metals, to carbide-forming elements (Ti, Zr, etc.), to Mg, to oxygen-containing materials (carbonates, hydroxides, etc.), to inert elements (P, Cu, Zn, etc.) to hydrides.

Crystals above 1 mm size are grown by the temperature gradient method. Growth temperature, temperature gradient, growth time, type of catalyst, and impurities all affect the growth. Crystals up to 10–12 mm in size are commercially available from high-temperature–high-pressure growth, see *Sumiya* [12.74]. Growth rates can reach 10 mg/h and are governed by the growth temperature and the temperature gradient. If a high-quality diamond seed is used crystals free of major defects, such as inclusions, stacking faults and dislocations, can be obtained. Impurities, mainly form the catalysts used, are still an issue, as is their nonuniform distribution.

More recent work on CVD techniques has led to diamond crystals up to 100 mm in diameter and 1–2 mm thickness [12.75]. This book also gives details of the use of diamond in a very wide range of device applications, including radiation/neutron detectors, electronic devices, for example, field effect transistors (FETs), electrochemical, and biological sensors and microelectromechanical devices. It even describes the area of superconductivity in diamond films.

Table 12.2 Typical sizes (i. e., diameter) of a selection of bulk-grown crystals (in mm and/or weight in kg) currently in production and in R&D

Crystal	Commercial	R&D
Silicon (Cz)	300 (250 kg)	450 (450 kg)
Silicon (FZ)	100	
Silicon (multicrystalline)	680 × 680 mm (400–600 kg)	
Germanium	75	200–300
Silicon/Germanium		35 (120 mm long)
SiC	50	100
Diamond	100 (1–2 mm thick)	100
GaAs	200 (50 kg)	200
InP	150	150
GaSb	50	75
GaInSb	50	
InSb	75	100
InAs	50	
InGaAs		10
GaInAsSb		30
GaN (sublimation)	50	
AlN (physical vapor transport, PVT)	25 (5 mm thick)	40 (core in 50 mm slices)
MCT	50	70
CdZnTe	140 (10 kg)	140 (12 kg)
Bi_2Te_3	12	28
ZnSe (vapor, LEC)	60	
ZnTe	80	
ZnO	50	75 (10 mm thick)
HgMnTe	30	
CdMnTe		40
HgZnTe	30	
$LiNbO_3$		40
$YCa_4O(BO_3)_3$	80	
$PbZnNbTiO_3$		75
YAG	20	75
GGG	110 (25 kg)	
$LiTaO_3$	100	125
Ruby	200	
Sapphire	350 × 500 × 40	500
BGO	140	
$La_3Ga_5SiO_{14}$	100	
Quartz	15–30 × 150–250, (0.5–18 kg)	
β-BaB_2O_4		60
CaF_2	385 (100 kg)	
Alkali halides	520 (550 kg)	1000 (poly)
BaBrI	400	
Ce:$Li_6Lu(BO_3)_3$	30	
KDP	660 × 500 (380 kg)	
$Ca_5(PO_4)_3F$	70	
TGS	40	

12.4.2 Groups III–V

Gallium Arsenide

Mullin [12.46] provided a comprehensive discussion on all aspects of the growth of III–V and II–VI compounds. He starts his treatment with the early work done on purification in Ge and Si, which highlighted the need for both high purity and for single-crystal growth. He notes that *Pfann* [12.76] initiated zone melting, in which, in the simplest case, a horizontal molten charge is progressively frozen from one end. Both zone leveling, in which a liquid zone within a solid bar is moved through

the bar in one direction and then in the reverse direction, thus producing a uniform distribution of a dopant, and zone melting, in which liquid zones are repeatedly passed through a solid bar to force impurities to segregate to the ends of the bar and then these are subsequently removed before the bar, are used in growth. Horizontal techniques were also used to produce single-crystal material by slight back-melting of a seed crystal, followed by progressive freezing. These various horizontal techniques were subsequently applied to the purification of both elements and compounds in the materials from groups III–V and II–VI.

Table 12.3, taken from [12.46], summarizes the growth techniques that have been used for the various compounds in the groups III–V and II–VI. There has been much debate about the relative advantages and disadvantages of these techniques as applied to compound crystal growth.

GaAs is the most important group III–V compound. Horizontal growth can be used to produce low-temperature gradients at the solid/liquid interface, which reduces stress-induced slip and hence dislocations. This is particularly beneficial for the use of GaAs in laser diodes, where dislocation densities are required to be very low. However, there is a potential problem in using these low-temperature gradients and that is constitutional supercooling, which may result in unstable growth and second-phase inclusions. In addition, there is the issue of impurity uptake from the crucible and nucleation of twins, grain boundaries, and even polycrystalline growth from the crucible walls. These problems can be minimized by taking care in experimental detail but they still make horizontal growth unattractive where large-area uniformity is required, particularly as scaling up to ever larger diameters is difficult.

Early efforts to produce this material by the vertical Czochralski method failed due to dissociation of the melt. This problem was solved by the LEC technique [12.46]. A layer of boric oxide floats on the melt and the seed crystal is dipped through this to contact the melt (Fig. 12.14). PBN crucibles are normally used and heating can be by resistance or r.f. means but commercial systems use graphite heaters. Most semi-insulating GaAs, which is required for integrated circuits, is produced at pressures of 100–200 atm. The advantage of this modification is that elemental As and Ga can be used as the source. Diameter control is normally via crystal weighing. Currently, LEC produces material of 150 mm diameter [12.77] from 28–40 kg melts using 400 mm diameter PBN crucibles. Also reported were modifications to the basic Czochralski technique to reduce stresses, and hence dislocations, in crystals up to 100–150 mm diameter. These are vapor-pressure-controlled Czochralski (VCZ), fully encapsulated Czochralski and hot-wall Czochralski. The reader is referred to the reference for more details of these techniques. Friedrich et al. [12.8, Chap. 5] note that 200 mm diameter crystals have also been grown.

An alternative to Czochralski is that of vertical gradient freeze. For reproducible growth of large-diameter crystals by this technique it was found necessary to use B_2O_3 in a PBN crucible. Freezing is accomplished by moving the temperature gradient via furnace-controller changes, rather than movement of the furnace itself. This naturally produces low-temperature gradients, which give low dislocation densities, and it pro-

Table 12.3 General applicability of growth techniques to compound semiconductors. (The more *asterisks* there are the more appropriate the technique; P: potentially applicable; C: conventional VGF; L: LEC VGF.) (After [12.46])

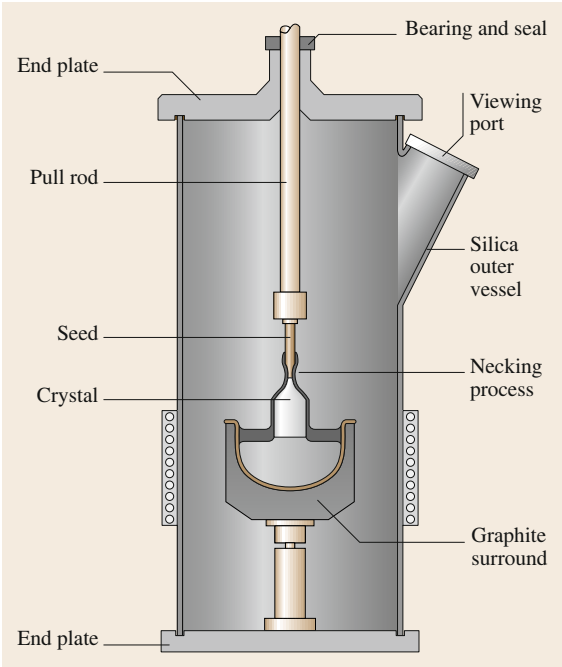

Fig. 12.14 Schematic of liquid-encapsulated Czochralski growth equipment. A silica outer vessel with viewing port is held between end-plates. The induction heating coils couple into the graphite surround. The seed is fixed in the chuck on the pull rod that rotates and moves through the bearing and seal. The crystal grows from the seed through a necking process, and on withdrawal pulls out a layer of B_2O_3 over its surface. (After [12.44], copyright Wiley-VCH (1998), used with permission)

duces a crystal of the right size and shape for subsequent slicing and processing. *Rudolph* [12.77] reports that in 1999 LEC growth of GaAs accounted for ≈ 90% of all SI GaAs, with the remaining 10% via vertical Bridgman or VGF growth. By 2000, he puts the figures at ≈ 50% LEC and ≈ 50% VGF. Rudolph also notes that VGF has been reported to grow up to 150 mm diameter material. *Rudolph* and *Kakimoto* [12.47] have shown how application of a magnetic field in VGF growth can produce nearly striation-free material.

Indium and Gallium Phosphides

As for GaAs, high-pressure LEC growth of both InP and GaP is normally used [12.46]. The problems were analogous to those of GaAs, with the major addition of an increased tendency to twinning. Loss of phosphorus (P_4) is still a problem and leads to deterioration in crystal quality. Dislocation densities are still seen to be high. *Asahi* et al. [12.78] report that some of these problems have been alleviated by modifications to the basic LEC process, for example, thermal-baffled LEC, phosphorus-vapor-pressure controlled LEC, and VCZ. Dislocations tend to increase with crystal diameter, although crystals up to 100 mm with low-disclocation densities have been grown by VCZ. Lower dislocation densities are produced by the VGF method, at a given crystal diameter. High-pressure VGF growth of InP is difficult and temperature fluctuations cause twinning. By improving the temperature control (to within ±0.03 °C). Asahi et al. show that twin-free ⟨100⟩ InP single crystals of 100 mm diameter and 80 mm length can be obtained. Temperature gradients of < 10 °C/cm reduced the etch pit densities below those of comparable LEC material. *Friedrich* et al. [12.8, Chap. 8] report that crystals of InP up to 150 mm diameter have also been produced.

Indium and Gallium Antimonides

Mullin [12.46] has detailed the early work on InSb; much less work has been done on GaSb. The low melting point combined with the negligible vapor pressure of Sb over the melt make zone-refining methods attractive. However, certain impurities render this route troublesome, although means to overcome this issue were found. Crystal-pulling methods were preferred for their versatility, although twinning was seen as a major issue. Growth on the (111) Sb face produces this twinning and it is recommended that growth takes place instead on [211] Sb or [311] Sb faces.

Micklethwaite and *Johnson* [12.79] summarized the position for InSb production for IR detector applications. InSb expands by ≈ 13% on freezing, leading to a net flow away from the growth interface. This *density effusion* must be accounted for in modeling this system. Hydrogen is used as the atmosphere, as it reduces floating InO_x. The basic Czochralski method is used for commercial production and 75 mm diameters are routine. Defect densities can be as low as 10 cm^{-2}. Many of the details of the growth process are proprietary. Growth proceeds without a liquid encapsulant, and as such resembles Si growth more closely than its arsenide and phosphide cousins. However, there are significant differences from the silicon case in terms of reduced radiative heat transfer and increased convective flow in the hydrogen atmosphere. Fluid mechanics in the melt are complicated both by the *density effusion* and the facet effect [12.46].

Dutta [12.8, Chap. 12] reports on the VB and VGF (+ACRT) growth of ternary III–V crystals, for example, GaInSb, up to 50 mm diameter and discusses the reasons why ternaries are so much more difficult to grow than binaries. Later, he described the growth of sev-

eral other III–V ternaries, for example, GaInAs, from quaternary melts by VB/VGF, including the addition of melt replenishment during growth [12.9, Chap. 9].

Group III Nitrides

There was an increase in interest in these compounds following successful development of blue laser diodes. Ideally, epitaxial thin films of these nitrides would be grown on bulk substrates of similar compounds, to minimize lattice mismatch. However, growth of these compounds by the more normal Czochralski and Bridgman techniques is not possible due to the high melting temperatures (2200–3500 K) and high-decomposition pressures (0.2–60 kbar) [12.80, 81]. One growth method that can be used is high-pressure solution growth. In this technique, liquid Ga (plus 0.2–0.5 at % Mg, Ca, Be or Zn) is held in a high-pressure chamber with a N_2 atmosphere. The maximum pressure is $\approx$ 20 kbar and the maximum temperature is 2000 K. Both pressure and temperature are controlled within tight limits and in situ annealing in vacuum is also allowed for. A temperature gradient of 2–20 °C/cm is maintained along the crucible axis and the N_2 dissolves in the hotter end and GaN crystallizes in the cooler end. No seeding was used and after 120–150 h of growth hexagonal needles or platelets are produced of size 10 × 10 mm. Growth by metal-organic vapor phase epitaxy (MOVPE) and molecular beam epitaxy (MBE) of GaN and InGaN multi-quantum wells (MQWs) on these bulk GaN samples was also reported by *Grzegory* et al. [12.81]. Light emitting diodes (LEDs) and laser diodes based on these epitaxial layers were also described.

This technique only produces very small crystals of both AlN and InN.

Nishino and *Sakai* [12.82] describe the sublimation growth of both GaN and AlN. Initially, the source powder is synthesized by heating Ga metal in NH_3. This powder is then annealed in NH_3 before loading into the growth chamber. Temperatures are 1000–1100 °C but atmospheric pressure can now be employed. Both NH_3 and N_2 are introduced into the growth chamber. Either small, 3 mm × several hundred μm, *bulk* crystals or free-standing films (10–30 μm thick) on sapphire substrates are produced. Thicker samples (up to 500 μm thick) can be produced by the sublimation sandwich method in which the distance from source to substrate is reduced to 2–5 mm. A hot-pressed polycrystalline source of AlN and a SiC-coated graphite crucible was used to grow 0.3–1.0 mm thick films on the 6H-SiC seed (10 × 10 mm in size) at temperatures of 1950–2250 °C. *Talalaev* et al. [12.9, Chap. 2] note the growth of 50 mm diameter AlN substrates with a central 40 mm diameter single-crystal core, plus totally single-crystal high-purity 25 mm AlN substrates.

12.4.3 Groups II–VI

Several reviews of the growth of a wide range of binary and ternary II–VI compounds have been published [12.46, 67, 83, 84]. One of the key concepts in the growth of these compounds is the ease with which phase transitions occur. This imposes limits on certain growth techniques for particular compounds.

There are two main types of bulk growth techniques, namely growth from the liquid and growth from the vapor. Most narrow-gap II–VI compounds are characterized by high melting points and/or high component partial pressures and early work concentrated on various forms of vapor growth, particularly for S- and Se-containing compounds. Problems of low growth rate and/or small crystal size and purity led to a switch to melt growth techniques, although there have been some significant developments in the growth of larger crystals from the vapor.

Many techniques have been used to grow narrow-gap II–VI compounds. Solid-state recrystallization (SSR) was used for ternary systems where there is a wide separation between solidus and liquidus, for example, MCT. Other names that have been used for this process are quench anneal (QA) and cast recrystallize anneal (CRA). The term anneal is used in the first case to define a high-temperature grain growth process while in CRA it is a low-temperature process to adjust stoichiometry. Strictly speaking SSR is crystal growth from the solid phase at temperatures close to the melting point but is included here for convenience.

Bridgman growth is the most widely used of the bulk growth techniques applied to narrow-gap II–VI compounds. It is the only technique that has produced crystals of all the binary and ternary compounds studied. Numerous modifications have been applied to the basic process but the three principle means of achieving growth are to move an ampoule through a temperature gradient, to move the furnace past a stationary ampoule and to move a temperature profile from high to low temperatures with both the furnace and ampoule stationary, the so-called vertical gradient freeze (VGF) method.

Usually, silica ampoules are used but various coatings have been applied and the use of other materials such as PBN has been reported [12.85]. Charges are prepared either using the appropriate elements or, for ternaries and quaternaries, pre-formed compounds of the binaries. Both vertical and horizontal configurations have been used and large crystal sizes coupled

with a relatively high growth rate (1–2 mm/h) make the basic technique relatively cheap and versatile. Marked segregation of both matrix elements, in ternaries and quaternaries, and impurities can occur. Difficulties in controlling component vapor pressures can be overcome by employing a reservoir of one of the components at a temperature lower than that of the growing crystal. High partial pressures in Hg-containing compounds can cause ampoule failure but means have been developed to cope with this situation [12.86].

The traveling heater method (THM) has mainly been used for Te-based binary and ternary compounds. Growth by THM combines the advantages of low-temperature solution growth with steady-state conditions, as in zone melting. A homogeneous alloy can be used as the starting ingot or segments of the binaries can be employed. If the Te zone height is made equal to the ring heater size then a flat interface is obtained, for particular geometries of crystal and furnace and growth parameters [12.87]. Very low growth rates (0.1 mm/h) are typical but diameters up to 40 mm have been accomplished. As in Bridgman, many variations on the basic THM method have been attempted. These include multipass-THM [12.88] and *cold* THM [12.89].

Hydrothermal growth has mainly been applied to S- and Se-based binary compounds and was reviewed by *Kuznetsov* [12.90]. The main advantages are in reducing growth temperature (to 200–250 °C) and dealing with the high partial pressures. Growth rates are very low (0.05 mm/d), and crystals are small (few mm) and contain subgrains and inclusions, but can still provide useful fundamental data.

Growth from the vapor is usually carried out at much lower temperatures than growth from the liquid, hence below unwanted phase transition temperatures, and can lead to less defective crystals. However, growth rates are generally much lower and uncontrolled nucleation and twinning are more prevalent. Techniques can be split essentially into unseeded and seeded methods. The simplest technique is that of chemical vapor transport (CVT), usually using iodine as the transport agent. The compound to be grown is reacted at a high temperature with the iodine, transported to a cooler region and deposited. The reverse reaction produces iodine, which diffuses back to the high-temperature region and the process repeats itself. The method uses a 2-zone furnace but has the disadvantages of iodine incorporation and small crystal sizes. *Mimila* and *Triboulet* [12.91] experimented with sublimation and CVT using water as a transporting agent for ZnSe and Triboulet has succeeded in the growth of CdTe by this means.

Most other vapor techniques are in some sense a derivative of the Piper–Polich method (Fig. 12.12b). Although this was developed originally for the growth of CdS [12.92], the technique may be applied to the vapor growth of any compound that sublimes readily below the melting point temperature. The crystal is grown in a closed crucible that is moved through a steep temperature gradient, such that the source material is always hotter than the growing surface and mass transport occurs from source to crystal.

Vapor growth under the controlled partial pressure of one of the constituents has been obtained by including small quantities of one of the elements in an extended part of the capsule located in a cooler part of the furnace [12.93]. The technique, termed *Durham*, is a vertical unseeded growth procedure, where the source is sublimed from bottom to top in an evacuated silica capsule over several days. Constituent partial pressures are independently controlled by placing one of the elements in a separately heated reservoir connected to the main capsule via a small orifice.

The vertical unseeded vapor growth (VUVG) method differs from the Durham technique in that the partial pressures are controlled by the initial deviation from stoichiometry of the charge material. It was initially developed to grow CdTe. The crystal is grown in an evacuated cylindrical silica capsule in a vertical furnace. A long quartz tube, which extends outside the furnace, is attached to the top of the capsule providing a heat pipe to create a cooler area for nucleation, which is closely monitored to ensure that the nucleus is single grained.

The sublimation traveling heater method (STHM) was developed from THM by *Triboulet* and *Marfaing* [12.88]. The Te-rich molten zone in conventional THM is replaced by an empty space or vapor zone. A problem arises in that the constituent partial pressures are not only functions of the temperature. However, the vapor can be maintained near the stoichiometric P_{min} condition if a small capillary, one end of which is at room temperature, is connected to the vapor chamber [12.94]. Excess species are sublimed down the capillary, preserving the relative constituent partial pressures and hence the growth rate.

In one version of the seeded technique, an oriented seed is placed on top of a long sapphire rod inside a sealed quartz capsule. The source material is placed in a basket above the seed and sublimation is top-down. The sapphire rod is carefully centered within the growth capsule to ensure a narrow gap between it and the walls of the capsule. The crystals grow clear of the container walls and generally consist of two or three large grains, some of which maintain the seed orientation. This *Markov* technique has been adapted for commercial production by the ELMA Research and Development Association of Moscow (cited in *Durose*

et al. [12.95]). Large crystals of CdTe, 50 mm in diameter and up to 10 mm in length have been grown.

HgS is grown by vapor means or by hydrothermal techniques, both of which are at low temperatures and hence low S partial pressures. HgSe has been produced by vapor growth and also by the Bridgman technique. Thick-walled silica ampoules are required in the growth of the Hg-containing compounds to contain the high Hg partial pressures. More details of the growth of the Hg-based binaries can be found in [12.89] for vapor and Bridgman growth, while Kuznetsov has reviewed the hydrothermal growth of HgS [12.90].

Early work on the growth of the Cd-based binaries was summarized by *Lorenz* [12.96]. Vapor growth was favored for CdS and CdSe, although hydrothermal growth was also discussed. The latter technique, as applied to CdS, was discussed in [12.90]. CdTe was grown by various melt growth techniques, including seeded zone melting and Bridgman, and by vapor growth methods. *Zanio* [12.97] reviewed the growth, properties and applications of CdTe, including radiation detectors. By that time, vapor growth had been essentially supplanted by both Bridgman and THM growth. A more recent review of CdTe can be found in *Capper* and *Brinkman* [12.98]. The main uses of CdTe (and CdZnTe/CdTeSe) are as a substrate material for the epitaxial growth of MCT and, more recently, as radiation detectors [12.99]. *Triboulet* et al. [12.100, 101] applied SSR to the growth of both CdSe and CdTe.

A wide variety of techniques for growth from the liquid have been used to produce crystals of CdTe. These include solvent evaporation [12.102], liquid encapsulated Czochralski [12.103], zone refining [12.104], VGF [12.105, 106], solution growth [12.107], heat exchanger method [12.108], float-zoning [12.109], Bridgman [12.98] and THM [12.51], and *Triboulet* et al. [12.100] have reviewed these materials as substrates for MCT epitaxial growth and compared them to the alternatives based on GaAs, sapphire, and Si. Problems with the growth of CdTe include low thermal conductivity, difficulty in seeding due to the need for superheated melts, ease of twin formation, tilts and rotations in the lattice, stoichiometry control, and impurities. However, *Triboulet* et al. [12.101] concluded that despite the progress made in the alternative substrate materials, lattice-matched substrates based on CdTe produced MCT epitaxial layers that gave the best device performance at that time.

Within the Bridgman growth technique, many alternatives have been attempted. These include holding excess Cd at a lower temperature in a separate reservoir [12.110], vibration-free growth [12.111], vibrational stirring [12.112], horizontal growth [12.113], low-temperature gradients [12.114], high-pressure (100 atm) growth [12.115], and the addition of the accelerated crucible rotation technique (ACRT) [12.116]. Work in the United States [12.113] aimed at improving both the horizontal and vertical techniques and scaling-up to large melts, up to 8 kg (horizontal). *Szeles* et al. [12.117] showed that crystals up to 140 mm diameter and 10 kg in weight can be grown by careful control of the temperature fields.

In the Bridgman process, elemental Cd and Te are loaded into a clean carbon-coated silica ampoule, homogenized by melting/rocking, heated to temperatures in excess of 1100 °C, and then frozen at rates of a few mm/h in a vertical or horizontal system. Single crystals or, more normally, large-grained ingots of size ≈ 75 mm in diameter and 10–15 cm in length are produced.

Growth by variations on the basic THM process have included the addition of ACRT [12.118, 119], focused radiant heating [12.120], sublimation-THM and multipass-THM [12.88], and *cold* THM at 780 °C [12.89]. Crystals are grown either from the precompounded binaries or the elements (as in cold THM). Growth rates tend to be low, few mm/d, but crystals are very pure due to segregation effects and high-resistivity material results (10^7 Ωcm in [12.88]). This makes THM material ideally suited for gamma- and x-ray detectors.

The vast majority of work on bulk growth of MCT has been from the melt. Although rapid progress has taken place in the epitaxial growth techniques for MCT, material grown by several bulk methods is still in use for infrared detection, particularly for photoconductive detectors (this is the case in this author's lab and others worldwide, for example, SPITFIRE in New Zealand). Several historical reviews of the development of bulk MCT have been published [12.121–123]. Many techniques were tried in the early years but three prime techniques survived: SSR, Bridgman and THM.

Two fundamentally different approaches have been followed to improve the basic Bridgman process. These are based on control of melt mixing and of heat flows, respectively. The former has been studied by this author and coworkers [12.124] while the latter includes the work of *Szofran* and *Lehoczky* [12.125] among others. Marked segregation of CdTe with respect to HgTe occurs in the axial direction but this leads to an advantage of the Bridgman process over other techniques, that is, material in all ranges of interest (1–2, 3–5 and 8–12 μm, for $x = 0.7$, 0.3 and 0.2 regions, respectively) is produced in a single run.

A means of stirring melts contained in sealed, pressurized ampoules was needed and the ACRT of *Scheel* and *Shulz-Dubois* [12.43], in which the melt is subjected to periodic acceleration/deceleration at rotation rates of up to 60 rpm, was chosen. The first report

of ACRT in MCT Bridgman growth was given in a patent [12.126]. These effects were developed and discussed in more detail in later papers, which are reviewed in [12.124]. Crystals were produced up to 20 mm in diameter and with x values up to 0.6 in the tip regions of some crystals (this has recently been increased to ≈ 0.93 at 20 mm diameter in this author's lab, *Capper* et al. [12.44, 49, 127], up to 0.4 in 40 mm diameter crystals, while the size has also been increased up to 70 mm).

Triboulet [12.51] developed the THM technique for MCT where diameters up to 40 mm were accomplished and x values up to 0.7 [12.128] for optical communication devices. *Durand* et al. [12.129] employed seeds to produce large, oriented crystals, an advantage of this technique over other bulk methods. *Gille* et al. [12.130] adopted a slightly different approach. A pre-THM step is carried out to quench a Te-rich (53–60%) MCT melt. The entire growth procedure takes several months but gives uniform material. This group also used rotation in the horizontal growth by THM with some success [12.131]. Two groups have applied ACRT to THM and obtained enhanced material properties. *Royer* et al. [12.132] used a saw-tooth ACRT sequence and obtained improved radial and axial compositional uniformity. *Bloedner* and *Gille* [12.133] used ACRT although no significant dependence of crystallinity on rotation sequence was seen. They did, however, achieve an increase in growth rate from 1.5 to 8.5 mm/d.

Bridgman is the main melt growth technique for the Hg- and Cd-based ternary and quaternary compounds while work on the vapor growth of these compounds has been limited. The various Hg-based ternaries (e.g., HgZnTe and HgMnTe) have been studied as potential alternatives to MCT for infrared detectors (*Rogalski* [12.134] gave more details including phase equilibria plots). This work was initiated by a theoretical prediction that the Hg–Te bond is stabilized by the addition of Zn, in particular. Rogalski concluded that THM produced the best quality HgZnTe while Bridgman growth of HgMnTe was described as being similar to MCT growth but with reduced segregation. Crystals of HgMnTe up to 40 mm diameter were produced. *Triboulet* [12.135] discussed alternatives to MCT. He concluded that HgMgTe, HgCdSe, and HgZnSe were not suitable, for a variety of reasons, but that HgMnTe and HgZnTe were potentially suitable.

The main Cd-based ternaries are CdZnTe and CdTeSe, which are used as substrates for epitaxial MCT growth by LPE and MBE. A vast literature exists on these compounds and it is still a very active area of research. Vertical and horizontal Bridgman are the main techniques used [12.98] although VGF has been used [12.98] as has THM [12.51]. High-quality crystals up to 100 mm (and even 125 mm) diameter can be produced by VGF [12.78, 106]. Even larger crystals are being grown by horizontal Bridgman [12.117, 136]. Two main problems remain in these compounds. These are uniformity of Zn, or Se, and impurities.

Pelliciari et al. [12.137] showed how solvent evaporation from a Te-rich solution of CdTe in an open tube system can produce large-grained and even single crystals of CdTe up to 300 mm diameter. This large-area material is aimed at the fabrication of x-ray and γ-ray detectors.

Dilute magnetic semiconductors (DMSs) are a class of semiconductor where the semiconducting properties are changed by the addition of a magnetic ion (e.g., Mn^{2+} or Fe^{2+}). These materials therefore display normal electrical and magnetic properties, and novel ones such as large Faraday rotations and giant magnetoresistance. *Pajaczkowska* [12.138] gave an early review of the phase diagrams, lattice parameters, and growth of many of the Mn- and Fe-based DMS compounds. Vapor growth and hydrothermal growth were mainly used, although the Te-based compounds were grown by the Bridgman technique. The most comprehensive review of DMSs is given in [12.139]. In that book, Giriat and Furdyna review the crystal structure of, and growth methods used for, the Mn-based compounds. The majority of the compounds, particularly the Te-based ones, were grown using Bridgman, or unspecified modifications of it. CdMnS was grown in graphite crucibles under high inert gas pressure, or by CVT (using iodine as transport agent). HgMnS was grown hydrothermally, yielding 2 mm diameter crystals. For Fe-based compounds similar preparation methods to those used for the Mn-based compounds were applied but less Fe can be incorporated in the lattice.

Bismuth telluride (strictly speaking a V–VI compound) is used in thermoelectric applications close to room temperature [12.140]. This material is also grown by the Bridgman technique. Both n-type and p-type materials are required to make the thermoelectric devices, and these can be achieved either by stoichiometric deviations or deliberate doping. In this author's lab bismuth telluride is grown at similar rates of 0.5–2.9 mm/h for 12 mm diameter ingots up to 100 mm length using antimony and iodine as acceptor and donor dopants, respectively.

12.4.4 Oxides/Halides/Phosphates/Borates

Oxides

Hurle [12.45] summarized the issues of the growth of oxides by the Czochralski technique. The high melting points of most oxides of interest necessitate the use

of precious metal crucibles, for example, iridium, platinum, although molybdenum and tungsten ones can be used for lower melting point materials. Extensive and efficient thermal insulation is required, using alumina, magnesia, zirconia, and thoria. Some materials require a partial pressure of oxygen in the growth chamber to prevent reduction of the melt. However, this can lead to oxidation of the crucible, which in turn enters the melt. Careful management of the oxygen pressure and gas flow is needed, together with physical baffles. Heating is normally by r.f. means. Mounting of the seeds is problematic and long seeds are necessary to avoid thermal degradation of the seed holder and pull rod. Rotation or translation of the crucible is normally not used, so the rate of growth has to be above the pulling rate to account for the fall in melt height. Crystals are normally limited to less than half the crucible diameter for stable growth. Growth rates are low, a few mm/h or less, to avoid unstable growth. Afterheaters are also employed to reduce the built-in stress in the crystal during the later stages of growth and subsequent cool down. Growth runs are several days so automatic diameter control, in this instance using weighing techniques, is mandatory. The high temperatures lead to high-temperature gradients and thus strong bouyancy-driven convection that is turbulent by nature. This turbulence gives rise to nonuniformities in the crystals. In addition, catastrophic failure can result from coupling between this turbulent flow and the flow due to the crystal rotation. Thus, understanding the convective flows in oxide growth is critical if large-diameter highly perfect crystals are to be produced.

Fukuda et al. [12.141, 142] have presented detailed reviews of the growth of a wide range of oxide materials of interest for optical and optoelectronic applications. They note that only $LiNbO_3$ (LN), $LiTaO_3$ (LT), and $Y_3Al_5O_{12}$ (YAG) have as yet reached production status. Many of the other materials exhibit superior properties but are not available in large quantities at sufficient perfection to warrant them being used in devices. In general, the growth methods are based on liquid–solid transitions, either from the melt or from high-temperature solutions (flux), for congruently and incongruently melting materials, respectively. Czochralski growth is still the mainstay of oxide growth, although problems with shape (diameter) control of some oxides (rare-earth vanadates, rutile, etc.) necessitate the use of edge-defined film-fed growth (EFG). Growth from fluxes is used for a range of oxide materials, although some incongruently melting materials can be produced from melts of the same composition as the crystal by a micro-pulling down technique.

In the micro-pulling down technique the melt is held in a Pt crucible and a micro-nozzle (die) is arranged at the bottom of the melt. Below this arrangement is placed an afterheater. This combination produces a steep temperature gradient (300 °C/mm), which ensures stable growth at high rates. Single crystals of 0.05–1.0 mm diameter are produced onto seeds. LN crystals, for example, are grown at 12–90 mm/h from stoichiometric melts up to 100 mm in length, assumed only to be limited by the melt volume used. Dislocations are introduced if the diameter of the crystals exceeds 0.8 mm. Growth of $K_3Li_2Nb_5O_{12}$ (KLN), which has outstanding electro-optic and nonlinear optical properties, is problematic by either Czochralski or Kyropoulos methods due to segregation effects at the solid/liquid interface and cracking. This material was grown by the micro-pulling down technique at rates of 20–80 mm/h with diameters of 0.15–0.5 mm. The crystal composition was found to be near to the melt composition and crystals were single domain.

Crystals in the $KTiOPO_4$ (KTPO) family were grown by the flux method using slow cooling from 1100 to 800 °C. Crystals of a few mm in size were obtained for second-harmonic generation measurements.

Crystals from the langasite family ($La_3Ga_3SiO_{12}$) are used for lasers. These were grown by the Czochralski method at 50 mm diameter and 130 mm length. High-purity oxide powders were used as starting materials and an Ar/O_2 mixture was used to suppress evaporation of the gallium suboxide. A pulling rate of 1.0 mm/h was used together with a crystal rotation rate of 10 rpm. The resulting crystals were single phase and crack free. These crystals show superior properties, as filters, to quartz. A range of langasite-type crystals up to 100 mm diameter have also been grown by both Czochralski and VB techniques ([12.8, Chap. 15], [12.143]).

Another means of overcoming problems in Czochralski growth of these materials is to use the EFG method. Rutile (TiO_2) is used as a polarizer in optical isolators and prisms for optical communication systems. Crystals of this material can be grown by Verneuil and float-zone methods but growth by Czochralski is difficult. Iridium is used for the die material and crystals up to 8×1 cm and 0.5 mm thick were grown. A modified die was used to grow a rod of 15 mm diameter and ≈ 40 mm length. A double-die system was shown that was used to produce a core-doped crystal of LN, using Nd^{3+} and Cr^{3+} as the dopants. A 5 mm diameter crystal some 60 mm in length was produced. Such crystals have potential in optical applications where pumping energy is only absorbed in the core region, reducing heat-induced energy losses.

Quartz is used in both piezoelectric and in various optical applications [12.144]. *Balitsky* [12.145] noted

that some 2500 t were produced per year at that time. Hydrothermal growth is the main growth technique used in order to keep the growth temperature below the β- (nonpiezoelectric) to α-quartz (piezoelectric) phase transition. Growth at temperatures of 250–500 °C and pressures of 50–200 MPa are used in both alkaline and fluoride solutions. Growth rates of 0.5–1.0 mm/d are achieved on (0001) or (1120) seeds and crystals up to $200 \times 70 \times 60$ mm in size weighing from 1–18 kg.

Various oxide materials are used widely in scintillator applications. The most common are $Bi_4Ge_2O_{12}$ (BGO), up to 140 mm diameter and 400 mm long [12.8, Chap. 8] and $PbWO_4$ (PWO) [12.146, 147]. These materials are grown by normal Czochralski and Bridgman techniques and the requirement is for thousands of each for large high-energy/astrophysics projects in several centers throughout the world. For example, some 85 000 PWO crystals were required for one application at the Large Hadron Collider at CERN. High-purity starting materials are important as are certain growth parameters and post-growth annealing, for example, in oxygen, to reduce stress in the material.

Sapphire is grown by several techniques for a wide variety of optical, microwave and microelectronics applications [12.148]. Verneuil [12.149] and Czochralski and EFG [12.45] have been used extensively to produce large single crystals, particularly for laser rods, and shaped pieces using various forms of dies. In addition, the horizontal directional solidification crystallization (HDC) technique [12.148] has been used. A molybdenum boat filled with the charge is simply moved through the temperature gradient. Low-temperature gradients lead to crystals with low stress and low-dislocation densities (compared with the Verneuil and pulling techniques. The growth rate is high at 8 mm/h and crystals up to 10 kg and up to $30 \times 30 \times 2.5\,cm^3$ and even $50 \times 35 \times 4\,cm^3$ [12.150] can be produced. Even larger crystals, up to 20 kg with a diameter of 200 mm) can be produced by a modified Kyropolous method [12.151] and 500 mm diameter crystals were noted by *Friedrich* [12.8, Chap. 5].

Another technique used is the heat exchanger method, which is a solidification technique from the melt [12.152]. By independently controlling the heat input and the heat output, large crystals can be grown onto seeds. The seed is prevented from melting by a helium gas flow at the bottom of the melt. By progressively increasing the helium flow, following partial melting of the seed, and/or decreasing the furnace temperature growth is progressed. After complete solidification, an annealing step is performed prior to cooling to room temperature. The submerged solid/liquid interface damps out any thermal and mechanical variations and also produces a low-temperature gradient at the interface. There is impurity segregation into the last-to-freeze parts of the crystal that form near the crucible walls. These areas are removed before machining takes place. Crystals up to 340 mm in diameter (65 kg) have been produced in this way. Slabs cut from these crystals are used as optical windows, between 5–25 mm thick. *Demina* et al. [12.9, p. 213] note that in 2007 the total volume of 2 in equivalent wafers for all applications was $\approx 5\,000\,000$.

Bruni [12.9, p. 267] reports on the growth of a 110 mm GGG crystal weighing 25 kg, which was used in laser applications.

There has been renewed interest recently in the growth and applications of ZnO [12.153, 154]. It is shown that 50 mm and even 75 mm diameter crystals (up to 10 mm thick) can be grown by both vapor and hydrothermal techniques.

Halides

Another class of scintillator materials are halides. These are used in a range of applications from high-energy physics, nuclear medicine, environmental monitoring and security systems [12.155]. Both large diameter, comparable with the human body, and large numbers, for the high-energy physics applications, are required. The simple Bridgman growth process is still used for many of these materials, although problems do arise due to the contact between crystal and crucible. Insufficient melt mixing also leads to inclusions and striations in crystals. The alternative technique for growth is that of continuously fed Czochralski/Kyropolous growth. A melt-level sensor is normally used to control the diameter over the tens/hundreds of hours of growth of large halide crystals. Replenishment of the melt by molten material from a closed feeder enables purification of the starting materials, and a conical crucible that is not too deep is used. Crystals of CsI up to 500 mm diameter and 750 mm height, weighing ≈ 550 kg have been produced [12.156] and CdF_2 up to 400 mm diameter [12.8, p. 140]. The ultimate aim is to produce crystals > 1 m in diameter so that entire crystals can be used to monitor the human body.

Phosphates, Borates and Tungstates

Nonlinear optical materials are very important for laser-frequency-conversion applications. One of the most important of the phosphates is potassium dihydrogen phosphate (KDP) that is used for higher harmonic generation in large laser systems for fusion experiments [12.105, 157]. Growth takes place at room temperature to 60 °C and growth rates can be as high as 10–20 mm/d with sizes of $\approx 40 \times 40 \times 85$ cm [12.157] or $45 \times 45 \times 70$ cm [12.105] or $50 \times 50 \times 50$ cm [12.158], the latter weighing some 300 kg, some taking over

a year to grow! *Schaffers* et al. [12.9, p. 229] noted that the National Ignition Facility required some 75 such large-scale crystals weighing over 100 t. They also reported on the production of 70 mm diameter crystals of $Ca_5(PO_4)_3F$ and 80 mm diameter crystals of $YCa_4O(BO_3)_2$ for laser applications, for example, frequency-conversion materials.

Another important phosphate is potassium titanyl phosphate (KTP) used to get green light by frequency doubling a Nd:YAG laser. Growth in this case is from high-temperature solution at about 950 °C [12.105]. Sizes up to $32 \times 42 \times 87$ mm (weight 173 g) can be grown in 40 days.

Borates, including barium borate, lithium borate, cesium borate and coborates, for example, cesium lithium borate are used in UV-generation applications. Crystals are again grown by the high-temperature solution method up to $14 \times 11 \times 11$ cm in size, weighing 1.8 kg, in 3 weeks [12.105]. Crystals of β-BaB_2O_4 have recently been produced up to 60 mm diameter [12.159], while $YCa_4O(BO_3)_2$ (YCOB) material up to 100 mm diameter for SHG have also been grown [12.160].

Crystals of $CaWO_4$ up to 40 mm diameter weighing 1.8 kg are currently being used in dark-matter research [12.161].

12.5 Conclusions

This chapter has summarized the current position on bulk growth of crystals for optoelectronic and electronic applications. It is not intended to be a completely comprehensive view of the field, merely serving to introduce the reader to the wide range of materials produced and the numerous crystal growth techniques that have been developed to grow single crystals. An historical perspective has been attempted to give the reader a feel for the scale of some of the activities. The sections on specific materials try to summarize the particular growth techniques employed, and those that cannot in some cases, and outline the typical sizes currently produced commercially and in the R&D areas. For more details on current developments see the books [12.8, 9, 44, 49, 69].

Acknowledgments. The author wishes to thank the management of Leonardo MW Ltd for permission to publish this chapter.

13. Single-Crystal Silicon: Growth and Properties

Fumio Shimura

It is clear that silicon, which has been the dominant material in the semiconductor industry for some time, will carry us into the coming ultra-large-scale integration (ULSI) and system-on-a-chip (SOC) eras, even though silicon is not the optimum choice for every electronic device. Semiconductor devices and circuits are fabricated through many mechanical, chemical, physical, and thermal processes. The preparation of silicon single-crystal substrates with mechanically and chemically polished surfaces is the first step in the long and complex device fabrication process. In this chapter, the approaches currently used to prepare silicon materials (from raw materials to single-crystalline silicon) are discussed.

Silicon, which has been and will continue to be the dominant material in the semiconductor industry for some time to come [13.1], will carry us into the ultra-large-scale integration (ULSI) era and the system-on-a-chip (SOC) era.

As electronic devices have become more advanced, device performance has become more sensitive to the quality and the properties of the materials used to construct them.

Germanium (Ge) was originally utilized as a semiconductor material for solid state electronic devices. However, the narrow bandgap (0.66 eV) of Ge limits the operation of germanium-based devices to temperatures of approximately 90 °C because of the considerable leakage currents observed at higher temperatures. The wider bandgap of silicon (1.12 eV), on the other hand, results in electronic devices that are capable of operating at up to ≈ 200 °C. However, there is a more serious problem than the narrow bandgap: germanium does not readily provide a stable passivation layer on the surface. For example, germanium dioxide (GeO_2) is water-soluble and dissociates at approximately 800 °C. Silicon, in contrast to germanium, readily accommodates surface passivation by forming silicon dioxide (SiO_2), which provides a high degree of protection to the underlying device. This stable SiO_2 layer results in a decisive advantage for silicon over germanium as the basic semiconductor material used for electronic device fabrication. This advantage has lead to a number of new technologies, including processes for diffusion doping and defining intricate patterns. Other advantages of silicon are that it is completely nontoxic, and that silica (SiO_2), the raw material from which silicon is obtained, comprises approximately 60% of the mineral content of the Earth's crust. This implies that the raw material from which silicon is obtained is available in plentiful supply to the integrated circuit (IC) industry. Moreover, electronic-grade silicon can be obtained at less than one-tenth the cost of germanium. All of these advantages have caused silicon to almost completely replace germanium in the semiconductor industry.

Although silicon is not the optimum choice for every electronic device, its advantages mean that it will almost certainly dominate the semiconductor industry for some time yet.

13.1 Overview

Very fruitful interactions have occurred between the users and manufacturers of semiconductor material since the invention of the point-contact transistor in 1947, when the necessity for *perfect and pure* crystals was recognized. The competition was often such that the crystal quality demanded by new devices could only be met by controlling crystal growth using electronic equipment built with these new devices. Since dislocation-free silicon crystals were grown as early as the 1960s using the *Dash technique* [13.2], semiconductor material research and developmental efforts have concentrated on material purity, production yields, and problems related to device manufacture.

Semiconductor devices and circuits are fabricated using a wide variety of mechanical, chemical, physical and thermal processes. A flow diagram for typical semiconductor silicon preparation processes is shown in Fig. 13.1. The preparation of silicon single-crystal substrates with mechanically and chemically polished surfaces is the first step in the long and complex process of device fabrication.

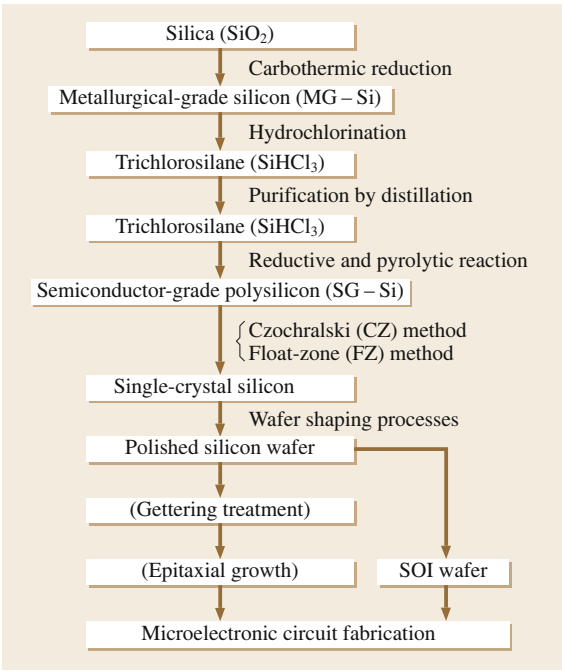

Fig. 13.1 Flow diagram for typical semiconductor silicon preparation processes. (After [13.1])

As noted above, silicon is the second most abundant element on Earth; more than 90% of the Earth's crust is composed of silica and silicates. Given this boundless supply of raw material, the problem is then to transform silicon into the usable state required by the semiconductor technology. The first and main requirement is that the silicon used for electronic devices must be extremely pure, since very small amounts of some impurities have a strong influence on the electronic characteristics of silicon, and therefore the performance of the electronic device. The second requirement is for large-diameter crystals, since the chip yield per wafer increases substantially with larger diameters, as shown in Fig. 13.2 for the case of DRAM [13.3], one of the most common electronic devices. Besides the purity and the diameter, the cost of production and the specifications of the material, including the grown-in defect density and the resistive homogeneity, must meet current industrial demands.

In this chapter, current approaches to the preparation of silicon – converting the raw material into single-crystalline silicon (see Fig. 13.1) – are discussed.

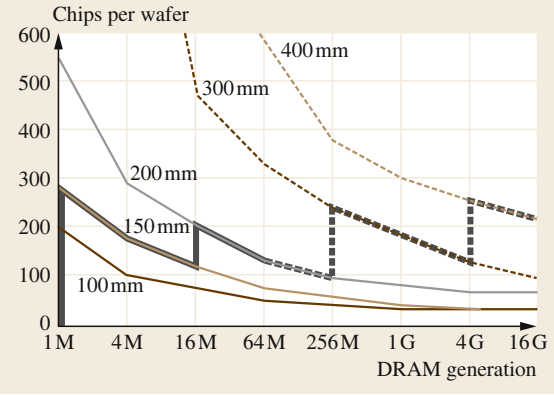

Fig. 13.2 Chips per wafer as a function of DRAM generation. (After [13.3])

13.2 Starting Materials

13.2.1 Metallurgical-Grade Silicon

The starting material for high-purity silicon single crystals is silica (SiO_2). The first step in silicon manufacture is the melting and reduction of silica. This is accomplished by mixing silica and carbon in the form of coal, coke or wood chips and heating the mixture to high temperatures in a submerged electrode arc furnace. This carbothermic reduction of silica produces fused silicon

$$SiO_2 + 2C \rightarrow Si + 2CO\,. \tag{13.1}$$

A complex series of reactions actually occur in the furnace at temperatures ranging from 1500 to 2000 °C. The lumps of silicon obtained from this process are called metallurgical-grade silicon (MG-Si), and its purity is about 98–99%.

13.2.2 Polycrystalline Silicon

Intermediate Chemical Compounds

The next step is to purify MG-Si to the level of semiconductor-grade silicon (SG-Si), which is used as the starting material for single-crystalline silicon. The basic concept is that powdered MG-Si is reacted with anhydrous HCl to form various chlorosilane compounds in a fluidized-bed reactor. Then the silanes are purified by distillation and chemical vapor deposition (CVD) to form SG-polysilicon.

A number of intermediate chemical compounds have been considered, such as monosilane (SiH_4), silicon tetrachloride ($SiCl_4$), trichlorosilane ($SiHCl_3$) and dichlorosilane (SiH_2Cl_2). Among these, trichlorosilane is most commonly used for subsequent polysilicon deposition for the following reasons:

1. It can be easily formed by the reaction of anhydrous hydrogen chloride with MG-Si at reasonably low temperatures (200–400 °C).
2. It is liquid at room temperature, so purification can be accomplished using standard distillation techniques.
3. It is easy to handle and can be stored in carbon steel tanks when dry.
4. Liquid trichlorosilane is easily vaporized and, when mixed with hydrogen, it can be transported in steel lines.
5. It can be reduced at atmospheric pressure in the presence of hydrogen.
6. Its deposition can take place on heated silicon, eliminating the need for contact with any foreign surfaces that may contaminate the resulting silicon.
7. It reacts at lower temperatures (1000–1200 °C) and at faster rates than silicon tetrachloride.

Hydrochlorination of Silicon

Trichlorosilane is synthesized by heating powdered MG-Si at around 300 °C in a fluidized-bed reactor. That is, MG-Si is converted into $SiHCl_3$ according to the following reaction

$$Si + 3HCl \rightarrow SiHCl_3 + H_2\,. \tag{13.2}$$

The reaction is highly exothermic and so heat must be removed to maximize the yield of trichlorosilane. While converting MG-Si into $SiHCl_3$, various impurities such as Fe, Al, and B are removed by converting them into their halides ($FeCl_3$, $AlCl_3$, and BCl_3, respectively), and byproducts such as $SiCl_4$ and H_2 are also produced.

Distillation and Decomposition of Trichlorosilane

Distillation has been widely used to purify trichlorosilane. The trichlorosilane, which has a low boiling point (31.8 °C), is fractionally distilled from the impure halides, resulting in greatly increased purity, with an electrically active impurity concentration of less than 1 ppba. The high-purity trichlorosilane is then vaporized, diluted with high-purity hydrogen, and introduced into the deposition reactor. In the reactor, thin silicon rods called slim rods supported by graphite electrodes are available for surface deposition of silicon according to the reaction

$$SiHCl_3 + H_2 \rightarrow Si + 3HCl\,. \tag{13.3}$$

In addition this reaction, the following reaction also occurs during polysilicon deposition, resulting in the formation of silicon tetrachloride (the major byproduct of the process)

$$HCl + SiHCl_3 \rightarrow SiCl_4 + H_2\,. \tag{13.4}$$

This silicon tetrachloride is used to produce high-purity quartz, for example.

Needless to say, the purity of the slim rods must be comparable to that of the deposited silicon. The slim rods are preheated to approximately 400 °C at the start of the silicon CVD process. This preheating is required in order to increase the conductivity of high-purity (high-resistance) slim rods sufficiently to allow for resistive heating. Depositing for 200–300 h at around 1100 °C results in high-purity polysilicon rods of 150–200 mm in diameter. The polysilicon rods are

shaped into various forms for subsequent crystal growth processes, such as chunks for Czochralski melt growth and long cylindrical rods for float-zone growth. The process for reducing trichlorosilane on a heated silicon rod using hydrogen was described in the late 1950s and early 1960s in a number of process patents assigned to Siemens; therefore, this process is often called the *Siemens method* [13.4].

The major disadvantages of the Siemens method are its poor silicon and chlorine conversion efficiencies, relatively small batch size, and high power consumption. The poor conversion efficiencies of silicon and chlorine are associated with the large volume of silicon tetrachloride produced as the byproduct in the CVD process. Only about 30% of the silicon provided in the CVD reaction is converted into high-purity polysilicon. Also, the cost of producing high-purity polysilicon may depend on the usefulness of the byproduct, $SiCl_4$.

Monosilane Process

A polysilicon production technology based on the production and pyrolysis of monosilane was established in the late 1960s. Monosilane potentially saves energy because it deposits polysilicon at a lower temperature and produces purer polysilicon than the trichlorosilane process; however, it has hardly been used due to the lack of an economical route to monosilane and due to processing problems in the deposition step [13.5]. However, with the recent development of economical routes to high-purity silane and the successful operation of a large-scale plant, this technology has attracted the attention of the semiconductor industry, which requires higher purity silicon.

In current industrial monosilane processes, magnesium and MG-Si powder are heated to 500 °C under a hydrogen atmosphere in order to synthesize magenesium silicide (Mg_2Si), which is then made to react with ammonium chloride (NH_4Cl) in liquid ammonia (NH_3) below 0 °C to form monosilane (SiH_4). High-purity polysilicon is then produced via the pyrolysis of the monosilane on resistively heated polysilicon filaments at 700–800 °C. In the monosilane generation process, most of the boron impurities are removed from silane via chemical reaction with NH_3. A boron content of 0.01–0.02 ppba in polysilicon has been achieved using a monosilane process. This concentration is very low compared to that observed in polysilicon prepared from trichlorosilane. Moreover, the resulting polysilicon is less contaminated with metals picked up through chemical transport processes because monosilane decomposition does not cause any corrosion problems.

Granular Polysilicon Deposition

A significantly different process, which uses the decomposition of monosilane in a fluidized-bed deposition reactor to produce free-flowing granular polysilicon, has been developed [13.5]. Tiny silicon seed particles are fluidized in a monosilane/hydrogen mix, and polysilicon is deposited to form free-flowing spherical particles that are an average of 700 μm in diameter with a size distribution of 100–1500 μm. The fluidized-bed seeds were originally made by grinding SG-Si in a ball or hammer mill and leaching the product with acid, hydrogen peroxide and water. This process was time-consuming and costly, and tended to introduce undesirable impurities into the system through the metal grinders. However, in a new method, large SG-Si particles are fired at each other by a high-speed stream of gas causing them to break into particles of a suitable size for the fluidized bed. This process introduces no foreign materials and requires no leaching.

Because of the greater surface area of granular polysilicon, fluidized-bed reactors are much more efficient than traditional Siemens-type rod reactors. The quality of fluidized-bed polysilicon has been shown to be equivalent to polysilicon produced by the more conventional Siemens method. Moreover, granular polysilicon of a free-flowing form and high bulk density enables crystal growers to obtain the most from of each production run. That is, in the Czochralski crystal growth process (see the following section), crucibles can be quickly and easily filled to uniform loadings which typically exceed those of randomly stacked polysilicon chunks produced by the Siemens method. If we also consider the potential of the technique to move from batch operation to continuous pulling (discussed later), we can see that free-flowing polysilicon granules could provide the advantageous route of a uniform feed into a steady-state melt. This product appears to be a revolutionary starting material of great promise for silicon crystal growth.

13.3 Single-Crystal Growth

Although various techniques have been utilized to convert polysilicon into single crystals of silicon, two techniques have dominated the production of them for electronics because they meet the requirements of the microelectronics device industry. One is a zone-melting method commonly called the *floating-zone*

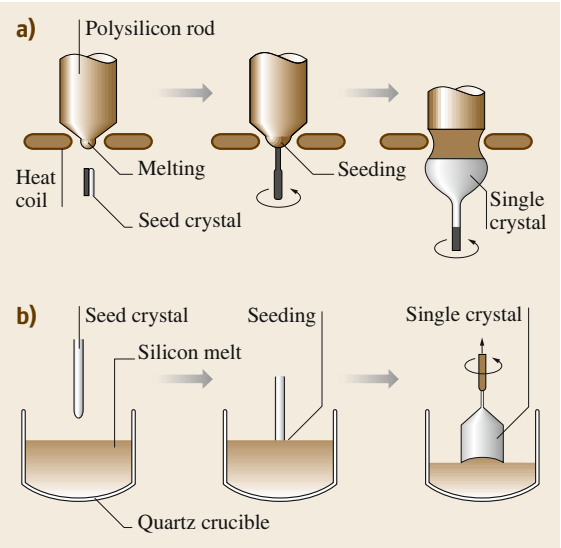

Fig. 13.3a,b Principles of single-crystal growth by **(a)** floating-zone method and **(b)** Czochralski method. (After [13.1])

(FZ) method, and the other is a pulling method traditionally called the *Czochralski (CZ) method*, although it should actually be called the *Teal–Little method*. The principles behind these two crystal growth methods are depicted in Fig. 13.3. In the FZ method, a molten zone is passed through a polysilicon rod to convert it into a single-crystal ingot; in the CZ method, a single crystal is grown by pulling from a melt contained in a quartz crucible. In both cases, the *seed crystal* plays a very important role in obtaining a single crystal with a desired crystallographic orientation.

It is estimated that about 95% of all single-crystal silicon is produced by the CZ method and the rest mainly by the FZ method. The silicon semiconductor industry requires high purity and minimum defect concentrations in their silicon crystals to optimize device manufacturing yield and operational performance. These requirements are becoming increasingly stringent as the technology changes from LSI to VLSI/ULSI and then SOC. Besides the quality or perfection of silicon crystals, crystal diameter has also been steadily increasing in order to meet the demands of device manufacturers. Since microelectronic chips are produced via a *batch system*, the diameters of the silicon wafers used for device fabrication significantly affect the productivity (as shown in Fig. 13.2), and in turn the production cost.

In the following sections, we first discuss the FZ method and then move on to the CZ method. The latter will be discussed in more detail due to its extreme importance to the microelectronics industry.

13.3.1 Floating-Zone Method

General Remarks

The FZ method originated from zone melting, which was used to refine binary alloys [13.6] and was invented by *Theuerer* [13.7]. The reactivity of liquid silicon with the material used for the crucible led to the development of the FZ method [13.8], which permits the crystallization of silicon without the need for any contact with the crucible material, which is needed to be able to grow crystals of the required semiconductor purity.

Outline of the Process

In the FZ process, a polysilicon rod is converted into a single-crystal ingot by passing a molten zone heated by a needle-eye coil from one end of the rod to the other, as shown in Fig. 13.3a. First, the tip of the polysilicon rod is contacted and fused with a seed crystal with the desired crystal orientation. This process is called *seeding*. The seeded molten zone is passed through the polysilicon rod by simultaneously moving the single crystal seed down the rod. When the molten zone of silicon solidifies, polysilicon is converted into single-crystalline silicon with the help of the seed crystal. As the zone travels along the polysilicon rod, single-crystal silicon freezes at its end and grows as an extension of the seed crystal.

After seeding, a thin neck about 2 or 3 mm in diameter and 10–20 mm long is formed. This process is called *necking*. Growing a neck eliminates dislocations that can be introduced into newly grown single-crystal silicon during the seeding operation due to thermal shock. This necking process, called the *Dash technique* [13.2], is therefore fundamental to growing dislocation-free crystals and is used universally in both the FZ and the CZ methods. An x-ray topograph of the seed, neck and conical part of a silicon single-crystal grown by the FZ method is shown in Fig. 13.4. It is apparent that dislocations generated at the melt contact are completely eliminated by necking. After the conical part is formed, the main body with the full target diameter is grown. During the entire FZ growth process, the shape of the molten zone and the ingot diameter are determined by adjusting the power to the coil and the travel rate, both of which are under computer control. The technique most commonly used to automatically control the diameter in both the FZ and CZ methods employs an infrared sensor focused on the meniscus. The shape of the meniscus on a growing crystal depends on its angle of contact at the three-phase boundary, the crystal diameter, and the magnitude of the surface tension. A change in meniscus angle (and therefore crystal diameter) is sensed, and the information is fed back in order to automatically adjust the growth conditions.

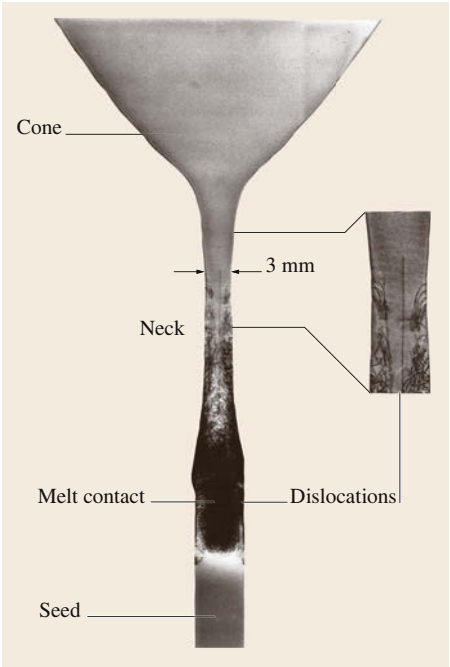

Fig. 13.4 X-ray topography of seed, neck and conical part of floating-zone silicon. (Courtesy of Dr. T. Abe)

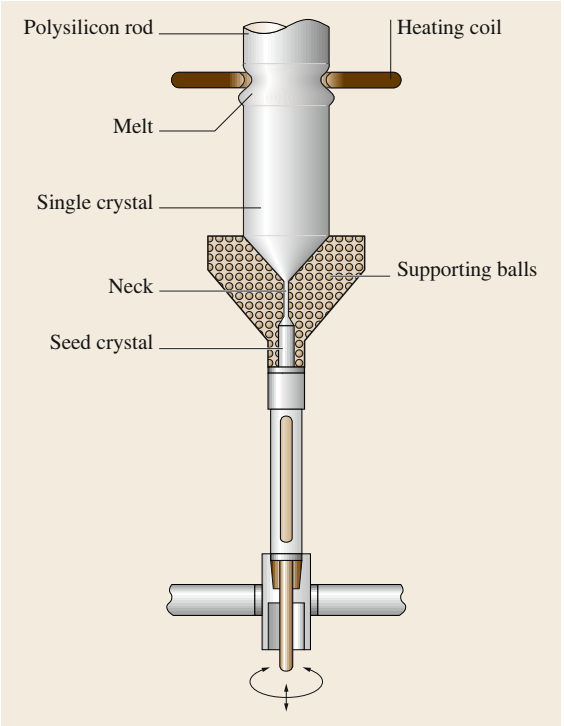

Fig. 13.5 Supporting system for floating-zone silicon crystal. (After [13.9])

In contrast with CZ crystal growth, in which the seed crystal is dipped into the silicon melt and the growing crystal is pulled upward, in the FZ method the thin seed crystal sustains the growing crystal, as does the polysilicon rod from the bottom (Fig. 13.3). As a result, the rod is balanced precariously on the thin seed and neck during the entire growth process. The seed and neck can support a crystal of up to a 20 kg so long as the center of gravity of the growing crystal remains at the center of the growth system. If the center of gravity moves away from the center line, the seed will easily fracture. Hence, it was necessary to invent a crystal stabilizing and supporting technique before long and heavy FZ silicon crystals could be grown. For large crystals, it is necessary to support the growing crystal in the way shown in Fig. 13.5 [13.9], particularly in the case of recent FZ crystals with large diameters (150–200 mm), since their weights easily exceed 20 kg.

Doping

In order to obtain n- or p-type silicon single-crystals of the required resistivity, either the polysilicon or the growing crystal must be doped with the appropriate donor or acceptor impurities, respectively. For FZ silicon growth, although several doping techniques have been tried, the crystals are typically doped by blowing a dopant gas such as phosphine (PH_3) for n-type silicon or diborane (B_2H_6) for p-type silicon onto the molten zone. The dopant gas is usually diluted with a carrier gas, such as argon. The great advantage of this method is that the silicon crystal manufacturer does not need to store polysilicon sources with different resistivities.

Since the segregation (discussed in the next subsection) of elemental dopants for n-type silicon is much less than unity, FZ crystals doped by the traditional method have radial dopant gradients. Moreover, since the crystallization rate varies in the radial direction on the microscopic scale, the dopant concentrations distribute cyclically and give rise to so-called *dopant striations*, resulting in radial resistivity inhomogeneities. In order to obtain more homogeneously doped n-type silicon, neutron transmutation doping (NTD) has been applied to FZ silicon crystals [13.10]. This procedure involves the nuclear transmutation of silicon to phosphorus by bombarding the crystal with thermal neutrons according to the reaction

$$^{30}\mathrm{Si}(\mathrm{n},\gamma) \rightarrow {}^{31}\mathrm{Si} \xrightarrow{2.6\,\mathrm{h}} {}^{31}\mathrm{P} + \beta\,. \qquad (13.5)$$

The radioactive isotope ^{31}Si is formed when ^{30}Si captures a neutron and then decays into the stable isotope ^{31}P (donor atoms), whose distribution is not dependent on crystal growth parameters. Immediately after irradiation the crystals exhibit high resistivity, which

is attributed to the large number of lattice defects arising from radiation damage. The irradiated crystal, therefore, must be annealed in an inert ambient at temperatures of around 700 °C in order to annihilate the defects and to restore the resistivity to that derived from the phosphorus doping. Under the NTD scheme, crystals are grown without doping and are then irradiated in a nuclear reactor with a large ratio of thermal to fast neutrons in order to enhance neutron capture and to minimize damage to the crystal lattice.

The application of NTD has been almost exclusively limited to FZ crystals because of their higher purity compared to CZ crystals. When the NTD technique was applied to CZ silicon crystals, it was found that oxygen donor formation during the annealing process after irradiation changed the resistivity from that expected, even though phosphorus donor homogeneity was achieved [13.11]. NTD has the additional shortcoming that no process is available for p-type dopants and that an excessively long period of irradiation is required for low resistivities (in the range of 1−10 Ω cm).

Properties of FZ-Silicon Crystal

During FZ crystal growth, the molten silicon does not come into contact with any substance other than the ambient gas in the growth chamber. Therefore, an FZ silicon crystal is inherently distinguished by its higher purity compared to a CZ crystal which is grown from the melt – involving contact with a quartz crucible. This contact gives rise to high oxygen impurity concentrations of around 10^{18} atoms/cm^3 in CZ crystals, while FZ silicon contains less than 10^{16} atoms/cm^3. This higher purity allows FZ silicon to achieve high resistivities not obtainable using CZ silicon. Most of the FZ silicon consumed has a resistivity of between 10 and 200 Ω cm, while CZ silicon is usually prepared to resistivities of 50 Ω cm or less due to the contamination from the quartz crucible. FZ silicon is therefore mainly used to fabricate semiconductor power devices that support reverse voltages in excess of 750−1000 V. The high-purity crystal growth and the precision doping characteristics of NTD FZ-Si have also led to its use in infrared detectors [13.12], for example.

However, if we consider mechanical strength, it has been recognized for many years that FZ silicon, which contains fewer oxygen impurities than CZ silicon, is mechanically weaker and more vulnerable to thermal stress during device fabrication [13.13, 14]. High-temperature processing of silicon wafers during electronic device manufacturing often produces enough thermal stress to generate slip dislocations and warpage. These effects bring about yield loss due to leaky junctions, dielectric defects, and reduced lifetime, as well as reduced photolithographic yields due to the degradation of wafer flatness. Loss of geometrical planarity due to warpage can be so severe that the wafers are not processed any further. Because of this, CZ silicon wafers have been used much more widely in IC device fabrication than FZ wafers have. This difference in mechanical stability against thermal stresses is the dominant reason why CZ silicon crystals are exclusively used for the fabrication of ICs that require a large number of thermal process steps.

In order to overcome these shortcomings of FZ silicon, the growth of FZ silicon crystals with doping impurities such as oxygen [13.15] and nitrogen [13.16] has been attempted. It was found that doping FZ silicon crystals with oxygen or nitrogen at concentrations of $1-1.5\times10^{17}$ atoms/cm^3 or 1.5×10^{15} atoms/cm^3, respectively, results in a remarkable increase in mechanical strength.

13.3.2 Czochralski Method

General Remarks

This method was named after J. Czochralski, who established a technique for determining the crystallization velocities of metals [13.17]. However, the actual pulling method that has been widely applied to single-crystal growth was developed by *Teal* and *Little* [13.18], who modified Czochralski's basic principle. They were the first to successfully grow single-crystals of germanium, 8 inches in length and 0.75 inches in diameter, in 1950. They subsequently designed another apparatus for the growth of silicon at higher temperatures. Although the basic production process for single-crystal silicon has changed little since it was pioneered by Teal and coworkers, large-diameter (up to 400 mm) silicon single-crystals with a high degree of perfection that meet state-of-the-art device demands have been grown by incorporating the Dash technique and successive technological innovations into the apparatus.

Today's research and development efforts concerning silicon crystals are directed toward achieving microscopic uniformity of crystal properties such as the resistivity and the concentrations of impurities and microdefects, as well as microscopic control of them, which will be discussed elsewhere in this Handbook.

Outline of the Process

The three most important steps in CZ crystal growth are shown schematically in Fig. 13.3b. In principle, the process of CZ growth is similar to that of FZ growth: (1) melting polysilicon, (2) seeding and (3) growing. The CZ pulling procedure, however, is more complicated than that of FZ growth and is distinguished from it by the use of a quartz crucible to contain the molten

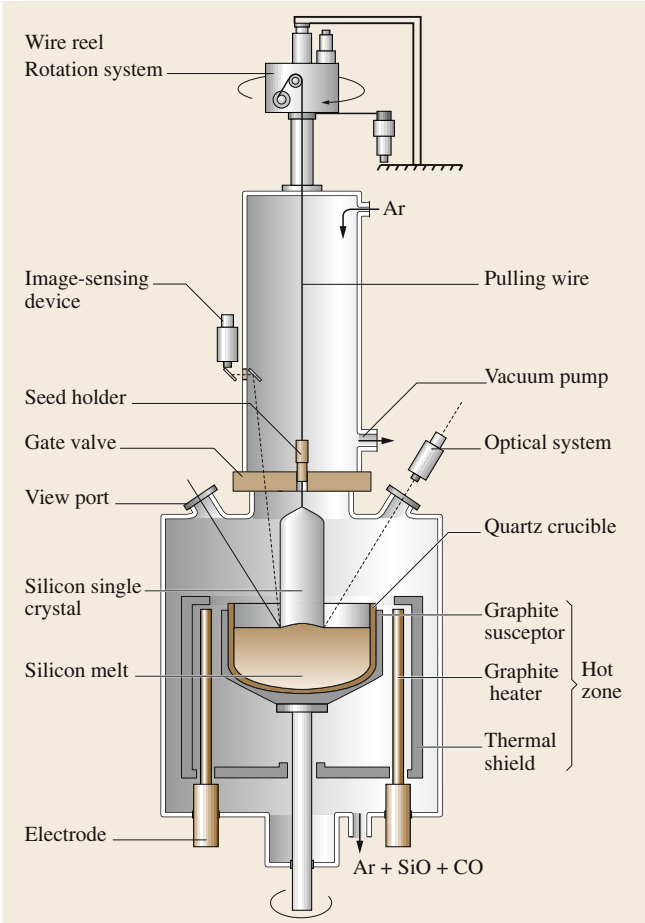

Fig. 13.6 Schematic view of typical Czochralski silicon crystal growing system. (After [13.1])

silicon. Figure 13.6 shows a schematic view of typical modern CZ crystal growth equipment. Important steps in the actual or standard CZ silicon crystal growth sequence are as follows:

1. Polysilicon chunks or grains are placed in a quartz crucible and melted at temperatures higher than the melting point of silicon (1420 °C) in an inert ambient gas.
2. The melt is kept at a high temperature for a while in order to ensure complete melting and ejection of tiny bubbles, which may cause voids or negative crystal defects, from the melt.
3. A seed crystal with the desired crystal orientation is dipped into the melt until it begins to melt itself. The seed is then withdrawn from the melt so that the neck is formed by gradually reducing the diameter; this is the most delicate step. During the entire crystal growth process, inert gas (usually argon) flows downward through the pulling chamber in order to carry off reaction products such as SiO and CO.
4. By gradually increasing the crystal diameter, the conical part and shoulder are grown. The diameter is increased up to the target diameter by decreasing the pulling rate and/or the melt temperature.
5. Finally, the cylindrical part of the body with a constant diameter is grown by controlling the pulling rate and the melt temperature while compensating for the drop in the melt level as the crystal grows. The pulling rate is generally reduced toward the tail end of a growing crystal, mainly due to increasing heat radiation from the crucible wall as the melt level drops and exposes more crucible wall to the growing crystal. Near the end of the growth process, but before the crucible is completely drained of molten silicon, the crystal diameter must be gradually reduced to form an end-cone in order to minimize thermal shock, which can cause slip dislocations at the tail end. When the diameter becomes small enough, the crystal can be separated from the melt without the generation of dislocations.

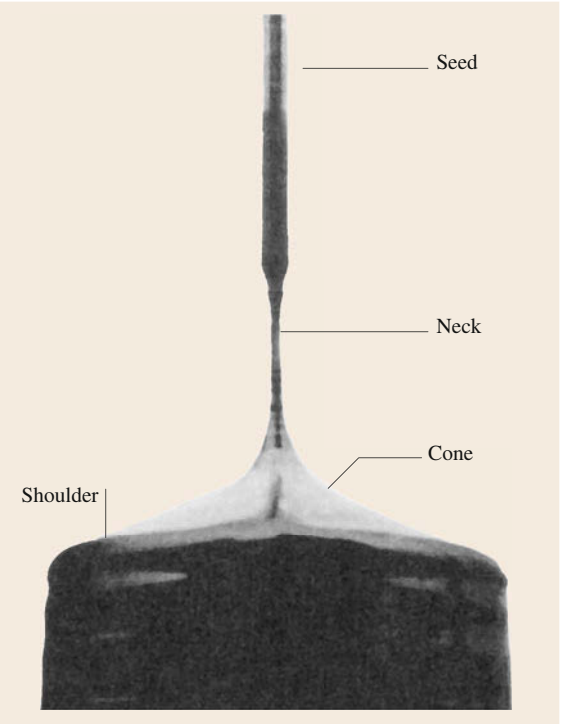

Fig. 13.7 Seed-end part of as-grown Czochralski silicon crystal

Figure 13.7 shows the seed-end part of an as-grown CZ silicon crystal. Although a seed-corn, which is the

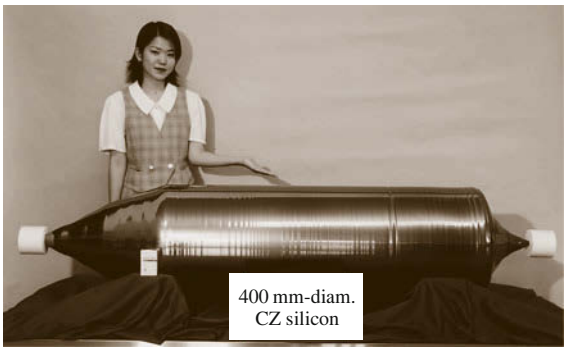

Fig. 13.8 Extra-large as-grown Czochralski silicon ingot 400 mm in diameter and 1800 mm in length. (Courtesy of Super Silicon Crystal Research Institute Corporation, Japan)

transition region from the seed to the cylindrical part, is usually formed to be rather flat for economic reasons, a more tapered shape might be desirable from a crystal quality point of view. The shoulder part and its vicinity should not be used for device fabrication because this part is considered a transition region in many senses and it exhibits inhomogeneous crystal characteristics due to the abrupt change in growth conditions.

Figure 13.8 shows an extra-large as-grown CZ silicon crystal ingot 400 mm in diameter and 1800 mm in length grown by the Super Silicon Crystal Research Institute Corporation in Japan [13.3].

Influence of Spatial Location in a Grown Crystal

As Fig. 13.9 clearly depicts, each portion of a CZ crystal is grown at a different time with different growth conditions [13.19]. Thus, it is important to understand that each portion has a different set of crystal characteristics and a different thermal history due to its different position along the crystal length. For example, the seed-end portion has a longer thermal history, ranging from the melting point of 1420 to around 400 °C in a puller, while the tail-end portion has a shorter history and is cooled down rather rapidly from the melting point. Ultimately, each silicon wafer prepared from a different portion of a grown crystal could exhibit different physico-chemical characteristics depending on its location in the ingot. In fact, it has been reported that the oxygen precipitation behavior exhibits the greatest location dependence, which, in turn, affects the generation of bulk defects [13.20].

Also, a nonuniform distribution of both crystal defects and impurities occurs across the transverse section of a flat wafer prepared from a CZ crystal silicon melt crystallized or solidified successively at the crystal–melt interface, which is generally curved in the CZ

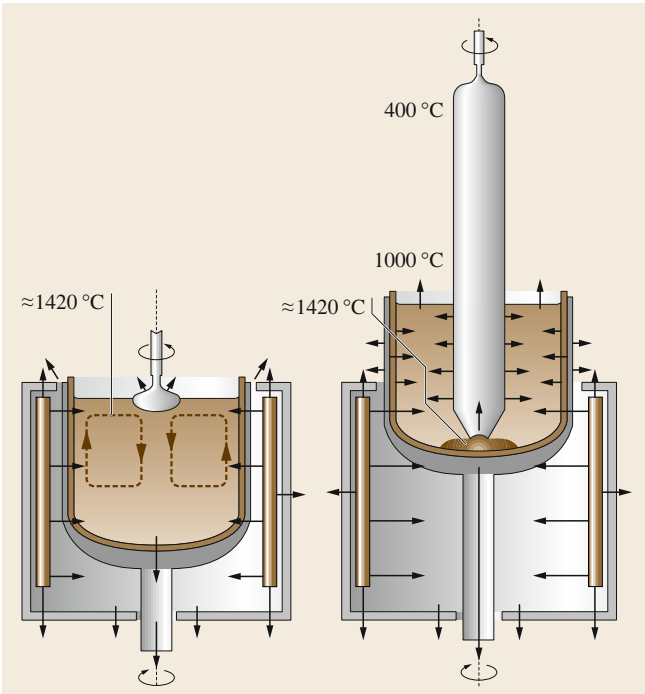

Fig. 13.9 Thermal environment during Czochralski crystal growth at initial and final stages. *Arrows* indicate approximate directions of heat flow. (After [13.19])

crystal growth process. Such inhomogeneities can be observed as *striations*, which are discussed later.

13.3.3 Impurities in Czochralski Silicon

The properties of the silicon semiconductors used in electronic devices are very sensitive to impurities. Because of this sensitivity, the electrical/electronic properties of silicon can be precisely controlled by adding a small amount of dopant. In addition to this dopant sensitivity, contamination by impurities (particularly transition metals) negatively affects the properties of silicon and results in the serious degradation of device performance. Moreover, oxygen is incorporated at levels of tens of atoms per million into CZ silicon crystals due to the reaction between the silicon melt and the quartz crucible. Regardless of how much oxygen is in the crystal, the characteristics of silicon crystals are greatly affected by the concentration and the behavior of oxygen [13.21]. In addition, carbon is also incorporated into CZ silicon crystals either from polysilicon raw materials or during the growth process, due to the graphite parts used in the CZ pulling equipment. Although the concentration of carbon in commercial CZ silicon crystals is normally less than 0.1 ppma, carbon is an impurity that greatly affects the behavior

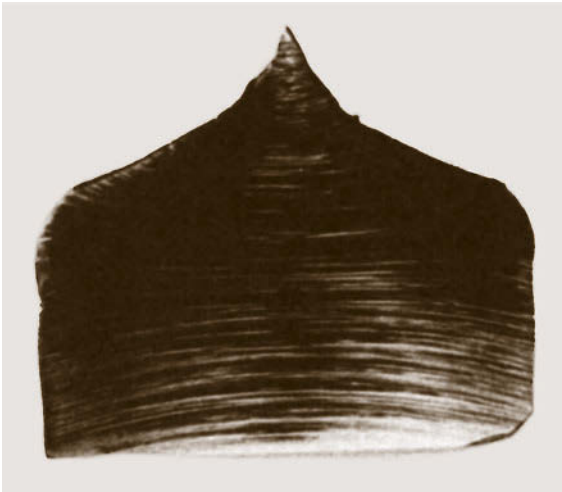

Fig. 13.10 Growth striations, revealed by chemical etching, in a shoulder of Czochralski silicon

of oxygen [13.22, 23]. Also, nitrogen-doped CZ silicon crystals [13.24, 25] have recently attracted much attention due to their high microscopic crystal quality, which may meet the requirements for state-of-the-art electronic devices [13.26, 27].

Impurity Inhomogeneity

During crystallization from a melt, various impurities (including dopants) contained in the melt are incorporated into the growing crystal. The impurity concentration of the solid phase generally differs from that of the liquid phase due to a phenomenon known as *segregation*.

Segregation. The equilibrium segregation behavior associated with the solidification of multicomponent systems can be determined from the corresponding phase diagram of a binary system with a *solute* (the impurity) and a *solvent* (the host material) as components.

The ratio of the solubility of impurity A in solid silicon $[C_A]_s$ to that in liquid silicon $[C_A]_L$

$$k_0 = \frac{[C_A]_s}{[C_A]_L} \qquad (13.6)$$

is referred to as the *equilibrium segregation coefficient*. The impurity solubility in liquid silicon is always higher than that in solid silicon; that is, $k_0 < 1$.

The equilibrium segregation coefficient k_0 is only applicable to solidification at negligibly slow growth rates. For finite or higher solidification rates, impurity atoms with $k_0 < 1$ are rejected by the advancing solid at a greater rate than they can diffuse into the melt. In the CZ crystal growth process, segregation takes place at the start of solidification at a given seed–melt interface, and the rejected impurity atoms begin to accumulate in the melt layer near the growth interface and diffuse in the direction of the bulk of the melt. In this situation, an *effective segregation coefficient* k_{eff} can be defined at any moment during CZ crystal growth, and the impurity concentration $[C]_s$ in a CZ crystal can be derived by

$$[C]_s = k_{eff}[C_0](1-g)^{k_{eff}-1}\,, \qquad (13.7)$$

where $[C_0]$ is the initial impurity concentration in the melt and g is the fraction solidified.

Consequently, it is clear that a macroscopic longitudinal variation in the impurity level, which causes a variation in resistivity due to the variation in the dopant concentration, is inherent to the CZ batch growth process; this is due to the segregation phenomenon. Moreover, the longitudinal distribution of impurities is influenced by changes in the magnitude and the nature of melt convection that occur as the melt aspect ratio is decreased during crystal growth.

Striations. In most crystal growth processes, there are transients in the parameters such as instantaneous microscopic growth rate and the diffusion boundary layer thickness which result in variations in the effective segregation coefficient k_{eff}. These variations give rise to microscopic compositional inhomogeneities in the form of *striations* parallel to the crystal–melt interface. Striations can be easily delineated with several techniques, such as preferential chemical etching and x-ray topography. Figure 13.10 shows the striations revealed by chemical etching in the shoulder part of a longitudinal cross-section of a CZ silicon crystal. The gradual change in the shape of the growth interface is also clearly observed.

Striations are physically caused by the segregation of impurities and also point defects; however, the striations are practically caused by temperature fluctuations near the crystal–melt interface, induced by unstable thermal convection in the melt and crystal rotation in an asymmetric thermal environment. In addition, mechanical vibrations due to poor pulling control mechanisms in the growth equipment can also cause temperature fluctuations.

Figure 13.11 schematically illustrates a CZ-grown crystal cross-section containing a curved crystal–melt interface, which results in inhomogeneities on the surface of a slice. As each planar wafer is sliced, it contains different portions of several curved striations. Different *phonograph rings*, referred to as *swirl*, can then occur in each wafer, which can be observed across the wafer using the techniques mentioned above.

Doping

In order to obtain the desired resistivity, a certain amount of dopant (either donor or acceptor atoms) is added to a silicon melt according to the resistivity–concentration relation. It is common practice to add dopants in the form of highly doped silicon particles or chunks of about 0.01 Ω cm resistivity, which are called the dopant fixture, since the amount of pure dopant needed is unmanageably small, except for heavily doped silicon materials (n^+ or p^+ silicon).

The criteria for selecting a dopant for a semiconductor material are that it has the following properties:

1. Suitable energy levels
2. High solubility
3. Suitable or low diffusivity
4. Low vapor pressure.

A high diffusivity or high vapor pressure leads to undesirable diffusion or vaporization of dopants, which results in unstable device operation and difficulties in achieving precise resistivity control. A solubility that is too small limits the resistivity that can be obtained. In addition to those criteria, the chemical properties (the toxicity for example) must be considered. A further consideration from the viewpoint of crystal growth is that the dopant has a segregation coefficient that is close to unity in order to make the resistivity as uniform as possible from the seed-end to the tail-end of the CZ crystal ingot. Consequently, phosphorus (P) and boron (B) are the most commonly used donor and acceptor dopants for silicon, respectively. For n^+ silicon, in which donor atoms are heavily doped, antimony (Sb) is usually used instead of phosphorus because of its smaller diffusivity, in spite of its small segregation coefficient and high vapor pressure, which lead to large variations in concentration in both the axial and the radial directions.

Oxygen and Carbon

As shown schematically in Figs. 13.3b and 13.6, a quartz (SiO_2) crucible and graphite heating elements are used in the CZ-Si crystal growth method. The surface of the crucible that contacts the silicon melt is gradually dissolved due to the reaction

$$SiO_2 + Si \rightarrow 2SiO\,. \qquad (13.8)$$

This reaction enriches the silicon melt with oxygen. Most of the oxygen atoms evaporate from the melt surface as volatile silicon mono-oxide (SiO), but some of them are incorporated into a silicon crystal through the crystal–melt interface.

However, the carbon in CZ silicon crystals originates mainly from the polycrystalline starting material. Levels of carbon ranging from 0.1 to 1 ppma,

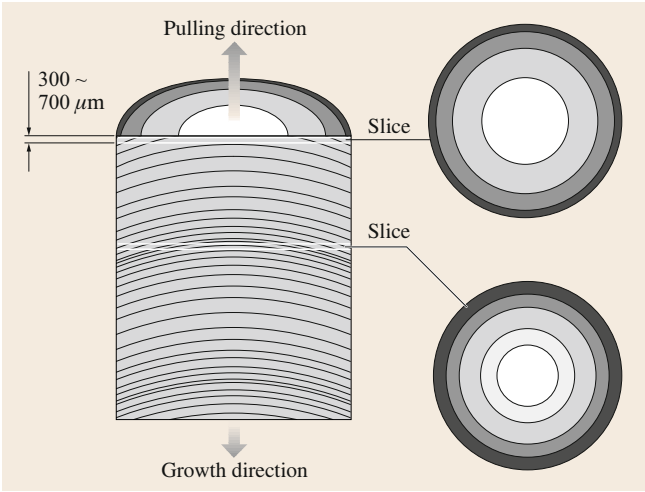

Fig. 13.11 Schematic illustration of Czochralski crystal cross-section containing a curved crystal–melt interface and planar wafers sliced into different portions. (After [13.1])

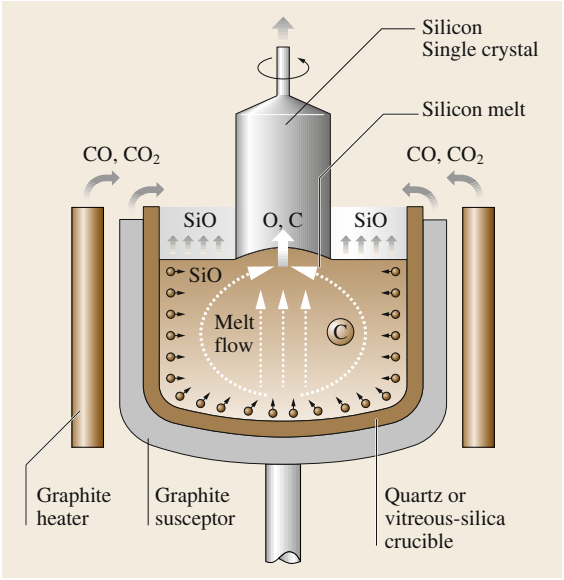

Fig. 13.12 Incorporation of oxygen and carbon into Czochralski silicon crystal. (After [13.1])

depending on the manufacturer, are found in the polysilicon. Sources of carbon in polysilicon are assumed to be mainly carbon-containing impurities found in the trichlorosilane used in the production of polysilicon. Graphite parts in CZ pulling equipment can also contribute to carbon contamination by reacting with oxygen, which is always present during the ambient growth. The resulting products of CO and CO_2 are dissolved into the silicon melt and account for the carbon impurities in silicon crystals. Thus, oxygen and

carbon are the two major nondoping impurities that are incorporated into CZ silicon crystals in the way shown schematically in Fig. 13.12. The behavior of these impurities in silicon, which affect a number of the properties of CZ silicon crystals, has been the subject of intensive study since the late 1950s [13.21].

13.4 New Crystal Growth Methods

Silicon crystals used for microelectronic device fabrication must meet a variety of requirements set by device manufacturers. In addition to the requirements for silicon *wafers*, the following crystallographic demands have become more common due to high-yield and high-performance microelectronic device manufacturing:

1. Large diameter
2. Low or controlled defect density
3. Uniform and low radial resistivity gradient
4. Optimum initial oxygen concentration and its precipitation.

It is clear that silicon crystal manufacturers must not only meet the above requirements but also produce those crystals economically and with high manufacturing yields. The main concerns of silicon crystal growers are the crystallographic perfection and the axial distribution of dopants in CZ silicon. In order to overcome some problems with the conventional CZ crystal growth method, several new crystal growth methods have been developed.

13.4.1 Czochralski Growth with an Applied Magnetic Field (MCZ)

The melt convection flow in the crucible strongly affects the crystal quality of CZ silicon. In particular, unfavorable growth striations are induced by unsteady melt convection resulting in temperature fluctuations at the growth interface. The ability of a magnetic field to inhibit thermal convection in electrically conducting fluid was first applied to the crystal growth of indium antimonide via the horizontal boat technique [13.28] and the horizontal zone-melting technique [13.29]. Through these investigations, it was confirmed that a magnetic field of sufficient strength can suppress the temperature fluctuations that accompany melt convection, and can dramatically reduce growth striations.

The effect of the magnetic field on growth striations is explained by its ability to decrease the turbulent thermal convection of a melt and in turn decrease the temperature fluctuations at the crystal–melt interface. The fluid flow damping caused by the magnetic field is due to the induced magnetomotive force when the flow is orthogonal to the magnetic flux lines, which results in an increase in the effective kinematic viscosity of the conducting melt.

Silicon crystal growth by the magnetic field applied CZ (MCZ) method was reported for the first time in 1980 [13.30]. Originally MCZ was intended for the growth of CZ silicon crystals that contain low oxygen concentrations and therefore have high resistivities with low radial variations. In other words, MCZ silicon was expected to replace the FZ silicon almost exclusively used for power device fabrication. Since then, various magnetic field configurations, in terms of the magnetic field direction (horizontal or vertical) and the type of magnets used (normal conductive or superconductive), have been developed [13.31]. MCZ silicon produced with a wide range of desired oxygen concentrations (from low to high) has been of great interest for different device applications. The value of MCZ silicon lies in its high quality and its ability to control the oxygen concentration over a wide range, which cannot be achieved using the conventional CZ method [13.32], as well as its enhanced growth rate [13.33].

As far as the crystal quality is concerned, there is no doubt that the MCZ method provides the silicon crystals most favorable to the semiconductor device industry. The production cost of MCZ silicon may be higher than that of conventional CZ silicon because the MCZ method consumes more electrical power and re-

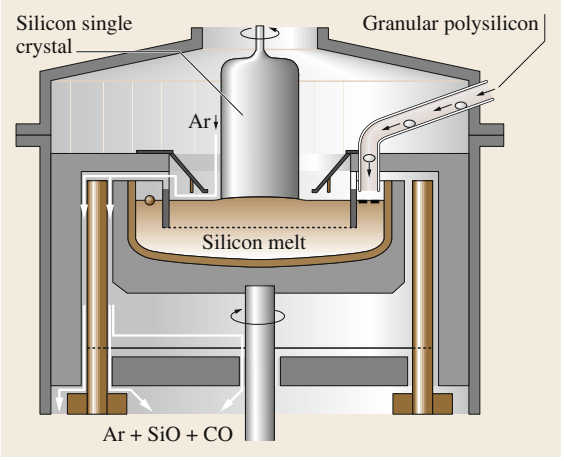

Fig. 13.13 Schematic illustration of the continuous-charging Czochralski method. (After [13.34])

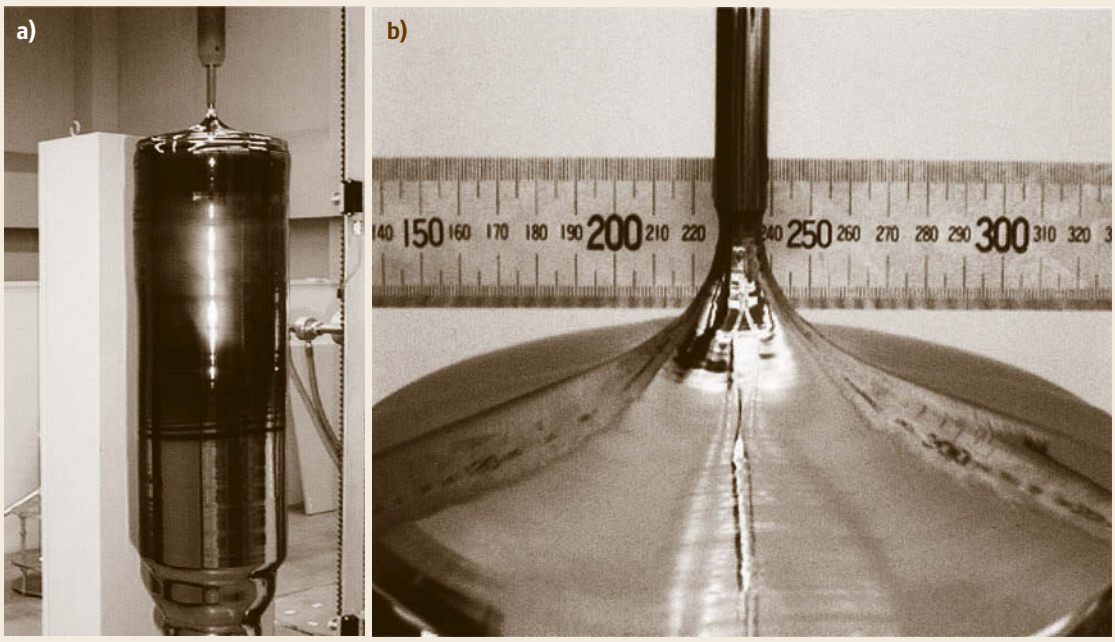

Fig. 13.14a,b 200 mm-diameter dislocation-free Czochralski silicon crystal grown without the Dash necking process. **(a)** Whole body, **(b)** seed and cone. (Courtesy of Prof. K. Hoshikawa)

quires additional equipment and operating space for the electromagnets; however, taking into account the higher growth rate of MCZ, and when superconductive magnets that need smaller space and consume less electrical power compared with conductive magnets are used, the production cost of MCZ silicon crystals may become comparable to that of conventional CZ silicon crystals. In addition, the improved crystal quality of MCZ silicon may increase production yields and lower the production cost.

13.4.2 Continuous Czochralski Method (CCZ)

Crystal production costs depend to a large extent on the cost of materials, in particular the cost of those used for quartz crucibles. In the conventional CZ process, called a *batch process*, a crystal is pulled from a single crucible charge, and the quartz crucible is used only once and is then discarded. This is because the small amount of remaining silicon cracks the crucible as it cools from a high temperature during each growth run.

One strategy for replenishing a quartz crucible with melt economically is to continuously add feed as the crystal is grown and thereby maintain the melt at a constant volume. In addition to saving crucible costs, the continuous-charging Czochralski (CCZ) method provides an ideal environment for silicon crystal growth. As already mentioned, many of the inhomogeneities in crystals grown by the conventional CZ batch process are a direct result of the unsteady kinetics arising from the change in melt volume during crystal growth. The CCZ method aims not only to reduce production costs but also to grow crystals under steady conditions. By maintaining the melt volume at a constant level, steady thermal and melt flow conditions can be achieved (see Fig. 13.9, which shows the change in thermal environments during conventional CZ growth).

Continuous charging is commonly performed by polysilicon feeding, as shown in Fig. 13.13 [13.34]. This system consists of a hopper for storing the polysilicon raw material and a vibratory feeder that transfers the polysilicon to the crucible. In the crucible that contains the silicon melt, a quartz baffle is required to prevent the melt turbulance caused by feeding in the solid material around the growth interface. Free-flowing polysilicon granules such as those mentioned previously are obviously advantageous for the CCZ method.

The CCZ method certainly solves most of the problems related to inhomogeneities in crystal grown by the conventional CZ method. Moreover, the combination of MCZ and CCZ (the magnetic-field-applied continuous CZ (MCCZ) method) is expected to provide the ultimate crystal growth method, giving ideal silicon crystals for a wide variety of microelectronic applications [13.1]. Indeed, it has been used to grow

high-quality silicon crystals intended for microelectronic devices [13.35].

However, it should be emphasized that the different thermal histories of different parts of the crystal (from the seed to the tail ends, as shown in Fig. 13.9) must be considered even when the crystal is grown by the ideal growth method. In order to homogenize the grown crystal or to obtain axial uniformity in the thermal history, some form of post-treatment, such as high-temperature annealing [13.36], is required for the crystal.

13.4.3 Neckingless Growth Method

As mentioned previously, Dash's necking process (which grows a thin neck 3–5 mm in diameter, Fig. 13.7) is a critical step during CZ crystal growth because it eliminates grown-in dislocations. This technique has been the industry standard for more than 40 years. However, recent demands for large crystal diameters (> 300 mm, weighing over 300 kg) have resulted in the need for larger diameter necks that do not introduce dislocations into the growing crystal, since a thin neck 3–5 mm in diameter can not support such large crystals.

Large diameter seeds that are typically 170 mm long, with a minimum diameter of > 10 mm and an average of 12 mm grown from silicon melt heavily doped with boron (> 10^{19} atoms/cm^3) have been used to grow dislocation-free 200 mm-diameter CZ silicon crystals [13.37, 38]. It is estimated that large diameter necks 12 mm in diameter can CZ support crystals as heavy as 2000 kg [13.39]. Figure 13.14a shows a 200 mm-diameter dislocation-free CZ silicon crystal grown without the Dash necking process, and Fig. 13.14b shows its enlarged seed (compare with Fig. 13.7). The mechanism by which dislocations are not incorporated into the growing crystal has been primarily attributed to hardening effect of the heavy doping of boron in the silicon.

14. Epitaxial Crystal Growth: Methods and Materials

Peter Capper, Stuart Irvine, Tim Joyce

Epitaxial growth of thin films of material for a wide range of applications in electronics, optoelectronics, and magneto-optics is a critical activity in many industries. The original technique, in most instances, was liquid-phase epitaxy (LPE) as this was the simplest and often the cheapest route to producing device-quality layers. While some production processes are still based on LPE, most of the research activities and, increasingly, much of the production of electronic and optoelectronic devices is now centered on metal organic chemical vapor deposition (MOCVD) and molecular beam epitaxy (MBE). These latter techniques are more versatile, although the equipment is more expensive, and can readily produce multilayer structures with atomic-layer control, which is becoming more and more fundamental to the nanoscale engineering being called upon now to produce device structures in as-grown multilayers. This chapter covers these three basic techniques, including some of their more common variants, and outlines the relative advantages and disadvantages of each of them. Some examples of growth in various materials systems of importance are also outlined for each of the three techniques.

This chapter outlines the three major epitaxial growth processes used to produce layers of material for electronic, optical, optoelectronic and magneto-optical applications. These are liquid-phase epitaxy (LPE), metal organic chemical vapor deposition (MOCVD), and molecular beam epitaxy (MBE) and their main variants. All three techniques have their relevant advantages and disadvantages for particular material systems and these will be highlighted where appropriate in the following sections.

14.1 Liquid-Phase Epitaxy (LPE)

14.1.1 Introduction and Background

Liquid-phase epitaxy (LPE) is a mature technology and has unique features that make it still applicable for use in niche applications within certain device technologies. It has given way in many areas, however, to various vapor-phase epitaxy techniques, for example, metalorganic vapor phase, molecular beam,

atomic layer, etc., epitaxies (MOVPE, MBE, ALE, etc.); see Sects. 14.2 and 14.3. When selecting an epitaxial growth technology for a particular material system and/or device application, the choice needs to take into account the basic principles of thermodynamics, kinetics, surface energies, etc., as well as practical issues of reproducibility, scalability, process control, instrumentation, safety, and capital equipment costs. A systematic comparison of the various epitaxy techniques suggests that no single technique can best satisfy the needs of all materials/devices combinations needed in microelectronics, optoelectronics, solar cells, thermophotovoltaics, thermoelectrics, semiconductor electrochemical devices, magnetic/magneto-optical devices, and microelectromechanical systems. LPE is still a good choice for many of these application areas [14.1, Chap. 10], [14.2, Chap. 14].

Scheel ([14.3, Chap. 17] and Foreword to [14.2]) has discussed the issues surrounding the use of LPE to produce compound semiconductors for III–V light-emitting diodes (LEDs), high-power devices in SiC and GaN, where device performance may be higher than in material grown by other techniques. He notes in [14.2] that LPE has lost its dominance but growth of near-perfect layers with extremely flat surfaces in homoepitaxy and near-lattice-matched heteroepitaxy is still being employed in several important niche areas, for example, HgCdTe (MCT), garnets, GaN, etc.

14.1.2 History and Status

LPE is basically a high-temperature solution growth technique [14.4] in which a thin layer of the required material is deposited onto a suitable substrate. Homoepitaxy is defined as growth of a layer of the same composition as the substrate, whereas heteroepitaxy is the growth of a layer of markedly different composition. A suitable substrate material would have the same crystal structure as the layer, have as close a match in lattice parameter as possible, and be chemically compatible with the solution and the layer. *Nelson* [14.5] is commonly thought to have developed the first LPE systems, in this case for producing multilayer compound semiconducting structures. In the following decades, a large technology base was established for III–V compound semiconductor lasers, LEDs, photodiodes, and solar cells. LPE has been applied to the growth of a wide range of semiconductors, for example, Si, Ge, SiGe alloys, SiC, GaAs, InP, GaP, GaSb, InAs, InSb (and their ternary and quaternary alloys), GaN, ZnSe, MCT, HgZnTe, and HgMnTe. It has also been used to produce a diverse range of oxide/fluoride compounds, such as high-temperature superconductors, garnets, para- and ferroelectrics, and for various other crystals for optical and magnetic applications. Dipping LPE is still in use to make magneto-optical isolators by epitaxially growing garnet layers on gadolinium gallium garnet substrates [14.2, Chap. 14].

It is probably true to say that most of these systems were first studied using LPE, where it was used in the demonstration, development, and commercialization of many device types, including GaAs solar cells, III–V LEDs and laser diodes, GaAs-based Gunn-effect and other microwave devices, and various IR detectors based on InSb and on MCT. Nevertheless, LPE does not appear in the research literature as often as MOVPE, MBE, ALE, etc., on work in these systems. However, it is still used in some industrial applications, including III–V LEDs, particularly those based on AlGaAs and GaP alloys, and IR detectors based on MCT. It often produces the highest sensitivity in devices, mainly due to it being a near-equilibrium process that can produce near-perfect layers.

Realistic industrial production data is difficult to obtain, but *Moon* [14.6] noted that the large majority of optoelectronic devices were still being grown by LPE at that time (1997), amounting to $\approx 4000\,\mathrm{m}^2$ per year. He estimated that despite the loss of market share to more advanced techniques, the total demand for LPE material was still increasing at $\approx 10\%$ per year. LPE was discontinued for many applications because of its perceived limitations with regard to control of layer thickness, alloy compositions, doping, interface smoothness, and difficulties in growing certain combinations of interest for heterostructure devices. LPE is normally dismissed for the production of superlattices, quantum wells, strained-layer structures, and heterojunctions with large lattice mismatch of chemical dissimilarities. It also suffers from a reputation for poor reproducibility, problems in scaling up in size or throughput, and difficulties in achieving abrupt interfaces between successive layers within structures.

14.1.3 Characteristics

LPE is characterized as a near-equilibrium-grown process, when compared to the various vapor-phase epitaxy techniques. Heat and mass transport, surface energies, interface kinetics, and growth mechanisms are different in LPE compared from those in vapor-phase epitaxy or bulk-growth techniques. These features produce both advantages and disadvantages of LPE, the former include:

- High growth rates. These are typically $0.1-1\,\mu\mathrm{m/h}$, $\approx 10-100$ times faster than in MOVPE or MBE. This feature is useful when thick layers or *virtual substrates* are required.

- Favorable segregation of impurities into the liquid phase. This can lead to lower residual or background impurities in the epitaxial layer [14.2, Chap. 10].
- Ability to produce very flat surfaces and excellent structural perfection (see Fig. 14.1 and [14.7]).
- Wide selection of dopants. Most solid or liquid elements can be added to a melt and incorporated in the layer, unlike in vapor-phase growth where development of volatile dopant precursors with suitable kinetics and sticking coefficients is a major undertaking.
- Suppression of certain types of defects. In general, LPE material has lower point defects (vacancies, interstitials, antisites) than material made by other techniques. For example, the Ga-rich conditions during GaAs LPE inhibits the formation of the As antisite defect that is responsible for the nonradiative losses in luminescent devices.
- Once the relevant phase diagram is established, growth can be made to occur over a wide range of temperatures.
- Absence of highly toxic precursors or byproducts.
- Low capital equipment and operating costs. A research LPE kit can be constructed for under $50 000.

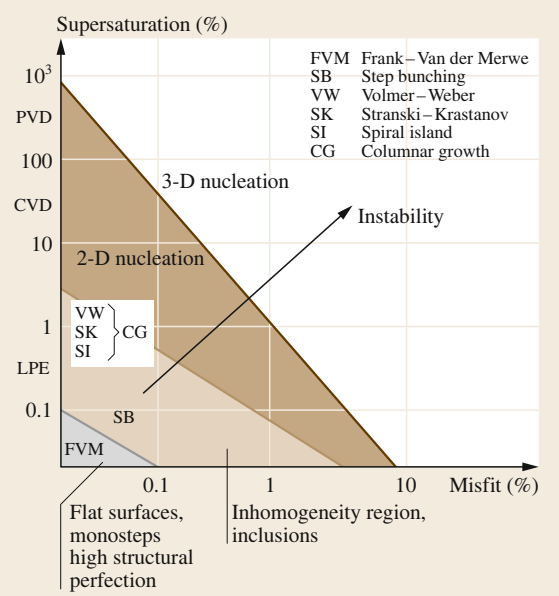

Fig. 14.1 The effects of both supersaturation (and the growth method) and misfit on the nucleation and growth regimes. Only at very low supersaturation in LPE using low-misfit substrates can really flat surfaces be expected. (After [14.7])

The main consideration in designing an LPE process is to determine accurate phase equilibria (S–L and/or S–L–V) of the required system [14.3, Chap. 2]. Solution modeling, extrapolations of existing phase equilibria, and semiempirical predictions are usually sufficient to guide developments in new systems/applications. The near-equilibrium nature of LPE provides for several important growth modes, for example, selective epitaxy (deposition through masks on a substrate) and epitaxial layer overgrowth (ELOG, where growth over a mask occurs), which are useful for defect reduction and new device structures.

14.1.4 Apparatus and Techniques

The basic requirement is to bring the substrate and growth solution into contact while the epitaxial layer grows, and then to separate them cleanly at the end of the growth cycle. The three main embodiments of the LPE growth method are tipping, dipping, and sliding boat (Fig. 14.2).

Figure 14.3 shows the tipping furnace system used by *Nelson* [14.5]. The boat, normally graphite or silica, sits in the work tube in the center of the tilted furnace such that the substrate is held at one end of the boat with the growth solution at the other end. Once the melt has been equilibrated, the temperature is slowly reduced and the furnace is tipped to roll the solution over the substrate. After a suitable time, the furnace is tipped back to the start position and the solution rolls off the

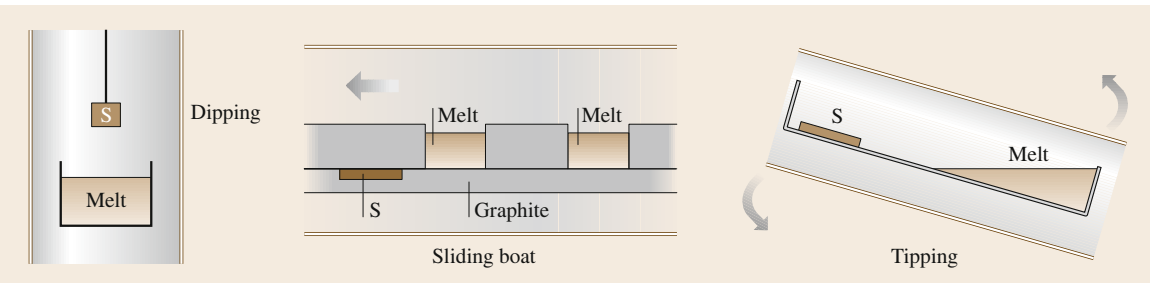

Fig. 14.2 Dipping, sliding boat, and tipping LPE arrangements. (After [14.8])

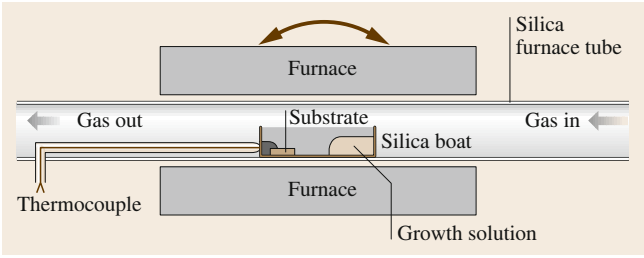

Fig. 14.3 Tipping LPE furnace. (After [14.5])

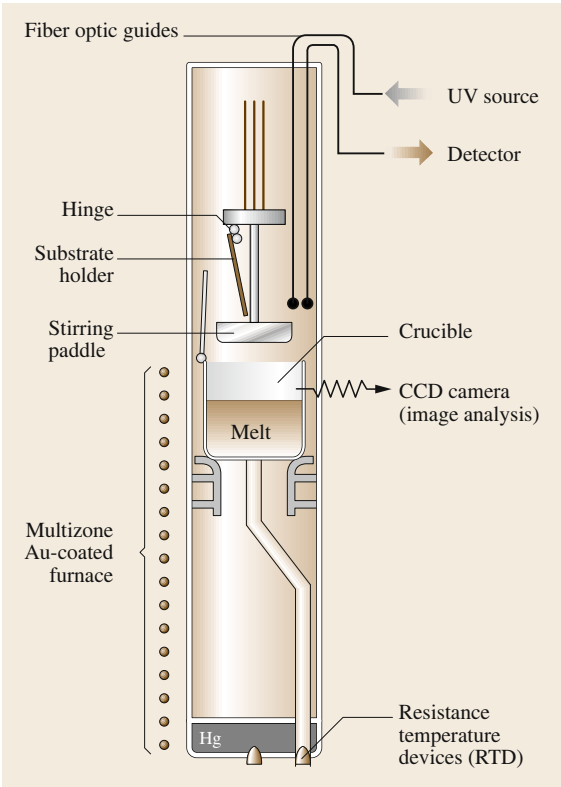

Fig. 14.4 Schematic diagram of a dipping LPE reactor showing the Te-rich melt, the mercury reservoir, and position of the sensors. (After [14.8])

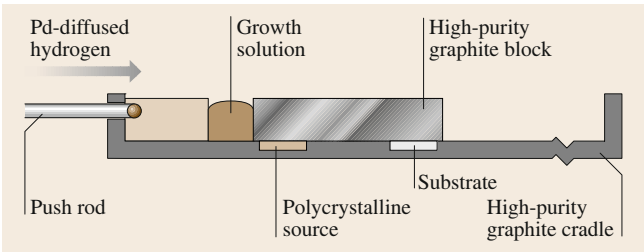

Fig. 14.5 Basic structure of graphite horizontal sliding boat LPE. (After [14.9])

grown layer. This is a relatively simple and cheap technique but has the limitations that solution removal is difficult and it is normally only suitable for single-layer growth.

Figure 14.4 shows the dipping system used for the growth of MCT [14.8]. The design and operation of a system for growth from Hg-rich melts is dominated by consideration of the high vapor pressure of Hg that comprises $\geq 90\%$ of the growth solution, which led to the evolution of a vertical high-pressure furnace design with a cooled reflux region. Such systems are capable of containing about 10–20 kg of melt at 550 °C for several years with no degradation in melt integrity or purity. The use of large melts results in a near-constant saturation temperature from run-to-run and ensures excellent reproducibility of layer characteristics.

Figure 14.5 shows the basic structure of a graphite sliding-boat system, which became the most popular and versatile of the three main methods [14.9]. The substrate sits in a recess in a slider supported by a base section. Growth solutions reside in wells in the upper section of the boat and can be repositioned over the substrate using a pushrod arrangement. The critical design feature of the boat to aid wipe-off is to control the gap between the top of the grown layer and the underside of the top section. If this is too large, melt retention occurs, but if it is too small the layer may be scratched. Multilayer growth is easily possible using this sliding-boat method, providing melt retention is kept to a minimum. The thin melts lead to suppression of thermal or solutal convection, and hence reduce enhanced edge growth. Scale-up has also been achieved in this method with several substrates (up to 16) growing three-layer GaAlAs structures in a single run.

In all the LPE methods, production of supersaturation in the growth solution drives the deposition of the layer on the substrate. This supersaturation can be produced by ramp cooling, step cooling, supercooled growth (a hybrid of the previous two techniques), two-phase growth, constant-temperature growth, or transient growth [14.10]. The choice between these various means will depend on the details of the particular material system and the precise requirement for the material. Another means of producing the required supersaturation is that of electroepitaxy (LPEE), in which an electric current is passed through the interface to stimulate layer growth. It is now thought that this occurs via an electromigration process rather than via Peltier cooling. Benefits claimed for the technique include reduced surface ripple, a reduction in certain microdefects, and an ability to grow millimeter-thick layers of GaAlAs with uniform composition.

14.1.5 Group IVs

Silicon and Silicon/Germanium

Ciszek [14.11] noted that high-quality Si layers had been grown on Si substrates at temperatures in the range 700–900 °C at a rate of 1 μm/min. The potential application was for solar cells, but because growth was on silicon, rather than a low-cost alternative, this was not considered to be a viable production process at that time.

However later, *Poortmans* [14.12] discussed the then current state of Si growth for thin-film solar cells. He notes that as LPE growth is close to thermal equilibrium and the Si atoms in the melt (700–900 °C) have a high diffusion coefficient, the layers have low defect density, low excess carrier recombination, leading to high lifetimes of ≈ 10 μs, and allows an in situ doping gradient to be achieved to increase diffusion length in the layer. He also discusses potential scale-up options by two methods. The first is the temperature difference method, which is a quasicontinuous means of growing Si on $10 \times 10\,\mathrm{mm}^2$ multicrystalline substrates at 0.3 μm/min, producing layers with lifetimes of 5–10 μs. The second method is a batch-type multisubstrate dipping method using substrate meltback to condition the melt. The University of Konstanz, Germany, [14.13] produced a system with 16 substrates, and an example 3 cm^2 solar cell produced a 10% efficiency.

Another report on Si for solar cells [14.14] quoted a conversion efficiency of 4.7% in Si grown from a Sn–Ga melt.

Alonso and *Winer* [14.15] grew SiGe alloys of various compositions from Si–Ge–In melts at temperatures between 640 and 900 °C. Layers were 1–5 μm thick and used to study Raman spectra features seen in material grown by MBE. The advantage of LPE-grown material was thought to lie in the random distribution of Si and Ge atoms, that is, no ordering is present, compared to the MBE-grown material. *Dost* [14.16] recently grew SiGe layers up to 14 mm diameter by LPEE with a magnetic field.

Liu et al. [14.17] grew Ge on Si for Ge-on-insulator applications, where layers showed no dislocations or stacking faults and were compatible with Si processing. More recently, *Tanaka* et al. [14.18] and *Toko* et al. [14.19] have studied the growth of Ge on Si (GoI) and on quartz, the latter as stripes on poly-Si islands for applications as thin-film transistors with high mobility.

Silicon Carbide

Dmitriev [14.20] described the production of high-quality 6H-SiC and 4H-SiC p–n junctions by LPE from Si melts. Layer thicknesses range from 0.2 to 100 μm with growth rates of 0.01–2 μm/min. Nitrogen is used as the donor impurity and aluminum, gallium, and boron as acceptor impurity elements. The material showed high carrier mobility and low deep-center concentrations. Initial attempts used a technique where molten silicon ran from an upper section of the crucible to a lower section where the SiC substrates were held fixed. Dipping was also used, in an attempt to grow material that was less stressed by Si melt solidification. Growth temperatures were 1500–1750 °C and layer thicknesses were 20–40 μm. Both these techniques produced material that was used successfully to make blue LEDs. A new version of LPE, so-called container-free LPE (CFLPE) based on the electromagnetic crucible technique, was also developed (Fig. 14.6). Liquid metal, that is, molten Si, is suspended in a high-frequency electromagnetic field at 1000 °C and the substrates, SiC, are placed on top of

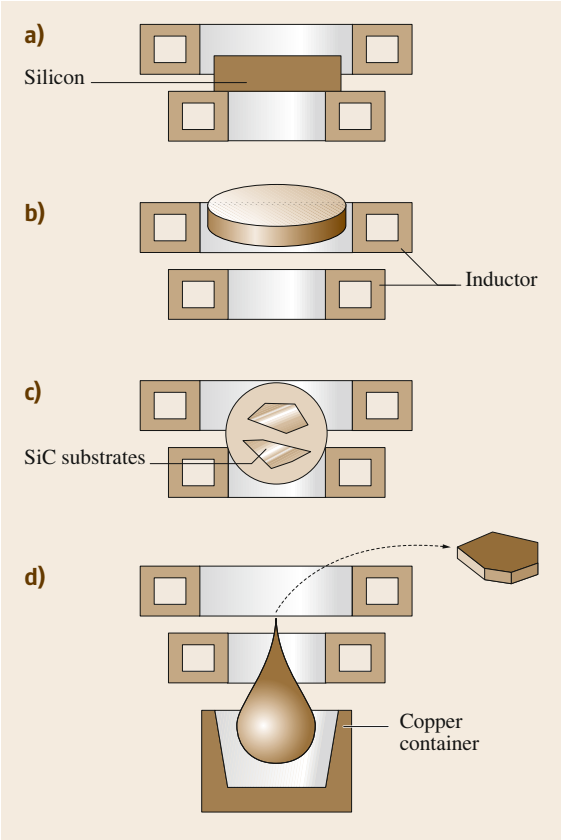

Fig. 14.6a–d Schematic of CFLPE: **(a)** solid Si in copper inductor, **(b)** solid Si suspended in the inductor, **(c)** liquid Si with SiC crystals suspended in the electromagnetic field, **(d)** Si is dropped into the container. (After [14.20])

the melt after heating to 1450 °C. A source of SiC is also placed at the bottom of the Si melt. Cooling of the solution was used to produce the epitaxial layer and the samples were then removed from the melt. The technique succeeded in producing p–n junctions by growing both layers in the same run. These formed the basis of several types of high-temperature devices (up to 500 °C), including diodes, FETs, bipolar transistors and dynistors, and optoelectronic devices such as green, blue, violet, and UV LEDs.

A more recent report [14.21] describes growth of SiC on Si substrates from a Sm:Co melt, producing an epitaxial layer initially followed by SiC whisker growth.

14.1.6 Group III–Vs

Arsenic- and Phosphorus-Based Materials

The majority of work in the area of III–V growth has been in GaAs and GaP, plus additions of As and Al. Following the earlier treatment by *Elwell* and *Scheel* [14.4], *Astles* [14.10] gave a comprehensive treatment of the LPE growth of GaAs and other III–V binaries and ternaries. He lists the advantages of LPE as high-luminescence efficiency due to the low concentration of nonradiative centers and deep levels, growth of ternary and quaternary alloys, controlled p- and n-type doping, multilayer growth with low interface recombination velocities, and good reproducibility and uniformity. Disadvantages included large areas required to be free of surface features (e.g., for photocathodes or ICs), very abrupt control of doping/composition profiles required (e.g., for microwave devices), accurate thickness control required (e.g., for microwave and quantum-well devices), and compositional grading between substrate and layer is inevitable.

All of the methods outlined above were attempted for the growth of GaAs and related materials. In addition, because LPE is a near-equilibrium technique that uses low supersaturation, nucleation is very sensitive to substrate lattice parameter and the growth rate is influenced by the substrate orientation. This enables localized growth in windows on the substrate surface and growth on nonplanar substrates with ribs or channels produced by preferential etching. The latter feature has been used to produce novel laser structures.

In fact, a vast array of both optoelectronic and microwave devices have been produced in LPE GaAs and related materials. The earliest were the GaAs Gunn devices and GaP/GaAsP LEDs. Later, GaAs/GaAlAs heterojunctions were produced for use in lasers, photocathodes, and solar cells. Other alloy systems such as GaInP for blue/green LEDs, GaInSb for improved Gunn devices, and GaInAs or GaAsSb for photocathodes were also studied. Later still came growth of ternaries, for example, GaInAsP (lattice matched to InP) for heterostructure optoelectronic devices. Finally, OEICs and buried heterostructure lasers were developed to exploit the potential for selective-area growth and anisotropy of growth rate.

Over the past several years, there have been research activities still progressing on LPE growth of some III–Vs. *Dhar* [14.22] grew a range of III–Vs on GaAs substrates, up to 8 μm thick. *Milanova* and *Vitanov* [14.23] reviewed solar-cell applications using GaAsN and InGaAsN. Addition of N into GaAs reduced the bandgap, but there was limited incorporation (0.15–0.6 at%) that nevertheless increased the carrier concentration and reduced the mobility compared to GaAs. *Mouleeswaran* et al. [14.24] grew thick GaAs layers on patterned GaAs substrates using selective-area growth while applying a DC current. Up to 268 × 318 μm^2 lateral films were produced for x-ray detector applications. This same group later [14.25] reported on Te-doped GaAs truncated pyramidal growth where the height was ≈ 9 times greater with the DC current. The dislocation density in the layer was reduced compared to that in the substrate. *Ashery* et al. [14.26] reported the growth of GaP/p-Si heterojunctions that produced moderate rectifying behavior. *Strak* et al. [14.27] grew 3–4 mm thick *bulk* GaAs by LPEE to produce large-diameter single-crystal layers with multielectrode systems. *Dost* [14.16] used a static magnetic field in his work on LPEE growth of GaAs/GaInAs, where growth rates were increased from 0.5 to 5 mm/day with application of a magnetic field. *Zytkiewicz* et al. [14.28] simulated the growth of GaAs by LPEE where Peltier cooling plus As electromigration produced a growth rate of 0.5 μm/min, which reduced with time as Joule heating took over.

III–V Antimonides

Commercially available substrates for epitaxy are limited in their lattice-constant spread and this imposes certain constraints in terms of lattice-matched growth and miscibility gaps. Ternary and quaternary alloy substrates with adjustable lattice parameters would open up new device applications. However, bulk-grown ternary alloys suffer from segregation and stress effects. An alternative approach is to grow very thick layers (> 50 μm) of these compounds for use as *virtual substrates* [14.29]. For III–V antimonides, where substrate and lattice-matching problems are acute, such thick layers are feasible by LPE due to the relatively fast growth rates (1–10 μm/min). The challenge for these virtual substrates is to produce lattice constants that are sufficiently different from those available using binary

substrates, without introducing an excessive level of defects.

Another interesting application of antimonides is that of InSb-based quantum dots [14.30]. The potential application here is in mid-IR lasers, LEDs, and detectors. In particular, there is a market for these materials as gas detectors based on IR absorption. The principle is that of rapid-slider LPE, in which a thin slit of melt is wiped across the substrate producing contact times of 0.5–200 ms. This produces low-dimensional structures such as quantum wells and quantum dots. InSb quantum dots were grown on InAs substrates at 465 °C with 10 °C supercooling and a 1 ms melt–substrate contact time. Both small (4 nm high and 20 nm in diameter) and large quantum dots (12 nm high and 60 nm in diameter) are produced.

Recently, *Compean-Jasso* et al. [14.31] grew Sn-doped GaSb at low temperatures (260 °C) to investigate the doping behavior – Sn was still an acceptor dopant, however. *Mondal* et al. [14.32] grew GaSbN on GaSb substrates with N incorporation up to 1.7%, thereby reducing the bandgap by 0.37 eV. *Sun* et al. [14.33] have grown InAsSb on InSb substrates with good full width at half-maximum values and suggested its use as an IR detector material at $\approx 8\,\mu$m cut-off.

Juarez-Diaz et al. [14.34] studied the growth of AlGaSb on GaSb substrates and found low surface roughness (39 Å), although some layers were strained and contained Te, C, and O as impurities. *Diaz-Reyes* et al. [14.35] grew InGaAsSb on GaAs substrates under lattice-matched conditions and studied the low-temperature luminescence due to the Zn dopant.

Group III Nitrides

LPE of GaN is difficult due to the low solubility of nitrogen in molten metals at atmospheric pressure. There are reports of growth of GaN from gallium and bismuth melts and in some instances the melt is replenished with nitrogen by introducing ammonia into the growth ambient, relying on a so-called VLS (vapor–liquid–solid) growth mechanism that essentially combines LPE with CVD (chemical vapor deposition). Another report [14.36] notes the use of Na fluxes as a solvent. *Klemenz* and *Scheel* [14.37] used a dipping mode at 900 °C with sapphire, $LiGaO_2$, $LiAlO_2$, and CVD GaN on sapphire substrates.

Iwahashi et al. [14.38] grew GaN layers on GaN/sapphire substrates ($10\times10\times0.5\,mm^3$) using a Na flux LPE system. The FWHM reduced from 3248 to 231 arcsec. *Hussy* et al. [14.39] modified the melt density to make problematic particles float on the melt to prevent their incorporation into the layer and thereby produce macrodefects. *Azizi* et al. [14.40] grew GaN onto AlN substrates for the first time. Cathodoluminescence measurements showed that the Al incorporation is orientation dependent. *Naritsuka* et al. [14.41] have recently grown GaN on GaN substrates using LPEE to increase the growth rate.

Other Topics

Doping with rare-earth elements (Dy, Er, Hl. Nd, Pr, Yb, Y, etc.) in the AlGaAs, InGaAs, InGaAsSb, and InGaAsP systems can lead to impurity gettering effects that radically reduce background doping and junction saturation currents and increase carrier mobilities and minority carrier lifetimes. Such rare-earth doping in InAsSb LEDs [14.42] increases the luminescence by 10–100 times.

There is no fundamental limit to the number of components in mixed alloy layers produced by LPE. For example, AlGaInPAs layers have been grown on GaAs by LPE [14.43]. Each additional element adds an extra degree of freedom for tailoring the properties of the layer, although more detailed phase equilibria data or models are required to determine accurate melt compositions and temperatures. However, as more constituents are added the melt becomes more dilute and more nearly approaches ideal behavior.

The low supersaturation of LPE makes selective modes of epitaxy feasible. A substrate can be masked (using SIO_2, Si_3N_4, TiN, etc.) and patterned with openings that serve as sites for preferential nucleation. In epitaxial lateral overgrowth (ELO), the selectively seeded material overgrows the mask. This technique has been used for defect filtering, stress reduction, substrate isolation, and buried mirrors and electrodes [14.1]. ELO is difficult with vapor-phase methods, aspect ratios (width to thickness of selectively grown material) are small, whereas that can be 100 in LPE. This could have potential for light-emitting diodes [14.1]. Another interesting application of selective LPE is the growth of pyramidal AlGaAs microtips for scanning near-field optical microscopy.

Another variant of the basic LPE process is that of LPEE, where application of an electric current through the growth interface can enhance growth rates for producing thick ternary layers [14.1]. Selective LPEE on patterned, tungsten-masked GaAs substrates can produce inverted pyramid-shaped crystals that can be used to make very high efficiency LEDs [14.1].

Mauk et al. [14.44] have reported on a massive scaling up of the LPE growth of thick ($> 50\,\mu$m) AlGaAs on 75 mm diameter GaAs substrates. The method produces a two orders of magnitude improvement in areal throughput compared to conventional horizontal sliding boat systems and has applications for LEDs, thermophotovoltaic devices, solar cells, and detectors. A large rectangular aluminum chamber is used instead

of a silica tube (Fig. 14.7). A modified sliding-boat arrangement is used with a top heater mounted above the boat cap, in conjunction with a heat exchanger/pedestal that acts as a cold finger to impose a vertical temperature gradient, which is the driving force for growth. These $> 50\,\mu m$ thick layers were then produced as free-standing layers bonded to glass.

14.1.7 Group II–VIs

Widegap Compounds

While vapor-phase methods are normally used, LPE has been used to grow some widegap Zn-based II–VI compounds [14.45]. This work was driven by the view at that time that blue LEDs could be made economically in ZnSe. The aim was to produce p–n junctions directly by LPE via growth at 950–650 °C, that is, much lower than the bulk crystal growth, to reduce the number of defects. The problems included the high Se vapor pressure, necessitating a closed-tube approach and the need to maintain the ZnSe substrates in the upper portion of the vertically held melt during deposition. Nevertheless, 10–20 μm thick layers were grown in 2 h. Growth at 950 °C produced smoother surfaces, but the layers contained more deep levels and impurities compared with those grown at the lower temperatures. Addition of a separate Zn vapor pressure source improved the properties, showing p-type conductivity, and doping with Au, Na, and Li was also attempted. All these produced p-type material but there was no n-type material reported. Later, the same group [14.46] reported growth of p-type ZnSe doped with Na_2Se from which p–n junctions were fabricated after Ga diffusion from a Zn solution, to produce the n-type layer. Blue light was emitted at a wavelength of 471 nm.

Astles [14.47] reviewed the work done on LPE of CdTe-based compounds. Most studies were carried out from Te-rich solutions in the temperature range 500–900 °C. Layers are p-type as-grown or n-type if doped with In or Al. Growth rates are typically 0.5 μm/°C at 500 °C. Growth from Bi-rich melts was also studied and this was found to improve melt wipe-off and surface morphology. Buffer layer growth of CdZnTe layers was used by *Pelliciari* et al. [14.48] as impurity barrier layers. Both CdMnTe [14.49] and HgCdMnTe [14.50] have also been grown by LPE. The latter compound was used to produce mesa diodes for room-temperature 1.3–1.8 μm applications. *Dost* [14.16] recently used a 0.45 T magnetic field in his LPEE growth of CdTe, producing 2 mm thick samples.

MCT (Mercury Cadmium Telluride)

The situation regarding LPE of MCT has been reviewed by *Capper* et al. in 1997 [14.8] and more recently by *Capper* [14.51]. In 1997, LPE had emerged as the predominant materials growth technology for the fabrication of both first- and second-generation MCT IR focal plane arrays (FPAs). The technology had advanced to the point where material could be routinely grown for high-performance photoconductive (PC), photovoltaic (PV), and laser detector devices in the entire 2–18 μm spectral region. Two different technical approaches were pursued, with virtually equal success: growth from Hg solutions and growth from Te solutions. One major advantage of the Hg-solution technology was its capability to produce layers of excellent surface morphology due to the ease of melt decanting. Two additional unique characteristics are now widely recognized as essential for the fabrication of high-performance double-layer heterojunction (DLHJ) detectors by LPE: low liquidus temperature (< 400 °C), which made the cap-layer growth step feasible, and ease of incorporating both p-type and n-type temperature-stable impurity dopants, such as As, Sb, and In, during growth.

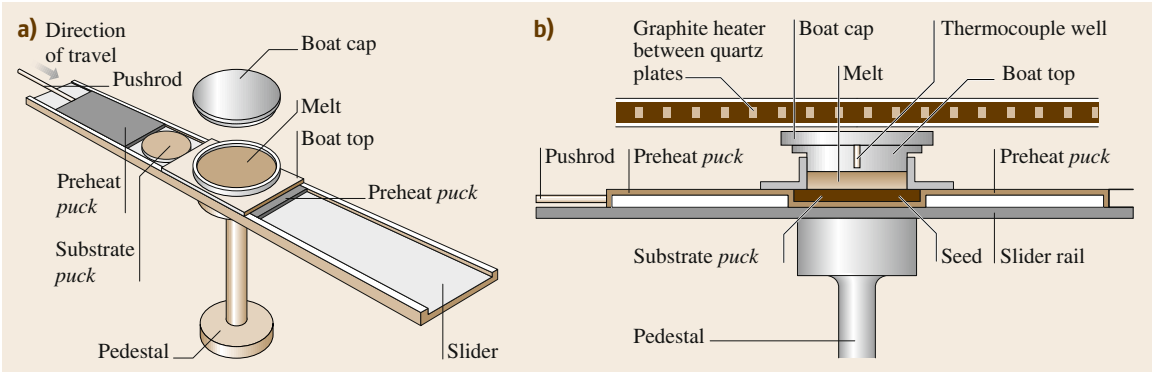

Fig. 14.7a,b Schematic of 3-inch LPE apparatus, **(a)** perspective view, **(b)** side view. (After [14.44])

Figure 14.4 shows the dipping system used for the growth of MCT [14.8]. Large melts allow the production of layers up to 30 cm^2 with excellent compositional and thickness uniformity and allow dopant impurities to be accurately weighed for incorporation into layers and to maintain stable electrical characteristics over a long period of time. Four layers (30 cm^2 each) with a total area of 120 cm^2 can be grown in a single run [14.52]. *Norton* et al. [14.53] also scaled up for the growth of cap layers from Hg-rich solutions, each reactor capable of growth on four 24 cm^2 base layers per run.

While layers grown from Hg-rich solutions are easily doped with group VB elements with high solubility, layers grown from tellurium-rich solutions are not. Group VB dopants have low solubility and are not 100% active electrically. Group IIIB elements, indium in particular, are easily incorporated from both solutions. Indium doping from tellurium-rich melts, however, has one advantage in that the segregation coefficient is near unity.

Astles [14.47] reviewed the experimental data of Te-rich LPE growth at 460–550 °C. As an example, to compare growth parameters for Te solutions with those for Hg solutions, consider the growth of LWIR MCT ($x = 0.2$) at 500 °C from both Te and Hg solutions. The x_{Cd} for Te-rich solutions is 8.3×10^{-3}, while x_{Cd} for Hg-rich solutions is 2.6×10^{-4}. This is one of the difficulties encountered in LPE growth from Hg-rich solutions. Use of large melts, however, overcomes the Cd depletion problem.

A typical sliding-boat arrangement was described by *Capper* et al. [14.54]. The LPE boat is made from purified, high-density, small-grain, electronic-grade graphite. The precompounded growth solution is placed in a growth well, and crushed HgTe is placed in a blind well. The HgTe acts as a buffering source of the volatile elements to help stabilize the growth solution composition and also to deliver an overpressure to control the metal vacancy level during annealing. The control over the impurity levels in the major constituent elements is a crucial part of the control of the overall process.

Surface morphology is controlled at two levels: microtexture and long-range variation. The micro-texture is a result of misalignment of the substrate crystal plane with the growing surface. Deviations $> 0.1°$ from the ⟨111⟩B plane lead to significant surface texture. Growth on accurately orientated substrates gives a specular surface on which atomic-scale growth features can be seen using atomic force microscopy (AFM). Figure 14.8 shows a classical Frank–Read site on an as-grown LPE layer surface [14.55].

In addition to the normal MW (3–5 μm) and LW (8–12 μm) IR detectors made in this LPE material, work has also been carried out in the SW/MW (1–3 μm) region [14.2, Chap. 10]. Using avalanching produces signal gains up to 10, with a sensitivity of ≈ 10 photons rms, attesting to the extremely high material quality. Figure 14.9 shows an example of its application in active IR imaging, combined with a laser for range finding. This SW material is also being used currently in several astronomical applications, where again the high level of material quality is essential for the correct operation of the device (see Chap. 34 in this book).

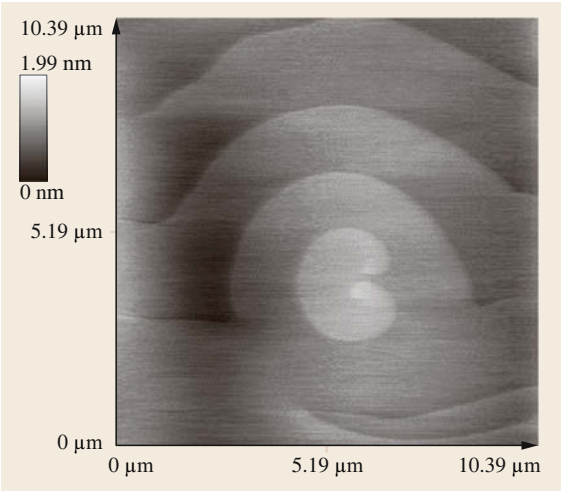

Fig. 14.8 AFM image of a Frank–Read growth spiral. (After [14.55])

Schirmacher et al. [14.56] recently reported on MCT gown by LPE for higher operating temperature (HOT) devices using Au as the p-type dopant, used to reduce the number of native mercury vacancies known to act as recombination centers. By lowering the p-type dopant level and improving the passivation they achieved Rule 07 performance, a normalized measure of the dark current, when operating the detectors at ≈ 140 K.

Other Narrowgap II–IV Compounds

HgZnTe was first proposed as an alternative detector material to MCT due to its superior hardness and its high energies for Hg vacancy formation and dislocation formation [14.57]. *Rogalski* [14.58] reviewed the LPE growth of HgZnTe and notes that Te-rich growth is favored due to the low solubility of Zn in Hg and the high Hg partial pressure. He also commented that the same factors apply to the growth of HgMnTe. *Becla* et al. [14.49] grew HgMnTe in a two-temperature, closed-tube tipping arrangement at 550–670 °C onto CdMnTe bulk substrates and CdMnTe LPE layers previously grown on CdTe substrates. *Rogalski* [14.58]

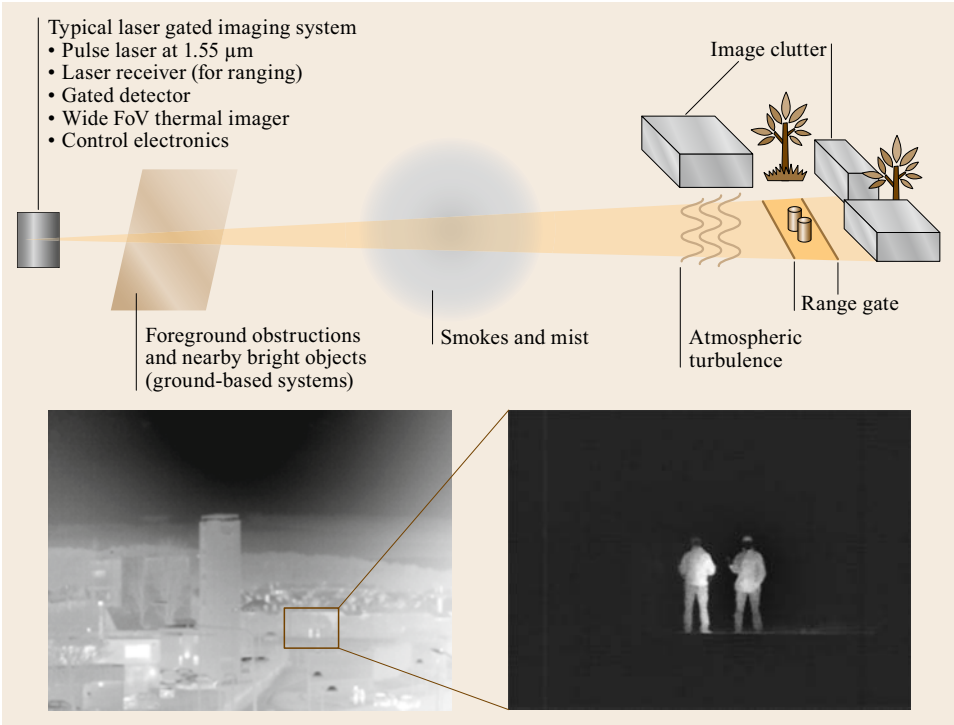

Fig. 14.9 Advantages of laser-gated imaging in conjunction with other sensors together with a typical pair of images. (Courtesy of Leonardo MW Ltd)

also reviewed the status of PC and PV detectors in both HgZnTe and HgMnTe.

14.1.8 Garnets

Comments have already been made earlier in this chapter regarding the growth of garnets by LPE. *Gornert* et al. [14.2, Chap. 14] have recently described the growth of garnets with large Faraday rotation for magneto-optical applications. Bi-substituted gadolinium, gallium garnet (GGG) layers are grown on 1-inch diameter GGG substrates from Pb/Bi/B/O melts that show low misfit, low effective anisotropy, low defect levels, and correct crystal orientation. LPE is noted as producing devices with the highest sensitivity compared to material produced by other techniques.

In a more recent report [14.59], Ce-doped multicomponent garnets for scintillating screens for x-ray imaging was described. Both YAG and GGG substrates were used.

14.1.9 Oxides/Fluorides

In a study of ZnO growth onto ZnO substrates *Ehrentraut* et al. [14.60] reported that AFM showed a monolayer step height. More recently, *Kobayashi* et al. [14.61] grew Al-doped ZnO (at 800 °C) and found subsequent well-defined excitonic luminescence.

Nasu et al. [14.62] grew YBCO on $NdGaO_3$ substrates and studied the orientation versus growth temperature. Work on Zn-substituted $LiNbO_3$ waveguides was described by *Dubs* et al. [14.63], where high crystalline perfection and extremely flat surfaces (0.2–0.3 µm) were produced. *Lu* et al. [14.64] worked on Yb:Zn $LiNbO_3$ in a K_2O flux and found that the segregation coefficient and surface roughness increased with dopant concentration. *Pena* et al. [14.65] grew Yb:CaF_2 layers on CaF_2 substrates up to a few hundred micrometers thick with structural and spectroscopy properties as good as the substrates and similar to bulk crystals, respectively.

14.1.10 Atomically Flat Surfaces

Chernov and *Scheel* [14.66] argued that far from the perceived drawback of LPE of producing rough surfaces, it may be uniquely suited to providing atomically flat, singular surfaces over distances of several micrometers. These surfaces could have applications in surface physics, catalysis, and improved homogeneity of layers and superlattices of semiconductors and superconductors.

In support of this view, Fig. 14.8 shows an AFM image of a Frank–Read growth spiral on the surface of an MCT layer grown by LPE in this author's laboratory [14.55].

14.1.11 Conclusions

LPE was generally the first epitaxial technique applied to most systems of interest in micro- and optoelectronics. It is now generally a mature technology, several optoelectronic, IR detectors, and other device types are still being made in LPE material, although some developments are still taking place. LPE has several advantages over the various vapor-phase epitaxial techniques, such as high growth rates, favorable impurity segregation, ability to produce flat faces, suppression of certain defects, absence of toxic materials, and low cost. There is much less emphasis on LPE in the current literature than on the vapor-phase methods, but LPE continues to seek out and develop in several niche markets where vapor-phase techniques are not suitable.

14.2 Metal Organic Chemical Vapor Deposition

14.2.1 Introduction and Background

The technique of MOCVD was first introduced in the late 1960s for the deposition of compound semiconductors from the vapor phase. The pioneers of the techniques, *Manasevit* and *Simpson* [14.67] were interested in a method for depositing optoelectronic semiconductors such as GaAs onto different substrates such as spinel and sapphire. The near-equilibrium techniques such as LPE and chloride VPE were not suitable for nucleation onto a chemically very different surface to the compound being deposited. These pioneers found that if they used combinations of an alkyl organometallic for the group III element and a hydride for the group V element, then films of GaAs could be deposited onto a variety of different surfaces. Thus, the technique of MOCVD was born but it was not until the late 1980s that MOCVD became a production technique of any significance. This success depended on painstaking work with improving the impurity of the organometallic precursors and hydrides. By this time, the effort was on high-quality epitaxial layers on lattice-matched substrates, in contrast with the early work. The high-quality epitaxial nature of the films was emphasized by changing the name of the growth method to metalorganic vapor phase epitaxy (MOVPE) or organometallic VPE (OMVPE). All these variants of the name can be found in the literature and in most cases they can be used interchangeably. However, MOCVD can also include polycrystalline growth that cannot be described as epitaxy. The early niche applications of MOVPE were with GaAs photocathodes, GaAs HBT lasers, and GaInAsP lasers and detectors for 1.3 μm optical fiber communications.

The characteristics of MOCVD that have taken it from a research curiosity to production have been in the simplicity of delivery of the reactive vapors and the versatility of selecting different alloy compositions, dopants, and layer thickness. These basic attributes have enabled the same basic technique to be used for narrow bandgap semiconductors such as the infrared detector materials $Cd_xHg_{1-x}Te$ and GaInSb and now for wide bandgap semiconductors such as GaN and ZnO. Indeed, the success of GaInN in the 1990s for high brightness blue LEDs has now led to this being the most popular material produced by MOCVD for high-brightness white LEDs for lighting [14.68, 69]. The early strength of MOCVD was its ability to grow onto different substrates but later abandoned in favor of the more conventional homoepitaxy; however, the nitrides rely on heteroepitaxy onto sapphire and SiC substrates bringing MOCVD back to its roots with the early work of Manasevit. The goal of more recent work has been to achieve a reduced density of dislocations in the GaN layer using patterned substrates [14.70]. This versatility with substrate materials presents MOCVD with the ultimate challenge of mating high-performance optoelectronic materials with silicon substrates to combine the best of optoelectronic and electronic performance.

This section of the chapter will cover the key elements of the MOCVD process from the physical characteristics of the precursors, through reactor design to getting the right materials properties for high-performance devices.

14.2.2 Basic Reaction Kinetics

The precursors for III–V MOCVD are generally a simple alkyl for the group III source and a hydride for the group V source. Both have the essential properties of being volatile in a suitable carrier gas stream (usually hydrogen) and being chemically stable at ambient temperature. These precursors are normally mixed outside the reaction chamber, introduced into the reaction chamber through a suitable injector arrangement and directed onto a hot substrate. This is schematically shown in Fig. 14.10. The details of reactor design will be discussed later in this chapter. The reaction of the precursors to yield the III–V compound on the substrate can occur either in the hot vapor above the surface or on the hot surface. The stoichiometric reaction for GaAs

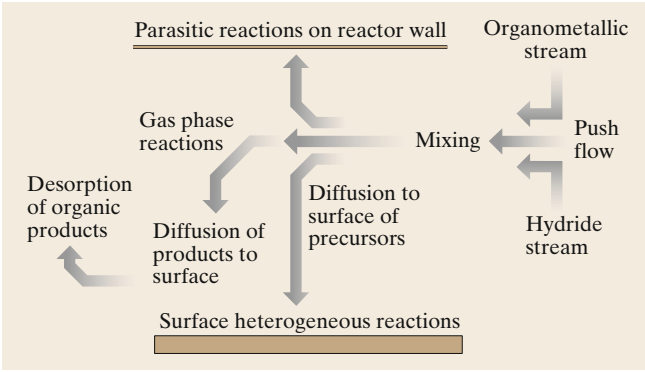

Fig. 14.10 Schematic of MOCVD process from mixing of gas streams to reaction on the substrate surface

growth is given as follows

$$(CH_3)_3Ga + AsH_3 \rightarrow GaAs + 3\,CH_4\,. \qquad (14.1)$$

This reaction has been the most widely studied of all the MOCVD reactions and was one of the original processes reported by *Manasevit* and *Simpson* [14.67]. One reason why it works so well is that the hydrogen required to satisfy the CH_3 radical bond is supplied from the arsine hydride and at normal growth temperatures (around 700 °C) avoids unsatisfied carbon bonds that could lead to carbon incorporation. In reality, this very simple picture covers a complexity of reaction steps that have to take place and has been discussed in great detail by *Chernov* [14.71]. However, some of the important reaction steps will be described here as an introduction to the kinetics of GaAs MOCVD.

The schematic shown in Fig. 14.11 gives some of the important reaction steps that have been identified

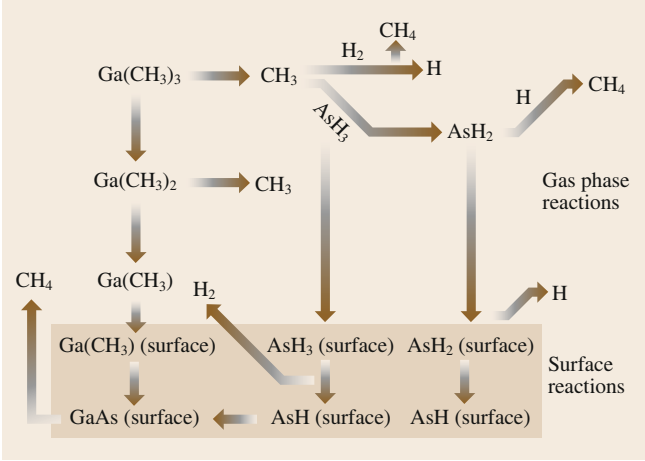

Fig. 14.11 Reaction scheme for epitaxial deposition of GaAs showing the most important vapor phase and surface reaction steps

for the reaction of GaAs. This gives some insight into the complexity of the reaction kinetics and it is worth remembering that this is a relatively straightforward reaction for MOCVD. Fortunately, one does not have to understand every step in the process before attempting to grow a layer and goes some way to explaining why MOCVD has developed along very empirical lines. An understanding of the reaction kinetics does, however, enable some of the features of MOCVD to be understood, particularly when these relatively simple precursors are replaced by more complex precursors.

It can be seen from Fig. 14.11 that the reaction process is started by a gas-phase homolysis of TMGa ($(CH_3)_3Ga$) to yield dimethylgallium and methyl radicals (CH_3). There are two important roles that the methyl radicals can take and this is generally important in all MOCVD processes for deposition of III–V semiconductors:

1. Methyl radicals can react with the ambient hydrogen carrier gas to yield stable methane and hydrogen radicals.
2. Methyl radicals can react with arsine (AsH_3) to yield stable methane and AsH_2.

Both these steps can initiate the decomposition of arsine either through a methyl radical or a hydrogen radical removing a hydrogen atom from the arsine; these reaction steps can be seen in Fig. 14.11. There are some important consequences of these initial reaction steps and one you may have already spotted is that the hydrogen carrier gas is not included in the stoichiometric reaction (reaction 1) but can play a part in the reaction process. Another consequence is that although it is highly unlikely that the two (or more) precursors have the same thermal decomposition characteristics, they can be used together to react at the same temperature through radical reaction mechanisms. The latter has been illustrated in many studies of different systems using Erzats reaction tube experiments and further information on these can be found in *Stringfellow* [14.72]. For example, in the case of GaAs, the pyrolysis of TMGa will occur at 500 °C but for arsine decomposition, a temperature of around 700 °C is required.

The stepwise removal of ligands from TMGa and arsine can occur in the vapor or on the surface. Figure 14.11 shows both alternatives and the dominant path will depend on both the surface temperature and vapor temperature above the substrate. A general rule is that more of the reaction process will occur on the surface at lower temperatures when the vapor reaction rate will be slower and the surface adsorption will be more efficient. It is also important to note that there are two different adsorption sites on the surface, the Ga sites that will

take the anion species and the As sites that will take the cation species.

Part of the early success of GaAs and the alloy GaAlAs was due to the absence of unwanted vapor-phase reactions that could lead to the formation of polymer chains that would contaminate the layer. This was not the case with InP where the liquid alkyl source TEIn was used instead of the solid TMIn. This led to a mist in the reactor resulting from the formation of an adduct between the precursors that subsequently polymerized [14.73]. This was overcome through the use of low-pressure reactors and this has remained a feature of most production reactors today. However, the preferred precursor is TMIn and the problems of uncertain supply from a solid source has been overcome by a variety of different innovative methods. One example is to form a liquid with a stable amine and the source will then behave in the same way as any other liquid precursor as discussed by *Frigo* et al. [14.74].

The details of the reaction kinetics will change with substrate temperature but as the temperature is increased a point will be reached where the rate of epitaxial growth will no longer be determined by the overall reaction rate but will be determined by the supply of precursors to the substrate. This will be reflected by a depletion of the precursor concentration immediately above the surface and a gradient in precursor concentration toward the undepleted free stream. The limitation to the rate of epitaxial growth then becomes the rate of diffusion through the depleted boundary layer to the substrate. This is called transport-limited growth and is characterized by high growth rates and only a weak dependence of growth rate on substrate temperature. This is shown schematically in Fig. 14.12. The plot is of ln(growth rate) versus $1/T$ because of the expected Arrhenius relationship in the rate constants. This really only applies to the low-temperature (kinetic regime) where the growth rate can be expressed as

$$\text{growth rate} = A \exp\left(-\frac{E_a}{RT}\right) , \qquad (14.2)$$

where A is a constant and E_a is an activation energy, R is the gas constant. It is unlikely that E_a can be attributed to the activation energy for a single reaction step but is still useful in characterizing the overall kinetics where different precursors are being tried.

In the transport-limited regime, there will still be a small dependence of growth rate on temperature due to the increase in diffusion rate with temperature and this is illustrated in Fig. 14.12. Most MOCVD growth processes will take place in the transport-limited regime where it is easier to control growth rate. However, there are a number of growth processes that will occur at lower temperatures in order to control the

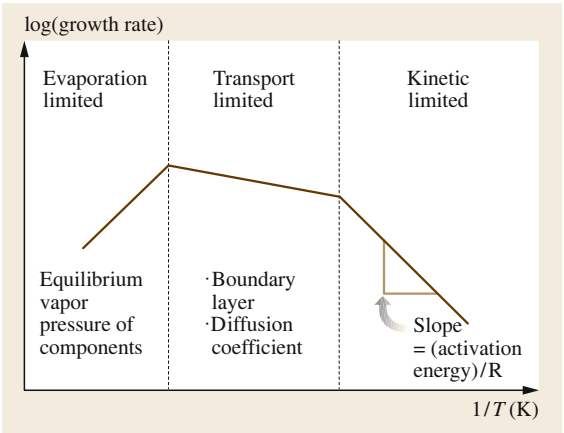

Fig. 14.12 Schematic of the three different temperature regimes for growth of a compound semiconductor by MOCVD

properties such as native defect concentration of the epitaxial films. This is generally the case with II–VI semiconductors, but can also apply to the formation of thermodynamically unstable III–V alloys.

In the high-temperature regime, the growth rate decreases with temperature as the equilibrium vapor pressure of the constituent elements in the film will increase and give desorption rates similar to the deposition rate, leading to significant loss of material through evaporation to the gas stream.

14.2.3 Precursors

The choice of precursors is not confined to simple alkyls and hydrides but can extend to almost any volatile organometallic as a carrier for the elemental components of a film. In the case of II–VI semiconductors, it is usual to use an alkyl for both the group II and the group VI elements. Hydrides have been used as Se and S sources but prereaction makes it difficult to control the growth process and in particular can make it difficult to incorporate dopants. The use of combined precursor sources has been extensively researched but is not in common use for epitaxial device-quality material. One reason for this is the difficulty in controlling the precursor ratio that is needed to control the stoichiometry of the material.

The important properties of precursors, and their selection, can be generalized and provide a basis for optimizing the MOCVD process. These properties can be summarized as follows:

1. Saturated vapor pressure (SVP) should ideally be in the range of 1−10 mbar in the range of temperatures of 0−20 °C.

2. Stable for long periods at room temperature.
3. Will react efficiently at the desired growth temperature.
4. The reaction produces stable leaving groups.
5. Avoids unwanted side reactions such as polymerization.

According to the Clausius–Clapeyron equation, the SVP of a liquid is given by an exponential relationship

$$\mathrm{SVP} = \exp\left(-\frac{\Delta G}{\mathrm{R}T}\right) , \tag{14.3}$$

where ΔG is the change in Gibbs free energy on evaporation, R is the gas constant, and T the temperature of the liquid in the bubbler. This can be expressed as the heat of evaporation ΔH and the entropy for evaporation ΔS, where $\Delta G = \Delta H - T\Delta S$; this gives the familiar form of the SVP equation

$$\begin{aligned}\mathrm{SVP} &= \exp\left(-\frac{\Delta H}{\mathrm{R}T} + \frac{\Delta S}{\mathrm{R}}\right) \\ &= \exp\left(\frac{\Delta S}{\mathrm{R}}\right)\exp\left(-\frac{\Delta H}{\mathrm{R}T}\right) .\end{aligned} \tag{14.4}$$

This is of the form

$$\log_{\mathrm{e}}(\mathrm{SVP}) = A - \frac{B}{T} , \tag{14.5}$$

where A and B are constants given by $A = \Delta S/\mathrm{R}$ and $B = \Delta H/\mathrm{R}$. Manufacturers of the precursors will generally give the SVP data in the form of the constants A and B in (14.5). It can also be given in the form

$$\log_{10}(\mathrm{SVP}) = A' - \frac{B'}{T} . \tag{14.6}$$

To convert the constants in (14.6) to (14.5), just multiply by ln 10. Some examples of the SVP constants, along with the calculated SVP at 20 °C, for a number of typical precursors are shown in Table 14.1.

Table 14.1 List of precursors with the vapor pressure constants according to (14.6)

Precursor	*A*	*B*	SVP at 20 °C (mmHg)

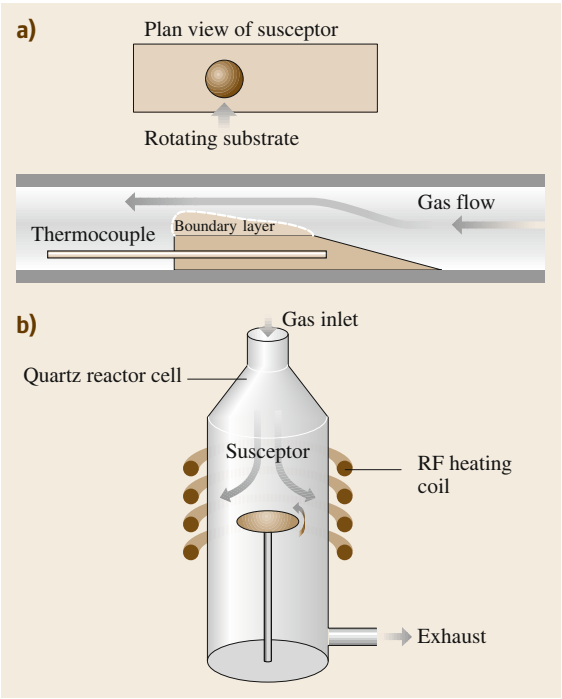

Fig. 14.13a,b Schematic of (a) horizontal and (b) vertical reactor cells

14.2.4 Reactor Cells

The design of reactor cells has formed a very important part of the development of MOVPE and has been crucial in scaling laboratory processes to large-scale production [14.75–77]. The original research reactors fell into one of two groups, either the vertical reactor or horizontal reactor. These reactor designs are schematically shown in Fig. 14.13. The substrate is placed onto a graphite susceptor that is heated by either RF coupling via a coil surrounding the reactor, a resistance heater underneath the susceptor or lamps placed underneath the susceptor. The reactor wall can be water-cooled or gas-cooled to minimize reaction and deposition onto these surfaces. Either of these reactor cells could be operated at atmospheric or reduced pressure. For reduced-pressure operation, the reactor-cell pressure would be typically a tenth of an atmosphere but a wide range of different pressures have been successfully used. Reduced pressure will increase the gas velocity and help to overcome the effects of free convection from a hot

substrate. The forced-convection parameter that is often quoted is the Reynolds number and is proportional to gas velocity. A high Reynolds number will ensure streamline flow and at low Reynold's number the buoyancy effects of the hot substrate will take over and the gas flow will be dominated by free convection (characterized by the Grashof number) and become disorganized with recirculation cells. In transport-limited growth, the exact nature of the gas flow will determine the uniformity of deposition and can also affect the defect concentration in the films due to particulates and reaction products being swept back across the growing surface. It is not normal to achieve the very high flow velocities and Reynold's numbers associated with turbulent flow in an MOVPE chamber; however, the disorganized flow due to free convection is often, wrongly, referred to as *turbulent flow*.

Another reason for using high flow velocities is to overcome the effects of depletion of the precursor concentration at the downstream end of the deposition region. For transport-limited growth, the growth rate is limited by the rate of diffusion from the free stream to the substrate. This region is called the boundary layer [14.78] and increases in thickness going downstream from the leading edge of the susceptor, as shown in Fig. 14.14. Some horizontal reactors are designed with a tilt in the susceptor so that the free cross-sectional area decreases and hence the flow velocity increases going downstream. This helps to flatten the boundary layer and ensure better uniformity.

Maintaining a boundary layer has a cost in high utilization of expensive precursors and gases as the flow throughput is typically very high and the proportion of precursors reacted in the region of the substrates is very low. This became a more serious problem when reactors were scaled to hold multiple wafers for production. These problems have been resolved with different solutions in the vertical and horizontal reactor configurations with the Emcore (now Veeco) turbo-disc reactor, the Thomas Swan (now Aixtron) showerhead reactor, and the Aixtron planetary reactor. A fourth type of reactor design was introduced by EMF, called the Titan, and works on the principal of introducing the precursors separately into the reactor chamber. This approach proved difficult to control and has not been developed further. A common feature to all these production reactor designs is the substrates are rotated so the concentration of precursors and reactants arriving at the substrate do not have to be uniform across the surface as a portion of the substrate will alternately experience high and low concentrations that will average out. Each of these reactor designs is schematically shown in Fig. 14.15.

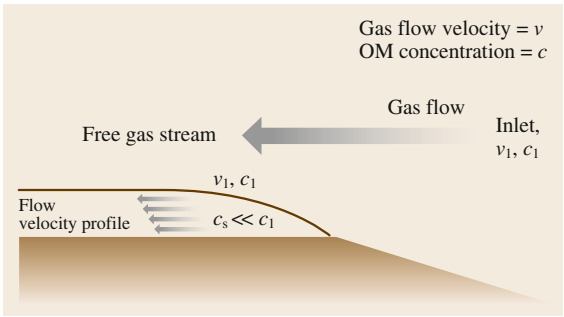

Fig. 14.14 Schematic of a boundary layer in a horizontal reactor

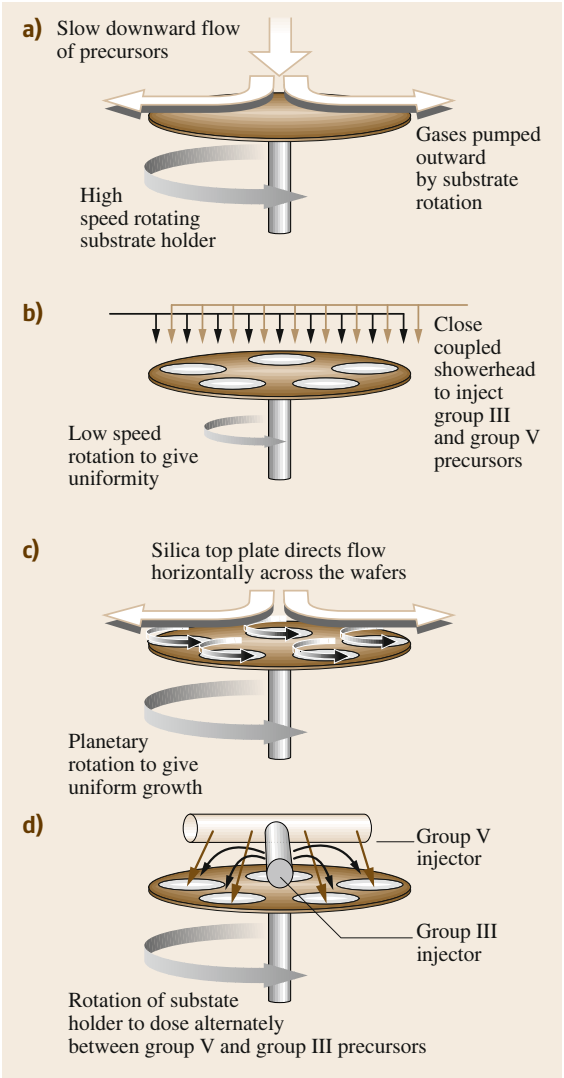

Fig. 14.15a–d Schematic of four different production reactor designs: **(a)** the Emcore (Veeco) Turbo-disc, **(b)** the Aixtron close-coupled showerhead, **(c)** the Aixtron planetary, and **(d)** the EMF Vector flow reactor

The turbo-disc reactor, schematically shown in Fig. 14.15a, is a vertical reactor configuration but the boundary layer is kept to a narrow region above the susceptor by high-speed rotation that pumps the gas radially outward due to viscous drag. The rotation speeds are up to 2000 rpm in order to create this lateral flow of the constituents above the substrate. This is continuously replenished from the slower downward gas stream and results in excellent uniformity of deposition across the wafers and a high utilization of the reactant gases *Tompa* et al. [14.79]. The reactor pressure is typically around 100 mbar.

The showerhead reactor is another vertical reactor arrangement but takes a different approach to overcoming free-convection currents and poor uniformity [14.76]. The precursors are introduced through a water-cooled showerhead placed just above the susceptor. The susceptor is rotated but typically at much lower speeds than for the turbo-disc reactor. The precursor distribution can be balanced across the width of the reactor to give a uniform supply of precursors.

The planetary reactor is a horizontal flow arrangement where the reactants enter at the center of rotation of the susceptor and flow outward. This is an example of a fully developed flow where depletion of the reactants is occurring as the gases move away from the center and this will be accentuated by a decrease in the mean flow velocity as the gases move outward [14.80]. This would normally give very poor uniformity but the planetary rotation mechanism will rotate each wafer on the platen so that it will sample alternately high and low concentrations giving uniform deposition. This approach has the advantage of a high utilization of the precursors and the ability to extend the design to very large reaction chambers for multiple wafers from 2 to 8 inches diameter.

14.2.5 III–V MOCVD

This section will consider the range of III–V materials grown by MOCVD and the precursors used. Most of the III–V semiconductors can be grown from organometallics of the group III element and hydrides of the group V element. Exceptions to this will be noted where appropriate.

Arsenides and Phosphides

The most commonly studied alloy system is $Al_{1-x}Ga_xAs$ that is used for LEDs and laser diodes from the near infrared to the red part of the visible spectrum. This is a well-behaved alloy system with only a small change in lattice parameter over the entire composition range and covering a range of bandgaps from 1.435 eV for GaAs to 2.16 eV for AlAs. One problem with this alloy is the sensitivity of aluminum to oxygen, which makes it extremely difficult to grow high-quality AlAs. Just 1 ppm of oxygen contamination will result in $10^{20}\,cm^{-3}$ incorporation of oxygen into $Al_{0.30}Ga_{0.7}As$ [14.81]. In addition to the normal MOCVD precautions of using ultrahigh-purity hydrogen carrier gas and ensuring that the moisture in the system is removed, the hydrides and organometallics also need to have extremely low oxygen content. Precursor manufacturers have tended to keep to the simple alkyl precursors but to find innovative ways of reducing the alkoxide concentrations.

Alternative group V precursors have been sought due to the high toxicity of arsine and phosphine. These hydride sources also suffer the hazard that they are stored in high-pressure cylinders and any leakage could result in the escape of large quantities of toxic gas. Alternative alkyl group V sources have been extensively researched but only two precursors have proved to be suitable for high-quality epitaxial growth, tertiarybutylarsine (TBAs), and tertiarybutylphosphine (TBP) [14.82, 83]. These precursors only have one of the hydrogen ligands replaced with an alkyl substituent but they are liquid at room temperature rather than high-pressure gases. In the reactor chamber, the likely reaction path is to form the hydride by a process called beta-hydrogen elimination. This entails one of the hydrogen atoms from the methyl groups satisfying the bond to As (or P) with a butene leaving group as shown below [14.43]

$$C_4H_9AsH_2 \rightarrow C_4H_8 + AsH_3\,. \qquad (14.7)$$

This process is more likely to dominate at the normal growth temperature for transport-limited growth and effectively yields the arsine precursor that can then react in the normal way. In the search for alternative alkyl precursors, this proved to be an important factor as the fully substituted alkyl arsenic sources tended to incorporate large concentrations of carbon, degrading the electrical properties of the film. The importance of the group V hydride was discussed in Sect. 3.2 and it can be understood why TBA and TBP (for the phosphorous alloys) have proved to be good alternatives to the hydrides. However, it is fair to say that these have never been widely utilized due to much higher cost than the hydrides and poor availability.

An alternative in improving the safety has been investigated and relies on the same principle of reducing the toxic gas pressure in the event of a system leak. This alternative stores the hydride in a reversible adsorption system [14.84]. The adsorption system keeps the hydride at subatmospheric pressure and requires pumping to draw-off the hydride when needed hence making it

inherently safer. One major advantage to this system, in addition to the inherent improvement in safety, is that the precursors and hence the precursor chemistry are unchanged in the reactor cell.

Other alloys commonly grown using MOCVD include $In_{0.5}Ga_{0.5}P$ that has a bandgap of approximately 2 eV and is lattice matched to GaAs. The quaternary alloy GaInAsP enables lattice matching to InP substrates while controlling the bandgap in the 1.3 and 1.55 μm bands used for long-range fiber-optic telecommunications.

More recent research in the arsenides and phosphides has focused around the nanostructuring of the materials through self-assembled quantum dots (QD) [14.85, 86] and nanowires [14.87, 88]. This has enabled bandgap engineering to overcome limitations of lattice-matched structures. For example, stacked lasers of InAs QDs produce emission beyond 1300 nm [14.86]. The mechanism is to take advantage of the inherent strain created when depositing InAs onto GaAs where the large lattice mismatch results in only 2 monolayers to be grown as a 2-D layer before strain relaxation creates three-dimensional (3-D) growth. This mechanism is called the Stranski–Krastanov process and results in a 2-D array of self-assembled QDs. These can be overgrown with an epitaxial layer of GaAs to cap the QDs and to allow another layer of InAs QDs to be grown on top [14.85]. Further refinements in the MOCVD of QD arrays uses a strain relaxation layer on top of the InAs QD with GaAsSb [14.86] to maintain the Type-I quantum transition to longer wavelengths.

The formation of nanowires has enabled greater relaxation of the lattice-matching requirement and is gaining attention as a means of making optoelectronic structures onto silicon substrates. The approach is to use a vapor–liquid–solid (VLS) mechanism where a thin gold film is heated to produce nanoscale gold droplets that are then exposed to the precursor gases. These will react in the normal way but the Ga (or In) and As (or P) released from the precursors will dissolve into the gold nano-droplet and start to nucleate a GaAs film at the gold/substrate interface. By changing the gas phase composition during the deposition, it is possible to grow junctions and heterostructures in the vertical nanowires. *Heurlin* et al. [14.88] have grown tandem InP p–n junctions in nanowires onto silicon substrates for photovoltaic devices. These structures have the added advantage that the nanowires will also help to capture the light, requiring less of the semiconductor material to achieve light capture than would be required for a conventional planar device. *Gu* et al. [14.89] grew GaAs/AlGaAs core–shell nanowires and assessed their optical absorption properties showing enhanced absorption compared with a planar structure. The core–shell structure has the advantage of passivating the large surface area created by the nanowires and is an alternative to the vertical junction structure.

Antimonides

The antimonides cover an important range of bandgaps from the near infrared to the mid-infrared bands, up to 5 or 6 μm. These compounds and alloys can be used in infrared detectors, thermophotovoltaic (TPV) devices, and high-speed transistors. The growth of the antimonides is more complex than for the arsenides and phosphides because the hydride, stibine, is not very stable at room temperature so the use of alkyl precursors has been a more natural choice. Another factor that has influenced the growth of the antimonides is the lower thermodynamic stability and decomposition of substrates such as InSb above about 400 °C. It is also desirable to grow the films at a much lower temperature than for the arsenides and phosphides in order to keep the native defect concentration low for controlled n-type and p-type doping. However, the antimonides have an advantage in the reaction chemistry that they do not incorporate carbon as readily as in the arsenides and phosphides and there is greater flexibility over the choice of antimony precursors [14.90]. The easiest choice is to use trimethylantimony (TMSb) or to use larger alkyl groups such as triethyl and triisopropyl to reduce the reaction temperature as required. It is also possible to reduce the reaction temperature by replacing TMGa with triethylgallium (TEGa) [14.91]. This approach has been particularly advantageous when growing aluminum-containing alloys where carbon incorporation can be a problem, but is reduced using TEGa. This serves to illustrate the flexibility of MOCVD and has given more scope for design of precursors, not envisaged in the early days of MOCVD.

Nitrides

The nitrides, mainly GaN and the alloy GaInN, have brought MOCVD into prominence as a manufacturing technology with the success of high-brightness blue LEDs making large-screen full-color LED displays a reality. This has extended in recent years to high efficiency and high-brightness white LEDs making huge inroads into the lighting market [14.92, 93]. The precursors used for the nitrides are standard with the methyl alkyls (TMGa and TMIn) for the group III elements and ammonia for the nitrogen. The key technological barriers to obtaining device-quality GaN were in overcoming the problems associated with heteroepitaxy onto the nonlattice-matched substrate, sapphire, or SiC and in controlling the p-type doping [14.94]. Some research has been carried out with homoepitaxy onto GaN substrates but the very high pressures needed in

bulk crystal growth of GaN will restrict the size of available substrates.

The heteroepitaxial problems have been overcome with a two-stage growth. High-quality GaN requires growth temperatures in excess of 1000 °C, much higher than is needed for the arsenides and phosphides. At these temperatures, the nucleation onto sapphire is poor and large facetted islands grow before complete coalescence of the film occurs. This not only leads to very poor surface morphology but also a high dislocation density where the islands coalesce. The two-stage growth overcomes this by growing a uniform nucleation (or buffer) layer onto the sapphire at 600 °C. This is then heated to the normal growth temperature where a thicker GaN film is then grown. The whole nucleation process can be monitored in situ using laser reflectometry and an example is shown in Fig. 14.16 [14.95]. It can be seen that approximately 50–100 nm of GaN is grown as a smooth layer but during heating this changes to a rough layer. A remarkable part of the process is that during the high-temperature growth, shown in Fig. 14.16 by the interference oscillation, there is a recovery in the surface morphology, resulting in smooth, device-quality layers. In some cases, the GaN buffer layer is substituted with an AlN layer [14.96], but in all cases a two-stage growth process is required. The growth of device layers is achieved by controlling the bandgap through growth of the alloys GaInN or GaAlN. The bandgap of GaN is 3.4 eV, which is in the UV, so the color of the LED is determined by the alloy composition where increasing the In content will reduce the bandgap and push the emission wavelength from blue to green. However, this is not an easy alloy to form due to the different stabilities of the GaN and InN bonds [14.97]. In fact, it cannot be grown to any useful In content at temperatures above 1000 °C, so the temperature has to be reduced to around 800 °C. Even with this compromise, the different lattice parameters of GaN and InN result in poor solubility and In content above 40% is not practical. In principle, it is possible to prepare LEDs of any color by just changing the In content in the alloy, but in practice the high-brightness diodes can only be prepared from nitrides covering the blue to green portion of the spectrum. The high brightness white LEDs are formed from violet LEDs combined with phosphors to provide the color balance at the longer wavelengths [14.93]. The growth of Al-containing alloys is desirable to achieve wider bandgaps for applications such as UV LEDs and solar-blind detectors. The problems are similar to those of the In, Ga alloys but in the case of Al, Ga, the stability of AlN is much greater than that of GaN, which will tend to form AlN clusters. The growth of different alloy compositions, particularly the growth of higher In content GaInN, has stimulated some research on alternative precursors for nitrogen as ammonia pyrolysis is not very efficient at temperatures below 800 °C. One of the favorite candidates is dimethylhydrazine that will react readily with TMGa at temperatures down to 400 °C.

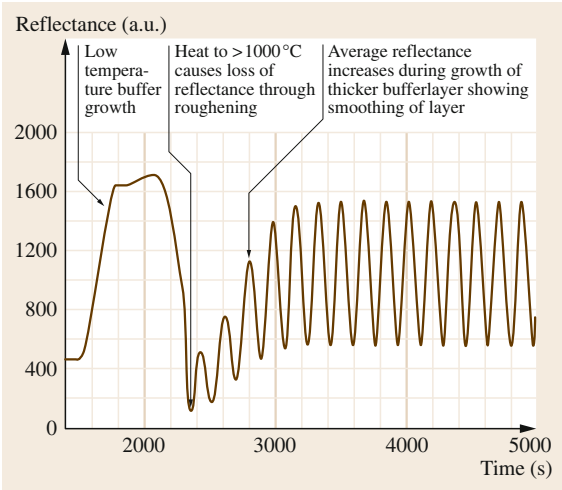

Fig. 14.16 Laser reflectometry of GaN nucleation and growth

The reaction of the ammonia with the group III alkyls to form adducts that can then polymerize is a problem associated with the high growth temperature. This requires special care in the introduction of the precursors, control of gas flows and wall temperatures. A failure to adequately control these parasitic reactions will lead to poor growth efficiency, higher defect concentration in the GaN layer, and poor dopant control. The dopants used for n-type and p-type GaN are Si from silane and Mg from dicyclopentadienylmagnesium. The n-type doping has proved to be fairly straightforward but Mg doping results in the formation of Mg–H bonds that passivate the acceptor state. This problem was solved by annealing the epitaxial films after growth to remove the hydrogen. This is possible due to the thermal stability of GaN and the high mobility of hydrogen in the lattice. A further problem with p-type doping is that the Mg acceptor has an ionization energy between 160 and 250 meV and only about 10% of the chemically introduced Mg is ionized at room temperature [14.98].

Despite the materials challenges of GaN and its alloys, MOCVD has enabled the production of a wide range of devices based on these alloys over the past two decades, from high-power transistors to laser diodes. Both these examples have required improvements in the material quality and a reduction in the relatively high dislocation densities. In fact, the potential for nitrides is enormous as the quaternary GaInNAs can be tuned to

around 1 eV with just 4% nitrogen and is a challenger for InP-based materials for the 1.3 μm telecommunications lasers and as an additional infrared junction in four junction solar cells [14.99].

14.2.6 II–VI MOCVD

The MOCVD of II–VI semiconductors is carried out at much lower temperatures than for their III–V counterparts and this has stimulated a wide range of research on alternative precursors, growth kinetics, and energy-assisted growth techniques such as photo-assisted. The basic principles are the same as for III–V MOCVD and, in general, the same reaction chambers can be used but the lower growth temperatures have led to the development of new precursors, particularly for the group VI elements. Hydrides are, in general, not used now but early work on ZnSe and ZnS used hydrogen selenide and hydrogen sulfide [14.100]. A strong prereaction occurred between the hydrides and dimethylzinc that could result in deposition at room temperature, but as with III–V MOCVD prereactions can make it difficult to control the defect chemistry and the doping. These II–VI compounds and their alloys have been investigated as blue emitter materials with similar bandgaps to GaInN. Alternatively, ZnTe is a potential green emitter and the narrower bandgap tellurides are used for infrared detectors. More recently, MOCVD of CdTe has been gaining attention for photovoltaic solar energy [14.101]. As this is polycrystalline growth on glass substrates, this will not be discussed further here but in Chap. 43 by Stuart Irvine. To date, the only commercial application of II–VI MOCVD has been for the fabrication of HgCdTe alloys for infrared detectors. However, the processes used are quite different to standard MOCVD and require different designs of reactor cells, as will be shown in the next section.

MOCVD of HgCdTe

HgCdTe is one of the few direct bandgap semiconductors suitable for infrared detection in the important 10 μm band. The alloy only has a 0.3% mismatch over the entire composition range and will cover the entire infrared spectrum from the near infrared with CdTe to the far infrared (HgTe is a semimetal so there is no lower limit to the bandgap). The main difficulty for growing HgCdTe by MOCVD has been the very high equilibrium vapor pressure of Hg over the alloy even at relatively low temperatures. For example, MBE has to be carried out at temperatures below 200 °C. A further difficulty created by the instability of HgTe is that the tellurium-rich phase boundary, which represents the minimum Hg pressure to achieve growth, has a high concentration of doubly ionized metal vacancies that make the material p-type. At typical MOCVD growth temperatures for HgCdTe, 350–400 °C, the equilibrium vapor pressure for Hg would have to be close to the SVP for liquid Hg in order to keep the metal vacancy concentration below the impurity background. This is clearly not realistic in MOCVD as the walls of the reaction chamber would have to be heated to the same temperature as the substrate to avoid mercury condensation and this, in turn, would cause pyrolysis of the precursors before they arrived at the substrate. Fortunately, it is possible to grow HgCdTe film on the tellurium-rich phase boundary where the Hg source and reactor walls can be held at around 250 °C. At this temperature, the pyrolysis of the Cd source, dimethylcadmium (DMCd), and the tellurium source, diisopropyltellurium (DIPTe) are sufficiently slow to minimize the premature reaction.

A schematic of an MOCVD reactor suitable for the growth of HgCdTe is shown in Fig. 14.17. The main features are the heating of the reactor wall and the internal source of liquid Hg. This is the only MOCVD process that uses an elemental source and is only possible because of the high vapor pressure of liquid Hg. Hg is unusual in that a higher partial pressure can be achieved using the elemental source than an organometallic source and is the only metal where this is true. Another feature of this reactor cell is the injection of DMCd past the Hg source to avoid a radical exchange reaction between DMCd and Hg [14.102].

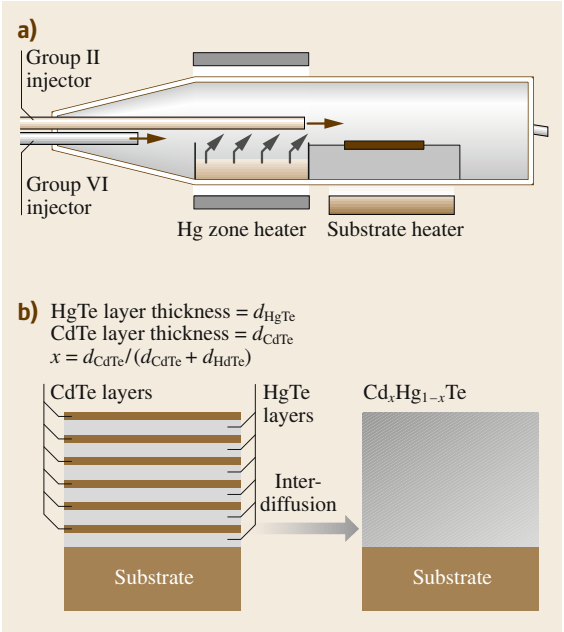

Fig. 14.17 (a) Schematic of MOCVD cell for HgCdTe growth, (b) schematic of IMP

The alloy composition needs to be precisely controlled in order to control the detection wavelength of the infrared detector. For a 10 μm detector, the proportion of Cd on the metal sublattice is 21% and needs to be controlled to better than 0.5%. The reaction rates for CdTe and HgTe require different optimum flow rates, which makes simultaneous alloy control very difficult. This problem was overcome using the interdiffused multilayer process (IMP) where alternate layers of HgTe and CdTe were grown and the flow rate optimized for each [14.103]. This process relied on a very rapid Cd/Hg interdiffusion in the HgCdTe alloy, which enables complete homogenization of the alloy at the growth temperature. The composition is now simply controlled by the relative thicknesses of HgTe and CdTe as shown schematically in Fig. 14.17b.

The IMP process has enabled controlled doping of the homogenized HgCdTe layers leading to production of heterojunction infrared detectors manufactured by MOCVD [14.104] by introducing the dopant into the CdTe layers. A concern for using dopant precursors such as AsH_3 has been the incorporation of hydrogen, which passivates the substitutional As dopant. Work by *Mitra* et al. [14.105] using the precursor *tert*-Butylarsine, followed by a 230 °C anneal under Hg vapor to remove Hg vacancies, yielded higher minority carrier lifetime than vacancy-doped HgCdTe. More recent work has concentrated on using tris(dimethylamino)arsine to minimize hydrogen incorporation. In a paper by *Hails* et al. [14.106], it was argued that a high-temperature anneal followed by a low-temperature Hg anneal helped to break the remaining As–H bonds in a HgCdTe layer as opposed to the alternative explanation of amphoteric As substitution. This procedure can result in As activation in excess of 50%.

Sulfides and Selenides

Low-temperature growth of ZnSe (below 400 °C) has been achieved using di-*tert*-butyl selenide (DTBSe) with dimethylzinc (DMZn) or the adduct DMZn.TEN. The amine, triethylamine (TEN) was first introduced to suppress gas-phase reactions with the hydrides H_2Se and H_2S. However, this adduct has the additional advantage of reducing the SVP of DMZn and making it easier to manage. The significance of keeping the growth temperature low is to avoid deep-level native defects that act as trapping sites for donor and acceptors. The p-type doping of ZnSe with nitrogen was problematic due to hydrogen passivating the dopant. Incorporation of nitrogen from a variety of precursor sources such as amines and azides up to concentrations of $10^{18}\,cm^{-3}$ could readily be achieved but active dopant concentration, in general, remained below $10^{15}\,cm^{-3}$. This was in contrast with the success of MBE growth of ZnSe that was doped from a nitrogen-plasma source. *Fujita* and *Fujita* [14.107] overcame this problem by ex-situ annealing in a similar manner to GaN but the weaker crystal lattice gives less scope for this treatment compared with GaN.

An alternative approach for low-temperature growth of ZnSe was to use short-wavelength light and UV wavelengths to illuminate the growing surface and promote surface photocatalytic reactions [14.108]. It was shown by *Irvine* et al. [14.109] that the reaction kinetics did not depend on the Se precursor, giving similar growth rates for DMSe, DESe, and DIPSe, but depended on a hydrogen radical reaction that was initiated by a surface decomposition of the group II precursor. Although this was effective in growing epitaxial films of ZnSe at temperatures well below 400 °C, it was clear that hydrogen incorporation was a natural consequence of the reaction mechanism.

MOCVD of Group II Oxides

Resurgence of interest in ZnO and related materials such as ZnMgO and ZnCdO has arisen because of the success of GaInN as a blue emitter and the potential for further developments with UV laser diodes and a solid-state replacement for domestic lighting. GaInN white light LEDs are ubiquitous but the efficiency of the phosphors would improve if they were excited with UV rather than blue photons. However, the interest in ZnO and other group II–O compounds extends beyond emitters and the flexibility in the morphology of growth makes these oxides attractive as nanowire templates [14.110].

All the early work on ZnO, MOCVD used oxygen or water vapor as the oxygen source. These react strongly at room temperature with DMZn and DEZn. Although reasonably good-quality ZnO films have been deposited with this approach, it is unlikely that it will lead to high-quality epitaxial growth or good doping control. Essentially, prereaction in all the III–V and II–VI semiconductors has been a barrier to obtaining device-quality material. The favored alternative oxygen precursors are the alcohols: isopropanol and tertiarybutanol. For higher temperatures, N_2O is a suitable precursor. In general, for epitaxial growth on sapphire or ZnO substrates it is necessary to grow at temperatures above 600 °C but for polycrystalline, transparent conducting oxides (TCOs) these precursors can react at temperatures as low as 300 °C. It is possible to readily dope ZnO n-type using TMAl but as with ZnSe it has been difficult to achieve p-type doping. Some encouraging results have been obtained using ammonia [14.111], but this work is still at an early stage of development and must be solved before electroluminescent devices

can be made. This is proving to be another class of materials where the versatility of MOCVD has a lot of potential for innovative solutions.

14.2.7 Conclusions

This section of the chapter has covered the basic principals of MOCVD and reviewed the range of III–V and II–VI semiconductor epilayers that can be grown by this method. This can be contrasted with LPE and MBE where each will have its own strengths and weaknesses for a particular material or application. The strength and the weakness of MOCVD is in its complexity. With the right precursors, it is possible to deposit almost any inorganic material but in many cases the reaction mechanisms are not well understood and the development is empirical with the researcher spoilt by a very wide choice. This is not to deny the very considerable successes that have led to major industries in compound semiconductors that has been epitomized in the past 10 years with the large-scale productionization of GaN and the plethora of large LED displays that would not have been possible without MOCVD. It has been shown in the last few years that MOCVD is very attractive for producing nanowires of compound semiconductors leading to many more possibilities for materials selection and applications. Without the pioneering work of Manasevit and Simpson who demonstrated the potential to grow so many of these materials in the early years, and the fortuitous ease with which GaAs/AlGaAs could be grown. Without this, we might not have tried so hard with the more difficult materials and hopefully we will see many more innovations in the future with MOCVD.

14.3 Molecular Beam Epitaxy (MBE)

14.3.1 Introduction and Background

MBE is conceptually a very simple route to epitaxial growth, in spite of the technology required, and it is this simplicity that makes MBE such a powerful technique. It can be thought of as a refined form of vacuum evaporation, in which neutral atomic and molecular beams from elemental effusion sources impinge with thermal velocities on a heated substrate under ultrahigh vacuum (UHV). Because there are no interactions within or between the beams, only the beam fluxes and the surface reactions influence growth, giving unparalleled control and reproducibility. Using MBE, complex structures can be grown by atomic layer with precise control of thickness, alloy composition, and intentional impurity (doping) level. UHV confers two further advantages; cleanliness, because the partial pressures of impurities are so low, and compatibility with in-situ analytical techniques – essential for understanding the surface reaction kinetics. The basic elements of an MBE system are schematically shown in Fig. 14.18. A number of reviews [14.112–114] and books [14.115, 116] have discussed the physics, chemistry, technology, and applications of MBE.

The technique that became known as MBE evolved from surface kinetic studies of the interaction of silane (SiH_4) beams with Si [14.117] and of Ga and As_2 beams with GaAs [14.118]. Cho and coworkers, who first used the term MBE, demonstrated that MBE was a viable technique for the growth of III–V material for devices, leading the way for a worldwide expansion of effort.

Much early MBE equipment had a single vacuum chamber for loading, deposition, and analysis, which led to prolonged system pumpdown between growths. The technique required significant improvements in vacuum conditions before very high quality thin films were grown. *Cho* surrounded the effusion cells with a liquid nitrogen cryopanel to give thermal isolation and reported the MBE growth of thin films of n- and p-type GaAs for device purposes [14.119]

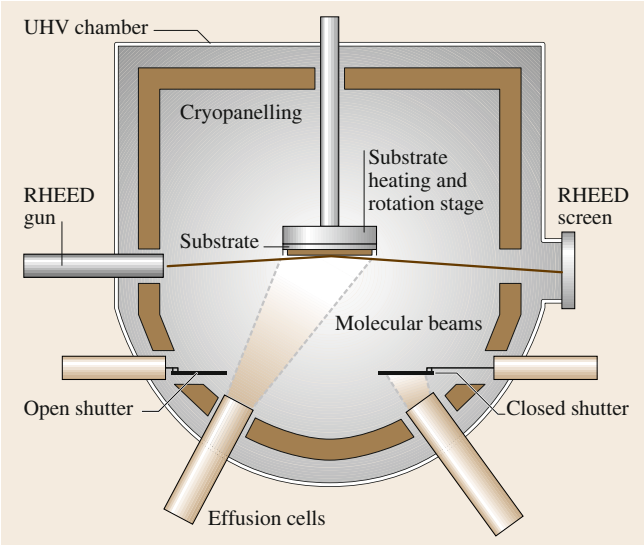

Fig. 14.18 Schematic diagram of an MBE growth chamber, showing the effusion cells and shutters, the substrate stage, and the arrangement of the RHEED system

and of GaAs/AlGaAs heterostructures [14.120]. The introduction of a substrate-exchange load lock [14.121] drastically reduced pumpdown times and reduced contamination of the deposition chamber. The installation of extensive internal liquid-nitrogen-cooled cryopanels [14.122] substantially increased pumping of oxygen-containing species and permitted the growth of AlGaAs with superior quality. *Tsang* [14.123] demonstrated lasers with threshold current densities superior to those grown by LPE. Uniform growth over a 2-inch diameter wafer was achieved by the introduction of a rotating substrate holder capable of 5 rpm [14.68]. Advanced forms of these features are now standard on commercial MBE systems, many of which feature a modular design. The technology of MBE is now mature, with increasing numbers of ever larger high-throughput, multiwafer production MBE machines in widespread use since the early 1990s.

MBE has been used to grow a wide range of materials, including semiconductors, superconductors, metals, oxides, nitrides, and organic films. In almost all cases, there is a drive to produce structures with ever smaller dimensions, whether for higher performance devices, quantum confinement or, more recently, nanotechnology. This is longest established in III–V semiconductors, from the GaAs/AlGaAs superlattice [14.124] through quantum wells (QWs) and modulation doping to quantum wires and quantum dots [14.125]. Such low-dimensional structures form the basis of the QW lasers and p-HEMTs produced in huge volumes by MBE for optoelectronic and microwave applications. The combination of precise growth control and in-situ analysis makes MBE the pre-eminent technology to meet such demands.

14.3.2 Reaction Mechanisms

One of the first and most important of the in-situ analytical techniques to be used in MBE is reflection high-energy electron diffraction (RHEED). From an early stage [14.126], it was used to determine the surface structure of the clean substrate and growing layer. This revealed that, in general, all surfaces are reconstructed, that is, have a lower symmetry than the bulk, and Cho was the first to propose that the twofold periodicity observed in the [$\bar{1}$ 10] direction on the (001) surface was the result of dimerization of As atoms on the arsenic-terminated surface, which was confirmed many years later by scanning tunneling microscopy [14.127]. RHEED is a forward-scattering technique and therefore more compatible with the MBE arrangement of normally incident fluxes than the back-scattering geometry of LEED.

A further application of RHEED is the in-situ measurement of growth rate. It was found [14.128, 129] that the intensity of any diffraction feature oscillated with a period corresponding to the growth of a single monolayer (ML), that is, a layer of Ga + As, in the [001] direction on a (001) substrate. These oscillations arise from surface morphological changes during two-dimensional (2-D) layer-by-layer growth, the Frank–van der Merwe mode, and a typical result for GaAs is shown in Fig. 14.19. The exact origin of the oscillations is still a subject of debate [14.114] but the technique was found to be applicable to many other material systems, including elemental semiconductors, metals, insulators, superconductors, and even organic compounds.

Thus RHEED provided information on surface reconstruction and quantitative measurements of growth dynamics, which could be combined with that from other in-situ techniques and related to theoretical treatments. In the early 1970s, the surface chemistry involved in the MBE growth of III–V compounds was studied extensively using a combination of RHEED and modulated molecular beam mass spectrometry [14.130] or temperature-programmed desorption [14.131].

Detailed information was obtained on surface reactions involving gallium and arsenic. It was found that the dissociation of GaAs results in the desorption of As_2, and not of As or As_4 [14.132], and that a significant amount of desorption takes place at MBE growth temperatures. The sublimation of elemental arsenic, as from an effusion cell, results in the formation of As_4 alone [14.130]. It was also shown that growth from Ga + As_2 is a first-order reaction (Fig. 14.20), whereas growth from Ga + As_4 is second order. These results suggest that in MBE growth Ga sticks to available As sites and chemisorption of As_2 occurs on available Ga atoms. Chemisorption of As_4 occurs with 2 As_4 molecules interacting on adjacent Ga atoms. The sticking coefficient of As_4 is observed to be less than or equal to 0.5, whereas the sticking coefficient of As_2 can be equal to 1, in agreement with this model. This implies that maximum coverage will be less than 100%, since single Ga sites cannot be occupied, and that As vacancies will be introduced into material grown using As_4. This was thought to be responsible for the higher deep level concentrations observed, which were found to be reduced when As_2 was used or at higher growth temperatures. It is now known that above 580 °C, As_4 dissociates to As_2 on the surface [14.133].

Detailed models were established for the growth of GaAs [14.134, 135] and AlAs [14.136]. With minor modifications, these models are also valid for ternary alloys such as AlGaAs [14.137]. It was established that growth rate depends solely on the net group III flux (i. e., incident flux minus desorbing flux), and that

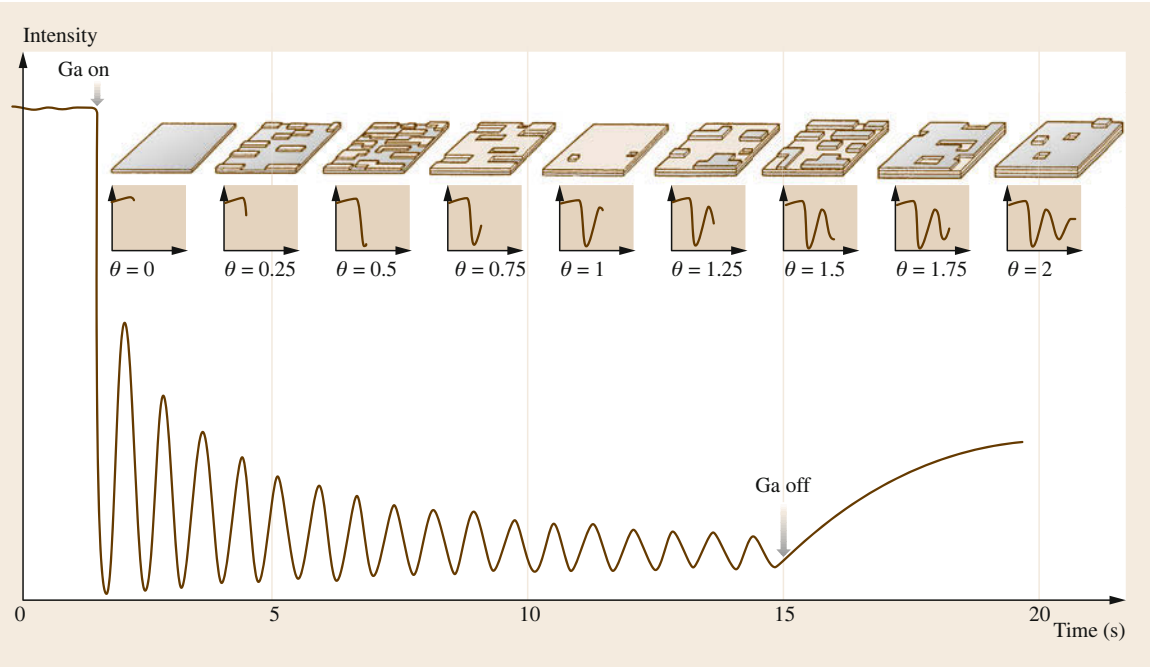

Fig. 14.19 Diagram illustrating the development of RHEED intensity oscillations during 2-D layer-by-layer growth, together with an actual experimental plot. (Courtesy of B.A. Joyce)

ternary alloy composition can be controlled by adjusting the ratio of the group III fluxes provided account is taken of the thermal stability of both of the binary compounds that make up the alloy. The group V element need only be supplied in excess. The situation is more complicated for alloys containing both arsenic and phosphorus, since the presence of one group V element influences the sticking coefficient of the other. *Foxon* et al. [14.138] found that phosphorus has a much lower incorporation probability than arsenic.

More recent studies have made use of in-situ STM and more powerful theoretical treatments to consider nucleation and growth at the atomistic level, but the basic models are still sound.

14.3.3 MBE Growth Systems

The UHV system required for MBE is of conventional stainless steel construction, with an ultimate or background vacuum of less than 5×10^{-11} torr achievable with a clean system after baking, and with the liquid-nitrogen cryopanels filled. At such a pressure, molecules have a typical mean free path of 10^6 m and so only suffer collisions with the internal surfaces of the system. It would take several hours to build up a monolayer of impurity on the wafer surface.

Oil-free pumping is used to eliminate the possibility of contamination by hydrocarbon backstreaming, typically rough pumping is with sorption pumps and UHV pumping is with ion pumps and titanium sublimation pumps. Diffusion pumps or turbomolecular pumps can be used, however, provided suitable cold-traps are fitted, and such pumps are required for the higher gas loads involved in GSMBE and CBE. A two- or three-stage substrate entry load-lock and preparation chamber isolated by gate valves is used to minimize the system

exposure to air. In modular systems, further deposition and analysis chambers may be added to the system and samples are transferred via the preparation chamber under UHV conditions.

The growth chamber substrate stage is surrounded by a large liquid-nitrogen-cooled cryopanel, which has a high pumping speed for H_2O, CO, O_2, and other condensable species. This is arranged so that the heated (500–700 °C) substrate is not directly exposed to thermal sources other than the molecular beams themselves, and impurities emanating from any other source can only reach the substrate after suffering at least one collision with, and probable adsorption by, a surface at liquid-nitrogen temperatures. The cryopanel also reduces contamination arising from outgassing from the walls of the chamber that are exposed to radiation from the effusion cells.

Control over the composition and doping levels of the epitaxial layers is achieved by precise temperature control of the effusion cells and the use of fast-acting shutters in front of these cells. In most systems, the growth rate is about 1 monolayer per second, and the shutter operation time of 0.1 s thus corresponds to less than a monolayer of growth. A growth rate of 1 monolayer per second is closely approximate to 1 μm/h for GaAs/AlGaAs.

Although often referred to as K-cells, the solid-source effusion cells used in MBE growth have a large orifice so as to obtain a high flux at reasonable temperatures. A true Knudsen cell has a very small outlet orifice compared to the evaporating surface so that an equilibrium vapor pressure, typically 10^{-3} torr, is maintained within the cell. The diameter of this orifice is less than one-tenth of the molecular mean free path, which is typically several centimeters. Under these conditions, a near approximation to ideal Knudsen effusion is obtained from the cell, giving molecular flow with an approximately cosine distribution. The flux from such a cell can be calculated quite accurately, but a high temperature is required to produce a reasonable growth rate, for example a gallium Knudsen cell would need to be at 1500 °C to produce the same flux as an open-ended effusion cell at 1000 °C. The lower operating temperature helps to reduce impurities in the flux and puts a lower thermal load on the system. The beam from an open-ended cell may not be calculable with any degree of accuracy but it is highly reproducible. Once calibrated via growth rate, normally by in-situ measurement, the flux can be monitored using an ion gauge located on the substrate stage.

A number of effusion cells can be fitted to the growth chamber, generally in a ring facing toward the substrate with the axis of each cell at an angle of 20–25 °C to the substrate normal. Simple geometrical considerations, therefore, dictate the best possible uniformity that can be achieved with a stationary substrate [14.139]. Associated with each cell is a fast action refractory metal shutter with either pneumatic or solenoid operation.

Uniformity of growth rate for a binary compound can be achieved by rotating the substrate at speeds as low as a few rpm, but compositional uniformity of ternary or quaternary alloys requires rotation of the substrate at speeds of up to 120 rpm (normally rotation is timed so that one rotation corresponds to the growth of one monolayer). The mechanical requirements for a rotating substrate stage in a UHV system are quite demanding, as no conventional lubricants can be used on the bearings or feedthroughs and yet lifetime must exceed several million rotations. Magnetic rotary feedthroughs have largely replaced the earlier bellows type.

The need to rotate the substrate to give uniformity also leads to complications in substrate-temperature measurement. The substrate is heated by radiation from a set of resistively heated tantalum foils behind the substrate holder, and both the heater and the thermocouple are stationary. Without direct contact between the thermocouple and the wafer, the *indicated* thermocouple temperature will be very different from the *actual* substrate temperature. Some form of calibration can be obtained by using a pyrometer, although problems of window coating, emissivity change, and of substrate transparency below the bandgap impose limits on the accuracy of such measurements. Alternatively, a number of *absolute* temperature measurements can be obtained by observing transitions in the RHEED pattern, which occur at reasonably fixed temperatures. However, such transitions occur in the lower temperature range and extrapolation to higher growth temperatures is not completely reliable. If the substrate is indium bonded to a molybdenum block (using the surface tension of the indium to hold the substrate), then inconsistencies in wetting can lead to variations in temperature across the substrate. Most modern systems and all production machines use *indium-free* mounting, which avoids these problems. However, the substrate is transparent to much of the IR radiation from the heater, putting a higher thermal load on the system.

The substrate-preparation techniques used prior to MBE growth are very important, as impurities on the surface provide nucleation sites for defects. Historically, various chemical clean and etch processes were used, but wafers are now usually supplied *epi-ready*, with a volatile oxide film on the surface that protects the surface from contamination and can be thermally removed within the UHV chamber. RHEED is used to confirm the cleanliness of the surface prior to growth.

Historically, one of the major problems in MBE was the presence of macroscopic defects, with a typical density of 10^3–$10^5\,cm^{-2}$, although densities below $300\,cm^{-2}$ were reported for ultraclean systems [14.140]. Defects are generally divided into two types: small hillocks or pits and oval defects. Such defects are a serious obstacle to the growth of material for integrated circuits, and considerable effort was devoted to the problem. Oval defects are microtwin defects originating at a local imperfection, oriented in the [14.141] direction and typically 1–10 μm in length [14.142]. There are several possible sources of these defects, including foreign impurities on the substrate surface due to inadequate substrate preparation or to oxides from within the system, and possibly from the arsenic charge or the condensate on the cryopanels. The fact that oval defects were not seen when graphite crucibles were used but were common with PBN crucibles suggests that gallium oxide from the gallium melt is a major source of such defects since oxides would be reduced by the graphite. *Chai* and *Chow* [14.143] demonstrated a significant reduction in defects by careful charging of the gallium source and prolonged baking of the system. The irregular hillocks and pits seen in MBE-grown material were probably produced by microdroplets of gallium spitting from the effusion cells on to the substrate surface [14.144]. Gallium spitting can be caused by droplets of Ga that condense at the mouth of the effusion cell, fall back into the melt and explode, ejecting droplets of liquid Ga, or by turbulence in the Ga melt due to uneven heating that causes a sudden release of vapor and droplets.

Continuous developments in the design of group III effusion cells for solid-source MBE have largely eliminated the problem of macroscopic defects. Large-area Ta foil K-cell heaters reduced the uneven heating of the PBN crucible; the use of a *hot-lipped* or two-temperature group III cell, designed with a high-temperature front end to eliminate the condensation of gallium metal at the mouth of the cell, significantly reduced the spitting of microdroplets. Combined with careful procedures and the use of an arsenic cracker, cell defect densities as low as $10\,cm^{-2}$ have been reported [14.145].

There have also been developments in the design of group V cells. A conventional arsenic effusion cell produces a flux of As_4 [14.134], but the use of a thermal cracker to produce an As_2 flux resulted in the growth of GaAs with better optical properties and lower deep-level concentrations [14.146]. In the case of phosphorus, growth from P_2 was strongly preferred to that from P_4 for several reasons [14.147] and this was one reason behind the development of GSMBE described below. However, the use of phosphine requires suitable pumping and safety systems. The group V cracker cell has two distinct zones. The first comprises the As or P reservoir and produces a controlled flux of the tetramer; this passes through the second – high-temperature – zone, where dissociation to the dimer occurs. Commercial high-capacity cracker cells, some including a valve between the two zones to allow fast switching of group V flux, have been developed for arsenic and phosphorus.

Commercial MBE systems have increased throughput with multiwafer substrate holders, cassette loading and UHV storage, and preparation chambers linked to the growth chamber with automated transfer, while increased capacity effusion cells have reduced the downtime required for charging. In some cases, additional analytical and processing chambers have been added to permit all UHV processing of the device structure.

14.3.4 Gas Sources in MBE

A number of MBE hybrids were developed that combined the advantages of UHV deposition and external gas or metal-organic sources to produce a versatile technique that has some advantages over MBE and MOVPE. These techniques utilize the growth chambers developed for MBE and pumping systems with a high continuous throughput, typically liquid-nitrogen-trapped diffusion pumps or turbomolecular pumps. Layers are deposited from molecular beams of the precursor materials introduced via gas-source cells that are essentially very fine leak controllers. As in MBE, there are no interactions within or between beams and the precise control of beams using fast-acting gas-line valves is, therefore, translated into precise control of the species arriving at the substrate. Shutters are not generally required; atomically sharp interfaces and monolayer structures can be defined as a consequence of submonolayer valve switching times.

Panish [14.148] investigated the use of cracked arsine and phosphine in the epitaxial growth of GaAs and InP, later extending this work to the growth of GaInAsP, and suggested the name gas source MBE (GSMBE). The major advantage of gaseous group V sources was that the cracker cells produced controllable fluxes of the dimers As_2 and P_2, giving improved control of the As:P ratio. The MBE growth of high-quality GaAs from cracked arsine and elemental gallium was demonstrated at the same time by *Calawa* [14.149].

The extension to gaseous group III sources was made by *Veuhoff* et al. [14.150], who investigated the MOCVD of GaAs in a simple MBE system using trimethylgallium (TMGa) and uncracked arsine. Further study showed that cracking of arsine at the substrate surface was negligible, leading to the conclusion

that unintentional cracking of the arsine had taken place in the inlet system. The acronym metal-organic MBE (MOMBE) was used to describe GaAs growth from TMGa and cracked arsine in a modified commercial MBE system [14.151].

The growth of device-quality GaAs, InGaAs, and InP from alkyl sources of both group III and group V elements was demonstrated by *Tsang* [14.152], who used the alternative acronym chemical beam epitaxy (CBE). The use of group V alkyls, which had much poorer purity than the hydrides, was undertaken for safety reasons [14.153]. Material quality was improved when cracked arsine and phosphine were used [14.154]. RHEED observations indicated that reconstructed semiconductor surfaces could be produced prior to growth as for MBE [14.155] and GaAs/AlGaAs quantum well structures were demonstrated that were comparable with those grown by MBE or MOVPE [14.156].

Almost all this work was with III–Vs, where MOMBE/CBE was seen to have several significant advantages over MBE while retaining many of its strengths, including in-situ diagnostics. The use of vapor group III sources would avoid the morphological defects associated with effusion cells, and higher growth rate and greater throughput could be achieved. Both group III and group V sources were external, allowing for easy replacement without the need to break vacuum. Flux control with mass flow controllers (MFCs) and valves would improve control of changes in composition or doping level, since flow could be changed faster than effusion-cell temperature. Abrupt changes could be thus achieved that would require switching between two preset effusion cells in MBE (a problem when the number of cells was limited by geometry). It also offered improved long-term flux stability and greater precursor flexibility. As this was still a molecular-beam technique, precise control of layer growth and abrupt interfaces would be retained, without any of the gas-phase reactions, boundary-layer problems, or depletion of reagents associated with MOVPE. Other advantages included improved InP quality using a P_2 flux, lower growth temperatures, and selective area epitaxy.

There was, however, a price to pay in system complexity, with the need for gas handling and high-volume pumping arrangements added to the expensive UHV growth chamber. These would have been acceptable if CBE had demonstrated clear advantages but there were a number of other issues. The standard Al and Ga precursors used in MOVPE (trimethylaluminum and trimethylgallium) produced strongly p-type material when used in CBE, due to the incorporation of C as an acceptor. Triethylgallium proved to be a viable Ga source, but alloy growth was more complicated; no universally acceptable Al source was found, while InGaAs growth was found to be strongly temperature dependent. The surface chemistry involved with metal-organic sources proved complex and the temperature dependence of surface reactions not only restricted growth conditions, but also had a serious impact on uniformity and reproducibility, particularly for quaternary alloys such as GaInAsP [14.157]. The lack of suitable gaseous dopant sources, particularly for Si, was a further handicap [14.158], but the deliberate use of C for p-type doping proved a success and this was transferred to MBE and MOVPE. Carbon diffuses significantly less than the *standard* MBE and MOVPE dopants, Be and Zn, respectively [14.159], and proved an ideal dopant for thin highly doped layers such as the base region in heterojunction bipolar transistors (HBTs) and for p-type Bragg reflector stacks in vertical cavity surface emitting laser structures (VCSELs).

GSMBE remains important, not in the III–V field where, with some exceptions [14.160], the development of high-capacity group V cracker cells provided an easier route to an As_2 and P_2 flux, but in the III-nitride field. There are two major routes to nitride MBE: active nitrogen can be supplied by cracking N_2 in an RF or ECR plasma cell, or ammonia can be injected and allowed to dissociate on the substrate surface. In contrast, CBE has not demonstrated a sufficient advantage over its parent technologies to be commercially successful, particularly as both MOVPE and MBE have continued to develop as production techniques.

14.3.5 Growth of III–V Materials by MBE

Although they were among the earliest materials to be grown by MBE, GaAs-based alloys retain great importance, with MBE supplying materials for the mass production of optoelectronic and microwave devices and leading research into new structures and devices.

GaAs/AlGaAs

AlGaAs is an ideal material for heterostructures, since AlAs has a greater bandgap than GaAs and the two have negligible mismatch ($\approx 0.001\%$). The growth rate in MBE depends on the net group III flux, with $1\,\mu m/h$ corresponding to a flux of 6.25×10^{14} Ga (or Al) atoms $cm^{-2}\ s^{-1}$. At low-growth temperatures, all incident group III atoms are incorporated into the growing film, together with sufficient arsenic atoms to maintain stoichiometry, and excess arsenic atoms are desorbed. However, III–V compounds are thermally unstable at high temperatures. Above $\approx 600\,K$ [14.134] arsenic is preferentially desorbed, so an excess arsenic flux is required to maintain stoichiometry. At higher temperatures, loss of the group III element becomes significant so that the growth rate is less than would be expected for

the incident flux. This is particularly important for the growth of AlGaAs, where growth temperatures above 650 °C are generally used to give the best optical properties. The Ga flux has to be significantly increased above that used at lower temperatures in order to maintain the required composition of the alloy.

Typical growth temperatures for MBE of GaAs are in the range 580–650 °C and material with high purity and low deep-level concentrations has been obtained in this temperature range [14.161, 162]. The commonly used dopants, Be (p-type) and Si (n-type), show excellent incorporation behavior and electrical activity at these temperatures and at moderate doping levels. As was noted above, for highly doped layers Be has largely been replaced by C, which diffuses significantly more slowly. At doping levels above $\approx 5\times10^{17}$, Si occupies both Ga (donor) and As (acceptor) sites, producing electrically compensated material with a consequent reduction in mobility. It is still predominantly a donor, however, and is the best available n-type dopant. The electrical properties of GaAs also depend on the As/Ga flux ratio, since this influences the site occupancy of dopants. The optimum As/Ga ratio is that which just maintains As-stabilized growth conditions, which can be determined using RHEED observations of surface reconstruction.

MBE-grown GaAs is normally p-type, the dominant impurity being carbon [14.163]. The carbon concentration was found to correlate with CO partial pressure during growth [14.164] – CO is a common background species in UHV, being synthesized at hot filaments. The lowest acceptor levels commonly achieved are of the order of $5\times10^{13}\,\mathrm{cm}^{-3}$ and such layers can be lightly doped to give n-type material with high mobilities. However, very high purity GaAs has been produced by adjusting the operating conditions for an arsenic cracker cell [14.141], which suggests that carbon contamination originates from hydrocarbons in the As charge. Unintentionally doped GaAs was n-type with a total impurity concentration of $< 5\times10^{13}\,\mathrm{cm}^{-3}$ and a peak mobility of $4\times10^{5}\,\mathrm{cm}^2\,\mathrm{V}^{-1}\,\mathrm{s}^{-1}$ at 40 K, the highest reported for n-type GaAs. The 77 K mobility of $> 200\,000\,\mathrm{cm}^2\,\mathrm{V}^{-1}\,\mathrm{s}^{-1}$ is comparable with that for the highest purity GaAs grown by LPE [14.165].

MBE is capable of the growth of such high-quality material for structures whose physical dimensions are comparable to the wavelength of an electron (or hole) so that quantum size effects are important. Such structures have typical layer thicknesses from 100 Å down to 2.8 Å, the thickness of a monolayer of GaAs, and have doping and composition profiles defined on an atomic scale. These low-dimensional structures have become very important in III–V device technology, one example being the modulation-doped heterojunction.

The precise control of growth that is possible is demonstrated by the very high mobilities obtained for modulation-doped structures grown by MBE. The modulation-doped GaAs/AlGaAs heterojunction has a band structure that causes carriers from the highly doped AlGaAs to be injected into a thin undoped region in the GaAs (Fig. 14.21a). Since the carriers are now separated from the donor atoms that normally scatter them, and confined in a quantum well as a two-dimensional electron gas (2DEG), very high mobilities can be achieved. By suitable design of the structure and the use of lightly doped AlGaAs, a GaAs/AlGaAs 2DEG structure was produced with a peak mobility of $1.1\times10^{7}\,\mathrm{cm}^2\,\mathrm{V}^{-1}\,\mathrm{s}^{-1}$ at 1.3 K and 4 K mobility of $4.5\times10^{6}\,\mathrm{cm}^2\,\mathrm{V}^{-1}\,\mathrm{s}^{-1}$ and with a sheet carrier concentration of $10^{12}\,\mathrm{cm}^{-2}$ [14.166]. GaAs layers grown in the same machine typically exhibited 77 K mobilities of the order of $100\,000\,\mathrm{cm}^2\,\mathrm{V}^{-1}\,\mathrm{s}^{-1}$. Similar results can be obtained by delta doping the AlGaAs, that is, by confining the Si donor atoms to a single monolayer in the

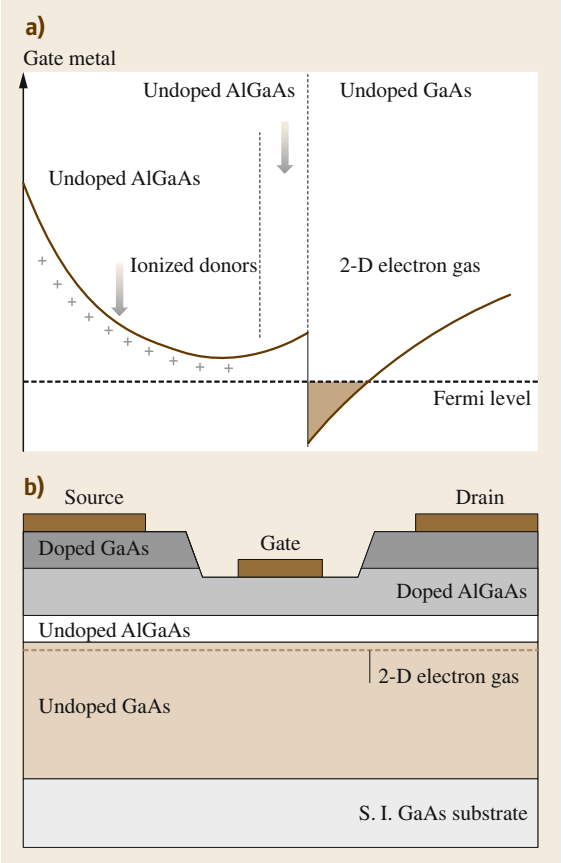

Fig. 14.21a,b Schematic diagrams of the band structure **(a)** and physical arrangement **(b)** of the high electron mobility transistor (HEMT)/modulation doped FET

AlGaAs separated by a few nanometer from the well, a technique with a wide range of applications [14.167]. The major application of this structure for device purposes is the high electron mobility transistor (HEMT), also known as the modulation-doped FET (MODFET), an FET in which the carriers are confined to the two-dimensional layer (Fig. 14.21b). The main advantage of the HEMT is not the increase in mobility, which is modest at room temperature for a practical device, but the very low noise when it is operated as a microwave amplifier, due to the reduction in impurity scattering. The HEMT is an essential component of many microwave systems, including mobile phones and satellite TV receivers.

MBE became used as a production technology for GaAs-based devices because of the excellent uniformity and reproducibility possible, and because the extensive UHV load-lock system of a production machine permits a large number of runs to be undertaken on a continuous basis. This was demonstrated as early as 1991 by a number of manufacturers producing both HEMTs and GaAs/AlGaAs lasers [14.168]. By 1994 some 5 million MQW lasers for compact disc applications were produced per month by MBE. Other devices included HEMTs and InAs Hall sensors. A comparison of production costs made at this time [14.169] showed that capital costs for MBE were very similar to those for MOVPE, which required costly safety systems for the hydride gases, while MBE costs per wafer were somewhat less than for MOVPE. The growth in demand for HEMTs for mobile phones drove a further expansion in production MBE, although MOVPE remained dominant in InP-based optoelectronic devices.

InGaAs

InGaAs is generally grown at lower temperatures than GaAs/AlGaAs because of the higher rate of In desorption. Both InGaAs and the quaternary InGaAsP can be lattice matched to InP substrates; heterostructures in these materials form the basis of the 1.3 and 1.55 μm optoelectronic devices used in telecommunications. InAs has a lattice mismatch of $\approx 7\%$ with GaAs; thin films of InGaAs can be deposited pseudomorphically but as the In content is increased the critical thickness falls so that little more than a ML of InAs can be grown in this way. Thicker films will be relaxed by the formation of dislocations, limiting their usefulness for devices. The pseudomorphic HEMT (or pHEMT) replaces the GaAs channel of the conventional HEMT with a strained InGaAs channel in order to take advantage of the greater carrier confinement and superior electron transport properties. The maximum In content of the channel is limited by the need to prevent relaxation.

Under certain growth conditions, InAs or InGaAs islands are spontaneously formed. It is generally accepted that the growth of InAs on GaAs (001) follows a version of the Stranski–Krastanov mode, which implies that following the deposition of ≈ 1.7 ML of InAs in a 2-D pseudomorphic form (sometimes referred to as the wetting layer), coherent 3-D growth is initiated by a very small increment (≤ 0.1 ML) of deposited material, to relax the elastic strain introduced by the lattice mismatch. The QDs rapidly reach a saturation number density, which is both temperature and In flux dependent, with a comparatively narrow size (volume) distribution. The actual process is rather more complicated, not least as a result of alloying with the GaAs substrate, and is the subject of much current research [14.114].

These islands can be embedded in a layer of GaAs to form self-assembled QDs, which have become a topic of immense interest due to the potential application of QDs in a wide range of devices, especially lasers. The volume fraction of QDs in an active layer can be increased by building up a 3-D array; the strain field induced around each dot influences not only the inter-dot spacing but also the capping layer growth so that subsequent layers of dots are aligned ([14.125] and references therein). QD lasers offer a route to long-wavelength emission from GaAs-based devices [14.170].

III–Nitrides

The growth of group III nitrides has been dominated by MOVPE since the demonstration of a high-brightness blue-emitting InGaN-AlGaN double heterostructure LED by Nichia [14.171] and the subsequent development of other optoelectronic devices, including laser diodes also emitting in the blue [14.172]. MBE has made a significant contribution to more fundamental studies and to the growth of nitrides for high-power and microwave devices. Once again, the wide range of in-situ diagnostic techniques available has been important.

For heteroepitaxial growth on the most commonly used substrates, sapphire and silicon carbide, several parameters strongly influence the quality of material produced. These include substrate cleaning, initial nitridation, the nucleation and coalescence of islands involved in the low-temperature growth of a buffer layer, and subsequent annealing at a higher temperature. The polarity (nature of the outermost layer of atoms) of {0001}-oriented hexagonal structure films also has a crucial influence on material quality, but both N- or Ga-polarity can occur with MBE growth on sapphire substrates [14.173]. Under typical growth conditions with MOVPE, however, Ga-polarity material is exclusively produced.

Several of these problems can be resolved using GaN templates obtained by growing thick layers on to suitable substrates using MOVPE and then exploiting the advantages of MBE to produce the functional layer on the GaN template. These advantages include well-controlled layer-by-layer growth and lower growth temperatures than those used for MOVPE so that InGaN phase separation and In desorption are less problematic and precise quantum wells can be grown. No post-growth thermal annealing is required to activate the p-type dopant. In this way films have been produced with smooth surface morphology and high performance, although MBE was still limited to low-power LEDs until the recent demonstration of laser diodes [14.174].

In the use of active nitrogen from plasma sources, the III/V flux ratio at the substrate during growth is also a critical parameter. GaN layers grown with a low III/V flux ratio (N-stable growth) display a facetted surface morphology and a tilted columnar structure with a high density of stacking faults. Smooth surfaces are only obtained under Ga-rich conditions, where not only is there a dramatic reduction of surface roughness, but significant improvements in structural and electrical properties are also observed. This is, of course, the exact opposite of the growth of most III–V compounds, such as GaAs. In the case of nitrides, it is thought that Ga-rich conditions (close to the point where Ga droplets are formed) promote step flow growth, whereas N-stable growth promotes the nucleation of new islands. In contrast, growth from NH_3 is smoother under N-rich conditions [14.175].

III–V-Nitrides

The *dilute nitrides* are III–V–N materials such as GaAsN and GaInNAs, where the N concentration is $\leq 2\%$. Replacing a small fraction of As atoms with smaller N atoms reduces both the lattice constant, and the bandgap. Adjusting the composition of GaInNAs allows the bandgap, band alignment, lattice constant and strain to be tailored in a material that can be lattice matched with GaAs [14.176]. This offers strong carrier confinement and thermal stability compared to InP-based devices operating at 1.3 and 1.55 μm, and allows GaAs VCSEL technology to be exploited at these wavelengths [14.177].

These materials are grown in a metastable regime at a low-growth temperature because of the miscibility gap in the alloys, so a less-stable precursor than NH_3 is needed. A nitrogen-plasma source provides active N without the incorporation of hydrogen during growth associated with hydride sources, thus avoiding the deleterious formation of N–H bonds. Material with excellent crystallinity and strong PL at 1.3 μm can be obtained by optimizing growth conditions and using post-growth rapid thermal annealing [14.178]. A number of challenges remain, particularly in the higher N material required for longer wavelengths, including the limited solubility of N in GaAs and nonradiative defects caused by ion damage from the N plasma source. These challenges may be met by using GaInNAsSb the addition of Sb significantly improves the epitaxial growth and the material properties, and enhanced luminescence is obtained at wavelengths longer than 1.3 μm [14.179].

14.3.6 Conclusions

MBE, historically seen as centered on GaAs-based electronic devices, has broadened its scope dramatically in both materials and devices. In addition to the materials described above, MBE has been used to grow epitaxial films of a wide range of semiconductors, including other III–V materials such as InGaAsP/InP and GaAsSb/InAsSb; silicon and silicon/germanium; II–VI materials such as ZnSe; dilute magnetic semiconductors such as GaAs:Mn [14.180] and other magnetic materials. It has also been used for the growth of metals, including epitaxial contact for devices, oxides [14.181]; and organic films [14.182]. Two clear advantages possessed by MBE are the wide range of analytical techniques compatible with a UHV system and the precise control of growth to less than a monolayer, which confer unrivalled capability in the growth of quantum dots and other nanostructures.

15. Narrow Bandgap II–VI Semiconductors: Growth

Peter Capper

The field of narrow bandgap II–VI semiconductors is dominated by the compound $Hg_{1-x}Cd_xTe$ (MCT), although some Hg-based alternatives to this ternary have also been suggested. The fact that MCT is still the preeminent infrared (IR) material stems, in part, from the fact that by varying the x value material can be made to cover all the IR regions of interest. In addition, the direct band transitions are responsible for large values of absorption coefficients, allowing quantum efficiencies to approach 100%. Long minority carrier lifetimes result in low thermal noise allowing high-performance detectors to be made at the highest operating temperatures of comparable wavelengths. This chapter covers the growth of MCT by various bulk growth techniques, used mainly for first-generation infrared detectors; by liquid phase epitaxy, used mainly for second-generation infrared detectors; and by metal-organic vapor phase and molecular beam epitaxies, used mainly for third-generation infrared detectors.

The field of narrow bandgap II-VI semiconductors is dominated by the compound $Hg_{1-x}Cd_xTe$ (MCT) [15.1–10], although some Hg-based alternatives to this ternary have been suggested and are discussed by *Rogalski* [15.11]. The fact that MCT is still the preeminent infrared (IR) material stems, in part, from the fact that by varying the x value material can be made to cover all the IR regions of interest. In addition, the direct band transitions are responsible for large values of absorption coefficients, allowing quantum efficiencies to approach 100%. Long minority carrier lifetimes result in low thermal noise allowing high-performance detectors to be made at the highest operating temperatures of comparable wavelengths. These three major advantages all stem from the energy band structure of the material and they apply to whichever device architecture is being used. It is thought that MCT is the third most studied semiconductor after silicon and gallium arsenide. This chapter covers the growth and characterization of MCT, mainly concentrating on the x region between 0.2 and 0.4 where the majority of applications are satisfied, and some of the Hg-based alternative ternary systems first described by Rogalski. Detectors made from these materials will be described in Chap. 34 in this Handbook.

In the first section, the growth of MCT by various bulk techniques is reviewed. These include solid-state recrystallization (SSR), Bridgman (plus the accelerated crucible rotation technique, ACRT) and the traveling heater method (THM), employing a Te zone. Despite the major advances made over the last three decades in the various epitaxial processes, which are discussed in subsequent sections, bulk techniques for MCT are still used for some photoconductive devices and for some niche applications, for example large-area optical components, and for large-size CdTe-based materials for substrates for MCT [15.10, Chaps. 3 and 4]. MCT material grown by LPE is currently in production for large-area focal plane arrays (FPAs) for both terrestrial and space thermal imaging applications. More complex,

fully doped heterostructures are being grown by metal-organic vapor phase epitaxy (MOVPE) and molecular beam epitaxy (MBE) for FPAs and novel nonequilibrium device structures.

For a fuller treatment of the topic matter in this chapter, plus further details of the characterization of MCT by various optical, electrical and structural means, the reader is referred to [15.1, Sect. A], [15.2, Chaps. 1–11], [15.3, Chaps. 1, 2, 10–12], [15.4, Chap. 7], *Baker* [15.5], [15.6, Chap. 7], and [15.7–10], including a useful list of books/papers in the Foreword of [15.10] by *Reine*.

15.1 Bulk Growth Techniques

Despite the large amount of progress that has taken place in various epitaxial growth techniques for MCT, bulk growth methods still play a key role in preparing device-quality material and in producing substrates for these epitaxial techniques. A critical aspect of these techniques is the establishment of a thorough knowledge of the relevant phase equilibria, and a brief description of these for MCT is now given.

15.1.1 Phase Equilibria

The understanding of two types of equilibria is of critical importance. One is the solid compound in equilibrium with the gaseous phase (vapor growth) and the other is solid–liquid–gaseous equilibria (growth from liquid/melt). These phase equilibria also help in understanding postgrowth heat treatments, either during cooldown to room temperature or during annealing processes to adjust the stoichiometry, and hence the electrical properties of compounds. Solid–liquid–gaseous equilibria are described by three variables, temperature (T), pressure (P) and composition (x). It is, however, far easier to understand the interrelations between these parameters by using two-dimensional (2-D) projections such as T–x, P–T and P–x plots.

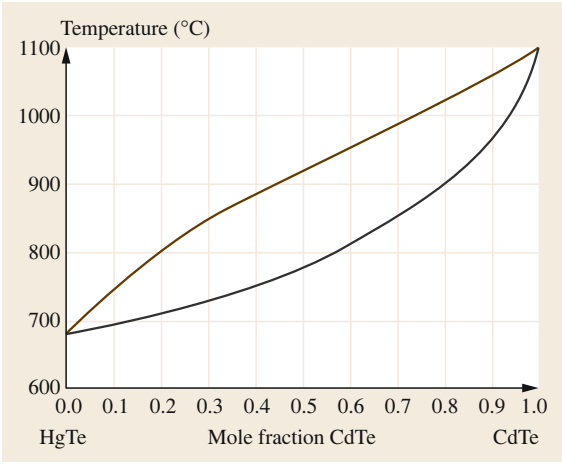

Fig. 15.1 T–x phase diagram for the pseudobinary CdTe-HgTe. (After [15.1])

A great deal of work has been carried out on the various phase equilibria ([15.1] contains reviews in this area). The liquidus and solidus lines in the pseudobinary HgTe-CdTe system are shown in Fig. 15.1. The wide separation between the liquidus and solidus, leading to marked segregation between the constituent binaries, CdTe and HgTe, was fundamental in the development of all the bulk growth techniques applied to this system. In addition to the solidus–liquidus separation high Hg partial pressures are also influential both during growth and postgrowth heat treatments. A full appreciation of the $P_{(Hg)}$–T diagram, shown in Fig. 15.2, is therefore essential. The curves are the partial pressures of Hg along boundaries for solid solutions of composition x where the solid solution is in equilibrium with another condensed phase as well as the vapor phase. For $x = 0.1$ and $10^3/T = 1.3$ (K^{-1}) MCT exists for Hg pressures between ≈ 0.1 (Te-saturated) and ≈ 7 (Hg-saturated) atm. Even at $x = 0.95$ and Te-saturated

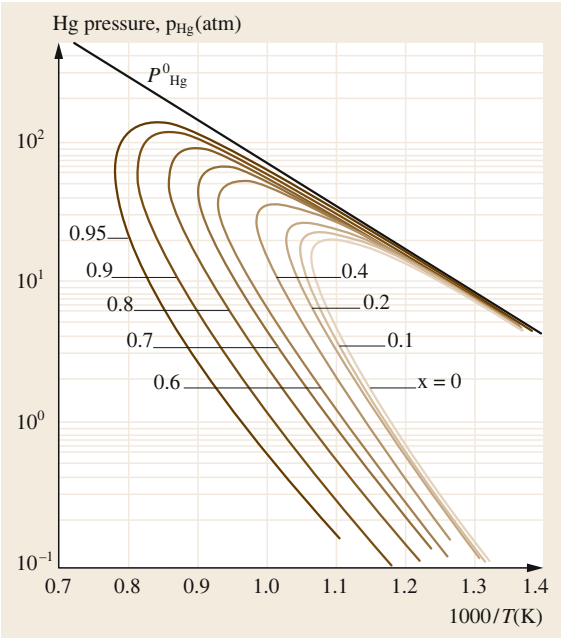

Fig. 15.2 P–T diagram for $Hg_{1-x}Cd_xTe$ (MCT). (After [15.1])

conditions, Hg is the predominant vapor species. It should also be noted that no solid solution contains exactly 0.5 atomic fraction Te. These features are highly significant in controlling the native defect concentrations and hence electrical properties in MCT.

15.1.2 Crystal Growth

Growth from the melt has constituted the vast majority of work on bulk growth of MCT, and material grown by bulk methods is still in use, particularly for photoconductive detectors. Several historical reviews have been published [15.1, 12–14]. *Micklethwaite* [15.12] and *Kruse* [15.13] gave detailed discussions on the growth techniques and material characterization prior to 1980. This situation up to 2005 was also summarized by this author [15.4, Chap. 7], [15.10, Chap. 1]. Many techniques were tried but three prime techniques survived these early attempts: SSR, Bridgman and THM [15.11]; some of which are still in production, for example Bridgman in the UK.

Solid-State Recrystallization (SSR)

This technique is used for ternary systems where there is a wide separation between solidus and liquidus, for example MCT. Other names that have been used for this process are quench anneal (QA) and cast recrystallize anneal (CRA). The term anneal is used in the first case to define a high-temperature grain-growth process, while in CRA it is a low-temperature process to adjust stoichiometry. In the basic technique, pure elements are loaded into a cleaned silica ampoule and the charge is melted and rocked to ensure complete mixing. Charges are then normally quenched rapidly to room temperature in the vertical orientation. This produces a dendritic structure that is reduced/removed by the recrystallization step that occurs at temperatures just below the melting point for many days. Grain growth occurs and microinhomogeneities in composition are removed.

Alternatives to the basic SSR process have included *slush* growth [15.1], high-pressure growth [15.16], incremental quenching [15.17], and horizontal casting [15.18]. In the *slush* process an initial homogeneous charge is prepared and then held across the liquidus-solidus gap with the lower-end solid and the upper-end liquid. High-pressure growth (30 atm He gas) was used in an attempt to reduce structural defects. The *slush* technique was used in production in the USA. Other developments were made in the basic process (e.g., [15.19, 20]) but details available in the open literature are sketchy, due to proprietary constraints. *Tregilgas* [15.21] has given a detailed review of the SSR process.

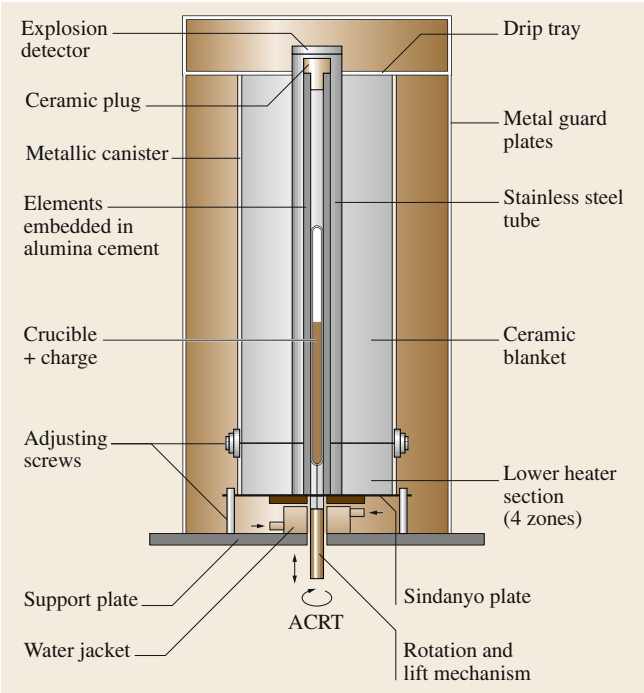

Fig. 15.3 Schematic of Bridgman growth kit for use with Hg-based compounds. (After [15.15])

Bridgman (plus ACRT)

In the standard Bridgman process, elemental Cd, Hg and Te are loaded into a clean silica ampoule, homogenized by melting/rocking and then frozen slowly from one end in a vertical system (Fig. 15.3, [15.15]) to produce a large-grained ingot [15.22]. There is marked segregation of CdTe with respect to HgTe in the axial direction, due to the wide gap between the solidus and liquidus, but this leads to an advantage of the Bridgman process over other techniques, i. e., material in both the main ranges of interest (3–5 and 8–12 μm, i. e., $x = 0.3$ and 0.2, respectively) is produced in a single run. The accelerated crucible rotation technique

Fig. 15.4 Comparison of 20, 40, 50 and 70 mm MCT slices. (Courtesy of Leonardo MW Ltd)

(ACRT) in which the melt is subjected to periodic acceleration/deceleration provided a means of stirring melts contained in sealed, pressurized ampoules.

The first report of ACRT in MCT Bridgman growth was given in [15.23]. These effects were developed and reviewed in [15.1, 4, 22]. Crystals were produced up to 20 mm in diameter and with x values up to 0.6 in the tip regions of some crystals. Currently in this author's laboratory crystals of 20 mm diameter, 200 mm in length weighing 0.5 kg are in routine production, while R&D activities have produced several 40 mm, 50 mm (up to 2.5 kg in weight) and even a 70 mm diameter crystal (Figs. 15.4–15.6 [15.10]). Extensions to the basic ACRT process enable material up to $x \approx 0.93$ (0.91 μm) to be produced in the first-to-freeze regions of crystals (Fig. 15.6 [15.10, 24]). These near-IR slices are highly transmissive and show a high degree of compositional uniformity ($\Delta x \approx 0.0005$) [15.24]. The use of ACRT produced material that enabled the fabrication of small two-dimensional arrays of photodiodes; this material was also used to demonstrate nonequilibrium detector operation and in the production of SPRITE detectors ([15.3, Chap. 11]). *Higgins* et al. [15.25] recently reported the history of their

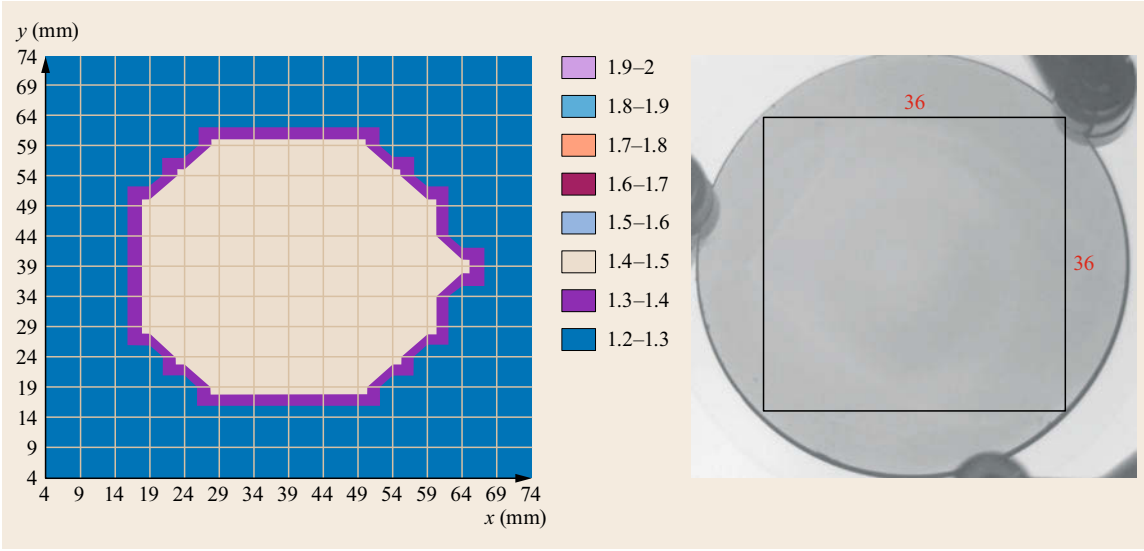

Fig. 15.5 Radial distribution of wavelength (in μm at room temperature) in 50 mm diameter high-x slice from 30% start

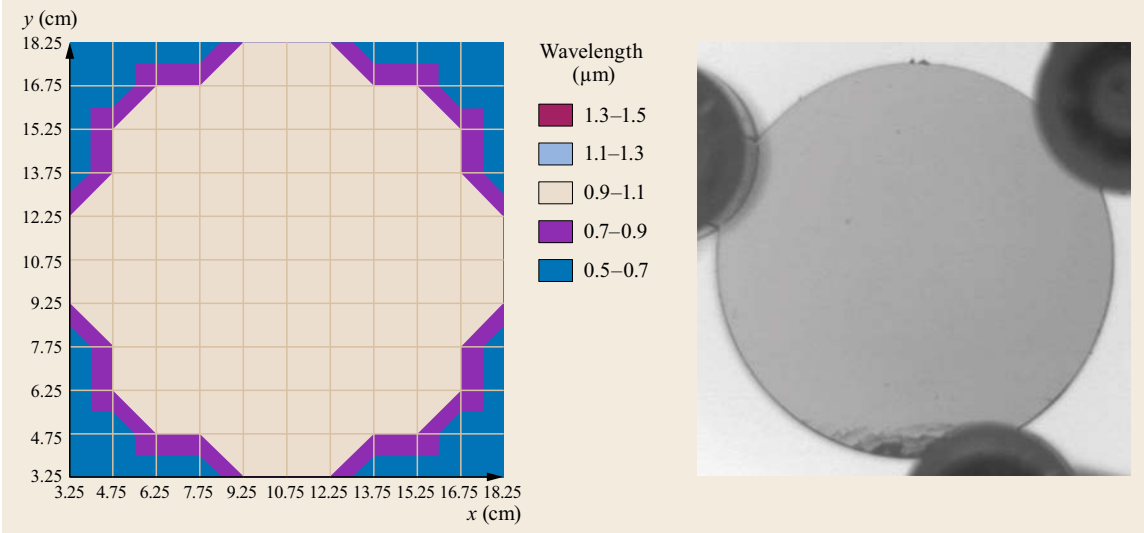

Fig. 15.6 Radial distribution of wavelength (in μm at room temperature – 0.91 μm ≡ $x \approx 0.93$) in 20 mm diameter slice

detector materials engineering (DME) process; in essence they grew crystals vertically at ≈ 700 °C with a piece of high-x MCT floating on the surface of the melt to provide replenishment and overcome the segregation effects. In addition, to increase the growth rate they reduced the boundary layer thickness by adding ACRT. (The authors note that the technique was conceived in 1981, in the same year as the patent [15.23], but not implemented until 1982, i. e., some years after Bridgman/ACRT crystals were being grown in this author's laboratory.) Crystals of 15 mm diameter were grown with good compositional uniformity, low Te precipitate density and high purity.

Traveling Heater Method (THM)

Triboulet [15.26] (and coworkers) developed this technique for MCT where diameters up to 40 mm were accomplished and x values up to 0.7 [15.27] for optical communication devices. *Durand* et al. [15.28] employed seeds to produce large oriented crystals, an advantage of this technique over other bulk methods. *Gille* et al. [15.29] adopted a slightly different approach. A pre-THM step was used to produce a quenched Te-rich (53–60%) MCT melt. The entire growth procedure took several months but gave uniform material. This group also used rotation in the horizontal growth by THM with some success [15.30]. Two groups also applied ACRT to THM and obtained enhanced material properties [15.31, 32].

15.1.3 Material Characterization

Compositional uniformity can be expressed in both axial and radial directions as $\Delta A(x)$ and $\Delta R(x)$, although the combination of the two determines the yield of useful material. Assessment is normally by Fourier transform infrared (FTIR) spectrometry. The recrystallization process (in SSR) improves $\Delta A(x)$ from ± 0.05 to ± 0.02 [15.13] and removes the microinhomogeneity in x in both directions [15.33]. Independent control of axial and radial variations was claimed by *Nelson* et al. [15.34] to achieve ± 0.002 over 95% of slices up to 25 mm in diameter. *Colombo* et al. [15.17] quote $\Delta R(x)$ of 0.005–0.01 in incremental-quenched material. *Su* et al. [15.35] report ± 0.008 for $\Delta A(x)$ and $\Delta R(x)$ in vertically cast material. *Galazka* et al. [15.36] showed that reduced gravity gives smaller $\Delta R(x)$, and they also noted that constitutional supercooling at the first-to-freeze end is also reduced and the growth is diffusion limited.

Bartlett et al. [15.37] grew SSR and Bridgman crystals over a wide range of growth rates and concluded that $\Delta R(x)$ was due to the combination of a concave (to the melt) growth interface and density-driven convective flow within a boundary layer close to the interface. This, added to the normal segregation of the low melting point HgTe to the center of the concave interface, led to the observed variation. It was also concluded that crystals with simultaneous small $\Delta A(x)$ and $\Delta R(x)$ were not possible; slow growth gave low $\Delta R(x)$ while fast growth minimized $\Delta A(x)$. In Bridgman/ACRT material, an 80 mm length at $x = 0.21$ with both $\Delta A(x)$ and $\Delta R(x)$ within ± 0.002, linked to a flat interface produced by strong Ekman flow in the interface region, was reported by *Capper* [15.22]. 20 mm diameter ACRT crystals have been grown that exhibited $\Delta R(x) = \pm 0.003$ at $x = 0.22$ [15.22] and $\Delta R(x) = \pm 0.0005$ at $x = 0.93$ [15.10].

Triboulet et al. [15.14] quoted values of ± 0.02 (over 3 cm at $x = 0.2$) and ± 0.002 for $\Delta A(x)$ and $\Delta R(x)$ respectively, for THM growth at 0.1 mm h^{-1}. For the very slow-grown material produced by *Gille* et al. [15.29], variations in composition were within experimental error for $\Delta R(x)$, while $\Delta A(x)$ was ± 0.005. *Royer* et al. [15.31] found improved radial uniformity with the addition of ACRT to THM but *Bloedner* and *Gille* [15.32] noted both $\Delta A(x)$ and $\Delta R(x)$ were only as good as non-ACRT crystals.

With regard to electrical properties, as-grown material from SSR, ACRT Bridgman (with $x < 0.3$) and THM is highly p-type in nature, believed to be due to metal vacancies. These types of material can all be annealed at low temperatures, in the presence of Hg, to low n-type levels, indicating that the p-type character is due to metal vacancies. However, Bridgman material is n-type as-grown [15.22] and the residual impurity donor level is found to be $< 5 \times 10^{14}$ cm^{-3}. *Higgins* et al. [15.20, 25] showed that n-type carrier concentrations can be $< 10^{14}$ cm^{-3} at $x \approx 0.2$ in melt-grown material. A great deal of work was done on the annealing behavior of SSR material, see *Tregilgas* [15.21]. n-Type levels of 2×10^{14} cm^{-3} after Hg annealing $x = 0.2$ and higher x material were reported by *Nguyen Duy* et al. [15.27]. *Durand* et al. [15.38] note that THM growth at 600 °C results in p-type behavior but growth at 700 °C gives n-type material. In this author's laboratory current 20 mm diameter ACRT material has reached mid-10^{13} cm^{-3} levels with high mobility after a low-temperature Hg anneal step. This is thought to reflect the improvements made in the purity of starting elements over recent years. The basic p to n conversion process [15.20] has recently been extended by *Capper* et al. [15.10, Chap. 13], [15.39], to produce analytical expressions that can account for the temperature, donor level and composition dependencies of the junction depth.

High minority n-type carrier lifetimes have been reported in all types of material. *Kinch* [15.40] noted values > 1 μs (at 77 K) in $x = 0.2$ SSR crystals, while

Triboulet et al. [15.14] quote 3 μs in THM material. *Pratt* et al. [15.41, 42] found high lifetimes, up to 8 μs in $x = 0.23$ Bridgman and ACRT material with n-type levels of $1-6\times10^{14}\,\mathrm{cm}^{-3}$ and up to 30 μs for equivalent $x = 0.3$ material (192 K). *Higgins* et al. [15.25] quote 3 μs in $x = 0.215$ DME material.

In terms of extrinsic doping, most elements are electrically active in accordance with their position in the periodic table. This is true in SSR material for Group V and VII elements only after a high-temperature treatment, and is linked to the stoichiometry level at the growth temperature, i. e., those elements that substitute on Te lattice sites have to be forced onto the correct sites in Te-rich material. Groups I and III elements are acceptors and donors respectively, on the metal sites. In ACRT crystals, Groups I and III are acceptors and donors respectively, on the metal sites as they are in Bridgman, with the exception of Au [15.22]. Groups V and VII are inactive dopants in those portions of ACRT crystals that are Te-rich as-grown, i. e., $x < 0.3$, but are active dopants for $x > 0.3$ where metal-rich conditions prevail, as found in Bridgman material. In doped material, grown by either standard Bridgman or ACRT, acceptor ionization energies were found to be lower than undoped counterparts [15.22]. Segregation of impurities in SSR is very limited due to the initial fast quench step. By contrast, Bridgman/ACRT, DME and THM benefit from marked segregation of impurities due to their relatively slow growth rate. Impurity segregation behavior was affected by ACRT [15.22]: in general, segregation coefficients decrease in ACRT crystals when compared to standard Bridgman. This segregation leads to very low levels of impurities in both THM [15.26] and Bridgman/ACRT material [15.43]. *Higgins* et al. [15.25] note that they used In and Ga for n-type doping but no p-type doping was reported.

Vere [15.44] has reviewed structural properties and noted grains, subgrains, dislocations, Te precipitates and impurities on dislocations as major problems. Grain boundaries act as recombination centers and generate noise and dark current in devices. Subgrain sizes range from 50–500 μm in both SSR and Bridgman material. *Williams* and *Vere* [15.45] showed how a recrystallization step at high pressure and temperatures > 600 °C coalesces subgrains and eventually eliminates them. Tellurium precipitation was extensively studied [15.45, 46] and was summarized in [15.45]. Precipitates were found to nucleate on dislocations during the quench from the recrystallization step but a 300 °C anneal dissolves the precipitates, generating dislocation loops that climb and lead to dislocation multiplication.

Quenching studies in Bridgman/ACRT crystals grown in flat-based ampoules [15.22] revealed not only a flat growth interface but also that the slow-grown material, produced prior to quenching, was a single crystal. This demonstrated the power of Ekman stirring and the importance of initiating the growth of a single crystal grain. In Bridgman material, which is close to stoichiometric (Te excess < 1%) little Te precipitation occurs. Above this limit, precipitates/inclusions of 0.1–0.5 mm in size are seen. Work in this author's laboratory [15.24] has demonstrated flat solid-liquid interfaces in the $x \approx 0.21$ region of 20 mm diameter ACRT crystals, mirroring the high level of compositional uniformity in these crystals.

Triboulet et al. [15.14] found no Te precipitates in their THM material, despite using a Te zone. Several groups [15.17, 47] noted an increase in dislocation density and in rocking curve widths on moving from the center to the edge of THM crystals. The addition of ACRT to the THM process led to increased growth rates with no detriment to the Te precipitation or grain structure. *Higgins* et al. [15.25] annealed their DME material at 500 °C in crystal form to reduce their Te precipitate content.

We have recently [15.10, Chap. 1], [15.24, 48] extended our ACRT growth process to produce high-x material for various near-IR applications (Figs. 15.4–15.6). This necessitated improving the ampoule sealing procedure to manage the higher pressures caused by the higher growth temperatures. Assessment techniques were extended beyond the normal FTIR wavelength characterization to include imaging of defects using a mid-IR camera system.

To summarize, the two main problems with all bulk material are the limitation on size, only Bridgman/ACRT and THM have reproducibly produced material above 20 mm diameter (up to 70 mm in the author's lab), and the fact that it is rarely completely single crystal in nature. These two limitations led to the drive in the late 1970s and early 1980s to develop various epitaxial growth techniques.

15.2 Liquid Phase Epitaxy (LPE)

The process of LPE emerged in the 1980s as the predominant materials growth technology for the fabrication of second-generation MCT focal plane arrays (FPAs). Material was routinely grown for high-performance photoconductive, photovoltaic, and laser-detector devices in the entire 2–18 μm spectral region. This is manifested by increased size (over bulk material), enabling large-array formats to be made; reduced cycle time; better material characteristics in terms of composition uniformity, crystal quality, and electrical properties, making the material no longer the limiting factor in FPAs; and the realization of some advanced device structures, either to simplify the FPA design (backside-illuminated detectors) or to enhance detector performance (double-layer heterostructures) [15.6].

Two completely different technical approaches were pursued: growth from Te solutions and growth from Hg solutions. One major advantage of the Hg-solution technology is its ability to produce layers of excellent surface morphology due to the ease of melt decanting. Two additional unique characteristics, essential for the fabrication of high-performance double-layer heterojunction (DLHJ) detectors by LPE, are low liquidus temperature (< 400 °C), which makes growth of the cap layer feasible, and ease of incorporating both p-type and n-type temperature-stable impurity dopants, such as As and In, during growth. While layers grown from Hg-rich solutions are easily doped with group VB elements with high solubility [15.49], layers grown from tellurium-rich solutions are not. Group IIIB elements, in particular indium, are readily incorporated from both solutions.

A number of LPE approaches have been used to grow both thin and thick films. The principal LPE techniques used are tipping, dipping and sliding boat techniques. A schematic diagram of these three processes is shown in Fig. 15.7. The tipping and dipping techniques have been implemented by using both tellurium- and mercury-rich solutions, whereas only tellurium-rich solutions have been used with the sliding boat. Both tipping and sliding boat Te-rich techniques are still in use.

Extensive experimental phase diagram and thermodynamic data have been critically reviewed, along with the results calculated by the associated solution model [15.50]. As in bulk growth, full knowledge of the solid–liquid phase relation is essential for proper use of solution-growth processes. In addition, the solid–vapor and liquid–vapor phase relations are of practical importance, especially in view of the high Hg pressure in the growth process and the effect of the vapor of constituent components upon postgrowth annealing and the consequent electrical properties. *Astles* [15.51] reviewed the experimental data of Te-rich LPE growth at 460 to 550 °C; also see *Capper* in [15.6], [15.10, Chap. 5].

15.2.1 Hg-rich Growth

For MCT growth from Hg-rich melts the design and operation of a system is dominated by consideration of the high Hg vapor pressure, which comprises ≥90% of the growth solution. A secondary, but related factor, is the requirement to minimize melt composition variation during and between growths due to solvent or solute loss. These factors led to the evolution of a vertical high-pressure furnace design with a cooled reflux region. The furnace has to provide a controllable, uniform and stable thermal source for the melt vessel, which has to be capable of maintaining at least 550 °C continuously. The cylindrical melt vessel consists of a high-strength stainless steel chamber lined with quartz. Such systems are capable of containing about 10–20 kg of melt at 550 °C for several years with no degradation in melt integrity or purity.

The system must be pressurized and leak-free to keep the Hg-rich melt from boiling or oxidizing at temperatures above 360 °C. Typical pressures range up to 200 psi and the pressurization gas may be high-purity H_2 or a less explosive reducing-gas mixture contain-

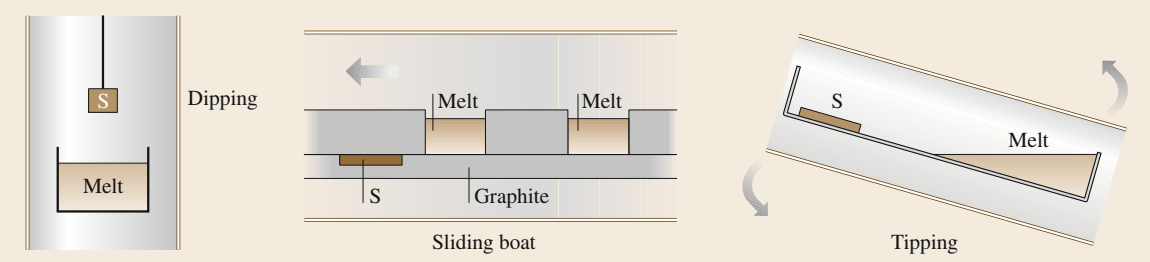

Fig. 15.7 Schematic diagram of the three principal LPE growth techniques. (After [15.2])

ing H_2. The melts are always kept saturated and are maintained near to the growth temperature and pressure between successive runs. The prepared substrates are introduced into the melt through a transfer chamber or airlock. A high-purity graphite paddle with externally actuated shutters holds the substrates.

Growth begins by lowering the paddle plus substrates into the melt and allowing thermal equilibrium to be reached while stirring. A programmed ramp then reduces the melt temperature to the required level at which point the shutters are opened and the substrates are exposed to the melt. The composition of the layer and its variation are determined mainly by the melt composition and its thermal uniformity. Large melts allow the production of layers up to 30 cm^2 with excellent compositional and thickness uniformity and allow dopant impurities to be accurately weighed for incorporation into layers and to maintain stable electrical characteristics over long periods of time. Four layers with a total area of 120 cm^2 can be grown in a single run [15.52]. *Norton* et al. [15.53] also scaled up for the growth of cap layers from Hg-rich solutions, each reactor capable of growth on four 24 cm^2 base layers per run.

15.2.2 Te-rich Growth

A number of problems encountered with bulk crystal growth techniques are solved using MCT growth from tellurium-rich solution. The most important of these is the reduction of the Hg vapor pressure over the liquid by almost three orders of magnitude at the growth temperature. Growth from Te-rich solutions is used in three embodiments: dipping, tipping and sliding boat technologies (Fig. 15.7). While the tipping process may be used for low-cost approaches, it was not as widely used as the sliding boat and the dipping techniques. A comparison of the three techniques is shown in Table 15.1.

Current dipping reactors are capable of growing in excess of 60 cm^2 per growth run and are kept at temperature for long periods, > 6 months. Melts, on the other hand, last a very long time, > 5 years. A sensor-based reactor capable of growing MCT thick layers at relatively high production volumes and excellent reproducibility was described by *Westphal* et al. [15.54]. The reactors utilize resistance temperature devices (RTDs) to control the temperature within a maximum range of $\pm 0.005\,^{\circ}C$ at a temperature of $\approx 480\,^{\circ}C$. The melts weigh about 4 kg with a liquidus temperature of $\approx 480\,^{\circ}C$ for a solid MCT composition $x = 0.225$. Accurate mercury vapor pressure control ensures constant liquidus and thus constant liquid composition.

Layers produced from Te-rich solutions are usually grown by isothermal supersaturation or programmed cooling techniques or a combination of both. The details of the mass transport of Hg-Cd-Te solutions during LPE growth were presented by *Shaw* [15.55].

Sliding-boat LPE normally consists of a graphite boat with a recess in the base for holding the substrate wafer and a movable block with wells that contain the LPE solution and that allows the solution to be brought into contact with the substrate and then wiped off after growth. The main advantages of the technique are the efficient use of solution and the possibility of growing multilayers. The main disadvantages are the need for careful machining of the boat components in order to obtain efficient removal of the solution after growth and the need for precisely sized substrate wafers to fit into the recess in the boat. The sliding-boat growth process has several variants but essentially a polished substrate is placed in the well of a graphite slider and the Te-rich solution is placed in a well in the body of the graphite boat above the substrate and displaced horizontally from it. Normally, a separate well contains the HgTe charge to provide the Hg vapor pressure needed during growth and during cooldown to control the stoichiometry. The boat is then loaded into a silica tube that is flushed with nitrogen/argon prior to the introduction of H_2 for the growth phase. The furnace surrounding the work tube is slid over the boat and the temperature is increased to 10–20 °C above the relevant liquidus.

Table 15.1 Comparison of three LPE growth techniques

LPE growth technique	Advantages	Disadvantages
Sliding boat	Thickness control Large area Double layers	Thick layers difficult to grow Substrate thickness/planarity Control High cost
Tipping	Thickness control Lowest investment for experimental investigation Closed system/good P_{Hg} control	High cost Scale up
Dipping	Thick layer growth High throughput Low cost Large/flexible area	Thin-layer thickness control Double layers

At that point a slow temperature ramp (2–3 °C h^{-1}) is initiated and when the temperature is close to the liquidus of the melt the substrate is slid under the melt and growth commences. After the required thickness of MCT has been deposited (typical growth rates are 9–10 μm h^{-1}) the substrate is withdrawn and the temperature is decreased to an annealing temperature (to fix the p-type level in the as-grown material) before being reduced rapidly to room temperature. Layer thicknesses of 25–30 μm are normally produced for loophole diode applications [15.56].

15.2.3 Material Characteristics

Good composition uniformity, both laterally and in depth, is essential to obtain the required uniform device performance. Growth parameters that need to be optimized in Hg-rich LPE include the degree of supercooling and mixing of the melt, the geometrical configuration of the growth system, the melt size, and the phase diagram. The standard deviation of the cutoff wavelength, for 12-spot measurements by Fourier transform infrared (FTIR) transmission at 80 K across a 30 cm^2 long-wavelength infrared (LWIR) layer, is reported as 0.047.

Composition control and uniformity of layers grown by dipping Te-rich LPE is one of the strengths of this process. The cutoff wavelength reproducibility is typically 10.05 ± 0.18 μm. Dipping Te-rich LPE is used mainly to grow thick films, about 100 μm, hence thickness control is not one of its advantages. Thickness control is about ±15% for layers < 20 μm due to the relatively large amount of solidified material.

For Te-rich sliding boat LPE layers of ≈ 30 μm thickness can show wavelength uniformity at room temperature of 6.5 ± 0.05 μm over 90% of the area of 20×30 mm layers [15.57].

The dislocation density of LPE MCT and its effects on device characteristics has received much attention [15.58, 59]. The dislocation density is dominated mainly by the dislocations of the underlying substrate [15.60]. For layers grown on substrates with ZnTe ≈ 3–4% the dislocations are present only in the interface region and the dislocation density is close to that of the substrate. For sliding boat LPE material, this same variation of dislocation density with depth is seen [15.56] (typical values are $3–7 \times 10^4$ cm^{-2}).

For the production of heterostructure detectors with MCT epitaxial layers, it is essential that proper impurity dopants be incorporated during growth to form well-behaved and stable p-n junctions. An ideal impurity dopant should have low vapor pressure, low diffusivity, and small impurity ionization energy. Group V and group III dopants, As and Sb for p-type, and In for n-type, are the dopants of choice. Hg-rich melts can readily be doped to produce n- and p-type layers, and solubilities of most of the useful dopants are significantly higher than in Te-rich solutions, most notably for group V dopants, which are among the most difficult to be incorporated into MCT.

The accurate determination of dopant concentration in the solid involves the use of Hall effect measurements and secondary ion mass spectrometry (SIMS) concentration profiles, preferably on the same or adjacent samples. The ease of incorporating Group I and Group III dopants into MCT, irrespective of nonstoichiometry, has been confirmed experimentally [15.5, 61].

Excess carrier lifetime is one of the most important material characteristics of MCT since it governs the device performance and frequency response. The objective is to routinely produce material with a lifetime that is limited by Auger processes, or by the radiative process in the case of the medium-wavelength infrared (MWIR) and short-wavelength infrared (SWIR) material [15.62]. It has been reported that intentionally impurity-doped LPE MCT material grown from As-doped Hg-rich melts can be obtained with a relatively high minority-carrier lifetime [15.63]. The 77 K lifetimes of As-doped MWIR ($x = 0.3$) MCT layers are significantly higher than those of undoped bulk MCT and are within a factor of two of the theoretical radiative lifetime. Various annealing schedules were proposed [15.57] that may lead to a reduction in Shockley–Read traps with a consequent increase in lifetime, even in undoped material. Lifetimes in In-doped MWIR MCT were also found to exhibit an inverse linear dependence on the doping concentration [15.63], with $N_d\tau$ products similar to $N_a\tau$ products observed for the As-doped material. The lifetimes of LWIR In-doped LPE material are limited by the Auger process typically at doping levels above 10^{15} cm^{-3}.

The first heterojunction detectors were formed in material grown by Hg-rich LPE [15.64]. For double-layer heterojunctions (DLHJ), a second LPE (cap) layer is grown over the first (base) layer. With dopant types and layer composition controlled by the LPE growth process, this approach offers great flexibility (p-on-n or n-on-p) in junction type and in utilizing heterojunction formation between the cap and absorbing base layers for optimization of detector performance. The key step in the process is to grow the cap layer doped with slow-diffusing impurities, In for an n-type cap layer, and As or Sb for a p-type cap layer.

For future large-area FPAs, Si-based substrates were developed as a replacement for bulk CdZnTe

Table 15.2 Summary of MCT PV detector technologies used for two-dimensional hybrid focal plane arrays. Upper case P and N denote wider-gap layers, e.g., *P-on-n* denotes a wider-gap p-type layer grown onto a narrow-gap n-type absorber layer. (After [15.5])

substrates. This effort is directed at improvements in substrate size, strength, cost, and reliability of hybrid FPAs, particularly during temperature cycling. These alternative substrates, which consist of epitaxial layers of CdZnTe or CdTe on GaAs/Si wafers [15.65] or directly onto Si wafers [15.66], are particularly advantageous for the production of large arrays. High-quality epitaxial MCT has been successfully grown on the Si-based substrates by the Hg-melt LPE technology for the fabrication of p-on-n DLHJ detectors. The first high-performance 128×128 MWIR and LWIR arrays were demonstrated by *Johnson* et al. [15.67]. MWIR arrays as large as 512×512 and 1024×1024 have also been produced [15.68]. A bias-selectable two-color (LWIR/MWIR) detector structure was first fabricated by growing three LPE layers from Hg-rich melts in sequence on a bulk CdZnTe substrate [15.68].

15.2.4 Device Status

The various MCT photodiode designs and processes used by the major FPA manufacturers for both back-illuminated bump-interconnected FPAs and front-illuminated loophole FPAs are summarized in Table 15.2, circa 2010.

Destefanis and coworkers [15.69] described work on large-area and long linear FPAs based on Te-rich sliding boat LPE material. Using a 15 µm pitch they were able to produce 1000×1000 MW arrays of photodiodes and 1500×2 MW and LW long linear arrays. *Gravrand* et al. [15.70] suggest that only by growing on lattice-matched substrates, i. e., CdZnTe plus LPE growth, will the very highest performance FPAs be produced. CdZnTe crystals up to 115 mm diameter are grown in-house to produce substrates up to 47×48 mm

in size. Layers with wavelengths from 1.7–12 μm can be produced.

Wenisch et al. [15.71] recently noted that LPE is still AIM's production process of choice due to its maturity, and they report detectors with 1280 × 1024 pixels on a 15 μm pitch. This was still the case a year later; see *Schirmacher* et al. and *Ziegler* et al. [15.72, 73].

Maxey et al. [15.74] reported that LPE material was also used for avalanche photodiodes in the short-wave (SW) regions of 1.5–1.8 and 2.0–2.4 μm to produce high gain figures.

15.3 Metal-Organic Vapor Phase Epitaxy (MOVPE)

Metal-organic vapor phase epitaxy (MOVPE) of MCT is dominated by the relatively high vapor pressures of mercury that are needed to maintain equilibrium over the growing film. This arises from the instability of HgTe compared with CdTe and requires much lower growth temperatures than are usual for more stable compounds. The MOVPE process was developed as a vapor-phase method that would provide sufficient control over growth parameters at temperatures below 400 °C. The main advantage of this is that the elements (although not mercury) can be transported at room temperature as volatile organometallics and react in the hot gas stream above the substrate or catalytically on the substrate surface. The first mercury chalcogenide growth by MOVPE [15.75, 76] was followed by intense research activity that has brought the technology to its current state of maturity.

Although the MOVPE reaction-cell conditions are far from equilibrium, an appreciation of the vapor-solid equilibrium can determine the minimum conditions needed for growth. At MOVPE growth temperatures, the pressure can vary by three orders of magnitude and remain in equilibrium with a single phase of HgTe. However, the Te_2 partial pressure varies across the phase field in the opposite sense to the Hg partial pressure.

The maintenance of vapor pressure equilibrium within the reactor cell does not automatically lead to the growth of an epilayer but it does enable us to eliminate conditions that would not be suitable. For example, the supply of Hg to the substrate for growth at 400 °C must be greater than the minimum equilibrium pressure of 10^{-2} bar. This pressure is higher than would be conveniently delivered from a mercury organometallic source that would typically be less than 10^{-3} bar. Almost all narrow-gap II-VI epilayers have used a heated elemental mercury source that is capable of delivering the required partial pressure.

Criteria for precursors that are generally applicable to MOVPE are volatility, pyrolysis temperature, stability and volatility of organic products and purity. The latter depends on the synthesis and purification routes for the precursors but techniques such as adduct purification of the group II organometallics have made a major contribution to epilayer purity. A good review of this topic is given by *Jones* [15.77].

The precise control over layer properties that is required for uniform detector arrays and tuning of the response wavelength can only be achieved if the cadmium concentration is controlled to better than 1%. Improvements in reactor design, growth techniques, such as the IMP (interdiffused multilayer process), choice of precursors and operating conditions have all contributed to successful targeting of the composition and thickness. Developments with in situ monitoring have been instrumental in gaining a better understanding of this technology and in reducing variance in epilayer properties. This has been achieved with better system monitoring to measure organometallic concentration and epilayer monitoring with laser reflectometry or ellipsometry [15.78].

A typical example of a horizontal reactor cell with an internal mercury source is shown in Fig. 15.8. The reactor-cell wall temperature is also determined by the thermodynamics, which requires a minimum temperature in order to avoid condensation of mercury and these requirements can be simply determined from the phase diagram. The organometallic supply shows that the DMCd is injected beyond the Hg source, which is the most common practice to avoid reaction in the Hg zone.

Much of the work on precursors was concerned with thermal stability of the tellurium source as this limits the growth temperature. From thermodynamic considerations, it would be desirable to grow at low temperature (below 400 °C) where the requirement on Hg equilibrium pressure will be lower. The initial demonstration of growth using MOVPE was with diethyl telluride (DETe), which requires a temperature above 400 °C for efficient pyrolysis [15.76].

The most successful tellurium source has been diisopropyltelluride (DiPTe), which is used for growth between 350 and 400 °C. In practice, the DiPTe bubbler is held at a temperature above ambient (up to 30 °C) and the lines to the reactor are heated to avoid condensation of the precursor in the feed lines.

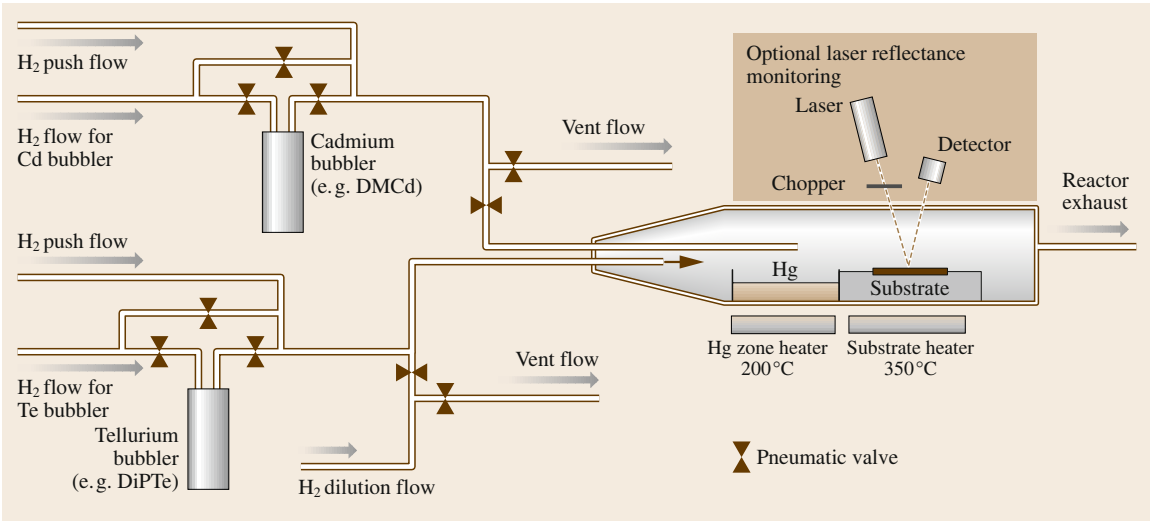

Fig. 15.8 Horizontal reactor cell with internal mercury source and gas supply suitable for the growth of $Hg_{1-x}Cd_xTe$ alloy. (After [15.2])

Unlike MOVPE growth of other II-VI and III-V semiconductors, the growth of an alloy in narrow-gap II-VIs can be achieved by one of two alternative processes: direct alloy growth (DAG) and the interdiffused multilayer process (IMP). The requirement on alloy uniformity is critical because this will determine the cut-on wavelength of a detector. The DAG approach suffers from disadvantages in the thermodynamics and reaction chemistry in that the reaction rate of the tellurium precursor is very different for growing the mercury-containing binary compared with Zn, Cd, or Mn. This leads to a preferential depletion of the non-Hg group II species as the gas flow passes over the substrate, and consequent composition changes in the flow direction.

The interdiffused multilayer process [15.79] separates the growth of HgTe and CdTe so that the growth of the binaries can be independently optimized. The procedure entails the growth of alternate layers of HgTe and CdTe that interdiffuse during the time of growth to give a homogeneous epitaxial layer. The IMP approach relies on the very high interdiffusion coefficients in the MCT pseudobinary and the basic principles are as follows:

1. Interdiffusion must occur at the growth temperature and a nominal time at the end of growth for the last periods to interdiffuse must be allowed.
2. There should be no residual compositional or structural modulation attributable to the IMP oscillations.
3. Interdiffusion at heterointerfaces should be no greater than for direct alloy growth (DAG) at that temperature.
4. Flow velocity is adjusted between the two binary growths to optimize growth uniformity.

The alloy composition is fixed by adjusting the times for growth of the HgTe and CdTe IMP layers. Figure 15.9 shows the uniformity of wavelength over a 75 mm diameter MOVPE layer grown on a GaAs substrate currently in the author's lab [15.80]. By introducing substrate rotation, uniformity was improved dramatically such that, to within a few millimeters of the wafer edge, the composition is uniform to within ± 0.004. The thickness uniformity also improved to within $\pm 2-3\%$. This was compatible with the production of twelve sites of large format 2-D arrays (640×512 diodes on 24 μm pitch) per layer or larger numbers of smaller arrays and was comparable with the uniformity achieved by *Edwall* [15.81]. In the past, other groups have established MOVPE reactor designs capable of large-area uniform growth of MCT on 75 mm wafers [15.81, 82] but these activities have now ceased as attention has focused on MBE growth techniques.

A Polish group has also been very active in MOVPE growth of MCT [15.83]. Growth takes place on 50 mm GaAs substrates, with iodine and arsenic being used as n- and p-type dopants, respectively, to produce fully doped heterostructures.

Piotrowski and Piotrowski [15.10, Chap. 22] have reported that MOVPE-grown material used in uncooled MCT photodetectors can bring their performance close to fundamental limits. These near-room-temperature photodetectors have found increasingly widespread civilian (pyrometry and thermography; gas analysis based on conventional, laser and Fourier transform spectroscopy; free space high transfer rate optical com-

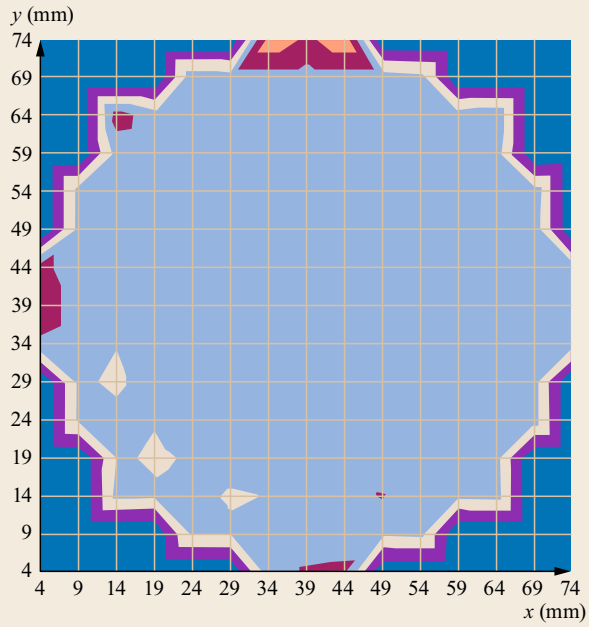

Fig. 15.9 Uniformity of wavelength over a 75 mm diameter MOVPE layer grown on a GaAs substrate. (After [15.10, Chap. 6])

munications; test equipment) and military (night vision, laser range finder and threat warning devices, gun sights, smart munitions) applications.

Maxey et al. [15.74] recently reported MOVPE-grown material being used in various applications at several wavelengths. This included single-color, both MW (MW) and LW (LW), dual-band (MW/LW) and MW higher operating temperature (HOT) devices grown on GaAs 75 mm substrates. Figure 15.10 shows a secondary ion mass spectrometery (SIMS) profile from a dual-band device heterostructure [15.10, Chap. 6]. Device sizes were 1024×768 on a 16 μm pitch (MW) and 640×512 on a 24 μm pitch (LW). The following year [15.84] the same group reported SW avalanche photodiodes made in MOVPE at 1.5−1.8 and 2.0−2.4 μm at a size of 320×256 on a 24 μm pitch, while the MW detectors had increased in size to 1920×1080 on a 12 μm pitch (Fig. 15.11), with a concept device of a 16-Mpixel detector made up of a 4×2 matrix of such arrays. In addition, MW 384×384 on a 20 μm pitch detectors were demonstrated that exhibited fast frame rates of 1000 frames s^{-1} (Fig. 15.12).

The usual methods for determining depth uniformity of an MCT layer are sharpness of the infrared absorption edge and SIMS depth profiles (in particular looking at the Te^{125} secondary ion). Results from

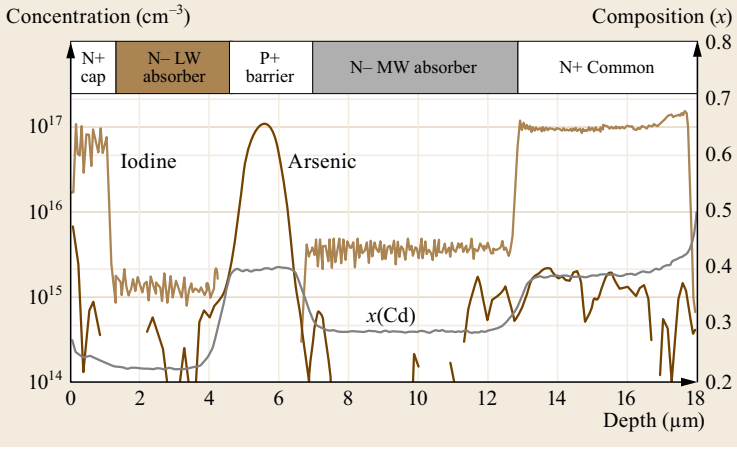

Fig. 15.10 Secondary ion mass spectrometery (SIMS) profile from a dual band device heterostructure. (After [15.10, Chap. 6])

these techniques indicate that the IMP structure is fully diffused for IMP periods of the order of 1000 Å and growth temperature in the range of 350 to 400 °C unless the surface becomes faceted during growth when microinhomogeneities may occur [15.85].

15.3.1 Substrate Type and Orientation

The search for the correct substrate material and orientation has been a major area for research in MCT because it is a limiting factor in the quality of the epilayers [15.10, Chap. 6]. Essentially, there are two categories of substrates: (i) lattice-matched II-VI substrates and (ii) nonlattice-matched *foreign substrates*. Examples of the former are CdZnTe and CdSeTe where the alloy compositions are tuned to the lattice parameter of the epilayer. Nonlattice-matched substrates include GaAs, Si and sapphire. The lattice mismatches can be up to 20% but, remarkably, heteroepitaxy is still obtained. The need for a ternary substrate to avoid substantial numbers of misfit dislocations has made the development of the CdTe-based substrate more complex. The small mismatch with CdTe substrates (0.2%) is sufficient to increase the dislocation density to greater than $10^6\,\mathrm{cm}^{-2}$, comparable with some layers on CdTe-buffered GaAs where the mismatch is 14% [15.81]. An additional problem encountered with the lattice-matched substrates is the lamella twins that form on (111) planes in Bridgman-grown crystals. It is possible to cut large (4 × 6 cm) (111) oriented substrates parallel to the twins but (100) substrates have a much lower yield. MOVPE-grown CdTe also twins on the (111), and these twins will propagate through an entire structure.

Hence, the majority of MOVPE growth has concentrated on orientations close to (100), normally with a misorientation to reduce the size of macrodefects, known as hillocks or pyramids. In an analysis of the frequency and shapes of defects on different misorientations, it was concluded [15.86] that the optimum orientation was (100) 3–4° towards the (111)B face. An alternative approach has been to use the (211)B

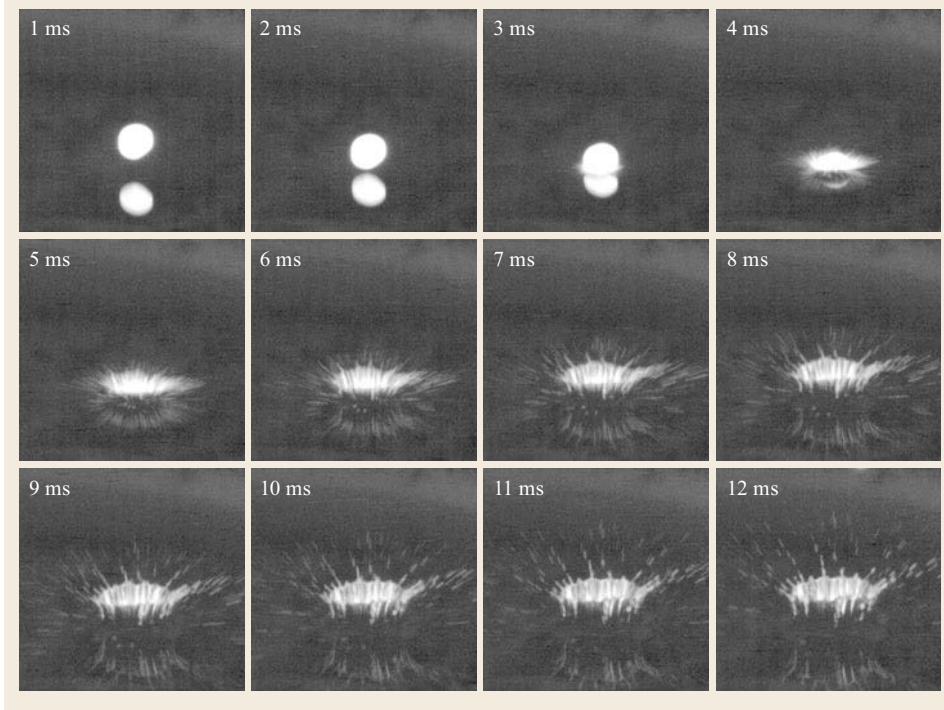

Fig. 15.12 Hot water drop entering cold water 1000 fps, 384 × 384 pixels. (Courtesy of Leonardo MW Ltd)

orientation. In this case the surface appears to be free of macrodefects and is sufficiently misoriented from the (111) to avoid twinning. Dislocation densities of $10^5\,cm^{-2}$ have been measured in MCT grown by IMP onto CdZnTe (211)B substrates [15.81], and diffusion-limited detectors have been fabricated using this orientation [15.87].

The alternative lattice-mismatched substrates were investigated as a more producible alternative to the variable quality of the CdTe family of substrates. As the MCT arrays have to be cooled during operation, there is the risk that the differential thermal contraction between the substrate and multiplexer will break some of the indium contacting columns. The ideal substrate from this point of view is, of course, silicon but, initially, the quality of heteroepitaxy with 20% lattice mismatch was poor. One of the more successful alternative substrate technologies has been the Rockwell PACE-I (producible alternative to CdTe epitaxy), which uses c-plane sapphire with a CdTe buffer layer grown by MOVPE and an MCT detector layer grown by LPE. The sapphire substrates absorb above 6 μm and can only be used for the 3–5 μm waveband. However, even with careful substrate preparation a buffer layer thicker than 5 μm is needed to avoid contamination of the active layer.

GaAs has been the most extensively used alternative substrate, which has been successfully used to reduce the macrodefect density to below $10\,cm^{-2}$ and X-ray rocking curve widths below 100 arcsec have been obtained [15.88]. Due to the large lattice mismatch, the layer nucleates with rafts of misfit dislocations that relieve any strain.

The majority of the MOVPE growth onto silicon substrates has used a GaAs buffer layer to step the change in lattice parameter between silicon and CdTe. By growing a 12 μm thick CdTe buffer layer, the X-ray rocking curve width is reduced to 120 arcsec, larger than the best values obtained on GaAs substrates [15.89]. The advantage of thermal expansion match with the silicon multiplexer has been demonstrated with a midwave 256×256 array where the entire structure was grown by MOVPE [15.90].

15.3.2 Doping

The earliest FPAs were made in as-grown, undoped MOVPE layers where the p-type nature was due to metal vacancies. However, for current and future FPAs, the more complex devices such as p/n heterostructures require extrinsic doping and low-temperature annealing in a mercury vapor to remove metal vacancies. Activation of donors is relatively easy, using either Group III metals or Group VII halogens. Indium has been used for doping concentrations from $< 10^{15}\,cm^{-3}$ up to $10^{18}\,cm^{-3}$. For the p/n structures, the n-type side of the junction is the absorber layer and therefore minority carrier lifetime and diffusion length are also important. An alternative n-type doping approach is to use a halogen such as iodine or chlorine that substitutes on the Group VI sites. The first use of iodine doping [15.91] used a crystalline iodine source, where the vapor was transported via a hydrogen flow and separate injector. The main advantage of iodine over indium is the slower diffusion, which enables more abrupt doped structures to be grown. A liquid source, ethyl iodide (EtI) was used by *Mitra* et al. [15.92] to dope over a range from 10^{15} to $10^{18}\,cm^{-3}$, with no apparent memory. Current work on doped heterostructures [15.80] uses isobutyl iodide (IBI) as with this source donor levels over a more useful range (mid-10^{14} to mid-$10^{17}\,cm^{-3}$) can be achieved.

Acceptor doping proved to be more problematic in MOVPE than donor doping. The first attempts at arsenic doping used AsH_3 that would normally be very stable at growth temperatures of 350 °C. It was proposed by *Capper* et al. [15.93] that the AsH_3 forms an adduct with DMCd in the vapor and causes the deposition of As at a low temperature. It was found that the doping incorporation was much higher in the CdTe layers and that activation of the dopant could be changed by adjusting the VI/II ratio during growth. A second-generation acceptor dopant source (tris(dimethylamino)arsine – DMAAs) is now the preferred route to introduce As into layers. Multilayer, fully doped heterostructures have been grown [15.80, 94], [15.10, Chap. 6] which demonstrate higher operating temperature performance due to Auger suppression techniques. These heterostructures were grown to investigate the device performance in the 3–5 μm and 8–12 μm IR bands. Figure 15.10 shows a SIMS profile of a 3–5 μm device structure grown on a 75 mm diameter GaAs substrate. The excellent control of the As concentration allows the active region to be doped at $4–5 \times 10^{15}\,cm^{-3}$ in the so-called *π-layer* of the heterostructure design. The iodine profile shows well-defined transitions that help define the junction depth. Such layers have been fabricated into mesa 2-D arrays that have been indium-bumped onto Si multiplexers. This material represents the current state of the art in MOVPE.

15.3.3 In situ Monitoring

The use of optical in situ monitoring probes for MOVPE is helping to both understand the kinetic mechanisms and provide monitors suitable for feedback control. Although in situ monitoring is not widely used in MCT growth there have been a number of notable examples where progress has been made as a result

of its application. Laser reflectometry measures the bulk of the film, measuring film thickness, growth rate and some indication of film composition. Reflection difference spectroscopy (RDS) is sensitive to surface composition and will monitor surface reconstruction and adsorbate composition. Spectroscopic ellipsometry is very sensitive to film composition and is useful as an in situ monitor with fast multichannel analysis. A number of in situ characterization techniques have been outlined in a review [15.78], [15.10, Chap. 6].

15.4 Molecular Beam Epitaxy (MBE)

An alternative to MOVPE for the production of advanced multilayer heterostructures is growth by MBE. Figure 15.13 shows a schematic of a simple molecular beam epitaxial system for the growth of semiconductors. Significant progress was made in MCT MBE technology in the 1990s [15.95, 96], [15.10, Chap. 7]. Current MCT MBE technology offers low-temperature growth under an ultrahigh-vacuum environment, in situ n-type and p-type doping, and control of composition, doping and interfacial profiles. All these are essential for the growth of advanced double-layer and multilayer structures for advanced FPAs.

A typical system consists of eight interconnected chambers, including two growth chambers, two preparation chambers with integrated ion etching capabilities and entry chambers, an ESCALAB chamber, two buffer chambers and a transport chamber. Each growth chamber is equipped with dual Hg reservoirs, several effusion cells and dual load locks for effusion cells to enable recharging of the materials without breaking the vacuum. Systems are modular in nature and designed to accommodate sample sizes up to 75 mm in diameter. Garland [15.10, Chap. 7] recently summarized all the issues pertaining to MBE growth and concluded that MBE can now produce LPE-like quality in layers grown on CdZnTe. However, more work still needs to be done to improve growth on CdTe/Si, partly in terms of defect densities and fully active p-type doping.

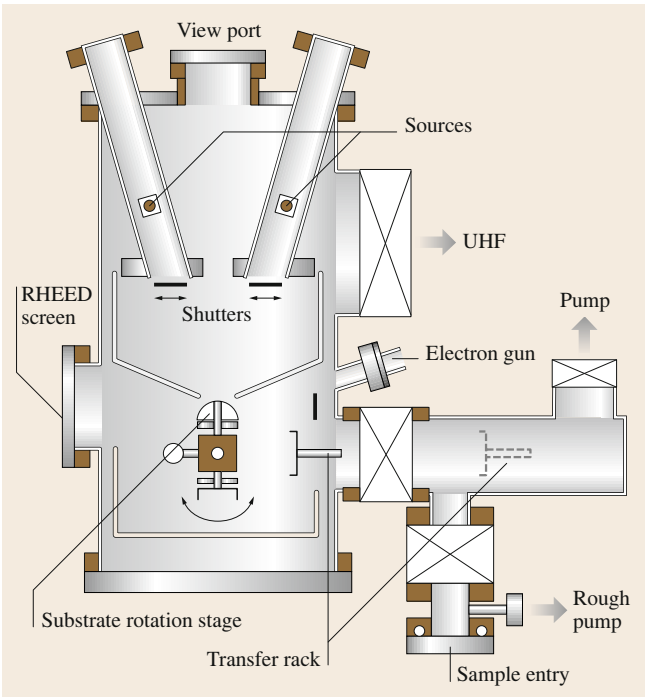

Fig. 15.13 Schematic of a simple molecular beam epitaxial system for the growth of semiconductors

Normally, growth of MCT is carried out at 180–190 °C on (211) CdZnTe substrates using Hg, CdTe and Te sources. However, *Garland* and *Sporken* [15.10, Chap. 4] have discussed the issues around various substrate systems, i. e., CdZnTe, GaAs and Si. They concluded that CdTe/Si is best for SW and MW growth, but CdZnTe is still preferred for LW applications. Typically, the CdZnTe substrates are degreased, etched in Br-methanol solution, rinsed with methanol, then blown dry with nitrogen and mounted on holders, and then thermally cleaned at 350–400 °C under vacuum to remove oxides prior to growth [15.97]. Although MBE is essentially a nonequilibrium growth process, the vapor pressure of the constituent species over an MCT layer is governed by thermodynamics. It has been shown [15.98] that the vapor pressure of Hg over an MCT layer at 170 °C is $\approx 7 \times 10^{-4}$ mbar and 8 mbar for the Te-rich and Hg-rich sides of the phase boundary, respectively. The value of the Hg vapor pressure on the Te-rich side of the phase boundary is similar to the beam equivalent pressure of Hg employed for the growth of MCT by MBE, suggesting that MCT growth occurs on the Te-rich side of the phase boundary, and reflection high-energy electron diffraction studies confirm this.

The MCT alloy composition can be varied readily by choosing the appropriate beam-flux ratios. Over the range from $x = 0.2$–0.50, excellent control of composition can be achieved readily by varying the CdTe source flux with a constant flux of Hg at 3×10^{-4} mbar and Te at 8×10^{-7} mbar during the MBE growth [15.96].

The most widely used n-type dopant for MCT alloys during MBE growth is indium [15.99, 100]. The In concentration can be varied from 2×10^{15} to 5×10^{18} cm^{-3} by adjusting the In cell temperature (450–700 °C) with

no evidence of a memory effect. The doping efficiency of In was almost 100%, evident from the Hall measurement and secondary ion mass spectrometry (SIMS) data, for carrier concentrations $< 2 \times 10^{18}\,\mathrm{cm}^{-3}$.

A critical issue in growing advanced MCT structures is the ability to grow high-quality p-type materials in situ. As, Sb, N, Ag and Li have all been used as acceptors during MBE growth of MCT, with varying degrees of success [15.101]. Most data available is centered on the use of arsenic and two approaches have been investigated. The first is based on photo-assisted MBE to enable high levels of p-type As-doping of CdTe [15.100]. For As-doping during compositionally modulated structure growth only the CdTe layers in a CdTe-MCT combination are doped, as in MOVPE growth. Since the CdTe does not contain Hg vacancies, and is grown under cation-rich conditions, the As is properly incorporated on the Te site and its concentration is proportional to the As flux. The structure then interdiffuses after annealing at high temperature to remove residual Hg vacancies, resulting in p-type, homogeneous MCT. The main disadvantage of this approach is that it requires a high-temperature anneal that results in reduced junction and interface control. An alternative approach is to use cadmium arsenide and correct Hg/Te ratios to minimize Hg vacancies during MCT growth [15.99]. As a result, the As is directed to the group VI sublattice to promote efficient p-type doping. A comparison of the net hole concentration and the SIMS measurement indicates an electrical activity of As acceptors in excess of 60%. *Garland* et al. [15.102] recently discussed the issue of As doping of MCT and conclude that achieving high-lifetime p-type material, i. e., not limited by Shockley–Read–Hall recombination, remains a very important task. Several areas of future work in this area were proposed.

Lateral compositional and thickness uniformity were evaluated on a $2.5 \times 2.5\,\mathrm{cm}^2$ sample and the results showed that the average alloy composition and thickness were $x = 0.219 \pm 0.0006$ and $t = 8.68 \pm 0.064\,\mu\mathrm{m}$, respectively [15.96].

The surface morphology of MCT layers is important from the device fabrication point of view. Scanning electron microscopy (SEM) studies indicate that the surface morphology of MBE-grown MCT alloys is very smooth for device fabrication, except for occasional small undulations ($< 1\,\mu\mathrm{m}$). The crystal quality of MBE MCT layers is illustrated by X-ray rocking curve data for an LWIR double-layer heterojunction structure. The In-doped n-type (about $8\,\mu\mathrm{m}$ thick) base layer peak has a width of < 25 arcsec and is indistinguishable from the CdZnTe substrate. Because the As-doped p-type cap layer is much thinner (about $2\,\mu\mathrm{m}$) and has a different alloy composition, its peak is broader (45 arcsec), but the X-ray FWHM (full width at half-maximum) width still indicates high quality [15.96].

Other material properties such as minority carrier lifetime and etch pit density (EPD) of the material are important for device performance. The lifetime of the photoexcited carriers is among the most important, since it governs diode leakage current and quantum efficiency of detectors. In the case of In-doped n-type layers ($x = 0.2$–0.3) results show that the lifetime ranges from 0.5–$3\,\mu\mathrm{s}$ depending upon the x value and carrier concentration. Measured lifetimes at 77 K approach the Auger recombination limit [15.103].

Extended defects including dislocations, pinholes, particulates, inclusions, microtwins, precipitates and inhomogeneities, occur over lengths of several micrometers and are often observable by selective etching and microscopy. Optical microscopy studies of etched MBE-grown MCT base layers indicate that the EPD of device-quality alloys is of the order of $2 \times 10^5\,\mathrm{cm}^{-2}$, which is in good agreement with the lifetime data and comparable to the best LPE materials for device applications.

15.4.1 Double-Layer Heterojunction Structures

To achieve these structures there have been two approaches pursued in MCT MBE, namely ion implantation and in situ doping [15.101]. The advantage of the in situ doping approach is that it is a simple layer-by-layer growth process and so it is relatively easy to grow multilayer structures. Reproducible p-type doping with low defect density is difficult to achieve, and it requires a very stringent passivation for mesa structures. However, high-performance MCT 64×64 and 128×128 FPAs for MWIR and LWIR infrared detection, using MCT double-layer heterojunction structures (DLHJ) grown by MBE have been demonstrated [15.104]. The performance of detectors fabricated from MWIR and LWIR layers compared very well to the LPE-based production process. An update in this area can be found in [15.10, Chap. 7].

15.4.2 Multilayer Heterojunction Structures

As infrared technology continues to advance, there is a growing demand for multispectral detectors. The original growth process developed for the DLHJ structures was applied and extended for the growth of n-p-p-n multilayer heterojunction (MLHJ) structures for two-color detector applications [15.105]. A SIMS profile of an MLHJ structure confirms that the in situ doping process is able to incorporate $> 2 \times 10^{18}\,\mathrm{cm}^{-3}$ As and control the n-type doping at 1–$2 \times 10^{15}\,\mathrm{cm}^{-3}$ for

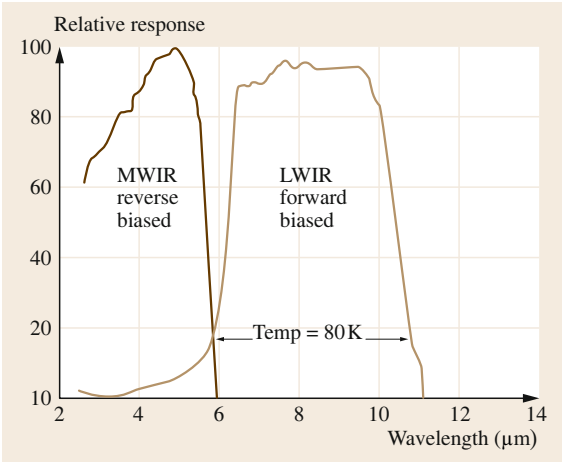

Fig. 15.14 The spectral response data for the MW-LWIR two-color detectors fabricated from an n-p-p-n multilayer heterojunction structure. The data indicate that the MWIR is detected in negative bias mode and LWIR is detected under forward bias conditions, as expected. (After [15.2])

both absorbing layers [15.106]. This dual-band detector is basically a four-layer structure with two p-n junctions, one for each spectral band. The top and bottom layers are the IR absorbers while the middle two layers are transparent. The spectral response of this MW/LW two-color detector is shown in Fig. 15.14. This demonstration indicated that MCT MBE in situ doping technology is capable of growing multilayer structures for advanced IR FPAs. An update in this area can be found in [15.10, Chap. 7].

15.4.3 MCT and CdZnTe Growth on Silicon

The move to the use of Si substrates for the epitaxial growth of MCT FPAs is motivated by several important technological factors [15.96]. Primarily there is the need to establish a thermal expansion match between the Si readout electronics chip and the array of MCT infrared detectors. As the size of such MCT hybrid IR FPAs increases, long-term thermal-cycle reliability can be compromised by the thermal expansion mismatch between Si and bulk CdZnTe substrates. One approach to solving this problem requires the fabrication of the MCT array on an Si substrate. Considerable research activity [15.107, 108] was directed towards achieving epitaxial deposition of high crystalline quality MCT films on Si substrates. Beyond their thermal expansion match to the readout electronics ship, Si substrates for IR FPAs offer additional advantages when compared with CdZnTe substrates, for example they are more readily available in larger sizes with superior mechanical strength and at substantially lower cost. The use of Si substrates also avoids potential problems associated with outdiffusion of fast-diffusing impurities, such as Cu, that has been identified [15.109] as a problem with CdZnTe substrates.

However, the most serious technical challenge faced in fabricating device-quality epitaxial layers of MCT on Si is reduction in the density of threading dislocations resulting from the accommodation of the 19% lattice constant mismatch and the large difference in thermal expansion coefficient between Si and MCT. Dislocation density is known to have a direct effect on IR detector performance [15.58], particularly at low temperature. All efforts to fabricate MCT IR detectors on Si substrates relied upon the prior growth of CdZnTe buffer layers on Si. Growth of $\approx 5\,\mu m$ of CdZnTe is required to allow dislocation annihilation processes to decrease the dislocation density to low $10^6\,cm^{-2}$ [15.108].

As an additional step, initiation layers of ZnTe have been used to facilitate parallel MBE deposition of CdTe(001) on Si(001) [15.104]; ZnTe nucleation layers are also commonly used for this same purpose for growth of CdZnTe on GaAs/Si substrates by other vapor-phase techniques [15.110]. CdTe(001) films with rocking curves as narrow as 78 arcsec and EPD of $1-2\times10^6\,cm^{-2}$ have been demonstrated with this technique. Both (111)- and (001)-oriented MBE CdTe/Si substrates have been used as the basis for demonstration of LPE-grown MCT detectors [15.103, 107]. The (001)-oriented CdTe/Si films have been used in the demonstration of 256×256 MCT hybrid arrays on Si [15.104].

Current state-of-the-art MBE material on 100 mm diameter Si substrates has been discussed in [15.10, Chap. 7]. Dry etching is used to produce array sizes of 128×128 and 1024×1024 with performance equivalent to LPE material. Similar material, grown on CdZnTe this time, by another group [15.111] in the MW and SW regions is used in astronomy applications [15.112].

Other applications of MBE-grown MCT include very long wavelength arrays (onto (211)B CdZnTe substrates) by *Philips* et al. [15.113], two-color (MW $4.5\,\mu m$/SW $2.5\,\mu m$) arrays of 128×128 diodes [15.69, 114], gas detectors in the $2-6\,\mu m$ region [15.115] and $1.55\,\mu m$ avalanche photodiodes using Si substrates [15.66]. All these applications demonstrate the versatility of the MCT MBE growth technique.

Recently, *Vilela* et al. [15.116] reported on the growth of dual-band FPAs in material grown on Si of a size 640×480 on a $20\,\mu m$ pitch, using As and In for p- and n-type doping. *Gavrand* et al. [15.70] describe the use of their material, grown on 100 mm GaAs substrates, for space applications, avalanche photodiodes and dual-band detectors. *Ziegler* et al. [15.117] report on the growth of material, again on 100 mm GaAs substrates, and its use in MW 1280×1040 on a $15\,\mu m$

pitch operating at 80–110 K, and LW 1280 × 1040 on a 15 µm pitch operating at 76 K. Reduced dark current was obtained by grading the composition in single-color devices, an advantage of MBE over LPE. An alternative substrate material has been proposed by *Lei* et al. [15.118]. They used GaSb, which is a better lattice match to MCT and has lower FWHM and EPD than equivalent GaAs substrates, but is three times more expensive, and grew CdTe buffer layers that were at least equivalent in quality to those grown on GaAs substrates. No growth of MCT has been reported on this substrate as yet. Garland [15.10, Chap. 16] recently reviewed the field of superlattices for very-LW detectors. Advantages include bandgap engineering to suppress Auger recombination, a decrease in band-to-band tunneling currents, sharper optical cutoffs whose absorptivities are higher and flatter as a function of wavelength, than their normal MCT counterparts. However, disadvantages include insufficient lateral uniformity across layers, difficulty in p-type doping and interdiffusion issues during p-type dopant activation and device processing.

15.5 Alternatives to MCT

Rogalski and coworkers [15.1, 119, 120] have given details about several Hg-based alternatives to MCT for infrared detection. He concludes that from the range of possibilities only HgZnTe and HgMnTe are serious candidates. Theoretical considerations of *Sher* et al. [15.121] showed that the Hg–Te bond is stabilized by addition of ZnTe, unlike the destabilization that occurs when CdTe is added, i. e., as in MCT.

The pseudobinary phase diagram of HgZnTe shows even more separation of solidus and liquidus than does the equivalent for MCT (Fig. 15.15). This leads to large segregation effects, large composition variations for small temperature changes, as well as the high Hg vapor pressure presenting the usual problems of containment. HgTe and MnTe are not completely miscible over the entire range, the single-phase region is limited to $\approx x < 0.35$. The solidus–liquidus separation in the HgTe-MnTe pseudobinary is ≈ half that in MCT, therefore for equivalent wavelength uniformity requirements crystals of the former must be much more uniform than MCT crystals.

Three methods – Bridgman, SSR and THM – are the most popular ones for the bulk growth of HgZnTe and HgMnTe. The best quality crystals have been produced by THM [15.123], with uniformities of ±0.01 in both axial and radial directions for HgZnTe. For HgMnTe, *Bodnaruk* et al. [15.124] produced crystals of $0.04 < x < 0.2$ with uniformities of ±0.01 and ±0.005 in the axial and radial directions, while *Gille* et al. [15.125] grew $x = 0.10$ crystals with ±0.003 along a 16 mm diameter slice. *Becla* et al. [15.126] achieved a decrease in radial variations by applying a magnetic field.

These bulk crystals are suitable for some device architectures but higher performance is obtained in more

sophisticated structures that can only be made by epitaxial techniques. The advantages are the usual ones of lower growth temperature, lower Hg vapor pressure, shorter growth times and less precipitation with improved uniformity of composition. These features have been discussed in detail and descriptions of the various epitaxial processes given by *Rogalski* [15.119, 122, 127]. LPE growth of HgCdZnTe and HgCdMnTe by *Uchino* and *Takita* [15.128] showed that incorporation of Zn or Mn improved the uniformity of composition. HgMnTe films have been grown by MOCVD using the IMP technique, with both n- and p-type layers being produced. As in all epitaxial growth techniques there is a need for suitable (i. e., nearly lattice-matched) large-area single-crystal substrates. Figure 15.16 shows the lattice constants of the Hg-based alloy systems at room temperature. There are larger differences between the lattice parameters of HgTe and ZnTe and HgTe and MnTe than between HgTe and CdTe. At first sight it would appear that CdMnTe would be a suitable substrate system for these ternary alloys, but CdMnTe crystals grown by the Bridgman process are highly twinned and therefore unsuitable for use as substrates.

16. Wide-Bandgap II–VI Semiconductors: Growth and Properties

Minoru Isshiki, Jifeng Wang

Wide-bandgap II–VI compounds are been applied to optoelectronic devices, especially light-emitting devices in the short-wavelength region of visible light, because of their direct gap and suitable bandgap energies. Many methods have been extensively applied to grow high-quality films and bulk single crystals from the vapor and liquid phases.

This chapter firstly discusses the basic properties and phase diagrams of wide-bandgap II–VI compounds such as ZnS, ZnO, ZnSe, ZnTe, CdSe and CdTe. Then the growth methods and recent progress in films and bulk crystal growth are reviewed. In the epitaxial growth methods, the focus is on liquid-phase epitaxy (LPE), vapor-phase epitaxy (VPE) containing conventional VPE, hot-wall epitaxy (HWE), metalorganic chemical vapor deposition (MOCVD) or metalorganic phase epitaxy (MOVPE), molecular-beam epitaxy (MBE) and atomic-layer epitaxy (ALE). In bulk crystal growth, two typical growth methods, chemical/physical vapor transport (CVT/PVT) and Bridgman techniques, are introduced.

References 381

Wide-bandgap II–VI compounds are expected to be one of the most vital materials for high-performance optoelectronics devices such as light-emitting diodes (LEDs) and laser diodes (LDs) operating in the blue or ultraviolet spectral range. Additionally, the high ionicity of these compounds makes them good candidates for high electro-optical and electromechanical coupling. The basic promises of wide-bandgap materials can be found in Fig. 16.1.

Thin films were commonly grown using the conventional vapor-phase epitaxy (VPE) method for 60 s. With the development of science and technology, new and higher requirements arose for material preparation. For this reason, novel epitaxial growth techniques were developed, including hot-wall epitaxy (HWE) [16.1], metalorganic chemical vapor deposition (MOCVD) [16.2], molecular-beam epitaxy (MBE) [16.3], metalorganic molecular-beam epitaxy (MOMBE) [16.4] and atomic-layer epitaxy (ALE) [16.5]. Using these growth methods, film thickness can be controlled, and quality can be improved.

On the other hand, basic research work into growing bulk crystals of wide-bandgap II–VI compounds has been carried out. Focus was put on high-purity, high-quality, large single crystals [16.6–10]. Since the electrical and optical properties of semiconductor compounds are drastically affected by impurities and native defects, purity and quality are very important for fundamental research and engineering application where they are used as substrates. Bulk single crystals of these wide-bandgap II–VI compounds have been grown from the vapor, liquid and solid phases. Vapor-phase growth includes chemical vapor transport (CVT) and physical vapor transport (PVT) methods; liquid-phase methods includes growth from the melt or solvent. Among these growth methods, melt growth is most suitable to pro-

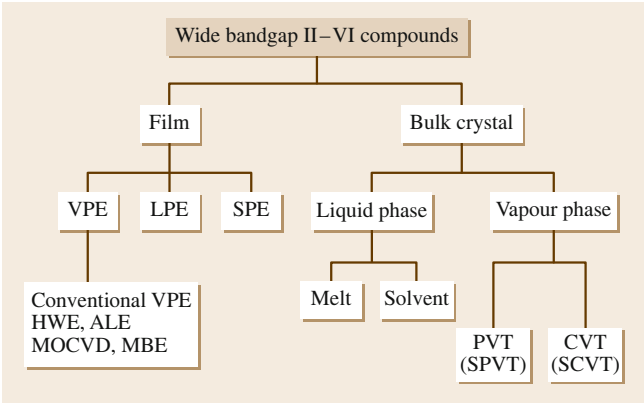

Fig. 16.2 Film and bulk-crystal growth techniques for II–VI wide-bandgap compounds

duce sizable bulk crystals for relatively short growth duration. Growth methods for films and bulk crystals of wide-bandgap II–VI compounds are summarized in Fig. 16.2 and the details can be found in Sects. 16.2 and 16.3.

This chapter firstly describes the physical and chemical properties of these wide-bandgap II–VI compounds, then reviews the growth techniques and introduces the main results in preparing film and bulk single crystals of ZnS, ZnO, ZnSe, ZnTe, CdTe, and so on.

16.1 Crystal Properties

16.1.1 Basic Properties

Wide-bandgap compound semiconductors have higher melting points. Due to their high ionicity, the overheating phenomenon occurs when they are heated to their melting point. Owing to the higher vapor pressures at their melting points, it is difficult to grow bulk crystals from melt. On the other hand, it is easy to grow bulk crystals as well as their films from the vapor phase. Therefore, before introducing film and bulk crystal growth, it is necessary to review their physical and chemical properties. Table 16.1 shows the properties of some of the main II–VI compound semiconductor materials [16.11–24].

16.1.2 Phase Diagram

It is necessary to understand the phase diagram to grow high-quality film and bulk single crystals. Figure 16.3 shows the phase diagrams reported for ZnS [16.25], ZnSe [16.25, 26], ZnTe [16.25], CdSe [16.27] and CdTe [16.28, 29]. Although much work has been done, there some exact thermodynamic data are still lacking, especially details close to the congruent point. Unfortunately, the phase diagram of ZnO is not available in spite of its growing importance in applications.

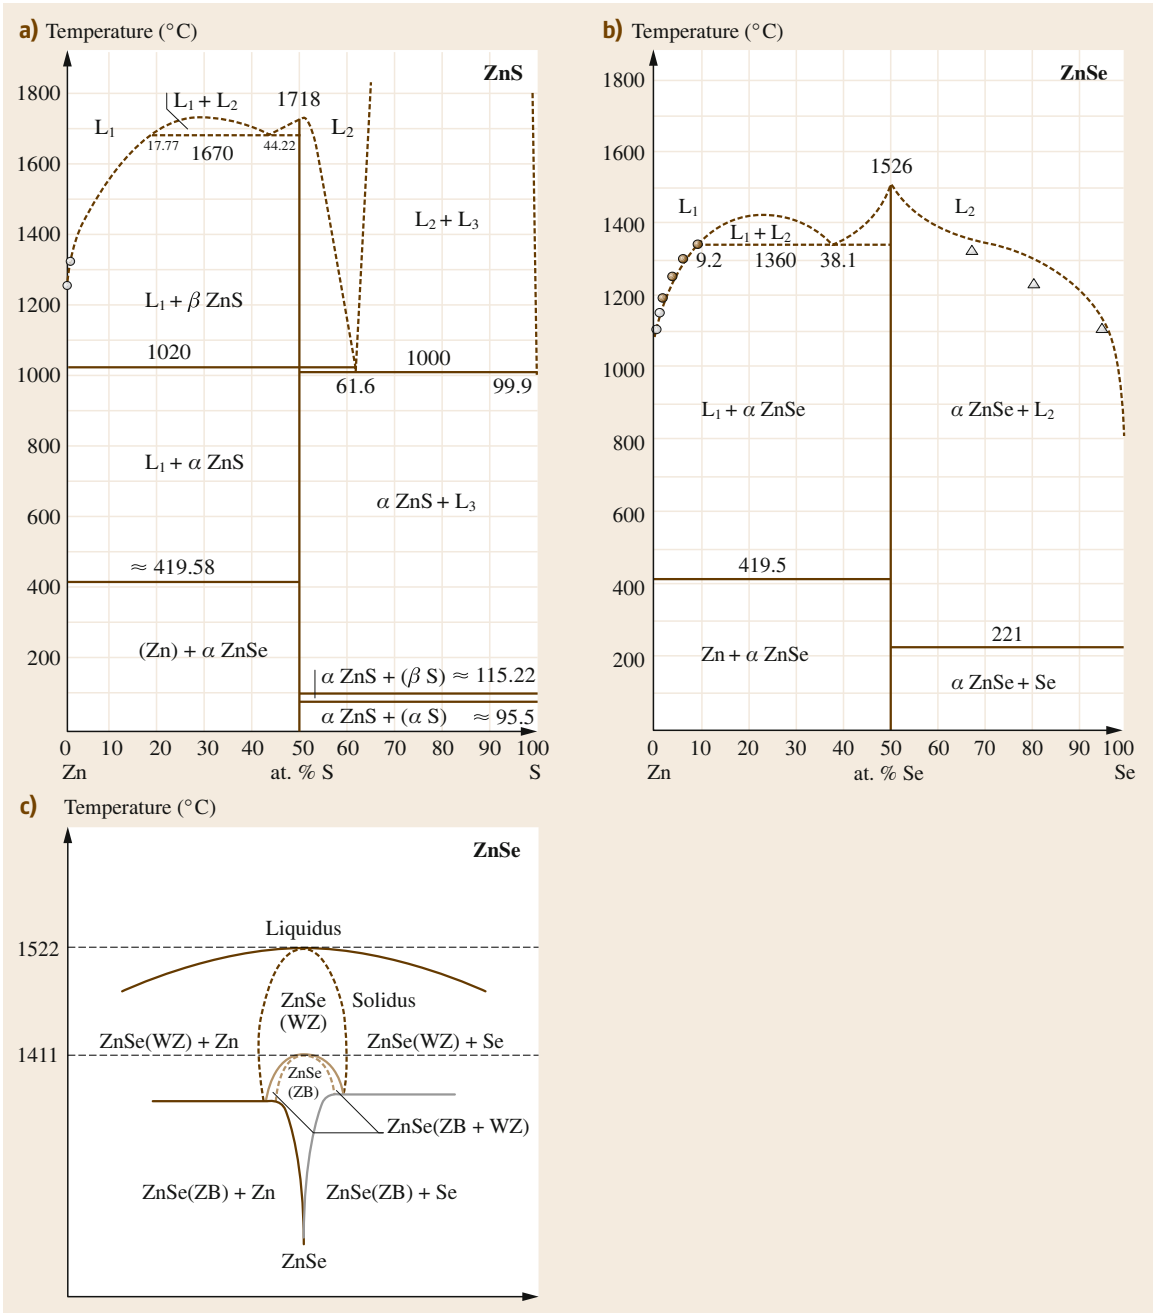

Fig. 16.3a–g Phase diagrams of some main wide-bandgap II–VI compounds. **(a)** ZnS, **(b)** ZnSe, **(c)** ZnSe phase diagram near the congruent point; **(d)** ZnTe; **(e)** CdSe; **(f)** CdTe; **(g)** CdTe phase diagram near the congruent point

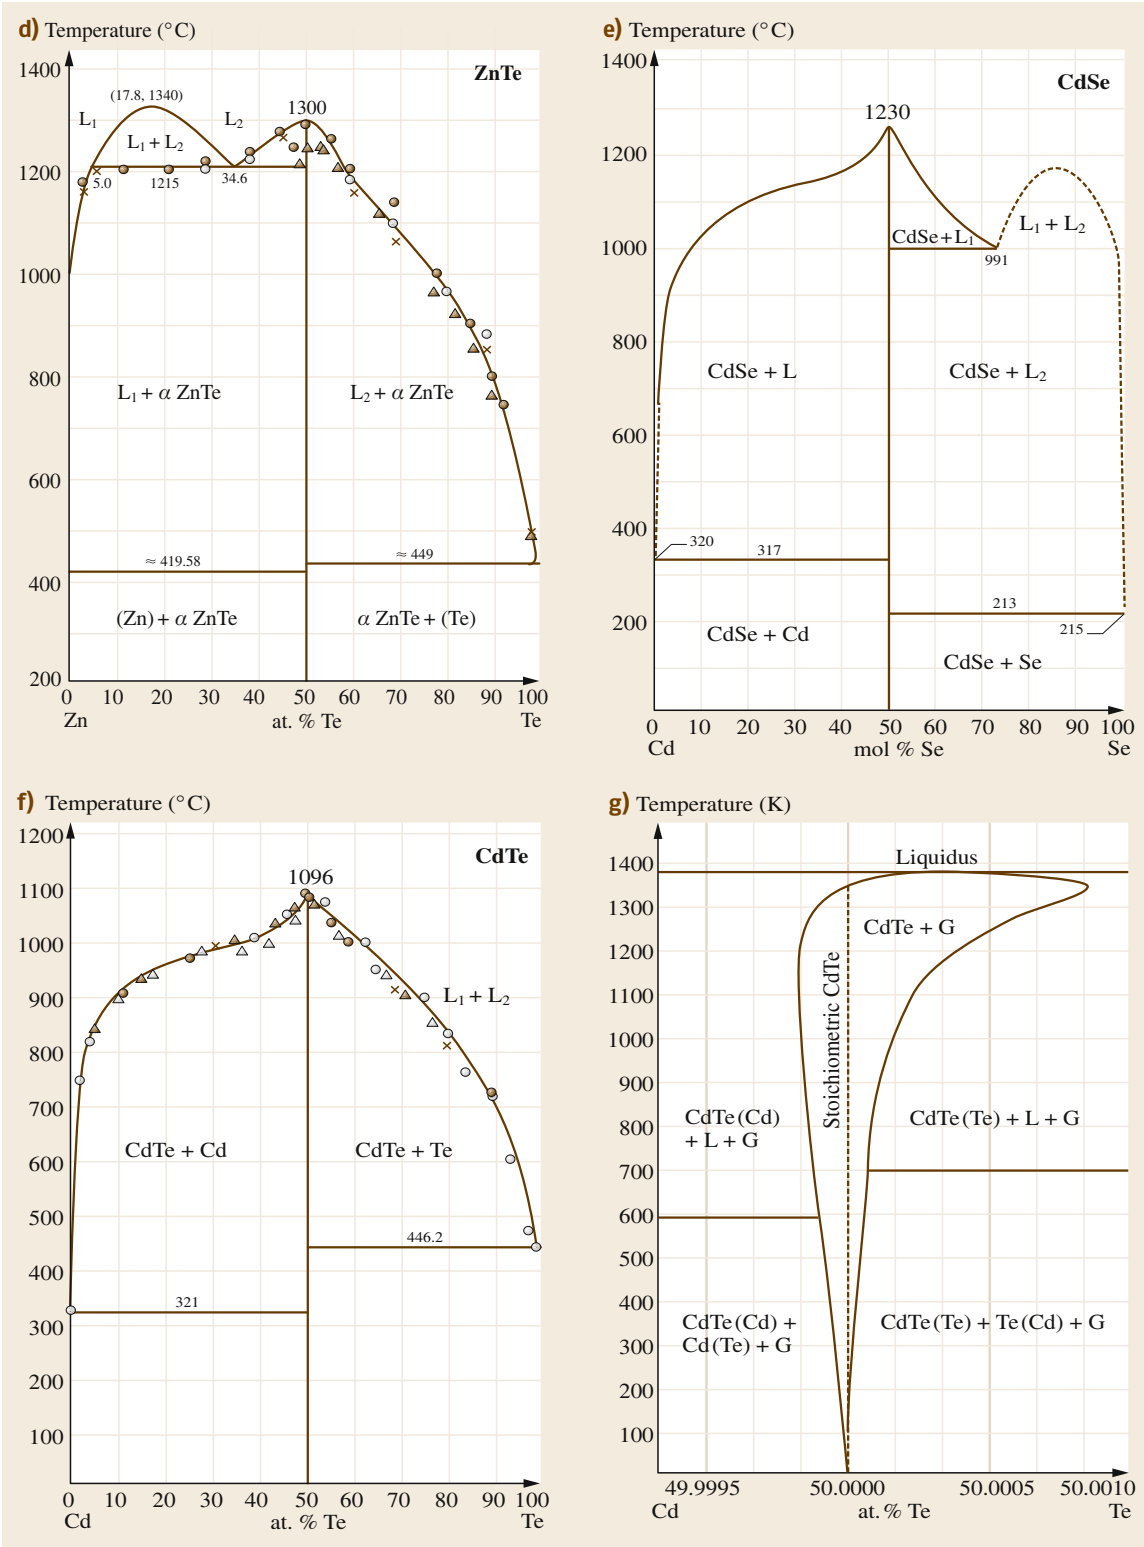

Fig. 16.3 (continued)

16.2 Epitaxial Growth

Epitaxial growth of wide-bandgap II–VI compounds was mainly carried out using liquid-phase epitaxy (LPE), or VPE. VPE includes several techniques, such as conventional VPE, hot-wall epitaxy (HWE), metalorganic chemical vapor deposition (MOCVD) or metalorganic phase epitaxy (MOVPE), molecular-beam epitaxy (MBE), metalorganic molecular-beam epitaxy (MOMBE) and atomic-layer epitaxy (ALE), etc. Each of these methods has its advantages and disadvantages. They are summarized in Table 16.2.

In the case of hetero-epitaxy, the mismatch between substrate material and epitaxial layer affects the growing structure and quality of the epitaxial layer. The mismatch should be made as small as possible when choosing the pair of materials (substrate and epitaxial material). Furthermore, the difference between the thermal expansion coefficients of the pair of materials has to be considered to obtain high-quality epitaxial layer [16.30].

16.2.1 The LPE Technique

LPE growth occurs at near-thermodynamic-equilibrium conditions. There are two growth methods. The first is called equilibrium cooling, in which the saturated solution is in contact with the substrate and the temperature is lowered slowly, the solution becomes supersaturated; meanwhile a slow epitaxial growth on the substrate is initiated. The second is the step-cooling process, in which the saturated solution is cooled down a few degrees (5−20 K) to obtain a supersaturated solution. The substrate is inserted into the solution, which is kept at this cooled temperature. Growth occurs first due to the supersaturation, and will slow down and stop finally. For both techniques, if the substrate is dipped in sequence into several different melt sources, multiple layer structures can be grown. LPE can successfully and inexpensively grow homo- and heterostructures. As the growth is carried out under thermal equilibrium, an epilayer with a very low native defect density can be obtained.

The LPE method can be used to grow high-quality epilayers, such as ZnS [16.31], ZnSe [16.31, 32], ZnSSe [16.33], ZnTe [16.34], etc. *Werkhoven* et al. [16.32] grew ZnSe epilayers by LPE on ZnSe substrates in a low-contamination-level environment. In their study, the width of bound exciton lines in low-temperature photoluminescence spectra was used to define the quality of the material, and the energy of the lines was used to identify trace impurities. The photoluminescence (PL) results showed that the ZnSe epitaxial layer has the high quality. The sharpest spectra occurred in layers grown rapidly on a previously grown buffer layer, indicating the importance of impurity out-diffusion from the substrate into the growing layer. The sharpness of these bound exciton lines indicates that the total concentration of electrically active impurities ($N_A + N_D$) was below $10^{17}\,\mathrm{cm}^{-3}$.

Table 16.2 Strengths and weaknesses of several epitaxial growth techniques

LPE	Thermodynamic equilibrium growth Easy-to-use materials Low-temperature growth High purity Multiple layers Thickness control not very precise Poor surface/interface morphology
HWE	Easy-to-use materials Low cost Thermodynamic equilibrium Hard to grow thick layers Thickness control not very precise
VPE	Easy to operate Economic Thinner layers High growth rates Easier composition control High temperature (800−1000 °C)
ALE	Gaseous reaction for deposition Low-temperature growth Precise composition Low growth rate Safety precautions needed
MOCVD	Gaseous reaction for deposition Precise composition Patterned/localized growth Potentially easier large-area multiple-wafer scale-up Low-temperature growth High-vapor-pressure materials growth allowed About 1 ML/s deposition rate Expensive equipment Safety precautions needed
MBE and MOMBE	Physical vapor deposition Ultra-high-vacuum environment About 1 ML/s deposition rate In situ growth-front monitoring Precise composition Low growth rate Sophisticated equipment Limit for high-vapor-pressure materials growth (MBE)

ML – monolayer

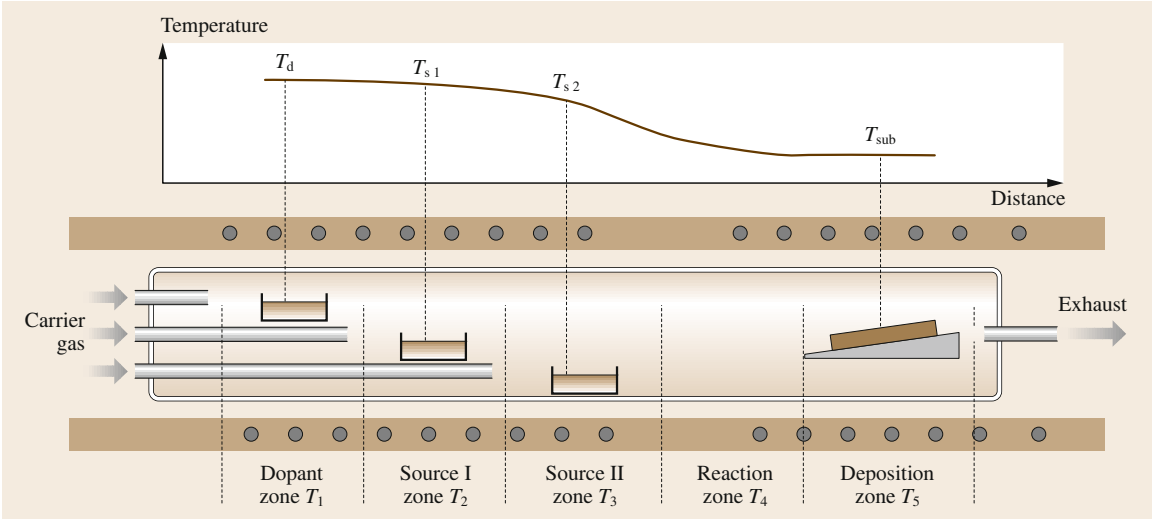

Fig. 16.4 A typical VPE growth system

16.2.2 Vapor-Phase Epitaxy Techniques

Conventional VPE

A typical VPE growth system is shown in Fig. 16.4. In VPE growth, thin films are formed by the deposition of atoms from the vapor phase. There are two types of transport mechanisms for the source materials, physical vapor deposition (PVD) without any chemical reaction, and chemical vapor deposition (CVD), where the formation of the deposited film is the result of a chemical reaction of the precursors on the substrate. In VPE growth, there are several important parameters, such as the source temperature, the substrate temperature, the flow rate of the carrier gas, the growth pressure, and so on. These determine the growth rate, composition, and crystallinity of the epitaxial layers.

The VPE technique is the most popular in semiconductor epitaxial growth. Since the vapor pressures of all wide-bandgap II–VI materials are high, their epitaxial layers can be grown by this method. As an example, high-quality ZnS single-crystal films have been grown on a Si substrate using hydrogen as a carrier gas [16.35, 36]. Furthermore, the Iida group [16.37] doped N and P into a ZnS epilayer and studied their behavior in details. The N and P were expected to compensate the native donor state and to result in an insulating material. The results showed that the doped acceptors N and P reduced the donor density and an insulating material was obtained. Later, this group was successful in preparing a p-type ZnS epilayer using NH_3 as an acceptor dopant [16.38]. Many efforts have been made to grow ZnSe epilayers on different substrates, especially on GaAs in the past two decades [16.39, 40]. p-type ZnSe was also obtained by this technique [16.41]. In addition, other compounds, ZnTe [16.42], CdS [16.43], CdSe [16.44], and CdTe [16.45], were also studied using this technique.

The HWE Technique

Hot-wall epitaxy [16.1] has proved to be a very successful growth method for II–VI compound epitaxial layers. Its principal characteristic is the growth of thin films under conditions near thermodynamic equilibrium. Compared with other VPE methods, the HWE technique has the advantages of low cost, simplicity, convenience, and relatively high growth rate. In particular, it can control deviation from stoichiometry during growth of an epilayer.

A schematic diagram of the improved HWE system is showed in Fig. 16.5; it consists of four independent furnaces. The source material placed at the middle is transported to the substrate. The region of the growth reactor between the source and substrate, called the hot wall, guarantees a nearly uniform and isotropic flux of molecules onto the substrate surface. To control the deviation from stoichiometry, the reservoir part is placed at the bottom with a constituent element.

HWE has been applied to growing II–VI compound epilayers, such as CdTe [16.46], CdS [16.47], CdSe [16.48], ZnTe [16.49], and also to producing heterostructures for laser and photovoltaic detector fabrication [16.50]. Most research using HWE technique has focused on CdTe growth. *Wang* et al. [16.46] optimized growth conditions and grew high-quality CdTe epitaxial films using the HWE apparatus shown in Fig. 16.5. All the CdTe epilayers show mirror-like surfaces. Results from PL and x-ray diffraction (XRD) show that CdTe epilayers on GaAs suffer from a bi-

axial compressive stress, that this stress is rapidly relaxed within a thickness of about 5 μm, and that it remains in the epilayer up to a film thickness of 15 μm. Although this heterosystem has a 14.6% lattice mismatch and −26% thermal expansion mismatch at 300 K, high-quality CdTe epilayers, with a full-width half-maximum (FWHM) of 0.26 meV for bound-exciton emission lines in 4.2-K PL, about 90 arcs for (400) diffraction in four-crystal XRD spectrum, were prepared by selecting suitable growth conditions and epilayer thickness.

Recently, significant results have been achieved for CdTe/Si (111) epilayer growth by HWE. *Lalev* et al. [16.51] reported that high-quality CdTe (111) epilayers with *A* polarity were directly grown on hydrogen-terminated Si (111) without any preheating treatment. Through the originally designed two-step growth regime, the crystal quality of CdTe film was significantly improved, and the best FWHM value of 118 arcs from four-crystal rocking curves was obtained for a 5 μm-thick epilayer.

The MOCVD Technique

MOCVD or MOVPE is an improvement over conventional VPE. Since its introduction in 1968 [16.52], this technique has been established as one of the techniques for epitaxial growth of compound semiconductors both for research and production. The factors that have allowed MOCVD to reach this popularity are the purity and abruptness of the grown layers together with the flexibility of the technique, which makes the growth of almost all compound semiconductors possible. This abrupt transition in the composition of the epitaxial structure is necessary for the fabrication of digital or analog alloy system.

The development history of MOCVD technique is equivalent to that of source precursors. Since ZnSe epilayers were grown by MOCVD [16.52], many source precursors of II–VI elements have been developed. $Zn(CH_3)_2$ dimethylzinc (DMZn) and $Zn(C_2H_5)_2$ diethylzinc (DEZ) were used at the beginning of MOCVD growth [16.53]. ZnSe and ZnS films were grown using these metalorganic sources and inorganic H_2Se or H_2S. Unfortunately, the quality of these films was very poor. For this reason, $Se(CH_3)_2$ dimethylselenide (DMSe) and $Se(C_2H_5)_2$ diethylselenium (DESe) were developed [16.54]. The quality of epilayers was greatly improved. From then, II and VI elemental gas precursors were proposed one after another. *Wright* et al. grew a ZnSe film using (DMZn-$(NEt_3)_2$) triethylamine adduct of dimethylzinc [16.55]. *Hirata* et al. [16.56] and *Nishimura* et al. [16.57] proposed methylselenol (MSeH) and tertiarybutylselenol (*t*-BuSeH) as Se sources, respectively. Methylallylselenide

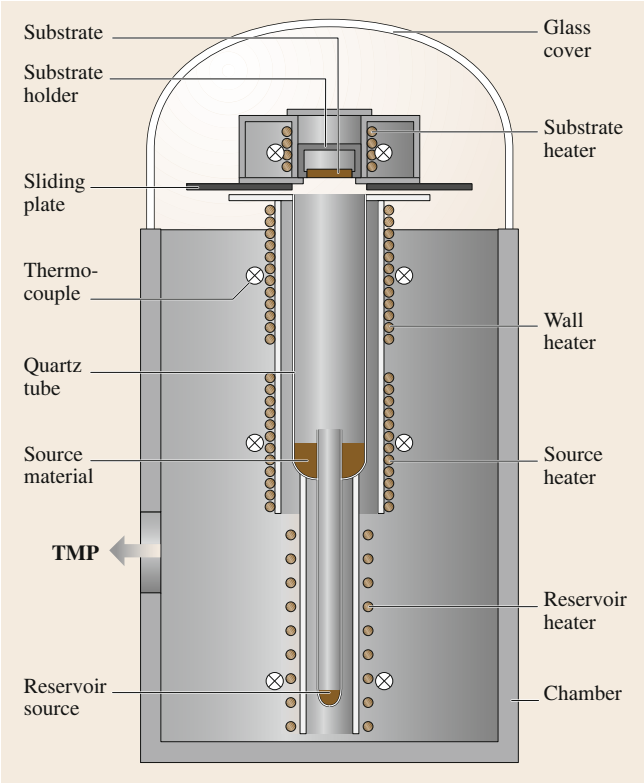

Fig. 16.5 Diagram of a typical HWE system growth chamber

(MASe) [16.58], diallyl-selenide (DASe) [16.59], t-butylallylselenide (*t*-BuASe) [16.60], tertiarybutyl-selenide (*Dt*-BuSe) [16.61], were also used as Se sources. *Fujita* et al. found methylmercaptan (MSH) as an S source [16.53]. Besides these, many other source precursors of II–VI elements, such as $Cd(CH_3)_2$ dimethylcadmium (DMCd) [16.62], $Te(CH_3)_2$ dimethyltelluride (DMTe) [16.62], $Te(C_2H_5)_2$ diethyltelluride (DETe), $Te(C_3H_7)_2$ diisopropyltelluride (DIPTe) [16.63], $S(C_2H_5)_2$ diethylsulfide (DES), $S(C_4H_9)_2$ ditertiarybutylsulfide (DTBS), $(C_4H_9)SH$ tertiarybutylthiol (tBuSH), have been used.

The great advantage of using metalorganics is that they are volatile at moderately low temperatures. Since all constituents are in the vapor phase, precise electronic control of gas flow rates and partial pressures is possible. This, combined with pyrolysis reactions that are relatively insensitive to temperature, allows efficient and reproducible deposition.

The substrate wafer is placed on a graphite susceptor inside a reaction vessel and heated by a radio-frequency (RF) induction heater. The growth temperature depends on the type of compounds grown. Growth is carried out in a hydrogen atmosphere at a pressure of 100–700 torr. The growth precursors decompose on

contact with the hot substrate to form epitaxial layers. Each layer is formed by switching the source gases to yield the desired structure.

The films of almost all wide-bandgap II–VI compounds have been grown by MOCVD technique. Most work has been done on p-ZnSe epilayers in the past two decades [16.64–66]. The highest hole concentration of $8.8 \times 10^{17}\,\mathrm{cm}^{-3}$ was reported with a NH_3 doping source [16.67]. Recently, quantum wells (QWs) and quantum dots (QDs) of these wide-bandgap compounds have become the focus. Successful pulsed laser operation at 77 K in ZnCdSe/ZnSe/ZnMgSSe QW-structure separated-confinement heterostructures has been realized [16.68].

MBE and MOMBE

MBE was developed at the beginning of the 1970s to grow high-purity high-quality compound semiconductor epitaxial layers on some substrates [16.69, 70]. To date, it has become a very important technique for growing almost all semiconductor epilayers. An MBE system is basically a vacuum evaporation apparatus. The pressure in the chamber is commonly kept below $\approx 10^{-11}$ torr. Any MBE process is dependent on the relation between the equilibrium vapor pressure of the constituent elements and that of the compound [16.71]. There are a number of features of MBE that are generally considered advantageous for growing semiconducting films: the growth temperature is relatively low, which minimizes any undesirable thermally activated processes such as diffusion; the epilayer thickness can be controlled precisely; and the introduction of different vapor species to modify the alloy composition and to control the dopant concentration can be conveniently achieved by adding different beam cells with proper shutters. These features become particularly important in making structures involving junctions.

Metalorganic molecular-beam epitaxy growth (MOMBE) is one of the variations of the MBE system [16.72, 73]. The difference is that metalorganic gaseous sources are used as the source materials. Therefore, this growth technique has the merits of MOCVD and MBE.

MBE or MOMBE techniques have been used to grow epilayers of almost all wide-bandgap II–VI semiconductors [16.74, 75]. Due to its features, it is very successful in growing super-thin layers, such as single quantum wells (SQWs), multiple quantum wells (MQWs) [16.76, 77] and nanostructures [16.78].

In nanostructures, quantum dot (QD) structures have attracted a lot of attention in recent years. This field represents one of the most rapidly developing areas of current semiconductor. They present the utmost challenge to semiconductor technology, rendering possible fascinating novel devices. QD are nanometer-size semiconductor structures where charge carriers are confined in all three spatial dimensions. They are neither atomic nor bulk semiconductor, but may best be described as artificial atoms.

In the case of heteroepitaxial growth there are three different growth modes [16.79]: (a) Frank–van der Merwe (FM) or layer-by-layer growth, (b) Volmer–Weber (VW) or island growth, and (c) Stranski–Krastanov (SK) or layer-plus-island growth. Which growth mode will be adopted in a given system depends on the surface free energy of the substrate, (σ_s), that of the film, (σ_f), and the interfacial energy (σ_i). Layer-by-layer growth mode occurs when $\Delta\sigma = \sigma_f + \sigma_i - \sigma_s = 0$. The condition for FM-mode growth is rigorously fulfilled only for homoepitaxy, where $\sigma_s = \sigma_f$ and $\sigma_i = 0$. If the FM-mode growth condition is not fulfilled, then three-dimensional crystals form immediately on the substrate (VW mode). For a system with $\Delta\sigma = 0$ but with a large lattice mismatch between the substrate and the film, initial growth is layer-by-layer. However, the film is strained. As the film grows, the stored strain energy increases. This strained epilayer system can lower its total energy by forming isolated thick islands in which the strain is relaxed by interfacial misfit dislocations, which leads to SK growth in these strained systems. The SK growth mode occurs when there is a lattice mismatch between the substrate and the epilayer, causing the epilayer to be strained, which results in the growth of dot-like self-assembled islands. Wire-like islands can grow from dot-like islands via a shape transition which helps strain relaxation.

For nanostructure fabrication, a thin epilayer is usually grown on a substrate. This two-dimensional (2-D) layer is used to fabricate lower-dimensional structures such as wires (1-D) or dots (0-D) by lithographic techniques. However, structures smaller than the limits of conventional lithography techniques can only be obtained by self-assembled growth utilizing the principles of SK or VW growth. For appropriate growth conditions, self-assembled epitaxial islands can be grown in reasonably well-controlled sizes [16.80].

Because wide-bandgap II–VI materials typically have stronger exciton–phonon interactions than III–V materials, their nanostructures are expected to be very useful in fabricating optoelectronics devices and in exploring the exciton nature in low-dimensional structure. Self-assembled semiconductor nanostructures of different system, such as CdSe/ZnSe [16.81], ZnSe/ZnS [16.82], CdTe/ZnTe [16.83], CdS/ZnSe [16.84], are thought to be advantageous for future application. MBE/MOMBE [16.81, 84], MOCVD [16.82], HWE [16.85] are the main growth techniques used

to obtain such structures. MBE is the most advanced technique for the growth of controlled epitaxial layers. With the advancement of nanoscience and nanotechnology, lower-dimensional nanostructures are being fabricated by lithographic techniques from two-dimensional epitaxial layers. Alternately, self-assembled, lower-dimensional nanostructures can be fabricated directly by self-assembly during MBE growth.

Atomic-Layer Epitaxy

ALE is a chemical vapor deposition technique [16.5] where the precise control of the system parameters (pressure and temperature) causes the reaction of adsorption of the precursors to be self-limiting and to stop with the completion of a single atomic layer. The precursors are usually metalorganic molecules. The special feature of ALE is that the layer thickness per cycle is independent of subtle variations of the growth parameters. The growth rate is only dependent on the number of growth cycles and the lattice constant of the deposited material. The conditions for thickness uniformity are fulfilled when material flux on each surface unit is sufficient for monolayer saturation. In an ALE reactor, this means freedom in designing the precursor transport and its interaction with the substrates.

The advantages obtainable with ALE depend on the material to be processed and the type of application. In single-crystal epitaxy, ALE may be a way to obtain a lower epitaxial crystal-growth temperature. It is also a method for making precise interfaces and material layers needed in superlattice structures and superalloys. In thin-film applications, ALE allows excellent thickness uniformity over large areas. The process has primarily been developed for processing of compound materials. ALE is not only used to grow conventional thin films of II–VI wide-bandgap compounds [16.5, 86, 87], but is also a powerful method for the preparation of monolayers (MLs) [16.88].

16.3 Bulk Crystal Growth

Bulk crystal is the most important subject studied in recent decades. The quality of bulk crystals is the most important aspect of electronic device design. To date, many growth methods have been developed to grow high-quality crystals. Significant improvements have been made in bulk crystal growth with regard to uniformity, reproducibility, thermal stability, diameter control, and impurity and dopant control. According to the phase balance, crystals can be grown from vapor phase, liquid (melt) phase, and solid phase.

16.3.1 The CVT and PVT Techniques

Crystal growth from the the vapor phase is the most basic method. It has advantages that growth can be performed at lower temperatures. This can prevent from phase transition and undesirable contamination. Therefore, this method has commonly been used to grow II–VI compound semiconductors. Crystal growth techniques from the vapor phase can be divided into chemical vapor transport (CVT) and physical vapor transport (PVT). CVT is based on chemical transport reactions that occur in a closed ampoule having two different temperature zones. Figure 16.6 shows a typical schematic diagram of the CVT technique. In the high-temperature region, the source AB reacts with the transport agent X

$$2\mathrm{AB} + 2\mathrm{X_2} \rightleftharpoons 2\mathrm{AX_2(gas)} + \mathrm{B_2(gas)}\ . \qquad (16.1)$$

In the low-temperature region, the reverse reaction takes place. The whole process continues by back-diffusion of the X_2 generated in the lower-temperature region. The transport agent X usually employed is hydrogen (H_2), a halogen (I_2, Br_2, Cl_2), a halide (HCl, HBr), and so on. For example, I_2 has been used as a transport agent for ZnS, ZnSe, ZnTe and CdS [16.89]; HCl, H_2, Cl_2, NH_3 [16.90], and C and CH_4 [16.91] have been used as the transport agents for ZnO. According to [16.89]: the typical growth temperature for ZnS is 1073−1173 K, for ZnSe 1023−1073 K, for ZnTe

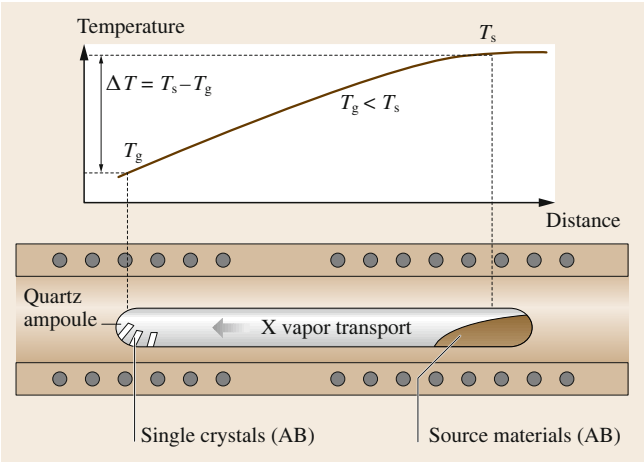

Fig. 16.6 Diagram of a conventional chemical vapor transport system

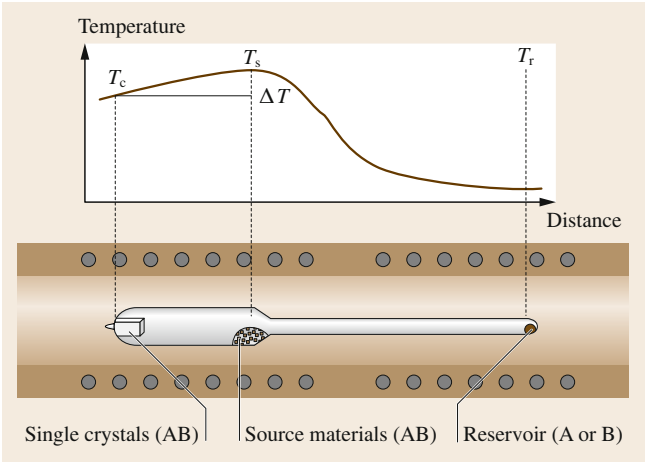

Fig. 16.7 Diagram of the physical vapor transport Piper–Polich method

973−1073 K; ΔT is 5−50 K; the concentration of the transport agent is 0.5−5 mg/cm^3 of the ampoules vapor space; the aspect ratios are 5−17 at ampoule diameters of 10−20 mm. According to [16.91]: the growth temperature for ZnO is 1228−1273 K, and ΔT is 5−10 K. The transport rate does not strongly depend on the initial amount of carbon when the concentration of the transport agent is over 0.3 mg/cm^3.

The PVT method is similar to CVT, but the transport agent is not used. This technique is based on the dissociative sublimation of compounds. Initially, the Piper–Polich method was developed, in 1961 [16.92]. *Prior* [16.93] improved the PVT method using a reservoir to control the deviation from stoichiometry; the experimental arrangement is shown in Fig. 16.7. The constituent element is placed in the reservoir. The reservoir temperature can be calculated according to the solid–vapor equilibrium

$$2\mathrm{AB} \rightleftharpoons 2\mathrm{A(gas)} + \mathrm{B_2(gas)}\,. \tag{16.2}$$

The total pressure (p) in ampoule is given by

$$\begin{aligned} p &= p_\mathrm{A} + p_{\mathrm{B}_2} \\ &= p_\mathrm{A} + K p_\mathrm{A}^{-2} \\ &= \left(\frac{K}{p_{\mathrm{B}_2}}\right)^{1/2} + p_{\mathrm{B}_2}\,, \end{aligned} \tag{16.3}$$

where p_A and p_{B_2} are the partial pressures of the group II and VI elements respectively and $K = p_\mathrm{A}^{-2} p_{\mathrm{B}_2}$ is the equilibrium constant of (16.2). At any temperature, there is minimum total pressure (p_min), which corresponds to the condition,

$$p_\mathrm{A} = 2p_{\mathrm{B}_2} = 2^{1/3} K^{2/3}\,. \tag{16.4}$$

Under this condition, the vapor-phase composition is stoichiometric and growth rate is maximum [16.94]. After modifying this method to use a closed ampoule, it was applied to grow high-purity and high-quality crystals of II–VI compounds.

The PVT of II–VI compounds takes advantage of the volatility of both components of the compound semiconductor. This same volatility, coupled with typically high melting points, makes melt growth of these materials difficult. In the PVT process, an ampoule containing a polycrystalline source of the desired II–VI compound is heated to a temperature that causes the compound to sublime at a rate conducive to crystal growth. The ampoule is typically placed in a furnace having a temperature gradient over the length of the ampoule, so that the polycrystalline source materials sublime at the end with the higher temperature. The end of the ampoule where the crystal is to be grown is then maintained at a lower temperature. This temperature difference causes supersaturation, and vaporized molecules from source materials eventually deposit at the cooler end. In order to control the deviation from stoichiometry, a reservoir is often used (Fig. 16.7). One of the constituent elements is placed in it. By selecting the proper growth conditions, the rate of deposition can be set to a value leading to growth of high-quality crystals. Typically, PVT growth of II–VI compounds is carried out at temperatures much lower than their melting points; this gives benefits in terms of reduced defects, which are related to the melt growth of II–VI compounds such as voids and/or inclusions of excess components of the compound, and also helps to reduce the contamination of the growing crystal from the ampoule. Other effects, such as the reduction of point defects, are also typically found when crystals grown by PVT are compared to crystals grown by melt techniques. Although claims have been made that the lower temperatures of physical vapor transport crystal growth should also reduce the twinning found in most of the cubic II–VI compound crystals, the reduction is not usually realized in practice. The assumption that the twinning is a result of cubic/hexagonal phase transitions is not found to be the determining factor in twin formation.

Ohno et al. [16.95] grew cubic ZnS single crystals by the iodine transport method without a seed. By means of Zn-dip treatment, this low-resistivity crystal was used for homoepitaxial MOCVD growth, and a metal–insulator–semiconductor (MIS)-structured blue LED, which yielded an external quantum efficiency as high as 0.05%. They found that crystal quality was significantly improved by prebaking the ZnS powder in H_2S gas prior to growth. The growth rate also increased by three times.

Isshiki et al. [16.96] purified zinc by a process consisting of vacuum distillation and overlap zone melting in pure argon. Using refined zinc and commercial high-purity Se, high-quality ZnSe single crystals were grown by the same method, as reported by *Huang* and *Igaki* [16.97]. The emission intensities of donor-bound exciton (I_2) are remarkably small. The emission intensities of the radiative recombinations of free excitons (E_X) are very strong [16.98]. These intensities indicated the crystal had a very high purity and a very low donor concentration, and they suggest that the purity of the grown crystal strongly depends on the purity of the starting materials. This method is suitable for preparing high-purity crystals, since a purification effect is expected during growth. Impurities with a higher vapor pressure will condense at the reservoir portion and those with a lower vapor pressure will remain in the source crystal. This effect was confirmed by the PL results [16.99]. As for these crystals, photoexcited cyclotron resonance measurements have been attempted and cyclotron resonance signals due to electrons [16.100] and heavy holes [16.101] have been detected for the first time. The cyclotron mobility of electrons under $B = 7\,\mathrm{T}$ is $2.3\times10^5\,\mathrm{cm^2/(V\,s)}$. This indicates that the quality of the grown crystals is very high. Furthermore, the donor concentration in the crystal is estimated to be $4\times10^{14}\,\mathrm{cm^3}$ by analyzing the temperature dependence of the cyclotron mobility [16.99].

The crystals are grown in a self-seeded approach by the CVT or PVT techniques introduced above. This limits single-crystal volume to several $\mathrm{cm^3}$. Meanwhile, grain boundaries and twins are easy to form during growth. In order to solve these problems, seeded chemical vapor transport (SCVT) and seeded physical vapor transport (SPVT), the so-called modified Lely method, have been developed [16.102]. The difference between SCVT/SPVT and CVT/PVT is that a seed is set in the crystal growth space before growth starts. The most successful method of eliminating twin formation has usually been by using a polycrystal or single-crystal seed. Even this seeding cannot assure complete elimination of twinning unless seeding is done carefully. The usual method of using small seeds and increasing the diameter of the growing crystal are dependent on the preparation and condition of the walls of the ampoule and the furnace profiles required to eliminate spurious nucleation from the walls. Since the use of a seed crystal provides better control over the nucleation process, high-quality single crystals can be grown [16.103, 104]. Using this technique, sizable single crystals of II–VI wide-bandgap compounds has been commercialized.

Fujita et al. [16.105] grew ZnS single crystals as large as $24\,\mathrm{mm}\times14\,\mathrm{mm}\times14\,\mathrm{mm}$ by the SCVT method using iodine as a transport agent. The average linear growth rate was about $10^{-6}\,\mathrm{cm/s}$. The crystal size depended strongly on the ampoule geometry and the temperature difference between the seed and solvent. The study of the electrical properties showed that the annealed crystal was n-type.

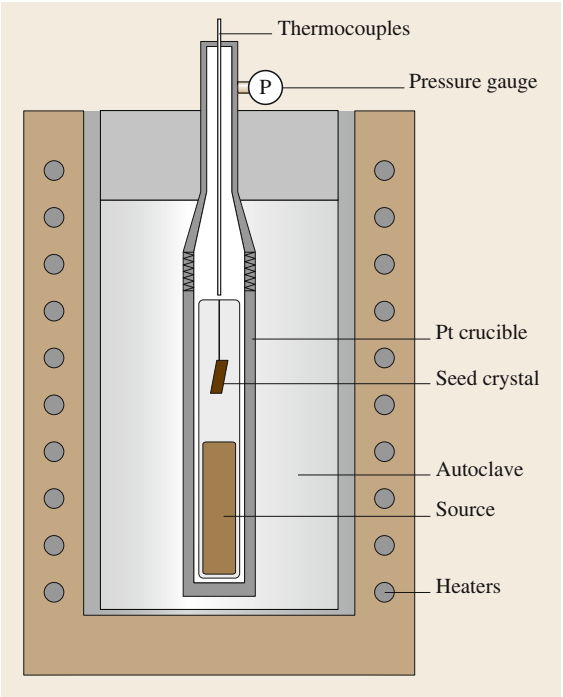

Fig. 16.8 Diagram of a typical hydrothermal technique for growing ZnO single crystals

16.3.2 Hydrothermal Growth

The hydrothermal technique is a method for growing crystal from aqueous solvent [16.106]. Figure 16.8 shows a diagram of hydrothermal techniques. The hydrothermal method of crystal growth has several advantages:

1. Due to the use of a closed system, it is easier to control oxidization or maintain conditions that allow the synthesis of phases that are difficult to attain by other methods, such as compounds of elements in oxidation states, especially for transition-metal compounds.
2. Crystal grow occurs under lower thermal strain, and thus may contain a lower dislocation density than when the crystal is grown from a melt, where large thermal gradients exist.
3. The method has proven to be very useful for the synthesis of the so-called low-temperature phases.

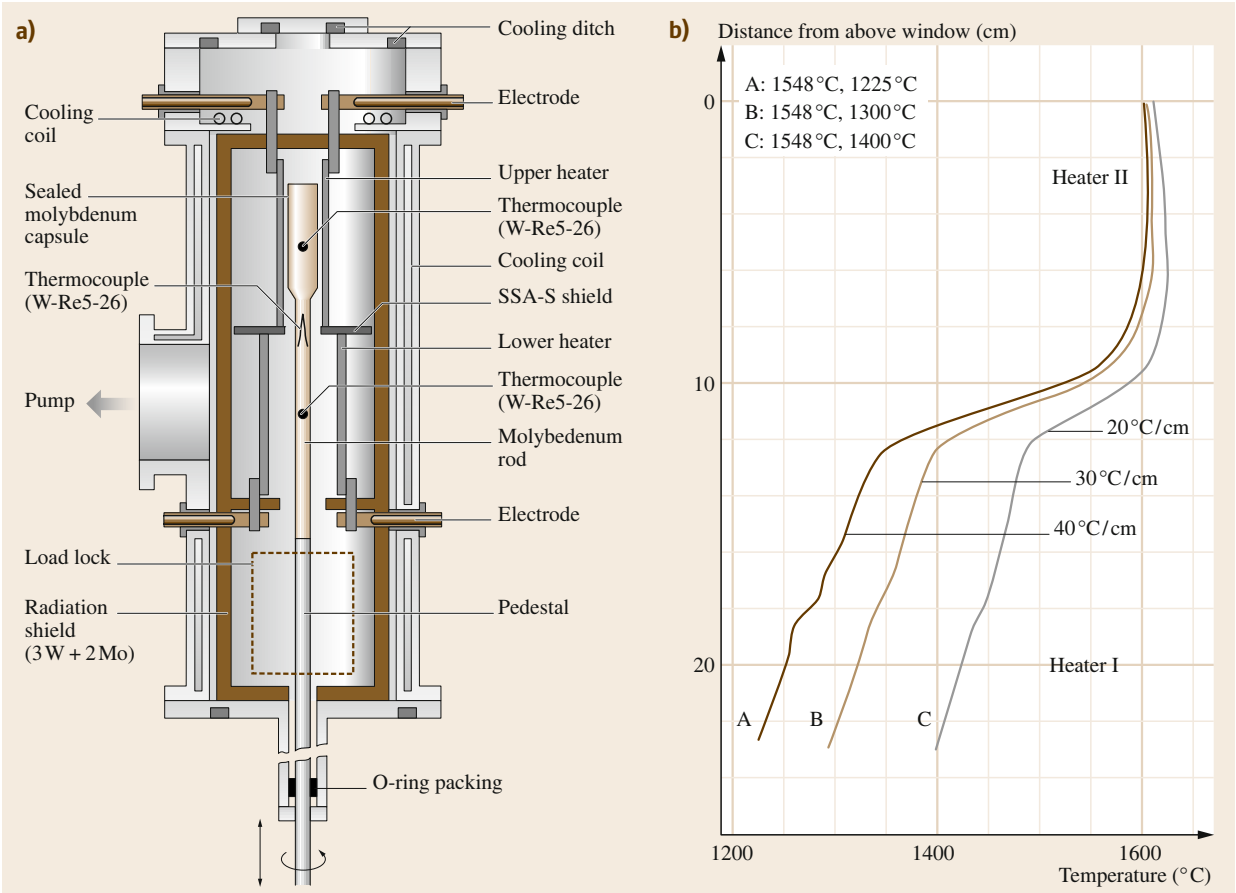

Fig. 16.9 (a) Scheme of the vertical Bridgman growth system, and (b) its temperature profiles

4. It can be employed for large-scale synthesis of piezoelectric, magnetic, optic, ceramic, and many other special materials.
5. Hydrothermal synthesis results in rapid convection and very efficient solute transfer, which results in comparatively rapid growth of larger, purer, and dislocation-free crystals.

The most successful example of obtaining II–VI compounds is growing single ZnO crystals.

ZnO crystals are considered extrinsic n-type piezoelectric semiconductors. Undoped crystals have a typical resistivity of 0.1−100 Ω cm and a drift mobility of 10−125 $cm^2/(V\,s)$. Low carrier concentrations can be approached by special growth and annealing methods. ZnO crystal is quite transparent in the range 0.4−6.0 μm. Slight absorption is sometimes found around 2.2−2.3 μm and an additional slight absorption is found at 3.42 μm. Since 1953, *Walker* [16.107] and many other researchers [16.108–111] have grown large ZnO single crystals with hydrothermal techniques and other methods.

The seed, suspended by a Pt wire, and sintered ZnO strings as a source material (nutrient), together with a KOH (3M) and LiOH (1M) aqueous solution, were put into a Pt crucible [16.112] (the hydrothermal conditions are different in different papers). The seed crystals and the source material were separated by a Pt baffle. The crucible was sealed by welding and put into an autoclave. This hydrothermal autoclave is made of high-strength steel. Then, the autoclave was put into a vertical furnace. The temperature of the autoclave was raised to about 673 K, which produced 0.1 GPa of pressure. the growth temperature was monitored by a thermocouple inserted in the autoclave. Seed crystals grew to about 10 mm or bigger after two weeks. The crystal habit of hydrothermal ZnO crystals grown on basal plane seeds shows that growth direction in [0001] is faster 3 times than $[000\bar{1}]$ [16.113].

16.3.3 Bridgman and Gradient Freezing (GF) Method

From the viewpoint of industrial production, melt growth is the most useful for obtaining large single crystals. VPE growth has limitations with regard to crystal size and productivity. The Bridgman technique is a typical crystal growth method from melt. Bridgman growth can be simply understood in terms of a molten charge that passes through a temperature gradient at a slow speed and solidifies when the temperature is below the melting point of this material. If the ampoule and furnace are stationary and the temperature is gradually reduced by keeping the temperature gradient at the interface constant, this growth process is called the gradient freezing (GF) method [16.114]. In Bridgman or GF growth, single crystals can be grown using either seeded or unseeded ampoules or crucibles.

The Bridgman method has been most extensively used to grow II–VI wide-bandgap compounds such as CdTe, ZnTe and ZnSe crystals, because of the simplicity of the growth apparatus, the high growth rate and the availability of crystals of appropriate size and quality. There are two Bridgman method techniques: the high-pressure technique [16.115] and the closed technique [16.116]. In the former, it is inevitable that a compositional deviation from stoichiometry occurs during melting. Since the properties and structural perfection of these compound crystals are correlated very strongly with this nonstoichiometry [16.117], compositional deviation must be controlled during melt growth. *Omino* et al. [16.116] and *Wang* et al. [16.118, 119] have adopted a closed double crucible to prevent deviation of the melt from stoichiometric composition during Bridgman growth. Figure 16.9 shows a closed vertical Bridgman growth furnace and its temperature profiles.

In Bridgman growth, the temperature gradient (G) and growth rate (R) are very important parameters since they determine the shape of the solid–liquid interface. For this reason, the relationship between temperature gradient and growth rate is investigated. The experimental results are summarized in Fig. 16.10 [16.120, 121]. The experimental results show that, to grow a ZnSe single crystal, it is necessary that the G/R ((temperature) gradient/(growth) rate) value should be limited to 57−175 K h/cm^2. The most suitable value of G/R, assessed from the determined optimum temperature gradient and growth rate, is 83 K h/cm^2. *Wang* et al. [16.118, 119] found the optimum conditions to include: a special temperature program for removing the gas bubbles generated in melt, an overheating temperature of 76 K from the melting point of 1797 K, a temperature gradient of 30 K/cm and a growth rate of 3.6 mm/h as marked by the open squares in Fig. 16.10. Under these growth conditions, twin-free high-quality ZnSe single crystals (Fig. 16.11) were grown using a polycrystalline seed. Chemical etching on the cleaved (110) plane revealed that the average value of the etch pit density (EPD) is about 2×10^5 cm^{-2}. The rocking curves of four-crystal XRD showed a full-width at half-maximum (FWHM) value of 19 arcs. The resolved intensive free-exciton, bound-exciton emission lines and the weak donor-acceptor-pair (DAP) emission bands are observed in the PL spectra at 4.2 K. The FWHM of the I_1^d emission was smaller than 0.5 meV. On the other hand, the deep-level emission bands were almost not observed. All these results suggest that the ZnSe single crystals grown by this method are of very high quality.

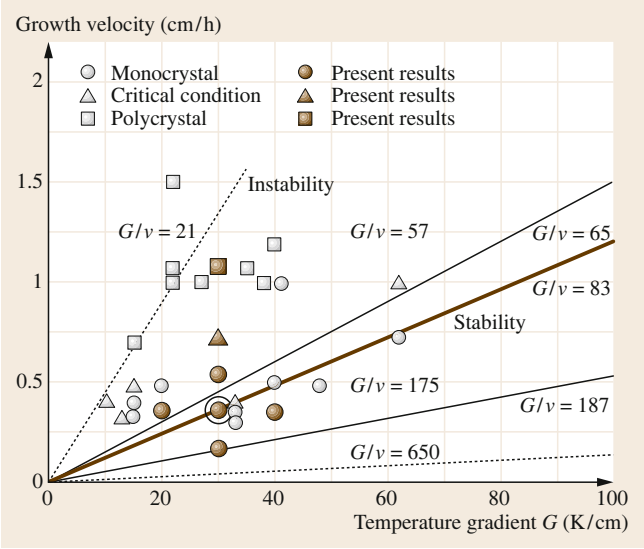

Fig. 16.10 Relationship between growth velocity and temperature gradient at the growth interfaces

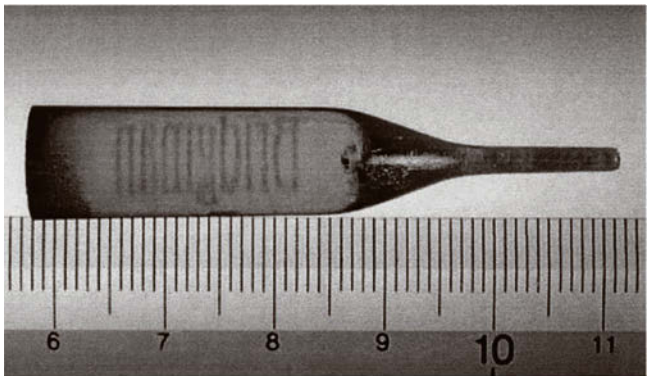

Fig. 16.11 Photograph of twin-free ZnSe single crystal grown by the vertical Bridgman technique

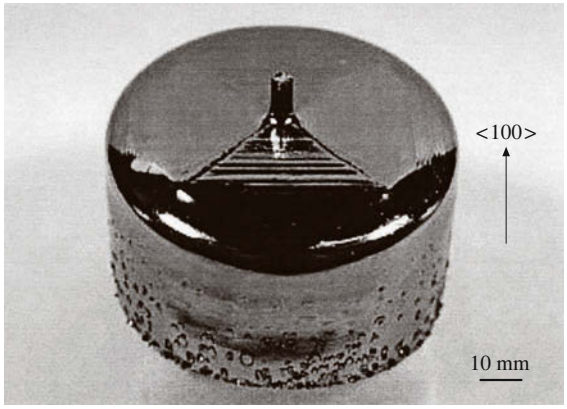

Fig. 16.12 ZnTe single crystal grown by a combination of the GF and Kyropoulos methods

Asahi et al. [16.122] successfully grew ZnTe single crystals with a diameter of 80 mm and a length of 50 mm by the vertical gradient freezing (VGF) method. In this method, a high-pressure furnace was used and the melt was encapsulated by B_2O_3 during crystal growth. The growth direction was nearly ⟨111⟩ or ⟨110⟩. When long ZnTe crystals were grown, polycrystals were found at the tail. It seems to be difficult to grow an ingot longer than 50 mm. The researchers believed that this is because the shape of the solid–liquid interface easily becomes concave against the liquid at the tail owing to the low thermal conductivity of ZnTe. Evaluation of the crystals showed that the FWHMs of the rocking curve measured by XRD were about 20 arcs, and the EPDs were 5×10^3–1×10^4 cm^{-2}.

16.3.4 The Traveling Heater Method (THM)

The traveling heater method (THM) [16.123] is a solution growth process whereby polycrystalline feed material with an average constant composition is progressively dissolved under the influence of a temperature gradient, followed by deposition in single-crystal form onto a seed with the same composition. The growth proceeds by the relative translation of the heater and charge. THM is particularly useful for the growth of binary and ternary semiconductor alloys, such as CdTe and CdZnTe [16.124]. In such materials, the wide separation between the solidus and liquidus in the pseudo-binary (CdTe–ZnTe) phase diagram imposes a monotonic variation in composition of the solid in the melt growth processes. The THM process ensures a constant macroscale composition in the crystal grown. Since the process takes place at a temperature below the melting point, contamination from the container is also reduced. The reduced operating temperature also leads to a lower ambient pressure within the growth environment, and a reduced risk of ampoule fracture.

16.3.5 Other Methods

Besides the growth methods described, there are many other techniques for growing single crystals of II–VI wide-bandgap compounds. Zone melting [16.125] and solid-state recrystallization (SSR) [16.126] are often used to grow bulk crystals of ZnSe, ZnS and CdTe.

Recently, *Asahi* et al. [16.127] proved that B_2O_3 is a suitable encapsulant for ZnTe melt growth. Furthermore, B_2O_3 and a total weight of 6N Zn and Te was charged into a pyrolitic boron nitride (pBN) crucible. Then this crucible was put into a high-pressure furnace with five heaters. A ZnTe seed was used to pull the ZnTe crystal. Before growth started, the starting materials were heated to 1573 K and kept at this temperature for several hours. The pressure in the growth furnace was kept at 1.5–2 MPa using Ar gas during growth. The temperature gradient on the solid–liquid surface was about 10–20 K/cm. The growth rate was 2–4 mm/h. Under these growth conditions, ZnTe single crystals with a diameter of 80 mm and a height of 40 mm were successfully grown using a combined GF/Kyropoulos method [16.127] (Fig. 16.12).

Some growth methods for film and bulk crystals are summarized in Table 16.3.

Table 16.3 Growth methods for films and bulk crystals of wide-bandgap II–VI compounds

16.4 Conclusions

It was expected that II–VI wide-bandgap compounds would become applicable to optoelectronic devices, especially LEDs and LDs in the short-wavelength visible-light region. However, as they are very strongly bonded with a nearly equal balance of covalent and ionic bonding, it is challenging to grow high-purity high-quality single crystals. Another problem with their application to devices is the difficulty of controlling the conductive type. This is because native defects commonly occur in these semiconductors. These native defects can have either a donor or acceptor character, or even be amphoteric, and they act as compensating centers. Furthermore, these defects react with dopant impurities to form complexes. This makes it difficult to reverse the conductive type. For example, in the case of ZnSe, it is still difficult to obtain low-resistivity p-type crystals or epilayers that can be used to fabricate devices. Therefore, a significant improvement in the understanding of the fundamental physical and chemical properties needs to be achieved. In particular, the specifications for many applications are very demanding, and considerable progress needs to be made in growth, particularly in the areas of reproducibility, convenient shape, conductivity, and structural perfection.

17. Structural Characterization

Paul D. Brown

The aim of this chapter is to convey the basic principles of x-ray and electron diffraction, as used in the structural characterization of semiconductor heterostructures. A number of key concepts associated with radiation–material and particle–material interactions are introduced, with emphasis placed on the nature of the signal used for sample interrogation. Various modes of imaging and electron diffraction are then described, followed by a brief appraisal of the main techniques used to prepare electron-transparent membranes for TEM analysis. A number of case studies on electronic and photonic material systems are then presented in the context of a growth or device development program; these emphasize the need to use complementary techniques when characterizing a given heterostructure.

The functional properties of semiconductors emanate from their atomic structures; and, the interrelationship between materials processing, microstructure and functional property lies at the heart of semiconductor science and technology. Hence, if we are to elucidate how the functional properties of a semiconductor depend on processing history (the growth or device fabrication procedures used), then we must study the development of the microstructure of the semiconductor by applying an appropriate combination of analytical techniques to the given bulk crystal, heterostructure or integrated device structure.

The main aim of this chapter is to provide a general introduction to the techniques used to characterize the structures of semiconductors. Thus, we consider techniques such as x-ray diffraction (XRD) and electron diffraction, combined with diffraction contrast imaging, alongside related techniques used for chemical microanalysis, since modern instruments such as analytical electron microscopes (AEMs) provide a variety of operational modes that allow both structure and chemistry to be investigated, in addition to functional activity. For example, chemical microanalyses of the fine-scale structures of materials can be performed within a scanning electron microscope (SEM) and/or a transmission electron microscope (TEM), using the techniques of energy dispersive x-ray (EDX) analysis, wavelength dispersive x-ray (WDX) analysis or electron energy loss spectrometry (EELS). In addition, the electrical and optical properties of semiconductors can be investigated in situ using the techniques of electron beam induced conductivity (EBIC) or cathodo-

luminescence (CL), respectively. Techniques such as x-ray photoelectron spectrometry (XPS; also known as electron spectroscopy for chemical analysis, ESCA), secondary ion mass spectrometry (SIMS) or Rutherford backscattering spectrometry (RBS), can also be used to study semiconductor chemistry. We should also mention reflection high-energy electron diffraction (RHEED), which can be used for the rapid structural assessment of the near surface of bulk or thin film samples.

A far from exhaustive list of acronyms one might come across when assessing a given sample is incorporated into the general list of abbreviations at the start of this book. We can organize these techniques used to characterize materials into groups based on a number of viewpoints: for example, with respect to the material property being investigated; whether they are destructive or nondestructive; bulk or near-surface assessment techniques; based on radiation-material or particle-material interactions, or based on elastic or inelastic scattering processes, or whether they are diffraction-, imaging- or spectroscopic-based techniques.

In this broad introduction to the structural characterization of semiconductors, we focus on the interaction of a material with radiation and/or particles. Thus, we start by considering the interactions of photons, electrons or ions with a sample and the nature of the signals used for structural or chemical microanalysis. We then briefly focus on the techniques of x-ray and electron diffraction, and issues regarding the formation of TEM images. The aim is simply to convey an appreciation of the underlying principles, the applicability of these characterization techniques and the information content provided by them. We also briefly consider aspects of sample preparation, and the chapter closes with a variety of TEM-based case studies of semiconductor heterostructures, which are included to illustrate some of the approaches used to characterize fine-scale microstructure, as well as to emphasise the need for complementary analysis when assessing the interrelationships between processing, structure and functional property. Much literature already exists in this area, and a selection of references is provided at the end of the chapter that tackle many of the topics we cover here in more detail [17.1–22].

17.1 Radiation–Material Interactions

Each part of the electromagnetic spectrum has quantum energies that can be used to elicit certain forms of excitation at the atomic or molecular level. Different parts of the electromagnetic spectrum will interact with matter in different ways, according to the energy states within the material, allowing absorption or ionization effects to occur. The salient features of these various radiation–material interaction processes are summarized in the schematics shown in Fig. 17.1.

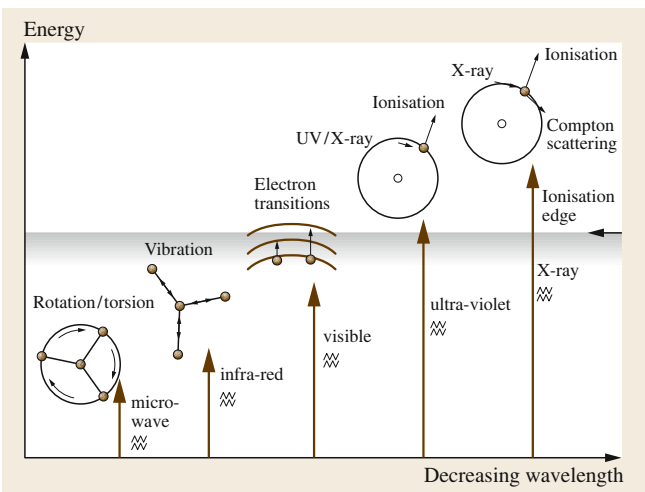

Fig. 17.1 Schematics illustrating the various interactions of energetic radiation with a molecule or atom

As the quantum energy increases from radio waves, through microwaves, to infrared and visible light, absorption increases, whilst specific quantized ionization effects come into play upon moving further into the ultraviolet and x-ray parts of the spectrum. Microwave and infrared radiation, for example, can interact with the quantum states of molecular rotation and torsion, leading to the generation of heat. Strong absorption also occurs within metallic conductors, leading to the induction of electric currents. Visible and ultraviolet light can elevate electrons to higher energy levels in what is known as the photoelectric effect, which is essentially the liberation of electrons from matter by short-wavelength electromagnetic radiation when all of the incident radiation energy is transferred to an electron. This process can be explained in terms of the absorption of discrete photon energies, with electrons being emitted when the photon energy exceeds the material's work function for the case of weakly bound electrons or the binding energy for more strongly bound inner shell electrons (Fig. 17.2a).

X-ray and γ-ray quantum energies are generally too high to be completely absorbed in direct

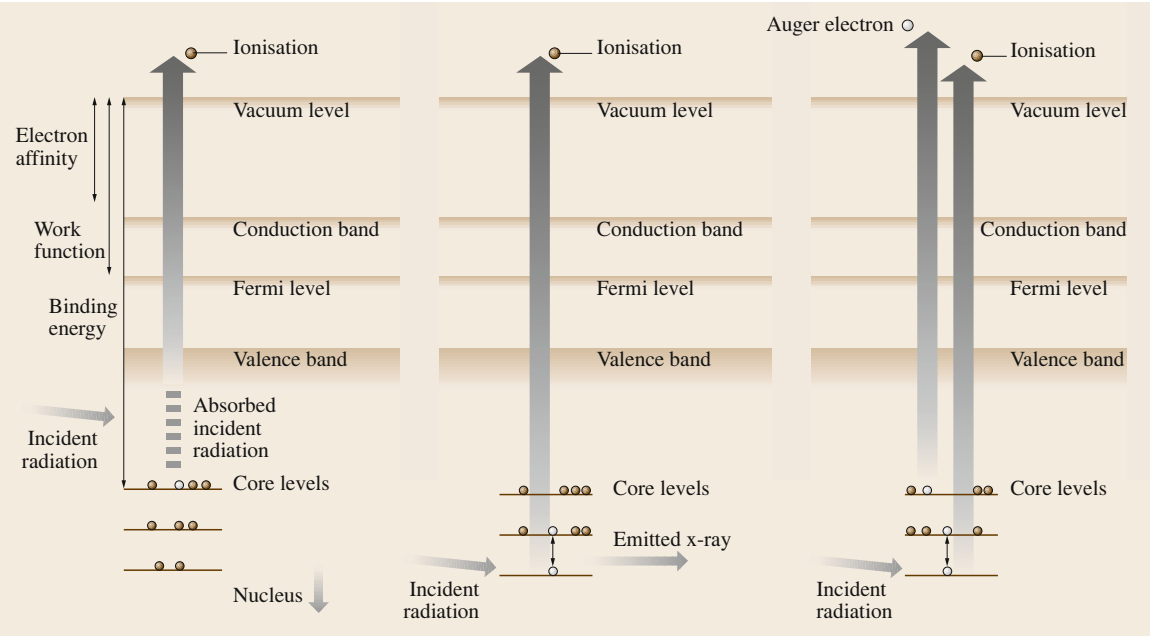

Fig. 17.2a–c Schematics illustrating **(a)** the photoelectric effect; **(b)** characteristic x-ray emission and **(c)** Auger electron emission

electron transitions, but they can induce ionization, with the displacement of electrons from atoms to form ions. The relaxation of a high-energy electron to the vacated state can lead to the emission of a characteristic x-ray (Fig. 17.2b) or the emission of an Auger electron (Fig. 17.2c). During the process of ionization, some of the incident photon energy is transferred to the ejected electron in the form of kinetic energy, and the scattering of a lower energy photon (longer wavelength x-ray) occurs, termed Compton scattering. x-rays can also be scattered elastically by shell electrons, without the loss of energy, through a process of absorption and re-emission.

17.2 Particle–Material Interactions

The interaction of an energetic particle with the surface of a material is most commonly associated with the process of sputtering – the non-thermal removal of atoms from a surface under ion bombardment. Transfer of momentum to the surface atoms is followed by a chain of collision events leading to the ejection of matrix atoms. Figure 17.3 illustrates the various signals produced when a particle interacts with a material, depending on the energy available. In broad terms, processes in the range 10^4–10^5 eV are associated with ion implantation, the 10–10^3 eV energy range is associated with sputtering, whilst the creation of activated point defects occurs in the 1–10^3 eV range. At lower 0.1–100 eV energies, desorption of surface impurity atoms occurs, whilst energies in the range 0.01–1 eV are associated with the enhanced mobility of surface condensing particles, such as those required during growth. In practical terms, the process of sputtering is most efficient when the masses of the incident and ejected particles are similar, whilst it is also dependent on the sputtering gas pressure, the energy spread of the particles, the bias conditions and the sample geometry.

In this context, we should briefly mention the technique of SIMS, which uses heavy ions, typically in the range 2–30 keV, with an ion current density of $\approx$ 1 mA/cm^2. The sputtered atoms consist of a mixture of neutrals and ions, and the latter may be mass-spectrally analyzed in order to perform elemental depth profiling. The sensitivity of the technique is very high – for example on the scale of dopant concentrations within semiconductors – but standards are required for quantitative analysis. One variant of SIMS makes use of lower energy primary ions (0.5–2 keV, $\approx$ 1 nA/cm^2) with an almost negligible sputter rate, thus enabling

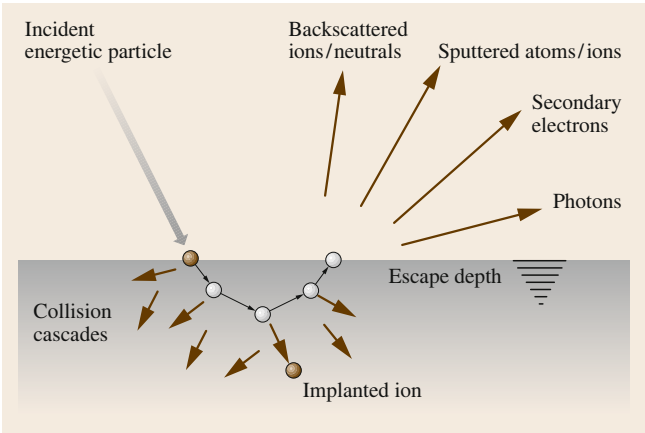

Fig. 17.3 Schematic illustrating the signals produced by the interaction of an energetic ion beam with a sample

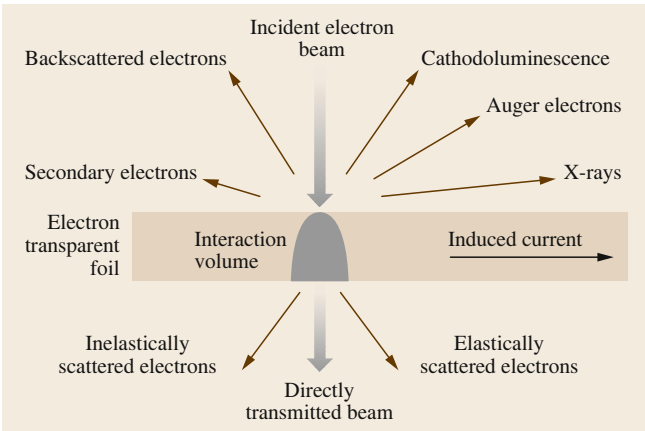

Fig. 17.4 Schematic illustrating the signals produced by the interaction of an energetic electron beam with a thin sample foil

surface chemical analysis. Conversely, the technique of RBS makes use of a very high energy (2−3 MeV) beam of light ions bombarding a sample normal to its surface. An ion such as helium is chosen to avoid the effects of sputtering, whilst high energy is required to overcome the problem of ion neutralization and the screening interaction potential between the ion and the nucleus associated with techniques such as low-energy ion scattering (LEIS). As an energetic positive ion penetrates the sample it loses energy, mainly due to collisions with electrons, but occasionally (and more significantly) with nuclei. The energy of the backscattered ion depends on the depth of the collision and the mass of the target atom. By measuring the energy spectrum of the recoiling ions, information on elemental composition and depth within a sample can be obtained.

By way of comparison, Fig. 17.4 illustrates the variety of signals produced from the interaction of an energetic beam of electrons with a thin ($< 1\,\mu$m) semiconductor sample. In order to make sense of the origins of the many different signals, we must consider the phenomenon of electron scattering, which underpins them all. The process of elastic (Rutherford) scattering arises from an electrostatic (Coulomb) interaction with the nucleus and surrounding electrons of an atom, leading to a change in the incident electron direction without loss of energy. Elastically scattered electrons contribute to the formation of diffraction patterns and diffraction contrast images in TEM. Conversely, inelastically scattered electrons have, by definition, lost a certain amount of energy. In this context, core–shell interaction processes produce scattered electrons whose energies depend on the atomic number of the scatterer, and an analysis of the loss of electron energy (up to ≈ 1000 eV) is the basis of the technique of electron energy loss spectroscopy (EELS). In addition, plasmon scattering (5−30 eV loss) can occur, due to the interactions of incident electrons with waves in the conduction band of a metal, or the bonding electrons of non-metals. The signatures from plasmon-scattered electrons can dominate the low-energy regimes of EEL spectra, providing information on sample thickness. Phonon scattering (≈ 1 eV loss) can also occur, which is the interaction of incident electrons with quantized atomic vibrations within a sample, leading to the production of heat. In an interaction of an electron beam with a bulk sample, nearly all of the incident energy ends up being dissipated through such phonon interactions. The probability of each type of scattering interaction is commonly expressed either as a cross-section, representing the apparent area the scattering process presents to the electron, or as a mean free path, which is the average distance the electron travels before being scattered.

A variety of secondary events also occur as a direct consequence of these primary electron scattering processes. For example, following interactions with a high-energy beam of electrons, excited atoms may subsequently relax in a number of different ways (in a similar fashion to the processes induced by incident high-energy x-ray photons). If core-level (inner shell) electrons are displaced, the relaxation of electrons from higher energy shells to the lower energy core states can lead to the discrete emission of x-ray photons characteristic of the atomic number of the element concerned. This is referred to as the *K, L, M, N*, series, and Moseley's law states that the square root of the frequency of the characteristic x-rays of this series, for certain elements, is linearly related to the atomic number. Discrimination of these characteristic x-rays, as a function of energy or wavelength, provides the basis for the EDX or the WDX techniques, respectively. Alterna-

Table 17.1 Overview of characterization techniques. EDS = energy dispersive x-ray spectroscopy, BSE = backscattered electron

Technique	Primary beam	Energy	Signals detected	Assessment	Spatial resolution	Elements detected	Detection limit
AES	Electron	0.5–10 keV	Auger electron	Surface composition	Lateral ≈ 200 nm (LaB_6 source) lateral ≈ 20 nm (FE source) depth ≈ 2–20 nm	Li–U	≈ 0.1–1 at % (sub-monolayer) accuracy ≈ 30%
RBS	Ion (He^{2+})	> 1 MeV	Ion (He^{2+})	Depth composition and thickness	Lateral ≈ 1 mm depth ≈ 5–20 nm	B–U	≈ 0.001–10 at %
SEM/EDS	Electron	0.3–30 keV	Electron (SE, BSE) x-ray (characteristic)	Surface morphology and composition	≈ 1–3 nm (SE) ≈ 2–5 nm (BSE) lateral > 0.3 µm (EDS) depth ≈ 0.5–3 µm (EDS)	B–U	≈ 0.1–1 at % accuracy ≈ 20% (depends on matrix)
SIMS	Ion (Cs^+, O_2^+, Ga^+)	1–30 keV	Ion (secondary)	Depth trace composition	Lateral ≈ 60 µm (Dynamic SIMS) lateral ≈ 1 µm (Static SIMS) depth ≈ 2–20 nm	H–U	≈ 10^{-10}–10^{-5} at %
TEM/EDS/ EELS	Electron	100–400 keV	Electron (elastic, inelastic) x-ray (characteristic)	Structure and chemistry of thin sections (high resolution)	≈ 0.1–0.3 nm lateral > 2 nm (EDS) lateral ≈ 1 nm (EELS) energy resolution ≈ 1 eV (EELS)	Up to U	≈ 0.1–1 at % accuracy ≈ 20% (depends on matrix)
XPS	X-ray	1–15 keV	Photo electron	Surface composition (chemical bonding)	Lateral ≈ 10 µm – 2 mm depth ≈ 1–10 nm	Li–U	≈ 0.1–1 at % (sub-monolayer) accuracy ≈ 30%
XRD	X-ray	1–20 keV	X-ray	Structure	Lateral ≈ 10 µm depth ≈ 0.1–10 µm	Low Z may be difficult to detect	≈ 3 at % in a two-phase mixture (≈ 0.1 at % for synchrotron) accuracy ≈ 10%
XRF	X-ray	30 kV/20 mA	X-ray (fluorescent)	Composition	Lateral ≈ 0.1–10 mm depth ≈ 10 nm	Na–U	≈ ppb–ppm, accuracy ≈ 10%

tively, a secondary process of Auger electron emission may occur, particularly for low atomic number materials, whereby outer shell electrons are ejected with a characteristic kinetic energy. It should be noted that characteristic x-rays may also induce the emission of lower energy x-rays within a sample, and this is the basis of x-ray fluorescence (XRF) and the origin of background scintillation during EDX analysis.

Further, if an outer (valence) electron state is vacant, relaxation across the band-gap of a semiconductor may occur with the emission of light, and this constitutes the basis of the CL technique. Alternatively, a current may be induced within a sample and nonradiative recombination pathways in the presence of structural defects (and a collection junction) provide the contrast mechanism for the EBIC technique that profiles the electrical activity within a crystalline semiconductor. Also, incident electrons that interact with atomic nuclei may become backscattered with energies comparable to the incident energy, and used to image a sample surface with contrast that is dependent on the average local composition. Secondary (low-energy, $< 50\,\text{eV}$) electrons (SEs), produced by a variety of mechanisms, may also be emitted and escape from the near-surface of a sample. SEs can be used to obtain topographic images of irregular surfaces since they are easily absorbed.

Table 17.1 lists the most commonly used characterization techniques based on x-ray, ion or electron beam interactions with a semiconductor, and broadly indicates their limits of applicability.

17.3 X-ray Diffraction

The basic concepts behind radiation-material interactions and scattering link into the concept of diffraction, whereby the spatial distribution and intensity of scattered x-rays or electrons provide information on the arrangement of atoms in a periodic sample. The theory of wave-particle duality proposes that an electron may be considered to be a wave rather than a particle when discussing diffraction. Electrons are scattered by electric fields within a crystal whilst x-rays are scattered by shell electrons. Nevertheless, the geometry of diffraction is very similar in both cases, being governed by Bragg's law.

The basic principles of diffraction (in reflection, transmission or glancing angle geometries) may be introduced with reference to x-ray scattering and interference. X-rays are a form of energetic electromagnetic radiation of wavelength $\approx 10^{-10}$–$10^{-11}\,\text{m}$, of comparable size to the spacing of atoms within a solid. A crystal lattice comprises a regular array of atoms; and the electron clouds around these atoms act as point sources for spherical x-ray wavelets, through a process of absorption and re-emission, when interaction with an incident x-ray beam occurs. Constructive interference of the scattered wavelets, related to the Huygens's principle for wave propagation (Fig. 17.5), occurs in preferred directions, depending on the Bravais lattice of the crystal and the x-ray wavelength. The positions of the resultant maxima in scattering intensity may be used to deduce crystal plane spacings and hence the structure of an unknown sample when correlated with database values. Geometrical considerations show that the scattering angles corresponding to diffracted intensity maxima can be described by the Bragg equation $n\lambda = 2d \sin\theta$ (sometimes expressed with Miller indices notation as $\lambda = 2d_{hkl} \sin\theta_{hkl}$). Formally, this equation describes the minimum condition for the coherent diffraction of a monochromatic x-ray beam from a set of planes of a primitive lattice. Figure 17.6 illustrates the geometrical conditions associated with Bragg diffraction from a set of $\{hkl\}$ planes spaced d_{hkl} apart, with x-rays incident at a Bragg angle θ being diffracted through an angle 2θ. The path difference between the x-rays *reflected* from successive planes must be equivalent to an integer number of wavelengths n for constructive interference to occur.

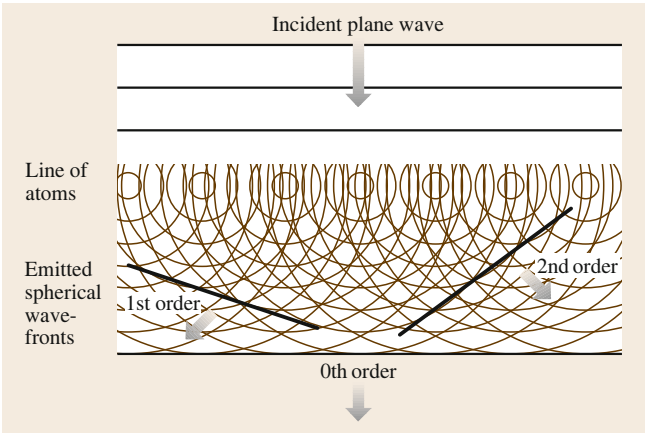

Fig. 17.5 Schematic illustrating Huygens's principle, with a reconstruction of spherically emitted x-ray wavefronts providing diffracted intensity in specific directions

In order to interpret the information contained in the *intensity* of the diffracted beam, which is measured in practice, it is necessary to consider the amplitude of

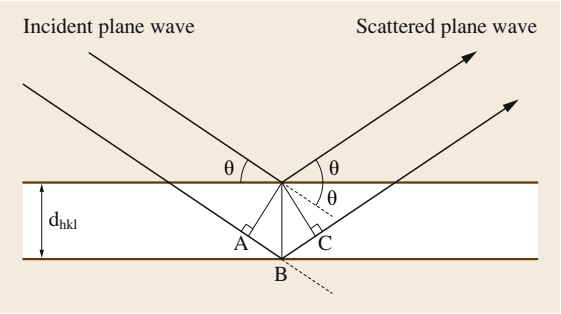

Fig. 17.6 Geometric illustration of Bragg diffraction. For constructive interference, $n\lambda = AB + BC = 2d \sin\theta$

the elastically scattered waves. (The phase of the scattered beam is much more difficult to measure.) A useful concept to introduce at this stage is that of the atomic scattering factor f, which is a measure of the amplitude of the wave scattered by an atom, which depends on the number of electrons in the atom. Formally, the atomic scattering factor is the ratio of the amplitude of the wave scattered by an atom to the amplitude scattered in the same direction by a free classical electron. (For the purpose of such discussions, an electron orbiting an atom is considered to be a free classical electron.) The scattered amplitude (and hence intensity = |amplitude|^2) varies with direction, with higher angles θ being associated with lower amplitudes.

When x-rays interact with a periodic crystal lattice, it is considered that each atom scatters with an amplitude f into an *hkl* reflection, while there is a summation of all of the scattering amplitudes from different atoms, with phase differences that depend on *hkl* and the relative positions of the atoms. This leads to the concept of the structure factor, F_{hkl}, which is the total scattering amplitude from all of the atoms in one unit cell of a lattice. Formally, the structure factor is the ratio of the amplitude scattered by a unit cell into an *hkl* reflection to that scattered in the same direction by a free classical electron. The phase difference between waves scattered from two different atoms depends on the Miller indices of the reflection being considered and the fractional coordinates of the atoms within the unit cell. In general terms, for a reflection from a set of $\{hkl\}$ planes, the phase difference ϕ between the wave scattered by an atom at the origin and that scattered by an atom with fractional coordinates x, y, z is given by $\phi = 2\pi(hx + ky + lz)$. In theoretical terms, the resultant intensity of the scattered beam is denoted $I_{hkl} \propto |F_{hkl}|^2$, where $F_{hkl} = \sum f_j(\theta) \exp(i\phi_j)$, which is a summation of the individual scattered sinusoidal waves, performed over both phase and amplitude. In a practical diffraction experiment, however, the combination of photoionization and Compton scattering can act to diminish the scattered beam intensity. Consideration also needs to be given to the effects of absorption, along with the effect of multiplicity, which arises from the number of symmetrical variants of a unit cell, and the geometrical and polarization factors specific to a given experimental arrangement.

The crystallographic structure of an unknown material can, nevertheless, be analyzed via the diffraction of x-rays of known wavelength. For example, for a crystal system with orthogonal axes, the general formula which relates plane spacing, d_{hkl}, to the plane index $\{hkl\}$ and the lattice parameters a, b, c is $1/(d_{hkl})^2 = h^2/a^2 + k^2/b^2 + l^2/c^2$. For a cubic system, this simplifies to

$$d_{hkl} = \frac{a}{\sqrt{(h^2 + k^2 + l^2)}} = \frac{a}{\sqrt{N}} .$$

Thus, $\lambda = 2a \sin\theta/\sqrt{N}$, from which $N = (4a^2/\lambda^2) \times \sin^2\theta$ and hence $N \propto \sin^2\theta$. Accordingly, the 2θ angles of scattering arising from the process of x-ray diffraction may be used to identify values for N, against which *hkl* indices can be assigned and the lattice identified. Information is contained within the intensities and widths of the diffracted x-ray peaks, in addition to their positions. The process of formal identification can be automated by electronically referencing crystallographic databases containing the positions and relative magnitudes of the strongest diffraction peaks from known compounds. Systematic or partial absences may also occur depending on the lattice symmetry, and the intensities of some peaks may be weak due to the motif of the crystal lattice – the number of atoms associated with each lattice point. For example, sphalerite or wurtzite lattices may show weak reflections that are absent for face-centered cubic or hexagonal close-packed structures, respectively.

Partial differentiation of the Bragg equation gives $2(\sin\theta)\delta d + 2d(\cos\theta)\delta\theta = 0$, from which $\delta d/\delta\theta = -d\cot\theta$. Thus, for a fixed error in θ, the error in d_{hkl} will minimize as $\cot\theta$ tends to zero (as θ tends to 90°). Hence, diffraction techniques are more accurate when measurements are made at high 2θ angles. Similarly, it can be shown that the sensitivities and resolutions of diffraction measurements improve at high scattering angles. The sensitivity of the x-ray diffraction technique, for example, is sufficiently high to enable subtle stress measurements to be made, with elastic changes in plane spacings leading to small shifts in diffracted peak positions. Accordingly, diffraction techniques may be used to investigate temperature-dependent order–disorder transitions within alloys and preferred orientation effects. The high accuracy of lat-

tice parameter measurement similarly enables good compositional analysis of an alloy when Vegard's law applies, i. e., the alloy exhibits a linear dependence of lattice parameter on composition, between the extremes of composition. Brief reference should be made here to the related technique of neutron diffraction, which is able to sample over a much larger range of d_{hkl} spacings, which makes it particularly useful for the ab initio determination of very complex structures. The very rigorous approach of Rietveld refinement can also be used to model a complete diffraction profile, deducing the structure from first principles using atom positions as fitted parameters.

The principle behind the generation of x-rays from characteristic transitions, used when performing chemical microanalyses of unknown samples by EDX or WDX, also provides the route to defining an x-ray source from a known target sample for the purpose of XRD. In practical terms, the x-ray tube of a diffractometer is an evacuated vessel in which electrons from a hot filament are focused onto a cooled metal target, such as Cu or Ni. The x-ray spectrum generated consists of x-rays characteristic of the target material, along with a background emission of x-rays of continuous wavelengths, termed Bremsstrahlung (braking radiation), which are caused by the acceleration of electrons in the vicinity of nuclei. The x-rays emerging from the tube, through a window made from a material of low atomic number, can be filtered and collimated to define a beam of specific wavelength.

The precise geometry used in a diffraction experiment will depend on the form of the sample and the information content required. For example, crystalline samples such as semiconductor heterostructures can be rotated within a cylindrical geometrical framework that enables successive sets of crystal planes to be brought into play for detection. Figure 17.7 illustrates the basic geometrical arrangements for a four-circle diffractometer that allows diffraction data to be acquired. Computer-controlled rotation of the sample around ω, χ and ϕ axes, as the detector is rotated about the 2θ axis, enables the positions and intensities of *hkl* reflections to be recorded. By way of example, Fig. 17.8 shows a $2\theta/\omega$ plot recorded from a heteroepitaxial GaN/GaAs(001) sample, with reflections attributable to both epilayer and substrate, whilst the full width at half maximum (FWHM) values for the diffraction peaks provide a measure of the mosaic spread of the subgrains within the sample.

Since amorphous materials do not exhibit long-range order, their diffraction profiles show diffuse intensities rather than well-defined maxima. Partially crystalline materials may show broad diffraction peaks, from which it is possible to approximate the crystal

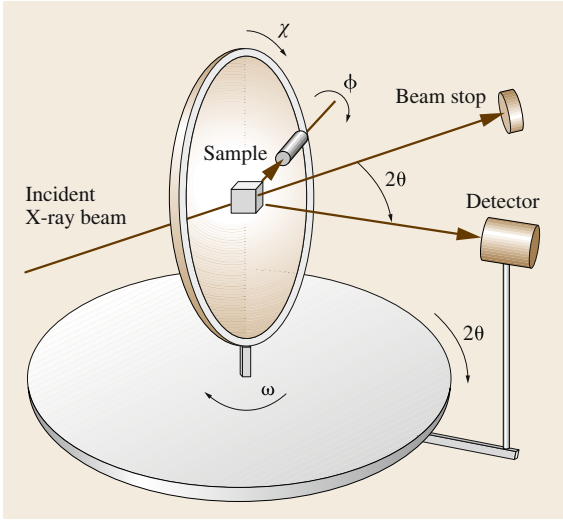

Fig. 17.7 X-ray four-circle diffractometer

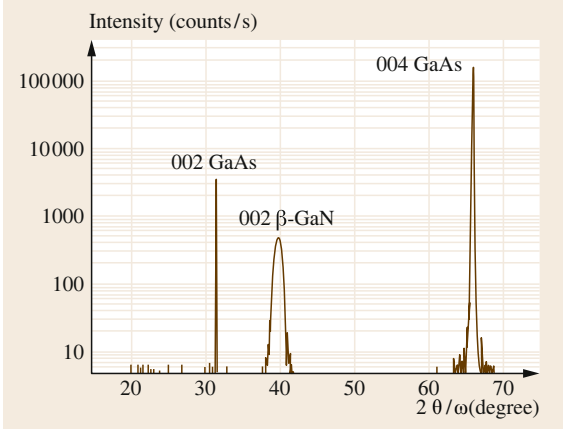

Fig. 17.8 Example of a $2\theta/\omega$ plot for cubic GaN/GaAs(001)

size from the λ–peak-width relationship. Other x-ray diffraction techniques include Laue back reflection, that can be used conveniently to orient bulk single crystals, for example for sectioning prior to use as substrates for heteroepitaxial growth. Alternatively, the Debye–Scherrer method can be used for powder samples, since a significant number of crystal grains will always be in an orientation that satisfies the Bragg equation for each set of {*hkl*} planes. In this scattering arrangement, the diffracted rays form cones coaxial with the incident x-ray beam, with each cone of diffracted rays corresponding to a Bragg reflection from a specific set of lattice planes in the sample.

To reiterate, it is the combination of Bragg's law and the structure factor equation that enables the directions and intensities of beams scattered from a crystal to

be predicted. In this context, it is instructive to briefly compare XRD with electron diffraction. Electrons are scattered by the periodic potential – the electric field – within a crystal lattice, whilst x-rays are scattered by outer shell electrons. Since x-rays and electrons exhibit comparable and comparatively small wavelengths, respectively, on the scale of the plane spacings of a crystal lattice, this equates to large and small angles of scattering, respectively, for the diffracted beams. Accordingly, XRD offers greater accuracy than electron diffraction for the measurement of lattice parameters. It should also be noted that XRD is essentially a kinematic process based on single scattering events, whilst electron diffraction is potentially more complex due to the possibility of dynamic (or plural) scattering processes which can affect the generated intensities. Also, electrons are more strongly absorbed than x-rays, so there is need for very thin sample foils, typically $< 1\,\mu m$, for the purposes of transmission electron diffraction (TED) experiments. However, electrons are more easily scattered by a crystal lattice than x-rays, albeit through small angles, so an electron-transparent sample foil is capable of producing intense diffracted beams. X-rays require a much greater interaction volume to achieve a considerable diffraction intensity. The effectiveness of the technique of electron diffraction becomes most apparent when combined with TEM-based chemical microanalysis and imaging techniques. This enables features such as small grains and embedded phases, or linear or planar defect structures such as dislocations and domain boundaries, to be investigated in detail.

Before describing some variants of the electron diffraction technique, a few concepts related to imaging and modes of operation of the TEM need to be introduced.

17.4 Optics, Imaging and Electron Diffraction

The aim of a microscope-based system is to image an object at high magnification, with optimum resolution and without distortion. The concepts of magnification and resolution associated with imaging in electron microscopy are usually introduced via light ray diagrams for optical microscopy. The constraints on achieving optimum resolution in TEM are generally considered to be lens aberration and astigmatism. The concepts of depth of field and depth of focus must also be considered.

If we consider the objective lens shown in Fig. 17.9, a single lens is characterized by a focal length f and a magnification M. The expression $1/f = 1/u + 1/v$ relates the focal length to the object distance u and the image distance v for a thin convex lens. The magnification of this lens is then given by $M = v/u = f/(u-f) = (v-f)/f$, from which it is apparent that $u-f$ must be small and positive for a large magnification to be obtained. In practice, a series of lenses are used to achieve a high magnification overall whilst minimizing distortion effects. For the combined projection optical microscope system shown in Fig. 17.9, magnification scales as $M' = (v-f)(v'-f')/ff'$.

Resolution may be defined as the smallest separation of two points on an object that can be reproduced distinctly within an image. The resolution of an optical lens system is diffraction-limited since light must pass through a series of apertures, and so a point source is imaged as a set of Airy rings. Formally, the minimum resolvable separation of two point sources, imaged as two overlapping sets of Airy rings, is given by the Rayleigh criterion, whereby the center of one set of Airy rings overlaps the first minimum of the second set of Airy rings. The defining equation for resolution is

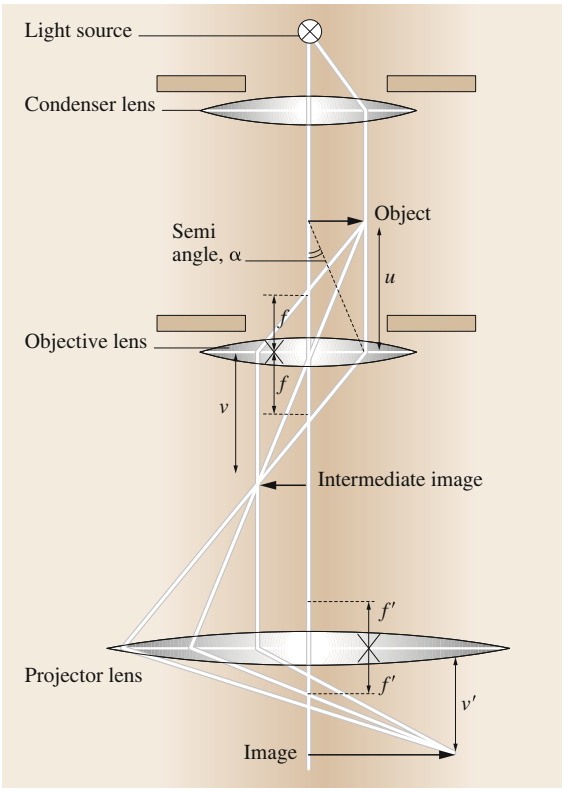

Fig. 17.9 Schematic ray diagram for a transmission projection optical microscope

given by $r = 0.61\lambda/n\sin\alpha$, where λ is the wavelength of the imaging radiation, n is the refractive index of the lens, and α is the semiangle subtended at the lens. The combined term $n\sin\alpha$ is the *numerical aperture* of the lens. Thus, resolution can be improved by decreasing λ or by increasing n or α. It is noted that magnification beyond the resolution limit of the system is possible, but there is no benefit to achieving this, and so it is termed *empty magnification*.

The performance of a TEM can be described in analogous terms, comprising an electron gun and a series of electromagnetic lenses for sample illumination, image formation and magnification: the condenser, objective and projector systems, respectively (Fig. 17.10). The electron source can be either a hot filament (e.g., W or LaB_6) for thermionic emission, or a hot or cold cathode (e.g., ZrO_2 coated W) for field emission. The gun and lenses are traditionally assembled in a column with a viewing screen and camera at the bottom to record images or diffraction patterns from an electron-transparent sample placed within the objective pole piece. A range of differently sized apertures are located in the condenser system to help collimate the electron probe, in the projector system to select a region of sample from which a diffraction pattern may be formed, and in the objective lens just below the sample to select the transmitted beam(s) used to form an image. The path of travel of the electron beam through the entire electron-optic column must be under conditions of high vacuum, considering the ease of absorption of electrons in air. The electrons are accelerated by high voltage, typically 100 or 200 kV, although there are TEMs that operate at MV conditions, depending on the intended application. An accelerated, high-energy electron acquires significant kinetic energy and momentum. It can also be represented by a wavelength (corrected to take into account relativity) that can be approximated in nanometers by $\lambda = [1.5/(V + 10^{-6}V^2)]^{0.5}$. By way of example, an electron beam within a conventional TEM operating at 200 kV has a relativistically corrected wavelength of 0.0025 nm, as compared with the range of $\approx 400-700$ nm for visible light. Since resolution is wavelength-limited, the technique of TEM is, in principle, able to provide a vast improvement in resolution over conventional optical systems. The equation for resolution becomes approximated by $r \approx 0.61\lambda/\alpha$ since $n = 1$ for electromagnetic lenses and $\sin\alpha \approx \alpha$ in view of the small angles associated with electron diffraction. A value of $\alpha \approx 150$ mrad would suggest a resolution approaching ≈ 0.01 nm. However, this level of resolution for TEM is generally not achievable in practice due to the effect of lens aberration, which degrades the resolution of an image to a *disc of least confusion* above the theoretical wavelength-limited resolution of the electron-optic system. Resolution values of $\approx 0.2-0.3$ nm are associated with the best conventional instruments. (When charting the historical development of TEM, improvements in resolution have depended on the construction of microscopes operating at higher voltages, in order to capitalize on the benefits from the reduced electron wavelength. However, it should be noted that recent improvements in techniques of compensating for spherical and chromatic aberration have now enabled a resolution of $\lesssim 0.1$ nm to be achieved for intermediate-voltage, field emission gun instruments.)

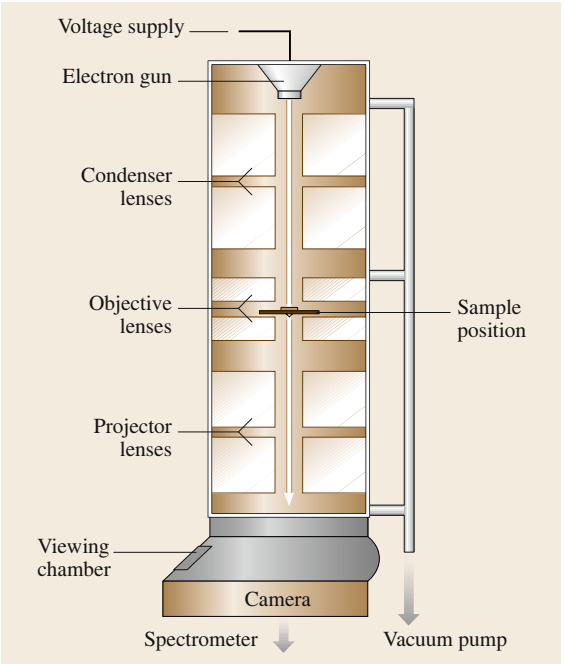

Fig. 17.10 Simplified lens configuration of a TEM

The variation in focal length of a lens as a function of the distance of a beam from the center of the lens results in rays traveling further from the optic axis being brought to focus closer to the lens (Fig. 17.11a). This spread in path lengths of rays traveling from an object to the image plane is termed spherical aberration. In this case, the radius of the disc of least confusion is given by $r_s = C_s\alpha^3$, when referred back to the object, where C_s is termed the spherical aberration coefficient and α is again the semiangle, in radians, subtended at the lens. Spherical aberration can be limited by reducing α; in other words by *stopping down* the lens by using smaller apertures (in this case, the term α corresponds to the *aperture collection angle*). However, this conflicts with the large value of α needed to optimize resolution, so a balance is required for optimum resolution, which is achieved when $\alpha_{opt} \sim (\lambda/C_s)^{1/4}$, corresponding to

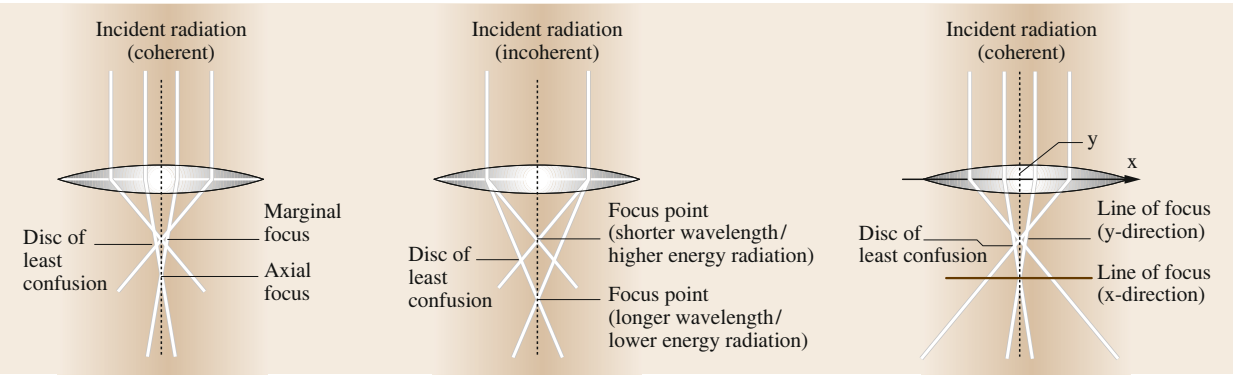

Fig. 17.11a–c Schematic illustration of **(a)** spherical aberration; **(b)** chromatic aberration and **(c)** astigmatism

an effective resolution of $r_{opt} \sim \lambda^{3/4} C_s^{1/4}$. Lenses also exhibit different focal lengths for electrons with different wavelengths; such a spread of wavelengths can arise from slight fluctuations in the accelerating voltage or from inelastic scattering (energy loss) processes within the specimen, and this effect is termed chromatic aberration (Fig. 17.11b). The radius of the disc of least confusion in this instance is given by $r_c = C_c \alpha (\Delta E/E_0)$, where C_c is the chromatic aberration coefficient, E_0 the accelerating voltage and ΔE the spread in electron energy.

An additional aberration, termed astigmatism, arises from the asymmetry of a lens about the optic axis. The different focal lengths of a lens for different orientations leads to a loss of sharpness of the image at focus. One measure of the astigmatism is the distance between the two foci formed at right angles along the optic axis (Fig. 17.11c), in contrast to a single point of focus. Astigmatism may be compensated for by using electromagnetic stigmators that generate a compensating field to bring the rays back into common focus. Distortion of an image can also occur due to slight variations in magnification with radial distance from the optic axis, leading to so-called *pin-cushion* or *barrel* distortion. This effect can become particularly noticeable at very low magnification.

The term *depth of field* is defined as the distance along the optic axis that an object can be moved without noticeably reducing the resolution. This effect is again dependent on the radius of the disc of least confusion that can be tolerated and α. The depth of field approximates to λ/α^2, and a typical value of a few tens of nm for electron microscopy means that every point within the thickness of a typical electron-transparent foil can be imaged at focus. Conversely, the *depth of focus* corresponds to the maximum permissible spacing between the imaging screen and the photographic plate or CCD used to record an image. The depth of focus approximates to $\lambda M^2/\alpha^2$, and since this works out at many meters, the viewing screen and recording system of an electron microscope need not coincide.

Following on from these general considerations affecting the process of imaging, we now move on to briefly describe the conventional modes of operation of a TEM. The accelerating stack and condenser system of the microscope defines the high-energy electron probe incident at a thin sample, within which many complex interactions occur and various signals are produced, as detailed earlier. A diffraction pattern is initially formed in the back focal plane of the objective lens and the recombination of diffracted beams allows the reconstruction of an inverted image in the first image plane. Changing the strengths of the intermediate lenses allows the back focal plane (corresponding to a projection of reciprocal space) or image plane (corresponding to a projection of real space) to be observed on the viewing screen (Fig. 17.12a,b). Placing an aperture with selected area in an intermediate image plane, around a feature of interest within a projected image, ensures that only beams from that particular area of the sample contribute to the diffraction pattern viewed on the screen.

It is sometimes convenient to think of the intersection of an Ewald sphere with a reciprocal lattice when describing the construction and projection of a diffraction pattern. A reciprocal lattice is constructed from a crystal lattice such that any vector from the origin to a diffracted spot is normal to a particular plane in the real lattice, with a reciprocal length given by the plane spacing. Thus, a three-dimensional crystal lattice can be transformed into a three-dimensional reciprocal lattice (mathematically, the process is a Fourier transform). The Ewald sphere can be thought of as a geometrical construction of radius $1/\lambda$ intersecting the reciprocal lattice. Figure 17.13a illustrates the construction of an Ewald sphere for the case of large-angle scattering (x-ray diffraction). The direction of the incident beam at the sample corresponds to the direction of the vertical radius of the Ewald sphere, and the point of emer-

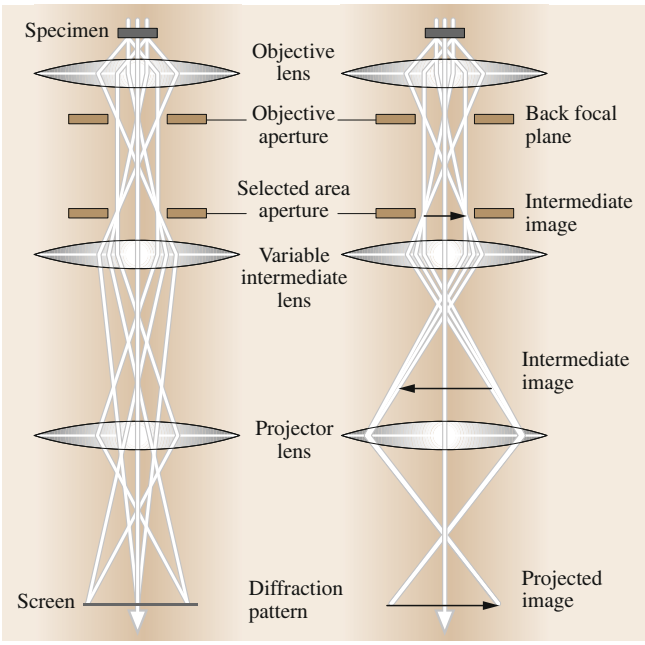

Fig. 17.12a,b Schematic ray diagrams showing the projection of **(a)** a diffraction pattern and **(b)** an image onto a TEM viewing screen

gence of this vector at the sphere surface, coincident with a reciprocal lattice point, is taken as the origin 000 of the diffraction pattern. The same construction applies for a beam of electrons, but the sphere surface has very shallow curvature relative to the reciprocal lattice spacings, due to the very small value of λ relative to d_{hkl} (Fig. 17.13b). Further, diffraction from a thin crystal is associated with a lengthening of the reciprocal lattice spots into rods in a direction parallel to the electron beam. Consequently, if the electron beam is incident along a low index zone axis, the Ewald sphere approximates to a plane and intersects a layer of reciprocal lattice points, and a two-dimensional array of diffraction spots is projected. In very general terms, it is considered that a set of {*hkl*} planes is at the Bragg condition when the reciprocal lattice point corresponding to *hkl* falls on the surface of the Ewald sphere. For the case of larger angles of electron diffraction, an outer ring of diffraction spots may be observed, termed a high-order Laue zone (HOLZ), since the Ewald sphere has sufficient curvature to intersect with a neighboring layer of points within the reciprocal lattice (Fig. 17.13c).

We should also mention the Kikuchi lines that arise in diffraction patterns due to the elastic scattering of incoherently scattered electrons. The intensities of these Kikuchi lines increase with increasing thickness of sample foil, and the line spacings are the same as the spacings of the diffraction spots from the associated crystal planes. Kikuchi lines move as the sample is tilted and hence can be used to establish very precise crystal orientations for the purpose of image contrast or convergent beam electron diffraction (CBED) experiments.

Referring back to Fig. 17.12, a diffracted beam may be selected using an aperture inserted into the back focal plane of the objective lens and used to form an image. If the undeviated, transmitted beam is used, then a bright field image is formed where the areas that diffract strongly appear dark. Image contrast also arises from a mass-thickness effect, whereby thicker or high-density regions of material scatter more strongly and hence appear dark. Alternatively, a centered dark field image may be created by tilting the illumination to center the diffracted beam, termed a $\boldsymbol{g}_{hkl}$ reflection, down the optic axis of the microscope (in contrast to moving the aperture over the diffraction spot, which would increase aberrations and degrade resolution). Areas where the {*hkl*} planes diffract strongly appear bright in such cases. Weak beam images can also be produced under dark field imaging conditions, with the sample tilted slightly away from a strong Bragg condition. The trade-off, in this instance, is reduced image contrast for the

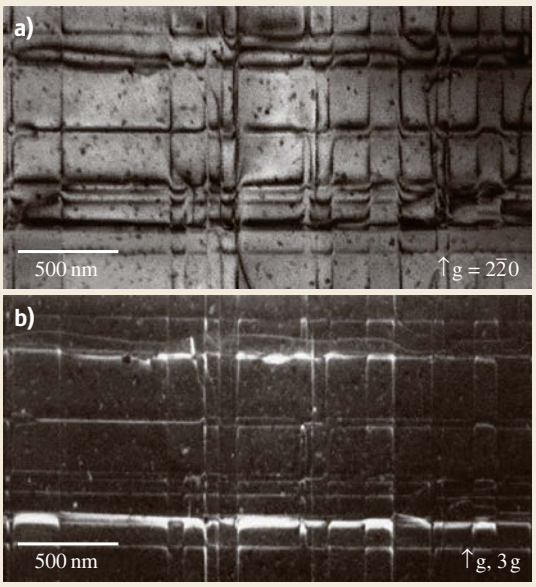

Fig. 17.14 (a) Bright-field and (b) weak-beam plan-view TEM images of Si/SiGe/Si(001)

improved resolution, which allows fine detailed features, such as partial dislocations bounding dissociated dislocations, to be delineated.

By way of example, Fig. 17.14 shows the different contrasts obtained from a plan-view $Si/Si_{0.96}Ge_{0.04}/Si(001)$ sample foil imaged under bright-field and weak-beam diffraction conditions, respectively. The sample foil contains orthogonal arrays of interfacial misfit dislocations that are generated as a consequence of the relaxation of the strain arising from the different lattice parameters of Si and $Si_{0.96}Ge_{0.04}$ [17.23]. The strain fields around the dislocations lead to a local deviation away from the exact Bragg condition, which can be used to delineate the (approximate) positions of the dislocation cores. The weak beam technique allows for complex dislocation tangle to be resolved more clearly. Imaging such sample foils using different diffraction vectors produces different contrasts that allow the nature of the dislocations to be precisely determined. Hence, the dislocation reaction mechanisms responsible for microstructure development can, in principle, be identified.

Some examples are now presented that illustrate how electron diffraction can contribute to the structural characterization of semiconductors. The use of conventional TED combined with image contrast analysis to assess the defect microstructure of a semiconductor heterostructure is initially considered. The application of the CBED technique, sometimes termed microdiffraction, in order to determine the polarities of noncentrosymmetric crystals is then described. We also focus on the RHEED technique, which may be used for rapidly assessing the near-surface microstructures of semiconductor thin films.

17.4.1 Electron Diffraction and Image Contrast Analysis

Figure 17.15 shows a TED pattern corresponding to a highly symmetric, low-index, zone axis projection, acquired from an electron-transparent foil of epitaxial GaN grown on the {0001} basal plane of sapphire, viewed in cross-section under spread beam conditions, i. e., near-parallel illumination.

It is generally instructive to view such diffraction patterns alongside direct images of the sample. Figure 17.16 compares high-resolution electron microscopy (HREM) and conventional TEM (CTEM) images of heteroepitaxial GaN–sapphire sample acquired for this projection. The HREM mode of imaging, otherwise termed *phase contrast* or *lattice imaging*, makes use of several diffracted beams selected by a large objective aperture; the resulting interference patterns can be used to elucidate the locations of atomic columns (Fig. 17.16a). Careful simulation is required to precisely assign atomic positions within such images, since the contrast is strongly dependent on defocus, foil thickness and sample orientation. However, the structural integrity of the interface between GaN and sapphire can be appraised, along with the presence of nanometer-scale, three-dimensional growth islands formed during the initial stages of epitaxy, prior to layer coverage. Conversely, the conventional *many-beam, bright-field* image of heteroepitaxial GaN–sapphire (Fig. 17.16b) was created using a small objective aperture placed over the directly transmitted beam, and recorded at lower magnification. The image contrast is again complicated

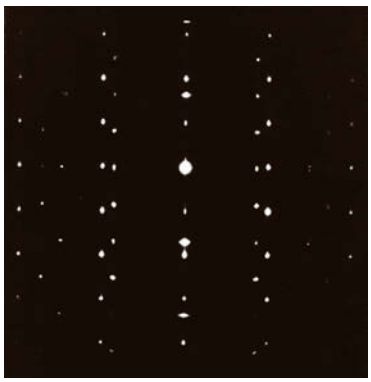

Fig. 17.15 TED pattern acquired from epitaxial GaN/sapphire{0001} viewed in cross-section, corresponding to the $\langle 11\bar{2}0\rangle_{\text{nitride}} \,||\, \langle 1\bar{1}00\rangle_{\text{sapphire}}$ axis projection

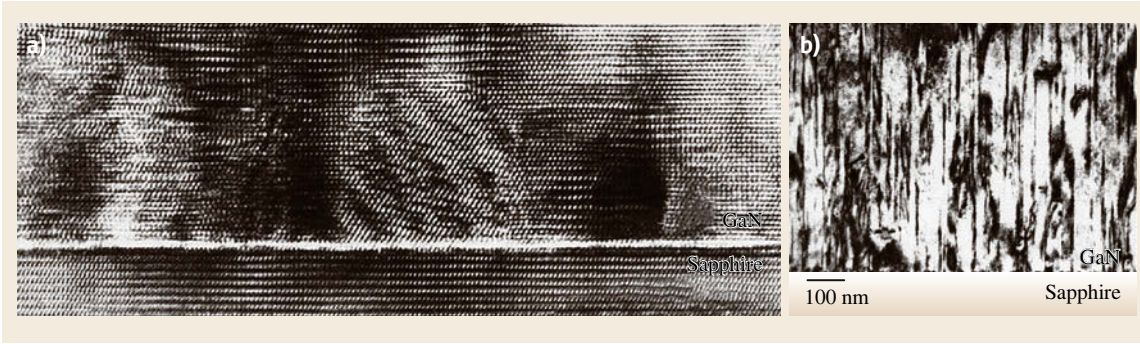

Fig. 17.16 (a) HREM and (b) many-beam CTEM images of GaN/sapphire{0001}

because there are many excited diffracted beams operating for this low-index crystal orientation combined with strain fields associated with the large number of threading defects ($\approx 10^{10}\,\mathrm{cm}^{-2}$) within this sample. Despite this level of defect content, the diffraction pattern of Fig. 17.15 still reflects a high level of crystallographic perfection of the matrix. Also, rotation of this sample foil by 30° about the growth axis enabled a $\langle 1\bar{1}00\rangle_{\mathrm{nitride}} \,||\, \langle 11\bar{2}0\rangle_{\mathrm{sapphire}}$ projection to be established, consistent with the hexagonal symmetry of this GaN–sapphire system. Indeed, establishing different diffraction patterns for different sample projections, for known angles of sample tilt, enables the phase and structural relationship of an epilayer and substrate to be clarified.

There is a need to characterize the precise nature of the fine-scale defect content within such samples. Dislocations, for example, generally act as nonradiative recombination centers, which can deleteriously affect the charge transport properties of a semiconductor [17.24]. Gaining an improved understanding of how dislocations are created and how they interact enables us to identify mechanisms that could be used to control their development, thereby improving the growth of a semiconductor and the resultant properties of devices made from it.

Dislocations are one-dimensional defects that can be pure edge, pure screw or *mixed edge-screw* in character. In certain circumstances, a dislocation can dissociate to form a pair of partial dislocations bounding a stacking fault ribbon, the separation of which depends on the material stacking fault energy. Dislocations can be described with reference to their line direction $\boldsymbol{u}$ and Burgers vector $\boldsymbol{b}$, representing the closure failure of a loop of equal atomic spacings around the defect core. Dislocations can move through a crystal lattice by glide or climb mechanisms; for example, when under deformation or as part of a strain relaxation mechanism during heteroepitaxial growth. Also, dislocations can interact to either self-annihilate or multiply to generate more dislocations depending on their respective type, habit plane and the slip system of the matrix.

The technique of diffraction contrast analysis allows the nature of dislocations to be ascertained. The approach used is to tilt the sample away from a highly symmetrical, low-index zone axis orientation in order to establish diffraction contrast images under selected *two-beam* conditions, with one strong diffraction spot excited ($\boldsymbol{g}$) in addition to the central transmitted beam, corresponding to one set of crystal planes at the Bragg condition. When $\boldsymbol{g}\cdot\boldsymbol{b} = 0$, the displacement associated with a dislocation does not affect the diffracting planes used to form the image and so the defect appears invisible. In practice, two examples of this invisibility condition are generally required to determine the precise displacement associated with a given defect. The dislocation will appear visible when $\boldsymbol{g}\cdot\boldsymbol{b} = 1$ and might show a more complex double image for the case of $\boldsymbol{g}\cdot\boldsymbol{b} \geq 2$. For example, since a screw dislocation is characterized by a Burgers vector $\boldsymbol{b}$ parallel to the line direction $\boldsymbol{u}$, the defect is invisible if a diffraction vector perpendicular to the line direction is chosen. In the case of an edge or mixed dislocation where $\boldsymbol{b}$ is not parallel to $\boldsymbol{u}$, there is a stricter requirement for both $\boldsymbol{g}\cdot\boldsymbol{b} = 0$ and $\boldsymbol{g}\cdot(\boldsymbol{b}\times\boldsymbol{u}) = 0$ for true invisibility, otherwise residual contrast might be present that acts to confuse image interpretation. We should also mention the deviation parameter $\boldsymbol{s}$ when establishing a diffracting condition, which represents a short distance in reciprocal space from the exact Bragg condition, since this is associated with imaging artefacts such as extinction contours and thickness fringes that may act to further complicate an image.

Bright-field, dark-field or weak-beam diffraction contrast imaging techniques can be used for defect analysis, depending on the resolution required. By way of example, epitaxial GaN–$\{\overline{111}\}$B GaAs grown by molecular-beam epitaxy (MBE) at 700 °C exhibits a mosaic cell structure with subgrain boundaries delineated by predominantly mixed-type threading dis-

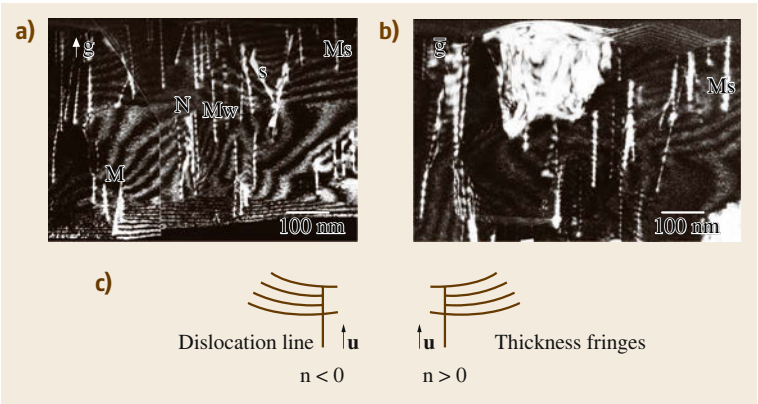

Fig. 17.17a–c Weak-beam images of the same regions of a GaN epilayer viewed in cross-section using **(a)** $\boldsymbol{g} = 000\overline{2}$ and **(b)** $\boldsymbol{g} = 1\overline{1}00$. **(c)** Schematic diagram summarizing Ishida's rule for determining $\boldsymbol{b}$ for $n = -2$ and $n = 2$

locations (typically $> 10^{11}\,\mathrm{cm}^{-2}$) [17.25]. The epitaxial relationship is given by $[000\overline{1}]_{\mathrm{GaN}}||[\overline{111}]_{\mathrm{GaAs}}$, $[1\overline{1}00]_{\mathrm{GaN}}||[2\overline{11}]_{\mathrm{GaAs}}$ and $[11\overline{2}0]_{\mathrm{GaN}}||[01\overline{1}]_{\mathrm{GaAs}}$, and the mismatch between GaN and GaAs is 38.2% between $\{1\overline{1}00\}_{\mathrm{GaN}}$ and $\{2\overline{2}0\}_{\mathrm{GaAs}}$, with the epilayer in tensile strain. Figure 17.17a,b are weak-beam images of the epilayer viewed in cross-section near the $[11\overline{2}0]$ zone axis, using $\boldsymbol{g} = 000\overline{2}$ and $\boldsymbol{g} = 1\overline{1}00$, respectively. Most of the dislocations have a line direction of $\langle 0001\rangle$. Examples of perfect edge, $\boldsymbol{b} = 1/3\langle 11\overline{2}0\rangle$, and screw-type dislocations, $\boldsymbol{b} = \langle 0001\rangle$, are apparent, but mostly dislocations (typically $\approx 70\%$) can be seen in both images, hence they are mixed-type, with Burger's vector components of $\boldsymbol{a}$ and $\boldsymbol{c}$, i. e., $1/3\langle 11\overline{2}3\rangle$.

It is possible to move this analysis forwards by applying Ishida's rule, which allows the magnitude and sense of a Burgers vector to be determined if there are terminating thickness fringes at the exit of a dislocation from a wedge-shaped sample foil [17.26]. If there are n fringes terminating at one end of a dislocation, then $\boldsymbol{g}\cdot\boldsymbol{b} = n$ and the sign of $n (n > 0$ or $n < 0)$ is defined according to Fig. 17.16c. For example, the screw dislocation S (Fig. 17.17a) imaged using $\boldsymbol{g} = 000\overline{2}$ has two thickness fringes terminating on the right-hand side of the dislocation, with the dislocation line pointing towards the $[000\overline{1}]$ growth direction. Hence, $\boldsymbol{g}\cdot\boldsymbol{b} = -2L = 2$, so $\boldsymbol{b}$ is $[000\overline{1}]$ for this screw-type dislocation. For dislocations of mixed type, Fig. 17.17a,b show that some have strong contrast in both images, while others have strong contrast when imaged using $\boldsymbol{g} = 000\overline{2}$ and weak contrast when $\boldsymbol{g} = 1\overline{1}00$. For the former, for example the dislocation denoted as $\boldsymbol{M}_{\mathrm{s}}$ in Fig. 17.17a, thickness fringes terminate at the left-hand side of the dislocation with reference to the dislocation line pointing downwards along [0001]. Hence, $\boldsymbol{g}\cdot\boldsymbol{b} = -2L = -2$ for $\boldsymbol{g} = 000\overline{2}$ and $\boldsymbol{g}\cdot\boldsymbol{b} = -1$ for $\boldsymbol{g} = 1\overline{1}00$, so its Burgers vector is either $1/3[\overline{2}113]$ or $1/3[\overline{1}2\overline{1}3]$. For the cases of strong contrast by $\boldsymbol{g} = 000\overline{2}$ and weak contrast by $\boldsymbol{g} = 1\overline{1}00$, such as the dislocation labeled $\boldsymbol{M}_{\mathrm{w}}$ in Fig. 17.17a, such dislocations have $\boldsymbol{b}$ of $\pm 1/3[11\overline{2}3]$ or $\pm 1/3[11\overline{23}]$, and the weak contrast is due to $\boldsymbol{g}\cdot(\boldsymbol{b}\times\boldsymbol{u}) \neq 0$. Because the thickness fringes connected with this defect type are not clear in the images, a more precise value for $\boldsymbol{b}$ cannot be determined. It is also noted that some dislocations have opposite values of $\boldsymbol{b}$ to others, such as those denoted as $\boldsymbol{M}$ and $\boldsymbol{N}$ in Fig. 17.17a. These two opposite types of dislocations delineate a subgrain, and the region showing bright contrast when imaged with $\boldsymbol{g} = 1\overline{1}00$ in Fig. 17.17b is a misoriented subgrain, tilted close to the Bragg condition.

17.4.2 Microdiffraction and Polarity

If an electron beam is converged to form a focused probe at the sample, then there will be a range of beam directions within the incident probe and within the transmitted and diffracted beams. This leads to the formation of diffraction patterns comprising discs rather than spots. The fine detail within such microdiffraction or CBED patterns contains space and point group information. Such patterns also provide a sensitive measure of lattice parameters and strain within a sample, and can be used also to assess defect type.

Two examples showing how focused probe diffraction patterns can be used to determine the absolute polarities of sphalerite and wurtzite noncentrosymmetric crystals, in situ in the TEM, are now illustrated. It is often important to know the polar orientation of a heterostructure since this can strongly influence the mode and rate of growth, the incorporation of dopants or impurities, and the development of extended defects, and hence the functional performance of the resulting device structure. The opposite polar faces of noncentrosymmetric crystals [17.27] may be distinguished in practice using appropriate chemical etchants. However, such reagents are discriminatory in their action and need to be correlated with some other experimental technique for the purpose of absolute polarity deter-

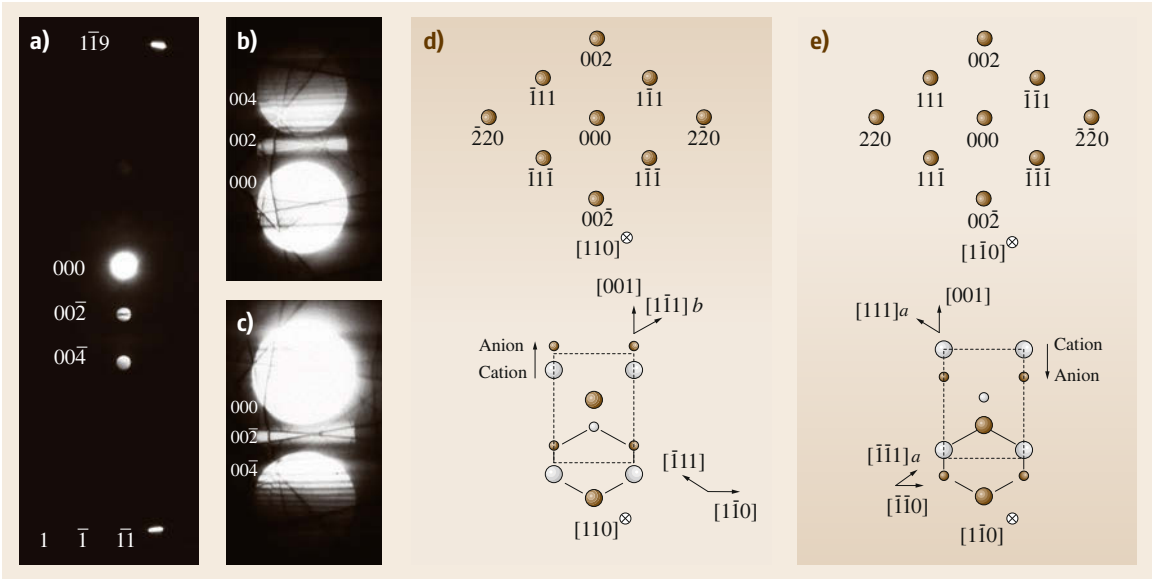

Fig. 17.18 **(a–c)** Microdiffraction patterns from [110] GaAs. **(a)** Destructive interference through an $00\bar{2}$ diffraction disc due to the interaction of doubly diffracted $1\bar{1}9$ and $1\bar{1}\,\bar{1}1$ beams. **(b,c)** Constructive and destructive interference through 002 and $00\bar{2}$ diffraction discs. **(d,e)** Sphalerite space lattice and reciprocal lattice projections for [110] and $[1\bar{1}0]$, indexed for an electron beam traveling down into the page

mination. For most cases of diffraction, there is no difference between the intensities of beams scattered by *hkl* and $\overline{hkl}$ diffracting planes. This indeterminacy is known as Friedel's law. However, the technique of microdiffraction coupled with a breakdown in Friedel's law allows the absolute polarities of sphalerite crystals to be determined when the anion and cation sizes are very similar (as with GaAs, ZnSe and CdTe) [17.28]. The diffraction condition shown in Fig. 17.18a corresponds to a projection tilted $\approx 10°$ off a GaAs [110] zone axis, arrived at following an $\approx 00\bar{4}$ Kikuchi band. The interaction of the doubly diffracted high-order, odd-index $1\bar{1}9$ and $1\,\bar{1}\,\overline{11}$ beams with directly scattered $00\bar{2}$ reflection gives rise to destructive interference through the $00\bar{2}$ disc when all of the reflections are close to the Bragg position. Figure 17.18c, corresponding to a more highly converged incident electron beam, emphasizes the formation of the dark cross through the $00\bar{2}$ diffraction disc. Similarly, Fig. 17.18b shows the bright cross formed through the opposite 002 diffraction disc, by constructive interference following interaction with the corresponding $1\,\bar{1}\,11$ and $1\overline{19}$ high-order, odd-index reflections. Figure 17.18d,e, showing the [110] and $[1\bar{1}0]$ projections of the sphalerite space lattice and reciprocal lattice, respectively, are given, to clarify this particular sample geometry. Establishing such microdiffraction patterns requires carefully balancing crystal orientation, probe convergence and layer thickness, and the technique is found to work best with freshly plasma-cleaned sample foils to minimize the effect of extraneous hydrocarbon contamination (which diffuses out fine-scale contrast under the imaging electron beam).

The dynamical equations of electron diffraction demonstrate that the 002 reflection, which exhibits constructive interference effects (bright cross), always occurs in the sense of the cation to anion bond (Fig. 17.18d), and hence is always associated with the sense of advancing $\{\overline{111}\}_b$ planes. To emphasise this, defining [001] as the growth direction of an epilayer on an (001) oriented GaAs substrate, and establishing a bright cross through an 002 diffraction disc, for example through the interaction of $1\bar{1}9$ and $1\,\bar{1}\,\overline{11}$ reflections, corresponds to the sense of advancing $(\bar{1}11)_b$ and $(1\bar{1}1)_b$ planes in the growth direction, which corresponds to the absolute [110] projection of the sample foil. Conversely, a dark cross through an 002 diffraction disc, such as that obtained through the interaction of $11\bar{9}$ and $1\;1\;11$ reflections, corresponds to the sense of advancing $(111)_a$ and $(\bar{1}\bar{1}1)_a$ planes in the growth direction, which corresponds to the $[1\bar{1}0]$ projection of the sample foil. Since microdiffraction patterns are directly sensitive to crystallographic polarity, a qualitative interpretation of such results allows the crystal orientation to be determined unambiguously, in situ within the TEM, without reference to any other technique.

Contrast reversals within diffraction discs of systematic row CBED patterns can similarly be used to

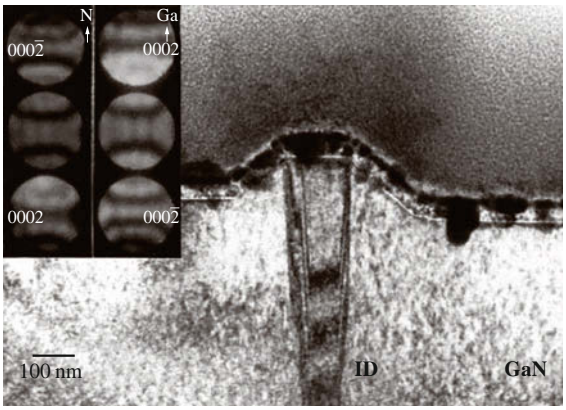

Fig. 17.19 Inversion domain within GaN with CBED patterns recorded across the boundary plane (*inset*)

determine absolute crystal polarity, since Friedel's law again breaks down due to dynamical scattering. In practice, this approach is found to be most effective when used with noncentrosymmetric crystals that have much larger differences in anion and cation sizes, such as wurtzite GaN [17.29]. Figure 17.19 presents a thin section through a columnar defect, imaged within homoepitaxial GaN grown on an N-polar $(000\bar{1})$ GaN substrate, with two associated CBED patterns inset, recorded either side of the boundary plane corresponding to matrix and core material, respectively. Simulation of the contrast within the 0002 diffraction discs, for a known sample foil thickness, demonstrates that the central bright and dark bands correspond to N and Ga-polar growth directions, respectively. The reversal of contrast within the 0002 diffraction discs across the boundary plane therefore indicates an inversion in crystal polarity, confirming the defect to be an inversion domain in this instance.

17.4.3 Reflection High-Energy Electron Diffraction

Electron-transparent samples are required for TED investigations. For the case of semiconductor heterostructures, sample preparation requires sequential mechanical polishing and ion beam thinning, which can be very time-consuming, but the advantage of this approach is that diffraction data can be directly correlated with projected images of the internal structure of the sample. A complementary approach is to use glancing angle electron diffraction techniques to characterize the near-surface microstructure of a bulk sample or an as-grown heterostructure. Coupling of the electron beam directly with the wafer surface at low angle allows scattering of the electrons to occur, producing a diffraction pattern that may be viewed or recorded directly. This provides valuable information on the near-surface crystallography of the sample, which can be correlated with the growth conditions used or surface modifications applied, without the need for time-consuming sample preparation.

There are three variants of reflection electron diffraction (RED) depending on the accelerating voltage available:

- Low (< 1 kV)
- Medium (1–20 kV)
- High (20–200 kV) energy.

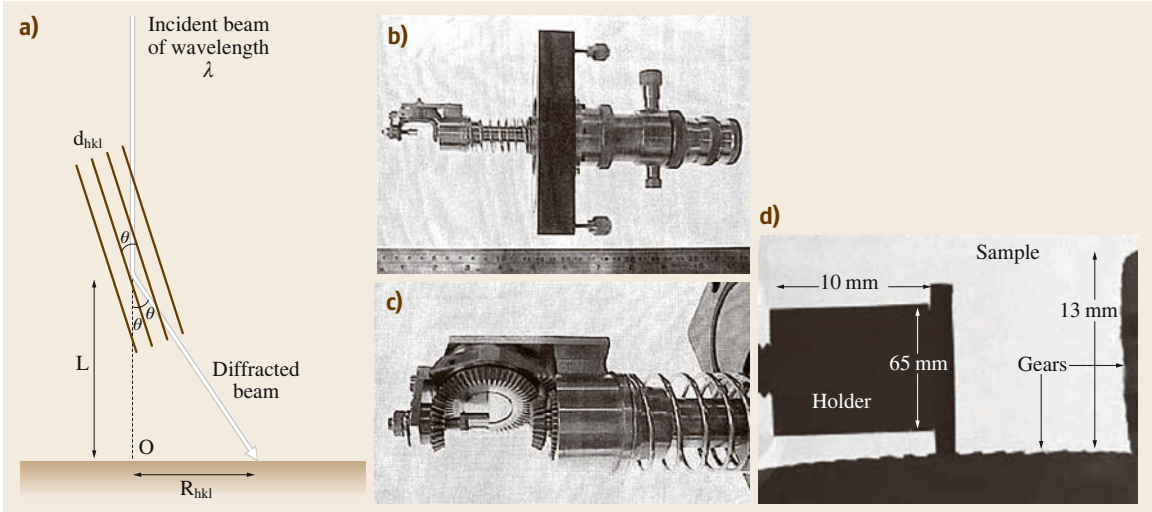

Fig. 17.20 **(a)** Schematic illustration of the RHEED diffraction geometry; **(b)** RHEED stage; **(c)** magnified view of the sample holder; and **(d)** projected shadow image of a specimen on TEM phosphor screen

Medium–energy electron diffraction (MEED) systems are commonly associated with UHV growth chambers, whilst a variant of RHEED can be performed using a conventional TEM. In general terms, the coupling of an electron beam with a flat single crystal tends to be associated with the formation of diffraction streaks normal to the surface, providing information on the reconstruction of atomic layers at the surface. More precisely, streaky RED patterns are indicative of a surface that is not quite perfectly flat, but has slight local misorientations combined with some degree of surface disorder [17.30]. When electrons are coupled with a slightly rougher surface, there is a tendency for more three-dimensional information to be obtained from interactions with the near-surface microstructure. This leads to the production of spotty diffraction patterns from crystalline materials (half-obscured by the sample shadow edge), in an analogous fashion to TED. It is noted that UHV-MEED systems allow for intensity fluctuations within the central beam to be monitored in real time, providing a way to monitor and control layer-by-layer growth.

In practice, RHEED is used most effectively for rapid comparative studies of samples sets; for appraising the effect of changing the growth parameters on the structural integrity of deposited thin films [17.31]. This approach to process mapping provides a convenient way to identify appropriate samples for more detailed TEM investigation prior to sample foil preparation. There are two variants of the RHEED technique that may be used in a TEM: one where small samples are mounted vertically in the objective lens pole piece, and the other where larger samples are mounted vertically below the projector lens; we focus on the latter variant here.

A schematic illustration of the diffraction geometry for a RHEED experiment is shown in Fig. 17.20a. The diffraction spacing R_{hkl} can be measured and the associated crystal plane spacing d_{hkl} determined using the equation, $\lambda L = R_{hkl}d_{hkl}$, where λL is known as the camera constant. Figure 17.20b,c shows a RHEED stage made to interface with a TEM through an existing cam-

era port at the base of the projector lens. The vacuum system of the TEM vents the space below the projector lens upon opening the camera chamber, and so the only waiting time is for the chamber to pump down upon changing a specimen. The RHEED stage is able to support centimeter-square sections of a crystalline specimen, whilst full tilt, twist and lateral movements enable any zone axis within the growth plane of the sample to be accessed. A shadow image of a sample, as projected onto the microscope phosphor screen, is shown in Fig. 17.20d. The area sampled by the glancing electron beam is typically $\approx 1\,\mathrm{mm}^2$, and so this experimental arrangement is closely associated with glancing angle XRD, although the acquisition time for RHEED data is extremely short, with photographic plate exposure times of ≈ 1 s. Three or four samples can typically be examined within 1 h.

The 100 kV RHEED patterns shown in Fig. 17.21a,b were acquired from a highly Si-doped GaN/GaAs(001) heterostructure, grown by MBE at 700 °C, before and after plasma cleaning. Surface hydrocarbon deposits arising from specimen handling can generate an amorphous background glow that can hinder RHEED pattern acquisition (Fig. 17.21a). The oxygen-argon plasma acts to remove such contaminants, allowing high-contrast RHEED patterns to be obtained (Fig. 17.21b). In this instance, the generated RHEED pattern remained effectively constant as the sample was rotated, indicating a random distribution of columnar grains. This predicted microstructure was subsequently confirmed by means of conventional plan-view TEM imaging (Fig. 17.21c, with TED pattern inset), which revealed a fine-scale distribution of rotated columnar grains ($\approx 20°$ of arc).

The RHEED patterns shown in Fig. 17.22a–f, acquired from a variety of III–V heterostructures grown by MBE, are presented to illustrate the variety of microstructures that can be readily distinguished. In the first instance, variations in spot, arc or ring spacings from the central beam provide evidence of the different phases present within a sample and show the general nature of the structural integrity of the near-surface layer (presumed to be representative of the bulk or thin film). Thus, polycrystalline, preferred orientation or single-crystal growth (Fig. 17.22a–c) can be rapidly distinguished, whilst embedded phases (Fig. 17.22d) and anisotropic defect distributions within zinc blende thin films (Fig. 17.22e,f) are also revealed.

17.5 Characterizing Functional Activity

There are many solid state analytical techniques that employ x-ray or electron probes, generating a variety of signals for chemical microanalysis. However, techniques for performing correlated assessment of the structural and functional performance of a material are perhaps less well-covered in mainstream texts. Accordingly, we introduce briefly the techniques of scanning transmission electron beam induced conductivity (STEBIC) and TEM-cathodoluminescence (TEM-CL), since these allow us to make correlated structure-property investigations of electrical and optical activity within a semiconductor, respectively.

When an electron beam is incident on a semiconductor specimen, electron-hole pairs are created by excitation of crystal electrons across the band-gap. These electron-hole pairs can, for example, recombine to emit light that may be detected by a photomultiplier providing, e.g., information on the semiconductor band-gap. A CL image can then be obtained by displaying the detected photomultiplier signal as a function of the position of the incident electron beam as it is scanned across the specimen. CL spectra can also be acquired in spot mode, which show features attributable to excitons, donor–acceptor pairs or impurities. The *information content* of CL images and spectra includes the location of recombination sites such as dislocations and precipitates, and the presence of doping-level inhomogeneities. Similarly, if the sample is configured to incorporate a collection junction, such as a Schottky-contacted semiconductor or an ohmic-contacted p–n junction, electron-hole pairs that sweep across the built-in electric field constitute a current flow. This can be amplified and an image of the recombination activity displayed as the electron beam is rastered across the sample. If the dislocations within a semiconductor act as nonradiative recombination centers, then they appear as dark lines in both CL and EBIC images because of the reduced specimen luminescence or reduced current that is able to flow through the collection junction when the beam is incident at a defect.

The techniques of CL and EBIC are most commonly performed in an SEM, but this precludes the direct identification of features responsible for a given optical or electronic signature. The resolution of extended defects achieved using EBIC and CL techniques is limited by the penetration depth of the electron beam, the effect of beam spreading and the diffusion length of minority carriers. Conversely, the resolutions of the STEBIC and TEM-CL techniques, as applied to

electron-transparent sample foils, are essentially limited by specimen geometry. The constraint of minority carrier diffusion length is removed due to the close proximity of the sample foil surfaces, and resolution depends on the incident probe size, the width of the electron hole pair generation zone and recombination velocity at the free surface. For the case of STEBIC, resolution also depends on defect position relative to the collecting junction. The trade-off is low electrical signal and a degraded signal-to-noise ratio due to the small generation volume and surface recombination effects, in addition to the practicality of contacting and handling thin foils.

Before presenting some material characterization case studies based on electron beam techniques, we now discuss the preparation of electron transparent foils that are free from artefacts and suitable for TEM investigation.

17.6 Sample Preparation

We should initially consider whether destructive or nondestructive preparative techniques need to be applied. Some characterization techniques allow samples to be examined with a minimal amount of preparation, provided they are of a form and size that will fit within the apparatus. For example, the crystallography of bulk or powder samples may be investigated directly by XRD, since the penetration depth of energetic x-rays within a sample is on the scale of $\approx 100\,\mu m$. The surface morphology and near-surface bulk chemistry of a sample may be investigated directly within the SEM, noting the interaction volume of electrons [on the scale of $\approx 1\,(\mu m)^3$] associated with the EDX and WDX techniques. It might, however, be necessary to coat insulating samples with a thin layer of carbon or gold prior to SEM investigation to avoid charging effects. Similarly, minimal preparation might be required before surface assessment using XPS or RHEED, such as cleaning using a degreasing protocol or plasma cleaning. Accordingly, the focus of this section is to introduce techniques used to prepare samples for TEM investigation, since the requirement is for specimens that are typically submicrometer in thickness and free of preparation artefacts. For example, a complex sequence of sequential mechanical polishing, dimpling, ion beam thinning and plasma cleaning may be required to produce a pristine semiconductor heterostructure sample, with each stage of the process

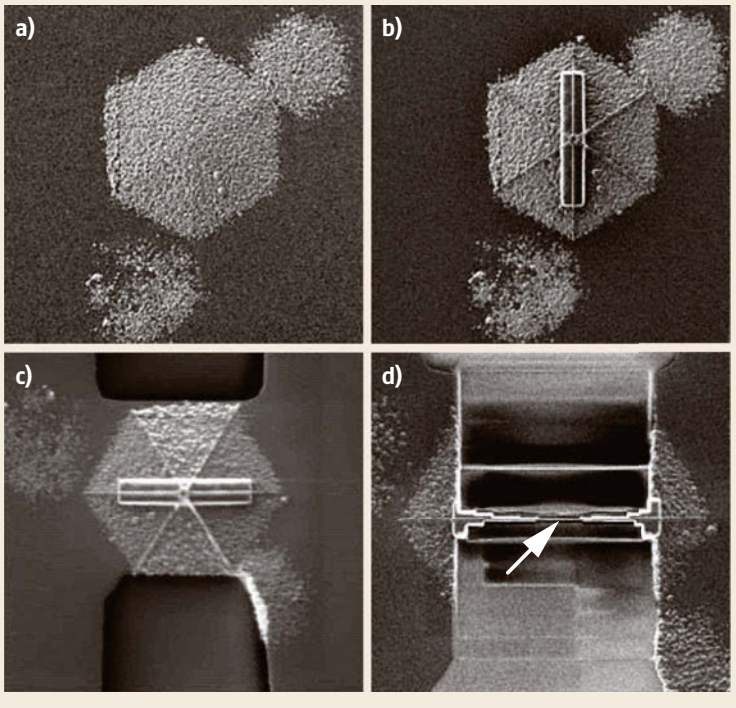

Fig. 17.23a–d SE images showing the application of FIB milling to target a source of defects buried beneath the emergent core of a growth hillock. **(a)** An etched CVD-grown GaN/sapphire hillock ($\approx 5\,\mu m$ in size; CVD – chemical vapor deposition). **(b)** Platimum stripes deposited along the hillock facet edges in order to retain sight of the defect core ($\approx 100\,nm$ in size). **(c)** A high Ga flux is used to create an access trench to the defect. **(d)** Decreasing the Ga flux enables an electron-transparent membrane (*arrowed*) to be defined at the position of the defect core

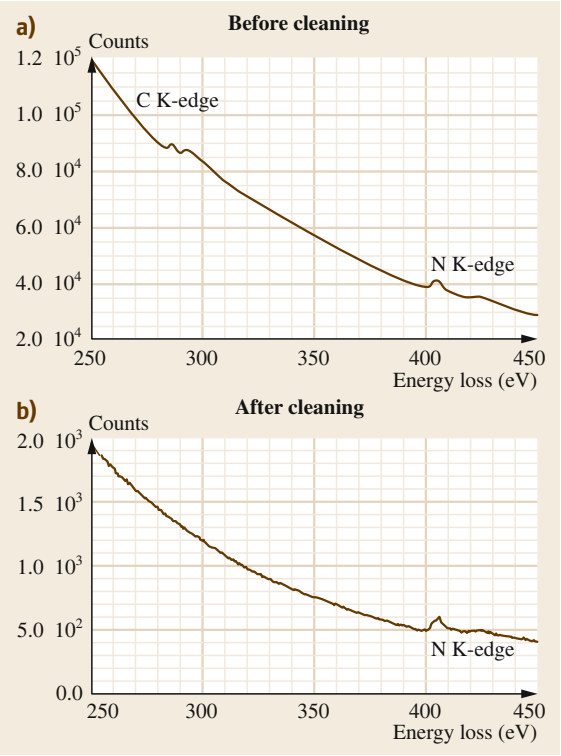

Fig. 17.24a,b EELS spectra from GaN (a) before and (b) after plasma cleaning

being designed to minimize artefacts from the previous stage of the preparation process. The idea being to minimize or eliminate artefacts from the preparation process, to ensure that the sample being investigated is representative of the starting bulk material. Care is also needed to avoid artefacts that might be introduced through interaction of the high-energy electron beam with the sample.

In this context, it is interesting to note how TEM sample preparation techniques have developed over the years. Small particles of MgO, produced by igniting the metal and drifting a specimen grid through the smoke, were typical of samples investigated in the 1940s, along with sample replicas made by a dry stripping technique using formvar films. Biological samples fashioned by enzymatic digestion, staining and microincineration were also possible by 1945. Glass and diamond knife microtomes were introduced in the 1950s and used to section soft biological materials. Advances in the controlled preparation of inorganic materials were made upon the introduction of argon ion beam thinning in the late 1960s, which allowed for cross-sectional observation of semiconductor heterostructures when combined with sequential mechanical polishing and dimpling. Significant development work in this area appears throughout the literature from the 1970s. The problem of surface amorphization, introduced by the argon sputtering process, was minimized by adopting low-voltage milling techniques to define the final electron-transparent sample foil. Low stacking fault energy semiconductors, such as II–VI compounds which are easily damaged or InP-based compounds that suffer from In droplet formation with conventional milling techniques, were also successfully prepared for TEM observation using the technique of iodine reactive ion beam etching (RIBE), otherwise known as chemically assisted ion beam etching (CAIBE), developed in the 1980s. The 1990s, however, saw the development of the most effective raft of sample preparation techniques for functional materials and complex semiconductor device structures in particular: i. e., tripod polishing, focused ion beam (FIB) milling and plasma cleaning.

The fine adjustment of micrometer supports is the key to tripod polishing that allows for direct mechanical polishing of specimens down to $< 10\,\mu m$ thickness, using diamond-impregnated polishing cloths on a stable, high-torque, low-speed polishing wheel. A brief final stage of low-voltage argon ion beam thinning (with liquid nitrogen cooling) then enables electron-transparent sample foils to be defined, free of differential mechanical polishing and shadowing artefacts, whilst minimizing remnant surface amorphization.

FIB instrumentation (now commonly integrated with SEM) was originally developed for the semiconductor industry as a diagnostic tool for silicon chip fabrication. The application of a focused beam of gallium ions enables sample material to be sputtered away in a controlled fashion to produce an electron-transparent membrane, for example through a specific device within a complex microprocessor. Samples may be periodically observed using SEs generated by gallium ion/material interactions in order to maintain control over and the precision of the sputtering process. In particular, the ability of FIB instruments to prepare site-specific TEM membranes provides a unique opportunity to access the subsurface microstructure of complex device structures or specific regions within a heterostructure identified as being particularly interesting from observations of the surface. By way of example, Fig. 17.23 shows a TEM membrane sectioned through the apex of a hillock identified within a sample of heteroepitaxial GaN–sapphire. Prior to sectioning, the sample was coated with a thin layer of gold and a platinum alkyl decomposed under the rastered Ga beam to define protective metallic stripes. Sequential sputtering and reduction of the incident Ga beam current density allowed a supported thin membrane to be defined (Fig. 17.23d). Care is required to minimize amorphization artefacts at the surfaces of

such membranes, arising from the sputtering action of the glancing, high-energy Ga ion beam. Further, charging effects associated with insulating samples can act to compromise the fine-scale control of the ion milling procedure. However, this particular problem can be addressed by using low ion dose and shadowing techniques, combined with charge neutralization procedures to inhibit the deflection of the incident ion beam.

Plasma cleaning using oxygen-argon gas, commonly used for the final stage of TEM sample preparation, enables pristine electron-transparent membranes to be obtained, suitable for detailed chemical microanalysis. The disassociated oxygen component of the plasma reacts with organic surface contaminants to produce CO, CO_2 and H_2O reaction products that can be pumped away conveniently. To illustrate the effectiveness of this procedure, it was found that the quality of EELS data from GaN electron transparent foils was significantly improved following plasma cleaning. Figure 17.24 shows the removal of the artefact carbon *K*-edge and enhancement of the sample nitrogen *K*-edge after a few minutes of exposure to the plasma. It is worth noting that in principle the argon component of the plasma permits gentle sputtering of the sample to occur if low-pressure conditions are used due to the larger mean free path and hence increased energy of the ions. However, this can be problematic due to the possibility of sample cross-contamination with material sputtered from the supporting sample stage. Another cautionary note on plasma cleaning relates to semi-insulating samples that can become too clean and consequently more susceptible to charging effects under the imaging electron beam.

17.7 Case Studies – Complementary Characterization of Electronic and Optoelectronic Materials

There are four general levels of interest when characterizing a given sample:

- What is it made of?
- What additional imperfections does it contain?
- How did it get to be that way?
- How does the microstructure influence the functional properties of the material/device?

For example, one might wish to identify the chemical constituents and crystal structure of a sample to start with, such as whether it is a compound or an alloy, and whether it is single-crystal, polycrystalline, exhibits preferred orientation, or is amorphous. One might then wish to characterize the additional fine-scale defect microstructure within the sample, including precipitates or extended structural defects such as dislocations, stacking faults or domain boundaries, since these could deleteriously affect the functional properties of the material. The next level of understanding focuses on how the material has formed via growth, processing or device usage, and seeks to make sense of the process of dynamic evolution, since this potentially enables us to find ways to improve the material in a controlled manner. A clear record of sample history is generally helpful in this context, particularly when trying to identify defect sources. The final level of understanding is possibly the most challenging, since it seeks to associate microstructure with the functional properties exhibited by the material, and thereby to make sense of its process–structure–property interrelationship at the fundamental level.

In this context, the structural characterization of semiconductor heterostructures tends to focus on the following issues:

- The integrity of the layer growth and the orientation relationship with the substrate.
- The nature of the structural defects within the epilayer, arising, e.g., from lattice mismatch or from differential thermal contraction following cool-down from the growth temperature.
- The structural integrities of critical interfaces within the device's active region, such as multiple quantum wells, and the chemical homogeneity of the associated alloy layers.
- Modification of the microstructure due to subsequent processing, such as contact formation and device usage.

XRD techniques are well-suited to assessments of the structural integrities of bulk and epitaxial thin film semiconductors. However, we should note the inherent averaging over a large number of microscopic features, such as dislocation distributions responsible for the twist and tilt of mosaic grains, associated with such techniques. Conversely, TEM and related techniques are more suited to assessing the fine-scale defect microstructure of heterostructures. For example, conventional weak-beam, HREM or CBED analysis can be used for fine-scale defect structural analysis, whilst EELS and EDX analysis can be used to profile composition. However, the ability to perform atomic-level structural characterization and chemical analysis on

the nanometer scale is offset by concerns about statistical significance and whether the small volume of material analyzed is truly representative of the larger object. Hence, electron microscopy-based techniques combined with FIB procedures for site-specific sample preparation tend to be favored when investigating integrated device structures.

The examples provided so far illustrate how various diffraction and imaging techniques can provide information on the structural integrity of a given sample. The following examples emphasize the need to apply complementary material characterization techniques in support of the development of semiconductor science and technology.

17.7.1 Identifying Defect Sources Within Homoepitaxial GaN

The emergence of the (In,Ga,Al)N system for short-wavelength light-emitting diodes, laser diodes and high-power field effect transistors has been *the* semiconductor success story of recent years. In parallel with the rapid commercialization of this technology, nitride-based semiconductors continue to provide fascinating problems to be solved for future technological development. In this context, a study of homoepitaxial GaN, at one time of potential interest for high-power blue–UV lasers, is presented.

The reduction in extended microstructural defects permitted by homoepitaxial growth was considered to be beneficial in the development of nitride-based technology, particularly in view of evidence confirming that dislocations do indeed exhibit nonradiative recombinative properties. However, in the case of metal organic chemical vapor deposition (MOCVD)-grown homoepitaxial GaN on chemomechanically polished $(000\bar{1})$, N-polar substrates, gross hexagonally shaped surface hillocks were found to develop, considered problematic for subsequent device processing [17.32]. The homoepitaxial GaN samples examined in this case study were grown at 1050 °C. The bulk GaN substrate material was grown under a high hydrostatic pressure of nitrogen (15–20 kbar) from liquid Ga at 1600 °C. Prior to growth, the $(000\bar{1})$ surfaces were mechanically polished using 0.1 μm diamond paste and then chemomechanically polished in aqueous KOH solution. Epitaxial growth was performed using trimethylgallium and NH_3 precursors with H_2 as the carrier gas, under a total pressure of 50 mbar. Figure 17.25 shows an optical micrograph of the resultant homoepitaxial GaN/GaN$(000\bar{1})$ growth hillocks, typically 5–50 μm in size depending on the layer thickness (and therefore the time of growth).

Electron-transparent samples were prepared in plan view using conventional sequential mechanical polishing and argon ion beam thinning procedures applied from the substrate side, whilst cross-sectional samples were prepared using a Ga-source FIB workstation. As shown earlier, the selectivity of the FIB technique enables cross-sections through emergent cores of the hillocks to be obtained, thereby allowing nucleation events associated with these features to be isolated and characterized. When prepared in plan-view geometry for TEM observation, each hillock exhibited a small faceted core structure at the center (Fig. 17.25b), but otherwise the layers were generally found to be defect-free. Low-magnification cross-sectional TEM imaging also revealed the presence of faceted column-shaped defects beneath the apices of these growth hillocks (Fig. 17.25c). It was presumed that these features originated at the original epilayer-substrate interface since no other contrast delineating the region of this homoepitaxial interface could be discerned. A reversal of contrast within 0002 diffraction discs from CBED patterns acquired across the boundary walls of such features (Fig. 17.19) confirmed that they were inversion domains. Thus, the defect cores were identified as having Ga-polar growth surfaces embedded within an N-polar GaN matrix. Once nucleated, the inversion domains exhibited a much higher growth rate than the surrounding matrix, being directly responsible for the development of the *circus tent* hillock structures around them. Competition between growth and desorption rates of Ga and N-polar surfaces allowed the gross hexagonal pyramids to evolve.

This initial approach of applying electron diffraction and imaging techniques thus enabled the nature of the inversion domains to be identified and their propagation mechanism established in order to explain the development of the hillocks. However, more detailed chemical analysis was required to ascertain the nature of the source of the inversion domains and how this related to substrate preparation and the growth process. A high-angle annular dark field (HAADF) image of the inversion domain nucleation event is shown in Fig. 17.25d. HAADF is a scanned electron probe imaging technique with a resolution defined by the size of the incident probe, with the scattering (and hence contrast) governed by local average atomic number. In this instance, the sample, tilted slightly to minimize the effects of diffraction contrast, showed dark contrast at the position of the inversion domain source, confirming the presence of a low atomic number material associated with the nucleation event. HREM subsequently confirmed that such nucleation events were

An enlarged ⟨0001⟩ projected image of the hillock core is shown in the *inset*. **(c)** Cross-sectional, weak-beam TEM image through a hillock core. CBED analysis confirmed the feature to be an inversion domain. **(d)** HAADF image indicating the presence of a low atomic number material at the inversion domain source. **(e)** HREM image indicating the presence of a narrow band of amorphous material at the inversion domain source. **(f)** EEL second difference spectrum indicating the presence of oxygen at the nucleating event ◄

due to narrow bands of amorphous material, 2–5 nm in thickness (Fig. 17.25e), whilst EELS confirmed the presence of oxygen (Fig. 17.25f) within these narrow amorphous bands. Accordingly, these defect sources were attributed to remnant contamination from the chemomechanical polishing technique used to prepare the substrates prior to growth. The oxygen-containing residue was presumed to be gallium oxide or hydroxide – being products of the reaction of the KOH etchant with GaN. An improved surface preparation method incorporating a short, final deoxidizing polishing procedure in an aqueous solution of NaCl led to a dramatic reduction in these nucleation sources and thus allowed N-polar homoepitaxial GaN films to be grown virtually free of these hillock structures.

17.7.2 Cathodoluminescence/Correlated TEM Investigation of Epitaxial GaN

The CL technique is ideally suited to studies of luminescence uniformity and spectral purity. The following case study illustrates how the defect microstructure of mixed-phase epitaxial GaN/GaAs($\overline{111}$)B can be correlated with the layer of luminescent properties [17.33].

Even though the majority of developments in GaN technology to date have come from material grown by MOCVD on sapphire and SiC substrates, there is much interest in exploring alternative growth techniques. The MBE technique offers a lower growth temperature than MOCVD and hence enables a greater range of candidate substrate materials to be investigated. One general issue for the MBE growth of heteroepitaxial GaN is the need for direct control of the process of nucleation, since this impacts on the phase and polarity of the deposit and the resultant structural integrity of the film. Epitaxial GaN preferentially adopts the wurtzite phase, with a band-gap of 3.4 eV_{hex}, although zincblende inclusions, with a band-gap of 3.2 eV_{cubic}, are sometimes associated with MBE-grown material (for conditions of high Ga flux); Fig. 17.26. The CL spectrum shown in Fig. 17.26a was recorded from a plan-view, electron-transparent foil of nominally single-crystal wurtzite GaN, cooled to liquid nitrogen temperature. The peak in the CL spectrum at 386 nm (3.21 eV) was used to create the image in Fig. 17.26b indicating the distribution of cubic phase inclusions throughout the hexagonal GaN matrix. The complementary conventional TEM image of this plan-view sample foil (Fig. 17.26c) allowed the nature of the fine-scale microstructure to be

characterized, with diffraction patterns confirming the presence of embedded sphalerite GaN growth. The size and distribution of these inclusions correlated nicely with the distribution of bright spots in the CL image of Fig. 17.26b. A subsequent cross-sectional investigation of this GaN/GaAs($\overline{1}\overline{1}\overline{1}$)B specimen confirmed that cubic inclusions nucleated at the epilayer/substrate interface (Fig. 17.26d).

17.7.3 Scanning Transmission Electron Beam Induced Conductivity of $Si/Si_{1-x}Ge_x/Si(001)$

The STEBIC technique was originally demonstrated in the late 1970s, using dedicated STEM instrumentation to obtain information on the electrical properties of dislocation core structures within (Ga,Al)(As,P), thereby providing the first evidence that nonradiative recombination processes at dislocations are related to jogs and kink sites. Dissociated 60° dislocations showed the highest electrical activity, while sessile Lomer–Cottrell edge dislocations were found to be electrically neutral, indicative of reconstructed core structures. STEBIC imaging of an electron-transparent foil allows the electrical and structural properties of defects to be observed simultaneously. The availability of electron sources with high brightness in modern scanning TEM instruments compensates for the main problem of small generation volume and provides an accessible way to perform STEBIC experiments.

The next case study illustrates how the electrical nonradiative recombination properties of MBE-grown $Si/Si_{1-x}Ge_x/Si(001)$ heterostructures correlate with the distribution of interfacial misfit dislocations [17.34]. The $Si_{1-x}Ge_x$ system has potential application in devices with high electron and hole mobilities. However, the introduction of dislocation networks, or the multiplication of existing dislocations, driven by the 4% misfit strain between Ge and Si, is generally regarded as being detrimental to device operation. With a view to gaining an improved understanding of the relationship between fine-scale structural defects and electron transport properties, the structures of capped MBE-grown $Si/Si_{1-x}Ge_x/Si(001)$ were investigated using STEBIC and a range of complementary microscopies. The samples incorporated buried p–n junctions to assist with charge collection and surmount the problem of surface recombination effects.

To prepare for the STEBIC investigation of the $Si/Si_{1-x}Ge_x/Si(001)$, evaporated Al contacts were attached to the top surface prior to preparing electron-transparent foils in plan-view by sequential mechanical polishing and argon ion milling of the substrate (Fig. 17.27a). Ohmic contact to the lower surface was

made using an InGa eutectic. Electrical activity images were acquired using an electrical contact stage and a scanning TEM. Signal amplification was performed using an amplifier with low noise current. By controlling the STEM scan rate, the beam could be rastered at a rate compatible with the low bandwidth constraint of the amplifier. STEBIC signals were typically ≈ 100 pA for an electron-transparent $Si/Si_{1-x}Ge_x/Si$ foil imaged at a magnification of $\times 1000$.

Figure 17.27a illustrates the physical parameters relevant to this STEBIC experiment. The silicon substrate was n-type $10^{18}\,cm^{-3}$, whilst the epilayer was p-type boron-doped to a level of $10^{16}\,cm^{-3}$. These values of sample doping were chosen to create a depletion region of ≈ 30 nm width to assist with charge

collection, away from the misfit dislocations delineating the Si/$Si_{1-x}Ge_x$ and $Si_{1-x}Ge_x$/Si interfaces. The low-magnification STEBIC image shown in Fig. 17.27b illustrates the recombination activity within a relaxed Si/$Si_{0.96}Ge_{0.04}$/Si(001) sample imaged in plan view. Submicron resolution of the recombination activity is readily achievable using this technique (Fig. 17.27c), with line scans from digitized images indicating a resolution of $\approx 0.3\,\mu m$ in this case. The spacing of $\approx 1\,\mu m$ striations in the STEBIC image is much greater than the spacing of individual misfit dislocations shown in the associated TEM image (Fig. 17.27d), and is more closely associated with the spacing of dislocation bundles. Thus, correlation with structural images shows that bunched arrays of orthogonal ⟨110⟩ misfit dislocations are primarily responsible for the enhanced recombination. For this particular sample, detailed $\boldsymbol{g} \cdot \boldsymbol{b}$ analysis confirmed the presence of bands of predominantly 60° misfit dislocations with a few 90° segments arising from dislocation interactions.

Supporting evidence for these dislocations being dissociated and probably decorated by transition metal impurities was obtained from complementary HREM and EDX investigations of metastable and relaxed Si/$Si_{1-x}Ge_x$/Si(001) samples from the same growth trial. As the relaxation of a low Ge content, metastable Si/$Si_{1-x}Ge_x$/Si structure proceeds, extensive arrays of orthogonal ⟨110⟩ dislocations form and interact, with

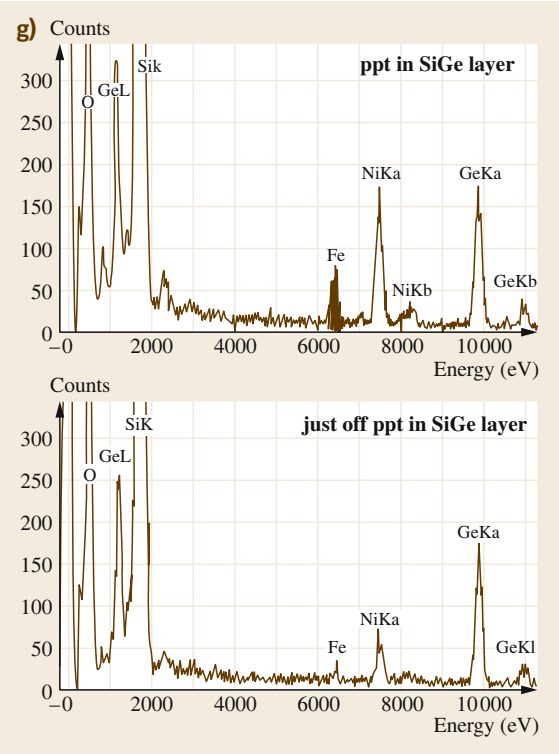

Fig. 17.27 (g) EDX spectra confirming the presence of Fe transition metal impurities

dislocations generated in the strained $Si_{1-x}Ge_x$ layer being pushed by repulsive dislocation forces into the Si substrate and cap on {111} glide planes. HREM observations of relaxed $Si/Si_{1-x}Ge_x/Si$ samples in cross-section confirmed that the misfit dislocations were dissociated, with tails associated with each of the partials, indicative of impurity decoration (Fig. 17.27e). This particular image was acquired before the development of electron beam-induced damage artefact structures within this sample foil and so is considered representative of the as-grown material. A distribution of small precipitates, of typical size 5 nm, was also identified within metastable samples prior to strain relaxation. These precipitates showed strong scattering in HREM (Fig. 17.27f) and revealed the presence of Fe when analyzed using EDX within a dedicated STEM (1 nm probe size), as shown in Fig. 17.27g. No Fe was present in spectra acquired immediately to the side of the precipitates. (The Ni signal was considered to be an artefact of EDX acquisition and attributed to fluorescence from x-rays and electrons interacting with the specimen's Ni support ring.) Hence, the suggestion is that enhanced transition metal impurity segregation at dissociated dislocations is responsible for the STEBIC contrast observed. This emphasizes the need to control dopants or impurity sources in the vicinity of heterostructure interfaces during the development of functional device structures.

17.8 Concluding Remarks

The above commentary has attempted to convey the framework underpinning a variety of analytical techniques used to investigate the structures of semiconductors. It is emphasized that an appropriate combination of assessment techniques should be applied generally, since no single technique of assessment will provide information on the morphology, composition, microstructure and (opto)electronic properties of a given functional material or processed device structure.

This type of considered approach to materials characterization is required in order to break free of the *black-box* mentality that can develop if one is too trusting of the output generated by automated or computerized instrumentation systems. One should always bear in mind the process of signal generation that provides the information content. This in turn helps us to develop an appreciation of performance parameters such as spatial or spectral resolution, in addition to sensitivity, precision and detection limits. One should consider technique calibration and the appropriate use of standards in order to ensure that the data acquired is appropriate (and reproducible) to the problem being addressed. Consideration should also be given to the form and structure of the data being acquired and how the data sets are analyzed. In this context, distinction should be made between the processing of analog and digital information and the consequences of data conversion. Issues regarding the interpretation (or misinterpretation) of results often stem from the handling of experimental errors. On a practical level, rigorous experimental techniques should be applied to ensure that the data generated is both meaningful and representative of the sample being investigated, free from artefacts from the preparation and investigation processes. There are clearly differences between qualitative assessment and the more rigorous demands of quantitative analysis. The level of effort invested often reflects the nature of the problem that is being addressed. A comparative assessment of a number of samples may simply require a qualitative investigation (for example, in order to solve a specific materials science problem within a growth or device fabrication

process). Alternatively, quantitative analysis may be required to gain a more complete understanding of the nature of a given sample, such as the precise composition. To summarize, an awareness of the methodology used in any investigation is required to establish confidence in the relevance of the results obtained. A range of complementary analysis techniques should ideally be applied to gain a more considered view of a given sample structure.

Acknowledgments. As ever, there are many people one wishes to acknowledge for their involvement in the growth, processing and underpinning characterisation research programmes drawn from to illustrate this chapter. University of Nottingham: with thanks to Tom Foxon, T.S. Cheng, Sergei Novikov and Chris Statton for the provision of MBE GaN samples and supporting XRD analysis; and to Mike Fay for GaAs CBED patterns. University of Cambridge: with thanks to Colin Humphreys for provision of instrumentation; Chris Boothroyd for STEM data on the SiGe and GaN samples; Michael Natusch for GaN EELS data; Robin Taylor for RHEED stage development; David Tricker for the Si-doped GaN micrograph; and Yan Xin for the GaN images used for dislocation analysis. University of Warwick: with thanks to Richard Kubiak and E.H.C. Parker for supplying SiGe/Si samples. Polish academy of Sciences, Warsaw: with thanks to Jan Weyher for homoepitaxial GaN samples. With thanks also to the EPSRC for funding support.

18. Surface Chemical Analysis

David Sykes

The physical bases of surface chemical analysis techniques are described in the context of semiconductor analysis. Particular emphasis is placed on the SIMS (secondary ion mass spectrometry) technique, as this is one of the more useful tools for routine semiconductor characterization. The practical application of these methods is addressed in preference to describing the frontiers of current research.

18.1 **Electron Spectroscopy** 414
18.1.1 Auger Electron Spectroscopy 414
18.1.2 X-Ray Photoelectron Spectroscopy (XPS) 415
18.2 **Glow-Discharge Spectroscopies (GDOES and GDMS)** 416
18.3 **Secondary Ion Mass Spectrometry (SIMS)** 417
18.4 **Conclusion** 423

Surface chemical analysis is a term that is applied to a range of analytical techniques that are used to determine the elements and molecules present in the outer layers of solid samples. In most cases, these techniques can also be used to probe the depth distributions of species below the outermost surface. In 1992 the International Standards Organisation (ISO) established a technical committee (TC) on surface chemical analysis (ISO TC 201) to harmonize methods and procedures in surface chemical analysis. ISO TC 201 has a number of subcommittees that deal with different surface chemical analytical techniques and this chapter will discuss the applications of these different methods, defined by ISO TC 201, in the context of semiconductor analyses. In particular, this discussion is intended to deal with practical issues concerning the application of surface chemical analysis to routine measurement rather than to the frontiers of current research. Standards relating to surface chemical analysis developed by the ISO TC201 committee can be found on the ISO TC201 web site www.iso.org (under *standards development*).

Traditional surface chemical analysis techniques include the electron spectroscopy-based methods Auger electron spectroscopy (AES or simply Auger) and x-ray photoelectron spectroscopy (XPS, once also known as ESCA – electron spectroscopy for chemical analysis), and the mass spectrometry method SIMS (secondary ion mass spectrometry). The ISO TC 201 committee also has a subcommittee that deals with glow discharge spectroscopies. Whilst these latter methods have been used more for bulk analysis than surface analysis, the information they produce comes from the surface of the sample as that surface moves into the sample, and so they have been finding applications in depth profiling studies.

One thing that is common to all of these surface chemical analysis techniques is that they are vacuum-based methods. In other words, the sample has to be loaded into a high or ultrahigh vacuum system for the analysis to be carried out. With the one exception of glow discharge optical emission spectroscopy (GDOES), where the analysis relies upon the detection of photons, all of the techniques also depend upon the detection of charged particles. This requirement for vacuum operation necessarily imposes limits on the types and sizes of samples that can be analyzed, although of course instruments capable of handling semiconductor wafers do exist. The quality of the vacuum environment around the sample can also affect the quality of the analysis, especially with regard to the detection of elements that exist in the atmosphere around us. The size and complexity of surface chemical analysis equipment has arguably tended to limit the wider use of these powerful methods.

18.1 Electron Spectroscopy

In the electron spectroscopies, Auger and XPS, the surface of the sample is probed by an exciting beam which causes electrons to be ejected from the atoms in the sample. These electrons are collected and their energies analyzed. The two techniques are similar but subtly different.

18.1.1 Auger Electron Spectroscopy

In Auger, a beam of electrons is used to excite the sample. During the interaction of the primary electron beam with the sample atoms, core electrons are knocked out, creating vacancies in the inner electron shells. Electrons from outer shells can fall into the vacancy, thus leaving the atom in an unstable state and, in order to return to equilibrium, the excess energy the atom possesses can be dissipated in one of two ways: either by the emission of an x-ray photon with a characteristic energy (the basis of energy- or wavelength-dispersive x-ray analysis), or by the emission of a third electron (the Auger electron), with an energy determined by the difference in energy between the original core state and those of the two other levels involved. Clearly these energies are uniquely determined by the energy levels in the atom and thus provide a route for analysis. As three electrons are necessary for the Auger process to occur, AES is incapable of detecting hydrogen or helium, but all other elements produce characteristic Auger electrons. The energies of the Auger electrons can range from a few tens of electron volts to a few thousand electron volts. In this energy regime, electrons can only travel of the order of monolayers through a solid before an interaction occurs which causes a loss of energy, thus destroying the analytical information the electron possessed. It is this property which gives the Auger technique its surface sensitivity – although Auger electrons will be produced as far into the material as the primary beam can penetrate, only those produced in the top few monolayers can escape with their characteristic energy intact. The Auger electrons excited deeper into the sample lose energy before escaping and contribute to a background signal, as do the scattered primary electrons and the initial core electrons ejected at the start of the process. These scattered electrons produce a background signal against which the Auger electrons must be detected; this limits the analytical sensitivity that can be achieved by Auger. This is also why Auger spectra are sometimes displayed as the differential of the number of electrons against energy, because the small Auger peaks are more rapidly varying functions than the larger, slowly changing background signal and hence are enhanced by the differentiation process. Figure 18.1 shows an Auger spectrum from GaInAsP, where the spectrum plotted as the number of electrons as a function of energy is compared to the differential of the number of electrons as a function of energy.

As the number of Auger electrons produced is proportional to the number of atoms excited, Auger offers the ability to perform quantitative as well as qualitative analyses, although some form of calibration is required, either through the use of local reference materials or instrument calibration and standard databases. So Auger offers quantitative analysis for all elements from lithium to uranium from layers only a few atoms in thickness. What gives Auger an extra dimension is the ability to profile into the sample by removing the outermost surface layers with an inert gas ion beam (usually argon) in order to expose the layers below. This sputter

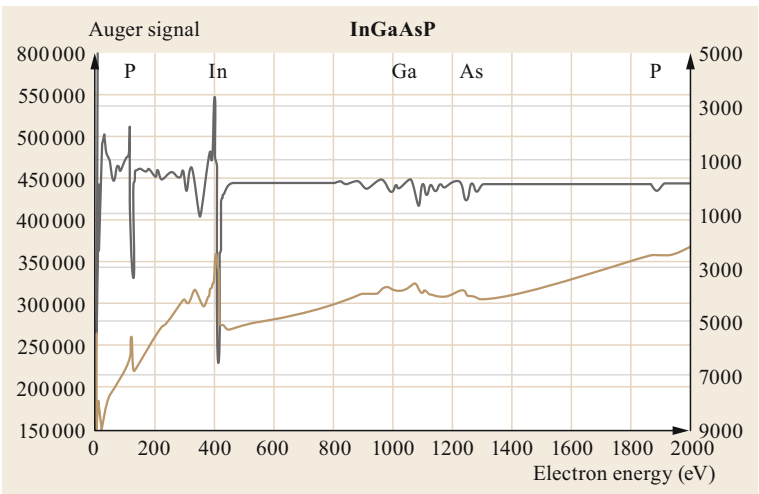

Fig. 18.1 Auger spectrum from GaInAsP, shown as the number of electrons and the differential of the number of electrons as a function of energy

depth profiling is the inverse of the sputter deposition widely used to deposit thin layers of material. Argon is the most widely used ion beam in Auger depth profiling, as its effects are physical rather than chemical, although it should be noted that some chemicals can be modified by the sputtering process. For example, some metal oxides can be reduced by sputtering while others are not, and so any chemical state data inferred from atomic compositions in sputter depth profiles should be treated with caution. Physical effects can also occur, for example atomic mixing and the development of surface topography, which can distort the shape of buried features.

One of the great advantages of Auger is that, as the excitation is provided by electrons, the primary beam can be easily focused and scanned over the surface of the sample. By detecting the scattered electrons, a physical image of the sample is produced as in the scanning electron microscope, and maps of elemental distributions can be obtained by detecting the Auger signal as a function of beam position. These elemental maps can be time-consuming to acquire but can be useful when making a point or illustrating a book chapter; however, for practical analyses it is often adequate to identify the feature of interest from the physical image. Figure 18.2 shows aluminium and oxygen Auger maps from a contaminated bond pad. In the region of the contamination, the aluminium signal is reduced and the oxygen signal is higher compared with the uncontaminated regions.

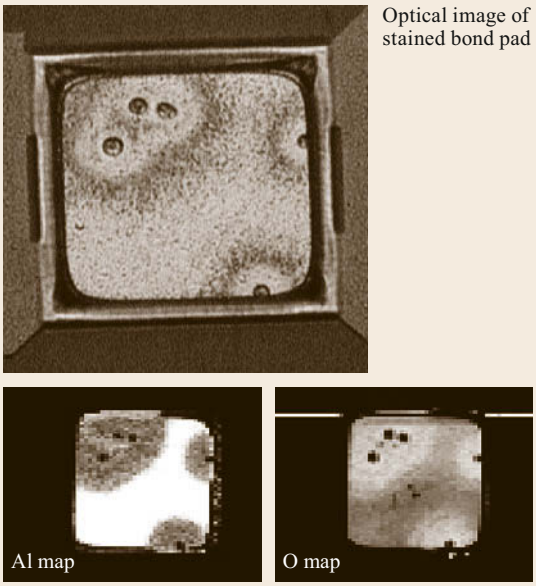

Fig. 18.2 Optical image and Auger maps of a stained aluminium bond pad

In terms of hardware, Auger systems can be standalone systems comprising an electron beam column, an electron energy analyzer, an inert gas ion gun and sample handling stage and an associated vacuum chamber (or chambers), or form a part of a multitechnique system with x-ray sources for XPS analysis or a mass spectrometer for basic SIMS studies.

18.1.2 X-Ray Photoelectron Spectroscopy (XPS)

XPS is very similar to Auger in terms of the instrumentation and physics involved. The primary excitation, as the name implies, is, in this case, a beam of x-rays. The x-rays, often magnesium or aluminium Kα, eject core electrons from the surface atoms by the photoelectron effect. The kinetic energy of the emitted photoelectrons will be equal to the difference between the x-ray photon energy and the core level binding energy, and thus will be less than $\approx 1100\,\mathrm{eV}$ or $\approx 1400\,\mathrm{eV}$ for magnesium and aluminium Kα respectively. So, as with Auger, the mean free paths of the photoelectrons are of the order of monolayers in solid materials. As a core level vacancy is produced by the excitation, Auger electrons will also be present in the XPS spectra but, by convention, Auger spectroscopy refers to the electron-excited situation. Whereas in Auger electron spectroscopy the electron energy is usually referred to in terms of the electron's kinetic energy, in XPS the electron binding energy is usually plotted as the ordinate in the spectra. This means that, whatever x-ray excitation is used, be it magnesium, aluminium or a more exotic material, the photoelectrons will appear at the same binding energy in the spectra but the apparent positions of the Auger peaks will change (on the binding energy scale) as their kinetic energy is independent of the excitation source. There are no scattered primary electrons (which are always present in Auger spectra) in the XPS spectra, so these spectra have better signal-to-background, and the photoelectron peaks are easily distinguished against the background arising from scattered photoelectrons produced deeper into the sample and other secondary processes.

As the problem of focusing electron beams is much simpler than focusing x-ray beams, XPS is perceived as a large-area technique, whereas Auger is the technique of choice for small area analysis. However, the relentless advances made in the performance and design of instruments means that XPS instruments can achieve spatial resolutions of the order of 1 to 10 μm. In XPS no charge is brought to the sample by the primary excitation, and so insulating samples are easier to analyze with XPS than with Auger; also, the photoelectron peaks show small energy differences in the peaks po-

sitions depending upon the local chemical environment of the atom from which they originated, the so-called chemical shift. While chemical shifts are present in some Auger peaks, this is the exception rather than the rule, and XPS is the technique of choice where information on the local chemical state of the surface is required. The physics of the XPS process is probably even better understood than the Auger process, and quantification of the spectra is relatively routine.

As with Auger, composition depth profiles can be produced by sputtering the surface of the sample with an inert gas ion beam. Again caution is advised when interpreting chemical state information from a surface that has been subject to ion bombardment. With both of the electron spectroscopies it is the surface of the sample that remains after sputtering that is analyzed in a depth profile, and there are two factors to be aware of (if not more). Once the passivating surface layer has been sputtered away, the surface of the sample may become chemically active and getter residual gas from the vacuum system. If the sample is a multicomponent material, one component may have a higher sputtering rate than the other, so as the sputtering process proceeds the surface will become depleted in the higher sputtering rate material. This process will continue until an equilibrium state is reached where the material leaving the surface is in the same ratio as the bulk composition; the corollary of this is that the surface will be enriched in the lower sputter rate material and so the composition of the material as measured by either XPS or Auger will be in error unless this effect is understood and accounted for.

Both Auger and XPS are capable of detecting all elements from lithium to uranium (and beyond), and have sensitivities in the parts per hundred to parts per thousand regime. The responses vary from element to element but typically sensitivities remain within an order of magnitude or so between elements.

18.2 Glow-Discharge Spectroscopies (GDOES and GDMS)

These are two apparently similar but quite unrelated techniques that rely upon glow discharges as the excitation source. In glow discharge optical emission spectroscopy (GDOES) a high-pressure glow discharge is used to sputter material from the surface of a sample, and this sputtered material is detected by the optical emissions it produces in the glow discharge. In glow discharge mass spectrometry (GDMS), a low pressure dc glow discharge is used to sputter material from the sample surface and ionized material from the discharge is extracted into a mass spectrometer for analysis.

GDOES is probably the simplest of all the surface chemical analysis techniques, at least as far as the vacuum requirements are concerned. There is no complex vacuum system, as needed for all of the other methods, and the sample itself sits with atmospheric pressure on one side of it while the opposite face acts as one electrode of a glow discharge cell that is pumped by a simple vacuum pump. A flow of high-purity argon gas flows through the cell, providing the sputtering and discharge gas and purging the cell of impurities and material removed from the sample. A window at the other end of the discharge cell transmits light from the discharge into an optical spectrometer. By using a spectrometer with a number of photomultiplier detectors, prepositioned at the known wavelengths of the expected element emission lines, data from a large number of elemental channels can be collected in parallel, making GDOES an extremely efficient analytical system. A scanning spectrometer can also be included in the instrument to provide a continuous spectral scan to detect emission lines from elements other than those built into the instrument, but this is, of course, a serial detection device and the advantages of parallel acquisition are lost.

Traditionally GDOES has been widely used for the analysis of metals and coatings on metals, but it is currently also finding application in the area of semiconductor materials. With the development of radio frequency glow discharge sources, the technique is capable of analyzing insulators, and with the high sputtering rates available, it can depth profile tens of μm into dielectric layers. With fast electronics and parallel detection, thin oxide layers can also be profiled. The sensitivity of the GDOES technique lies between that of Auger or XPS and that of SIMS. One potential weakness of the method is that the technique has no spatial resolution and the analysis area is millimeters in diameter. It is thus useful for large-area plain samples, but cannot be used with patterned material or to probe small features. The technique is useful for bulk analysis, but it is the ability to depth-profile into material, providing an insight into layer structures, that is its greatest appeal. However, because the technique has no ability to discriminate where the analytical signal is coming from, the quality of the depth profiles produced will be compromised by crater edge effects. In other words, while most of the analytical signal will originate from the bottom of the sputtered crater, there will always be some information

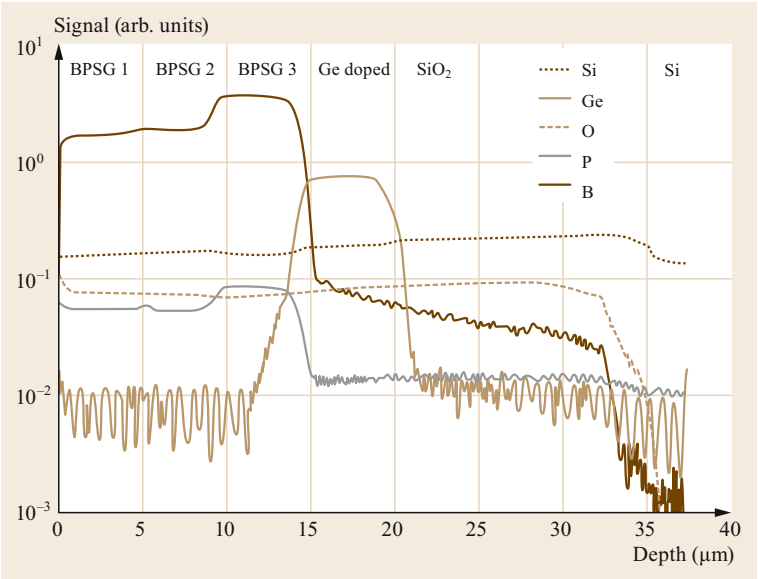

Fig. 18.3 GDOES depth profile through a DWDM multilayer glass structure

that comes from the crater side wall. The consequence of this is that, with layered structures, layers closer to the surface will appear to tail into layers beneath them, even though the interface between the layers is abrupt. This effect can be seen in the depth profile shown in Fig. 18.3, which shows a GDOES profile into a dense wavelength division multiplexing (DWDM) structure.

Glow discharge mass spectrometry (GDMS) is a considerably more complex technique, at least from an instrumental point of view. Originally developed as a method of bulk analysis, GDMS is probably the most sensitive, in terms of the detection limit achievable, of all of the techniques being considered here. As with GDOES, in GDMS the sample forms one electrode in a simple glow discharge cell. However, in the case of GDMS, the discharge cell is mounted within a high-vacuum system. In its original form, the sample (typically be 1 mm^2 by about 15 mm long) is placed in the center of a cylindrical cell into which argon is leaked at low pressure. By applying a dc voltage between the sample and the cell, an argon plasma is created which sputters the outside of the sample, removing material. This material, some of which is ionized but the majority of which is neutral as it leaves the surface, is ionized by a variety of processes as it passes through the glow discharge plasma. These ions are then accelerated into a high-resolution magnetic sector mass spectrometer where they are mass-analyzed and counted. Instruments can also be based on quadrupole mass spectrometers, but it is the magnetic sector instruments which offer the greater sensitivity. By sweeping the mass spectrometer through a range of masses, which can cover the entire periodic table, the major, minor and trace elements present in a sample can be determined. GDMS is a particularly powerful method of detecting the trace elements present in bulk semiconductor materials at levels down to parts per billion.

It is also possible to analyze flat, rather than matchstick-shaped, samples in GDMS. Just as in GDOES, the flat sample is positioned at the end of the discharge cell, and a cylindrical crater is etched into the sample surface. As with GDOES, with GDMS there is no spatial resolution, and the depth information from layered structures will be distorted by crater edge effects and loss of crater base flatness as it is not possible to discriminate between ions produced from the base of the crater and those produced from the sidewalls.

18.3 Secondary Ion Mass Spectrometry (SIMS)

SIMS is probably the most powerful and versatile of all of the surface analysis techniques and comes in the widest variety of instrumentations, from big, stand-alone instruments to bench-top instruments and add-ons to electron spectrometers. SIMS can offer chemical identification of submonolayer organic contamination, measurement of dopant concentrations, and can produce maps and depth profile distributions from nanome-

ters to tens of μm in depth. However, no one instrument is going to be capable of all of these tasks, and even if it could it would not be able to achieve all of them at the same time.

SIMS, in its simplest form, requires an ion gun and a mass spectrometer. The sample is placed in a vacuum chamber and ions from the ion gun sputter the sample surface. Material is sputtered from the sample surface and some of this will be ionized, although in most cases the major part of the sputtered material will be in the form of a neutral species. The ionized component of the sputtered material is mass-analyzed with the mass spectrometer.

The technique has evolved in various directions from this common origin to produce a variety of subtly different variants of the SIMS technique, including dynamic SIMS (DSIMS), static SIMS (SSIMS) and time of flight SIMS (ToFSIMS), each of which has its own distinct attributes. There are three main types of mass spectrometer used for SIMS analysis: the magnetic sector, the quadrupole and the time of flight, ToF. Dedicated depth-profiling SIMS machines, dynamic SIMS instruments, tend to employ either magnetic sector or quadrupole mass spectrometers. Magnetic sector instruments offer high transmission and high mass resolution capabilities, useful for separating adjacent mass peaks with a very small mass difference, for example ^{31}P from ^{30}SiH. Quadrupole mass spectrometers offer ultrahigh vacuum compatibility and, as well as being used in DSIMS instruments, smaller versions are also found as add-ons to Auger/XPS instruments and bench-top instruments. Time of flight instruments are remarkably efficient in their use of material in that the entire mass spectrum is sampled in parallel, whereas in the magnetic sector and quadrupole instruments the spectrum is produced by sequentially scanning through the mass range of interest. ToFs can also offer high mass resolution but profile relatively slowly because it is necessary to use a pulsed ion beam with a low duty cycle. Whilst static SIMS can be carried out on either a quadrupole or magnetic sector instrument, the ToF-based instruments are more suited to the task as less material is used in the course of the analysis. However, when dynamic SIMS, where only a few elements need to be monitored, is the goal, the magnetic sector or quadrupole instrument is the appropriate choice, although ToF machines can be used for shallow profiling.

Figure 18.4 shows a schematic diagram of the basis of these SIMS techniques. Ions from the ion gun bombard the sample surface and transfer momentum to the atoms in the sample creating a collision cascade. This cascade distributes the energy of the incoming ion amongst the atoms in the sample, causing them to be displaced from their original sites, possibly breaking

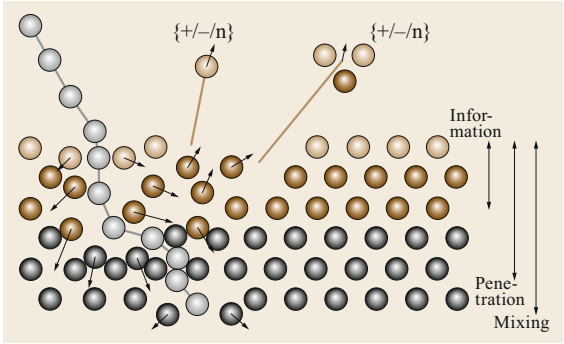

Fig. 18.4 Schematic diagram of the SIMS process

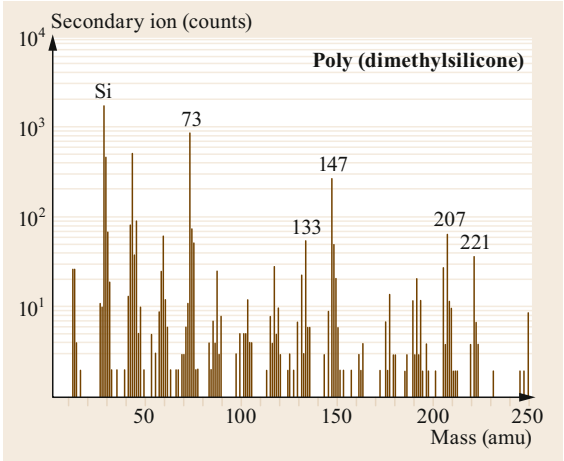

Fig. 18.5 Static SIMS spectrum from a thin film of poly(dimethylsilicone)

some bonds between atoms whilst creating others. The bombarding ion also can become implanted into the target material, modifying the chemistry of the material in the process. None of this is peculiar to SIMS – it happens in any sputtering process, be it in Auger depth-profiling, GDMS analysis or sputter deposition systems. It is probable that some of the energy deposited in the sample will cause atoms or molecules to be ejected from the surface of the sample, and those atoms or molecules that leave the surface as ions can be collected and detected by the mass spectrometer.

In the early stages of sputtering, the atoms and molecules sputtered from the surface will originate from areas of virgin surface – in other words from sites that have not yet been damaged by the primary ion – and thus carry with them information about the chemistry of the outer molecular layers of the sample. As the sputtering process proceeds, the probability of the sputtered particles being emitted from an area that has been modified by earlier ion impacts increases. Thus, at the start of the process the sputtered particles are characteristic

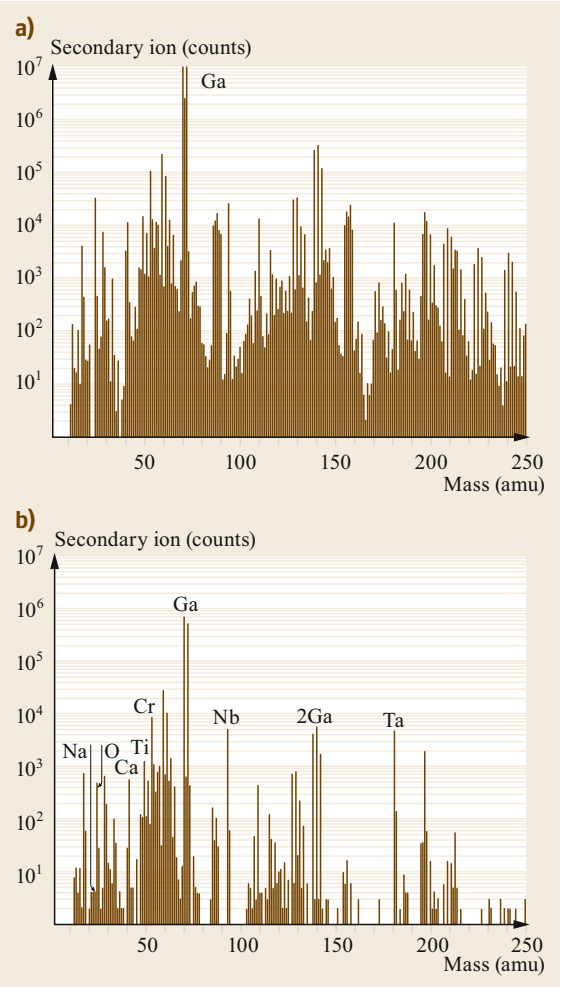

Fig. 18.6a,b SIMS mass spectrum from an unknown sample **(a)** without energy filtering, **(b)** with energy filtering

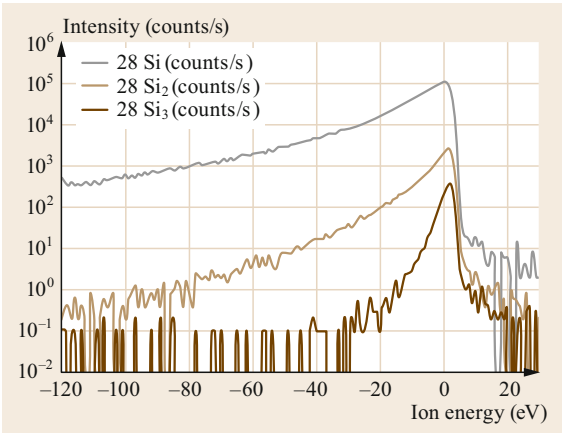

Fig. 18.7 The ion energy distributions of Si^+, Si_2^+ and Si_3^+ ions

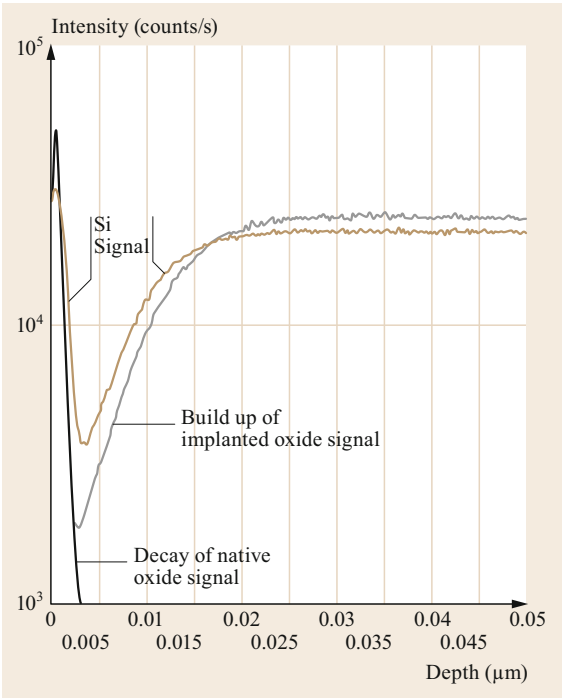

Fig. 18.8 The evolution of the Si^+ signal from a clean silicon wafer as a function of sputtering time with an oxygen primary ion beam, showing the decay of the surface oxide signal and the build-up of the implanted oxide layer

of the virgin surface, but they will eventually become characteristic of the ion beam-modified surface.

Static SIMS is concerned with the measurement of the sputtered molecules produced at the start of the process, where information about the surface chemistry of the sample can be obtained. In SSIMS a very low dose of primary ions is used, typically less than 10^{13} primary ions per square centimeter, so that there is a very low probability that the ions that are detected come from damaged material. Used in this way, SIMS can be used to identify organic contamination on surfaces and obtain information about the molecular structure of the sample. Figure 18.5 shows a typical SSIMS mass spectrum from poly(dimethylsilicone), a common surface contaminant, which can be recognized by prominent peaks in the mass spectrum at masses 73, 133, 147, 207 and 221, which originate from fragmentation of the parent molecule $(CH_3{-}Si(CH_3)_2{-}O{-}Si(CH_3)_2{-}O{-}\ldots{-}Si(CH_3)_2{-}CH_3)$.

Whilst the abundance of molecular fragments that can be produced by the sputtering process is of great value for revealing chemical information about the sample surface in the SSIMS context, it can also be something of a problem when carrying out elemental analysis

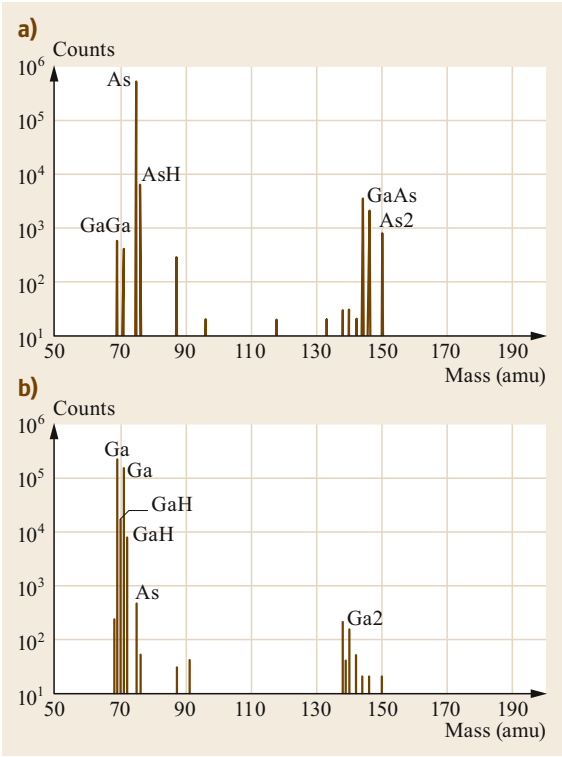

Fig. 18.9a,b Mass spectra from a GaAs wafer recorded **(a)** using Cs^+ primary ion bombardment and negative secondary ion detection, and **(b)** using O_2^+ primary ion bombardment and positive secondary ion detection

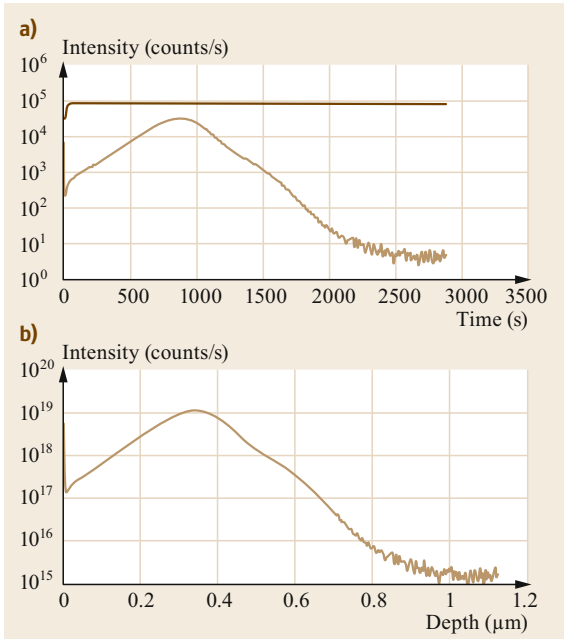

Fig. 18.10a,b Reference sample of boron ion-implanted silicon, **(a)** raw data profile and **(b)** quantified depth profile

of trace impurities in simple matrices. For example, the spectrum shown in Fig. 18.6a, from an unknown Ga-based material, illustrates the number and complexity of molecular species produced by the SIMS process, which can make interpretation difficult. Fortunately, the distribution of the number of secondary ions with energy is different between atomic ions and molecular ions. The atomic ions, in general, have a broader energy distribution than the molecular ions, and its energy distribution tends to become sharper as the complexity of the molecular ion increases. For example, Fig. 18.7 shows the ion energy distributions of the Si^+, Si_2^+ and Si_3^+ ions, illustrating the narrower energy distributions of the molecular ions. Thus, by selecting the ion energy range from which the spectrum is recorded, the molecular information can be suppressed, allowing the elements present in the material to be identified, see Fig. 18.6b.

The intensities of the peaks in the SIMS mass spectra reveal more about the relative ionization probability and instrument transmission function than the number of species of that mass on the sample surface. The signals that are measured in SIMS are proportional to the numbers of ions produced, and this is not simply related to the amount of material present. The degree of ionization can vary enormously from element to element and matrix to matrix. For example, the numbers of positive ions formed by the inert gas bombardment of clean metal samples can be several orders of magnitude lower than the numbers produced from oxidized surfaces of the same metals under identical bombardment conditions. Clearly it is not the concentration of the metal atoms on the surface that is important, as there will be fewer metal atoms in the oxide layer than in the pure metal. It is the presence of oxygen that increases the ionization probability for material leaving the surface as positive ions.

In SSIMS, the chemical nature of the primary ion species is of relatively little consequence in terms of its effect on the number of ions produced by the surface, but in DSIMS, where it is the deliberately modified surface that is of interest, oxygen ion beams are widely used for analyses of electropositive species. Figure 18.8 shows how the silicon matrix signal from a silicon wafer with a native oxide layer behaves as the sputtering process proceeds. Initially there is a strong signal from silicon as the surface oxide layer is still present on the sample surface. The signal then falls as the oxide layer is sputtered away, and then slowly recovers in intensity as oxygen from the primary ion beam is implanted into the silicon surface. Eventually a steady state is reached

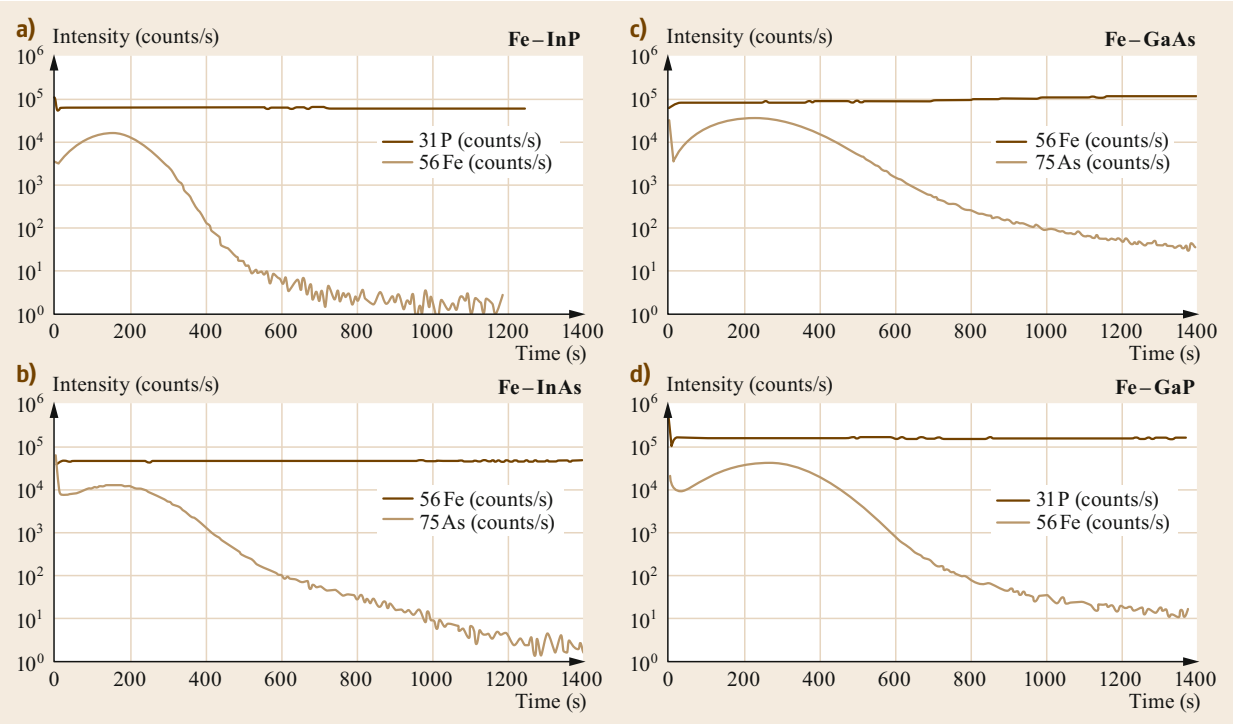

Fig. 18.11a–d Iron profiles, recorded under identical conditions, from implants into **(a)** InP, **(b)** InAs, **(c)** GaAs and **(d)** GaP, respectively

where the material that is being sputtered is constant-composition oxygen-implanted silicon. The thickness of this transient region will depend upon the energy and angle of incidence of the primary oxygen ion beam. The higher the ion beam energy, the thicker the transient region. In the transient region the sputtering rate of the material and the ionization probability may well be changing, and precise quantification in this part of the profile may be difficult. This is of particular importance when the features of interest are very close to the surface and within the transient region. The technological importance of shallow structures has driven the development of very low energy primary ion beam columns to enable the characterization of shallow implants.

Clearly, as is illustrated in Fig. 18.8, the number of positive ions produced in the sputtering process depends upon the concentration of oxygen in the sample surface. In order to maximize the positive secondary ion yield, the sample surface needs to be saturated with oxygen, and this can be achieved with normal-incidence primary ion beams or by deliberately allowing oxygen to flood the sample surface as well as using an oxygen primary ion beam. In the example shown in Fig. 18.8, the primary ion beam was incident at approximately 45° and so complete oxidation of the silicon surface was not achieved, meaning that the silicon and oxygen signals in the equilibrium region are not as high as from the fully oxidized native oxide layer.

Not all species prefer to form positive ions in the sputtering process; some prefer to produce negative ions. Oxygen is a case in point, and indeed it would be difficult to conduct an analysis for oxygen using an oxygen beam. For electronegative species, it turns out that high negative secondary ion yields can be achieved if the surface is sputtered using cesium ions. An illustration of the relative ion yields of gallium and arsenic as positive and negative ions from a gallium arsenide surface with oxygen and cesium ion bombardment are shown in Fig. 18.9. Some species can be reluctant to produce either positive or negative secondary ions, but in some cases (such as zinc), good sensitivity can be achieved by using cesium ion bombardment and monitoring the cesium–element molecular ion, $CsZn^+$ in the case of zinc.

Despite the wide variations in secondary ion yields from element to element and matrix to matrix, the quantification of impurities in semiconductors can be relatively straightforward when reference materials are used. For example, Fig. 18.10a shows a raw data depth profile of ^{11}B ions implanted in silicon; knowing the areal dose of ions implanted into the sample and the depth of the crater sputtered into the sample, it is a rel-

atively simple task (usually buried in the instrument software) to convert boron counts into concentrations (Fig. 18.10b). By recording a signal from the matrix element, either during the profile as in Fig. 18.10a, or in the crater after the profile, a relative sensitivity factor for the analyte (boron) in the matrix of interest (silicon) can be obtained which can then be used to determine the concentration of that analyte in another sample of the same matrix. Errors or uncertainties can arise from both the crater depth measurement and the implanted dose measurement. At the time of writing, there are only three metrologically traceable reference samples for SIMS (boron, arsenic and phosphorus in silicon) produced by NIST in the USA. For other species and other matrices, the analyst must rely upon locally produced materials with no traceability.

Care must be exercised when the analyte of interest is present in different matrices. For example, Fig. 18.11a–d show iron profiles, recorded under identical conditions (positive ion detection with O_2^+ primary ion bombardment), from implants into InP, InAs, GaAs and GaP produced in the same implant run. While the relative sensitivity of iron to the phosphorus matrix signal is the same for InP and GaP matrices, there is a variation of the order of 20% in the arsenide matrices. The useful ion yield of iron (the total number of ions produced as a fraction of the number of atoms present) increases approximately four-fold in the gallium-based matrices compared to the indium-based matrices. The profile in the GaAs sample, Fig. 18.11c, also shows a further complication: the arsenic matrix signal increases at about 1000 s into the profile. This could be interpreted as an upwards drift in the primary ion beam current, but it is actually caused by roughening of the GaAs surface as a result of the sputtering process. This effect is more common with oxygen primary ion bombardment than with cesium bombardment, and it has been shown that it is possible to reduce such effects by rotating the sample during analysis. Not only does the roughening modify the analytical signal, it also causes an apparent broadening of sharp features present in the sample as the surface roughness is convoluted with the feature width. The problems associated with sputter-induced roughness can become more severe when dealing with metal films but, once again, can be overcome by sample rotation.

Another example of how relative sensitivity factors vary with the matrix is shown in Fig. 18.12. Here a comparison is shown between the behavior of the Si^- and $AsSi^-$ signals as the matrix is changed from GaAs to $Ga_{0.16}Al_{0.84}As$. Molecular signals such as $AsSi^-$ are sometimes used to give increased signal compared to the atomic signal but, as in the example shown, the backgrounds are often similarly increased. What is interesting here is that whilst the ion yields from the Si^- and As^- signals increase, but at different rates with increasing Al content, the $AsSi^-$ signals decrease. Ideally the analyst needs to be aware of, and able to take account of, such variations in response. Simply using the

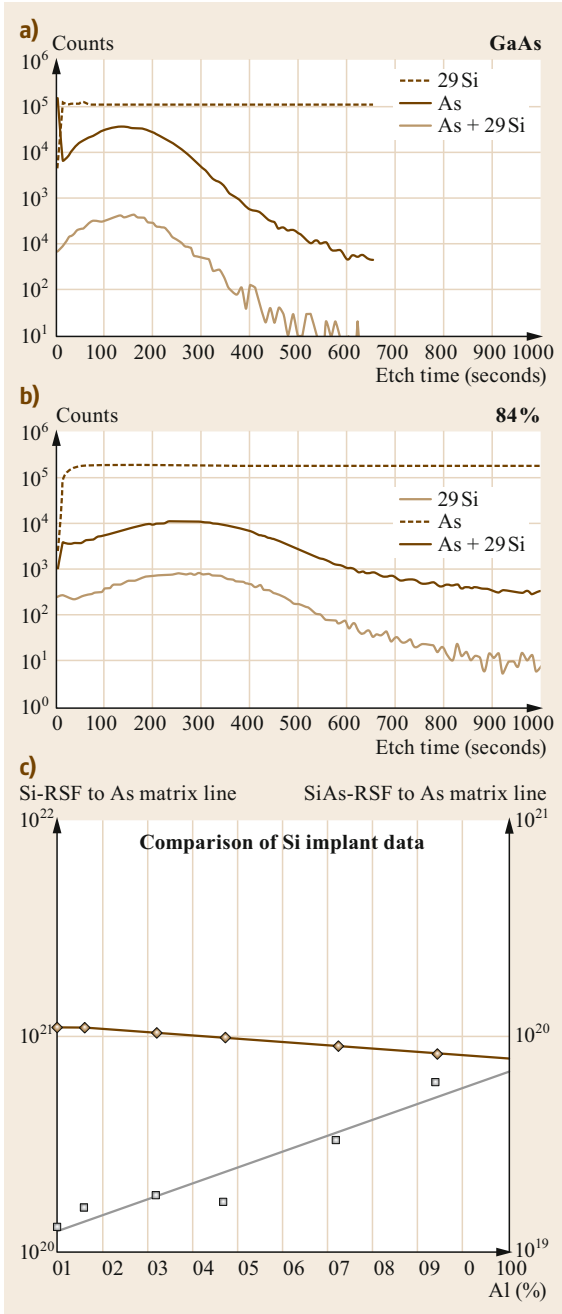

Fig. 18.12a–c Depth profiles of silicon as Si^- and $AsSi^-$ in **(a)** GaAs and **(b)** $Ga_{0.16}Al_{0.84}As$, and **(c)** variation in relative sensitivity factor as a function of aluminium content

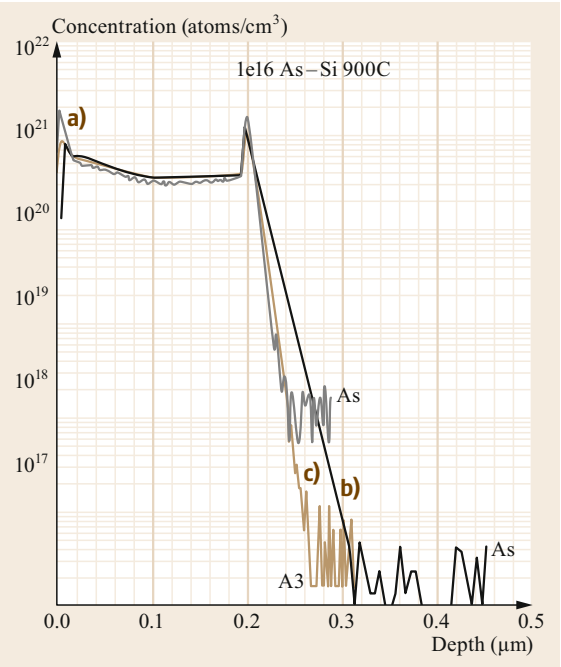

Fig. 18.13a–c Depth profiles of As in Si for different analytical conditions. **(a)** Oxygen ion bombardment, **(b)** cesium ion bombardment, **(c)** oxygen ion bombardment with oxygen flooding of the sample surface

relative sensitivity factor derived for a GaAs matrix and applying this to high Al content material using a point-by-point normalization to the As^- signal can lead to a 30% overestimate of the silicon content. However, monitoring the $AsSi^-$ signal instead and using the same normalization procedure can underestimate the silicon content by over 350%.

With an ideal analytical technique the analytical signal will vary linearly with concentration over all concentrations. With SIMS, for uniform matrices, the measured signal is indeed linear with concentration for dilute systems. However, once the analyte concentration begins to exceed a few percent of the material, the signal may begin to vary in a nonlinear way with concentration. Thus, whilst SIMS is the ideal technique for quantifying minor and trace contaminants, it is less than ideal for determining matrix element concentrations. The most successful method of measuring elemental concentrations at high levels was achieved by monitoring the cesium molecular species ($CsAl^+$ and $CsGa^+$ and $CsAs^+$) in GaAlAs. In GaAlAs the ($CsAl^+/CsAs^+$) and ($CsGa^+/CsAs^+$) ratios do vary linearly with the Al content.

Returning to practical analysis, another factor that needs to be considered in relation to DSIMS, and one that is related to the primary bombarding particles, is atomic mixing. The primary ions used to bombard the surface transfer momentum to the atoms in the sample surface. While some of the atoms will be sputtered from the surface, others will be driven deeper into the sample, thus broadening any concentration distributions that were present within the original sample. The higher the primary ion beam energy, the more severe the atomic mixing. Consequently, as the need to analyze shallower and shallower structures has increased, there has been a move to develop instruments that use lower bombardment energies and sources producing polyatomic ions. A simple example of how the analytical conditions can cause profile distortion is shown in Fig. 18.13. These profiles were recorded from an arsenic-implanted and annealed polysilicon layer on a thin oxide on silicon. Using an oxygen primary ion beam striking the surface at oblique incidence with an impact energy of 5.5 keV (a) produces a profile that shows a spike followed by a rapid fall at the polysilicon/oxide interface. Using a cesium primary ion beam striking the surface at close to normal incidence with an impact energy of 14.5 keV (b) gives a much better detection limit with smaller interface spikes but with a much less abrupt fall in the arsenic signal. Profile (c), which uses the same bombardment conditions as profile (a) but combined with oxygen flooding of the sample surface (and consequently took longer to acquire), shows good agreement with profile (b) in terms of the size of the interface spike – which is exaggerated in profile (a) because of the increased ion yield from the oxide layer compared to the polysilicon – and good agreement with profile (a) in terms of the decay of the arsenic signal in the interface region, and has better sensitivity than profile (a) but less than profile (b). These profiles demonstrate the trade-off that the analyst must make when choosing analysis conditions.

18.4 Conclusion

The various surface chemical analysis techniques have their own strengths and weaknesses. No one method is suitable for all of the tasks the analyst faces; sometime one technique is sufficient to address the problem at hand, sometimes a combination of them is required. However, the approach should be successful if the technique(s) is (are) fit for the purpose of the task.

19. Thermal Properties and Thermal Analysis: Fundamentals, Experimental Techniques and Applications

Safa Kasap, Jiří Málek, Roman Svoboda

The chapter provides a summary of the fundamental concepts that are needed to understand the heat capacity C_P, thermal conductivity κ, and thermal expansion coefficient α_L of materials. The C_P, κ, and α_L of various classes of materials, namely, semiconductors, polymers, and glasses, are reviewed, and various typical characteristics are summarized. A key concept in crystalline solids is the Debye theory of the heat capacity, which has been widely used for many decades for calculating the C_P of crystals. The thermal properties are interrelated through Grüneisen's theorem. Various useful empirical rules for calculating C_P and κ have been used, some of which are summarized. Conventional differential scanning calorimetry (DSC) is a powerful and convenient thermal analysis technique that allows various important physical and chemical transformations, such as the glass transition, crystallization, oxidation, melting etc. to be studied. DSC can also be used to obtain information on the kinetics of the transformations, and some of these thermal analysis techniques are summarized. Temperature-modulated DSC, TMDSC, is a relatively recent innovation in which the sample temperature is ramped slowly and, at the same time, sinusoidally modulated. TMDSC has a number of distinct advantages compared with the conventional DSC since it measures the complex heat capacity. For example, the glass-transition temperature T_g measured by TMDSC has almost no dependence on the thermal history, and corresponds to an almost step life change in C_P.

The new Tzero DSC has an additional thermocouple to calibrate better for thermal lags inherent in the DSC measurement, and allows more accurate thermal analysis.

The selection and use of electronic materials, one way or another, invariably involves considering such thermal properties as the specific heat capacity (c_s), thermal conductivity (κ), and various thermodynamic and structural transition temperatures, for example, the melting or fusion temperature (T_m) of a crystal, glass transformation (T_g) and crystallization temperature (T_c) for glasses and amorphous polymers. The thermal expansion coefficient (α_L) is yet another important material property that comes into full play in applications of electronic materials inasmuch as the thermal expansion mismatch is one of the main causes of electronic device failure. One of the most important thermal characterization tools is the differential scanning calorimeter (DSC), which enables the heat capacity, and various structural transition temperatures to be determined.

Modulated-temperature DSC in which the sample temperature is modulated sinusoidally while being slowly ramped is a recent powerful thermal analysis technique that allows better thermal characterization and heat-capacity measurement. In addition, it can be used to measure the thermal conductivity. The present review is a selected overview of thermal properties and the DSC technique, in particular MTDSC. The overview is written from a materials science perspective with emphasis on phenomenology rather than fundamental physics.

The thermal properties of a large selection of materials can be found in various handbooks [19.1, 2]. In the case of semiconductors, *Adachi*'s book is highly recommended [19.3] since it provides useful relationships between the thermal properties for various group IV, II–V and II–VI semiconductors.

19.1 Heat Capacity

19.1.1 Fundamental Debye Heat Capacity of Crystals

The heat capacity of a solid represents the increase in the enthalpy of the crystal per unit increase in the temperature, usually, per unit mass of the crystal; in which case, it is called the *specific heat capacity*. The heat capacity is usually defined either at constant volume or at constant pressure, C_V and C_P, respectively. C_V represents the increase in the internal energy of the crystal when the temperature is raised because the heat added to the system increases the internal energy U without doing mechanical work by changing the volume. On the other hand C_P represents the increase in the enthalpy H of the system per unit increase in the temperature. Thus,

$$C_V = \left(\frac{\partial H}{\partial T}\right)_V = \left(\frac{\partial U}{\partial T}\right)_V \quad \text{and} \quad C_P = \left(\frac{\partial H}{\partial T}\right)_P . \tag{19.1}$$

The exact relationship between C_V and C_P is

$$C_V = C_P - \frac{9T\alpha_L^2}{\rho K} , \tag{19.2}$$

where T is the temperature, ρ is the density, α_L is the linear expansion coefficient, K is the compressibility and the heat capacities in (19.2) are for unit mass of the crystal (specific heat capacities). For solids, C_V and C_P are approximately the same. The increase in the internal energy U is due to an increase in the energy of lattice vibrations. This is generally true for all solids except metals at very low temperatures where the heat capacity is due to the conduction electrons near the Fermi level becoming excited to higher energies. For most practical temperature ranges of interest, the heat capacity of most solids is determined by the excitation of lattice vibrations. The molar heat capacity C_m is the increase in the internal energy U_m of a crystal of Avogadro's number N_A atoms per unit increase in the temperature at constant volume, that is, $C_m = (\mathrm{d}U_m/\mathrm{d}T)_V$. The Debye heat capacity is still the most successful model for understanding the heat capacity of crystals, and is based on the thermal excitation of lattice vibrations, that is phonons, in the crystal [19.4]; it is widely known as a conventional heat capacity model in many textbooks [19.5, 6]. The vibrational mean energy at a frequency ω is given by

$$\bar{E}(\omega) = \frac{\hbar\omega}{\exp\left(\frac{\hbar\omega}{k_B T}\right) - 1} , \tag{19.3}$$

where k_B is the Boltzmann constant. The energy $\bar{E}(\omega)$ increases with temperature. Each phonon has an energy of $\hbar\omega$ so that the phonon concentration in the crystal increases with temperature. To find the internal energy due to all the lattice vibrations we must also consider how many vibrational modes there are at various frequencies. That is, the distribution of the modes over the possible frequencies: the spectrum of the vibrations. Suppose that $\mathrm{g}(\omega)$ is the number of modes per unit frequency, that is, $\mathrm{g}(\omega)$ is the vibrational density of states or modes. Then $\mathrm{g}(\omega)\mathrm{d}\omega$ is the number of vibrational states in the range $\mathrm{d}\omega$. The internal energy U_m of all lattice vibrations for 1 mole of solid is,

$$U_m = \int_0^{\omega_{max}} \bar{E}(\omega)\mathrm{g}(\omega)\mathrm{d}\omega . \tag{19.4}$$

The integration is up to certain allowed maximum frequency ω_{max}. The density of states $\mathrm{g}(\omega)$ for the lattice vibrations in a periodic three-dimensional lattice, in its most highly simplified form, is given by

$$\mathrm{g}(\omega) \approx \frac{3V}{2\pi^2}\frac{\omega^2}{v^3} , \tag{19.5}$$

where v is the mean velocity of longitudinal and transverse waves in the solid and V is the crystal volume. The maximum frequency is ω_{max} and is determined by the fact that the total number of modes up to ω_{max} must be $3N_A$. It is called the *Debye frequency*. Thus, integrating $\mathrm{g}(\omega)$ up to ω_{max} we find,

$$\omega_{max} \approx v\left(\frac{6\pi^2 N_A}{V_m}\right)^{1/3} , \tag{19.6}$$

where V_m is the molar volume. This maximum frequency ω_{max} corresponds to an energy $\hbar\omega_{max}$ and to a temperature T_D defined by,

$$T_D = \frac{\hbar\omega_{max}}{k_B} , \tag{19.7}$$

and is called the *Debye temperature*. Qualitatively, it represents the temperature above which all vibrational frequencies are executed by the lattice waves.

Thus, by using (19.3) and (19.5) in (19.4) we can evaluate U_m and hence differentiate U_m with respect to temperature to obtain the molar heat capacity at constant volume,

$$C_m = 9R\left(\frac{T}{T_D}\right)^3 \int_0^{T_D/T} \frac{x^4 e^x dx}{(e^x - 1)} , \tag{19.8}$$

which is the well-known Debye heat capacity expression.

Figure 19.1 represents the constant-volume Debye molar heat capacity C_m for a perfect crystal (19.8) as a function of temperature, normalized with respect to the Debye temperature. The well-known classical *Dulong–Petit rule* ($C_m = 3R$) is only obeyed when $T > T_D$. The Dulong–Petit (DP) rule is a direct consequence of the applications of Maxwell's theorem of equipartition of energy and the classical kinetic molecular theory to vibrations of atoms in a crystal. Notice that C_m at $T = 0.5T_D$ is $0.825(3R)$, whereas at $T = T_D$ it is $0.952(3R)$. For most practical purposes, C_m is within 6% of $3R$ when the temperature is $0.9T_D$. For example, for copper $T_D = 315$ K and above about $0.9T_D$, that is above 283 K (or 10 °C), $C_m \approx 3R$, as borne out by experiments. Table 19.1 provides typical values for T_D, and heat capacities for a few selected elements. At the lowest temperatures, when $T \ll T_D$, (19.8) predicts that $C_m \propto T^3$ and this is indeed observed in low-temperature heat capacity experiments on a variety of crystals. On the other hand, well-known exceptions are glasses, noncrystalline solids, whose heat capacity is proportional to $a_1T + a_2T^3$, where a_1 and a_2 are constants (e.g., [19.6, 7]).

It is useful to provide a physical picture of the Debye model inherent in (19.8). As the temperature increases from near zero, the increase in the crystal's vibrational energy is due to more phonons being created and higher frequencies being excited. The phonon concentration increases as T^3 and the mean phonon energy increases as T. Thus, the internal energy increases as T^4. At temperatures above T_D, increasing the temperature creates more phonons but does not increase the mean phonon energy and does not excite higher frequencies. All frequencies up to ω_{max} have been now excited. The internal energy increases only due to more phonons being created. The phonon concentration and hence the internal energy increases as T; the heat capacity is constant, as expected from (19.8).

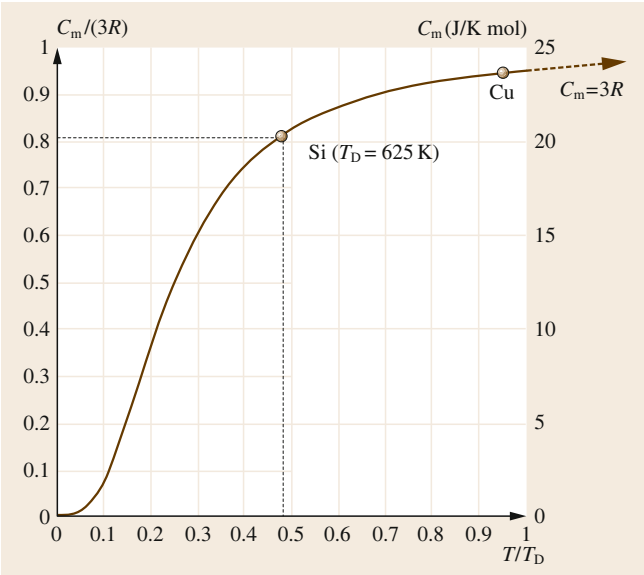

Fig. 19.1 Debye constant-volume molar heat capacity curve. The dependence of the molar heat capacity C_m on temperature with respect to the Debye temperature: C_m versus T/T_D. For Si, $T_D = 625$ K, so at room temperature (300 K), $T/T_D = 0.48$ and C_m is only $0.81(3R)$

In general terms, elements with higher atomic mass tend to have lower T_D, and their molar heat capacities are closer to the DP limit. Usually T_D is taken to depend on the temperature to accurately model the experimental C_P–T behavior; the dependence of T_D on T is only important at low temperatures, and can be neglected in most practical applications in engineering.

There are two important assumptions in the Debye theory. First is that all thermal excitations are lattice vibrations (i. e., involving phonons), which is usually the case in solids. Secondly, the interatomic potential-energy (PE) curve as a function of interatomic displacement x from equilibrium, is assumed to be parabolic, that is *harmonic* or symmetrical: $PE = PE_{min} + (1/2)\beta x^2$, where β is a constant (the spring constant in the equation of net force versus displacement, $F = -\beta x$). Within the harmonic approximation, the lattice vibrations are *plane waves* that are independent of each other; they are vibrational normal modes of the lattice. Further, a symmetrical PE curve does not allow thermal expansion, which means that C_V and C_P are identical. However, the actual interatomic PE is anharmonic, that is, it has an additional x^3 term. It is not difficult to show that in this case the vibrations or phonons interact. For example, two phonons can *mix* to

Table 19.1 Debye temperatures (T_D), heat capacities, thermal conductivities and linear expansion coefficients of various selected metals and semiconductors. C_m, c_s, κ, and α_L are at 25 °C. For metals, T_D is obtained by fitting the Debye curve to the experimental molar heat capacity data at the point $C_m = \frac{1}{2}(3R)$. T_D data for metals from [19.8]. Other data from various references, including [19.2] and the Goodfellow metals website

generate a third phonon of higher frequency or a phonon can decay into two phonons of lower frequency etc. Further, the anharmonicity also leads to thermal expansion, so that C_V and C_P are not identical as is the case in the Debye model. As a result of the anharmonic effects, C_P continues to increase with temperature beyond the $3R$ Dulong–Petit rule, though the increase with temperature is usually small.

19.1.2 Specific Heat Capacity of Selected Groups of Materials

Many researchers prefer to quote the heat capacity for one mole of the substance, that is quote C_m, and sometime express C_m in terms of R. The limit $C_m = 3R$ is the DP rule. It is not unusual to find materials for which C_m can exceed the $3R$ limit at sufficiently high temperatures for a number of reasons, as discussed, for example, by *Elliott* [19.6]. Most applications of electronic materials require a knowledge of the specific heat capacity c_s, the heat capacity per unit mass. The heat capacity per unit volume is simply c_s/ρ, where ρ is the density. For a crystal that has only one type of atom with an atomic mass M_{at} (g/mol) in its unit cell (e.g., Si), c_s is C_m/M_{at} expressed in J/K g.

While the Debye heat capacity is useful in predicting the molar heat capacity of a crystal at any temperature, there are many substances, such as metals, both pure metals and alloys, and various semiconductors (e.g., Ge, CdSe, ZnSe etc.) and ionic crystals (e.g., CsI), whose room-temperature heat capacities approximately follow the simple DP rule of $C_m = 3R$, the limiting value in Fig. 19.1. For a metal alloy, or a compound such as $A_xB_yC_z$, that is made up of three components A, B and C with molar fractions x, y and z, where $x + y + z = 1$, the overall molar heat capacity can be found by adding individual molar heat capacities weighted by the molar fraction of the component,

$$C_m = xC_{mA} + yC_{mB} + zC_{mC}\,, \tag{19.9}$$

where C_{mA}, C_{mB} and C_{mA} are the individual molar heat capacities. Equation (19.9) is *the additive rule of molar heat capacities*. The corresponding specific heat capacity is

$$c_s = \frac{3R}{\bar{M}_{at}}\,, \tag{19.10}$$

where $\bar{M}_{at} = xM_A + yM_B + zM_C$ is the mean atomic mass of the compound, and M_A, M_B and M_C are the atomic masses of A, B and C. For example, for ZnSe, the average mass $\bar{M}_{at} = (1/2)(78.96 + 65.41) = 72.19$ g/mol, and the DP rule predicts $c_s = 3R/\bar{M}_{at} = 0.346$ J/K g, which is almost identical to the experimental value at 300 K.

The modern Debye theory and the classical DP rule that $C_m = 3R$ are both based on the addition of heat increasing the vibrational energy of the atoms or molecules in the solid. If the molecules are able to rotate, as in certain polymers and liquids, then the molar heat capacity will be more than $3R$. For example, the heat capacity of molten Bi−BiI_2 mixture is more than the DP rule, and the difference is due to the rotational energies associated with various molecular units in the molten state [19.9].

The heat capacity of polymers are usually quite different than the expected simple Debye heat capacity behavior. Most polymers are not fully crystalline but either amorphous or semicrystalline, a mixture of amorphous and crystalline regions. Secondly, and most significantly, the polymer structures usually have a main chain (a backbone) and various side groups attached to this backbone. Stretching and possible bending vibrations and possible partial rotations of these side groups

provide additional contributions to the overall heat capacity. The extent of freedom the main chain and side groups have in executing stretching and bending vibrations and rotations depends on whether the structure is above or below the glass-transition temperature T_g. (The glass-transition temperature is defined and discussed later.) Above T_g, the polymer structure is floppy and has sufficient free volume for various molecular motions to be able to absorb the added heat. The heat capacity is therefore larger above T_g than that below T_g, where the structure is frozen.

The heat capacity of most polymers increases with temperature. For most solid polymers (below the glass-transition temperature), the fractional rate of increase in the heat capacity with temperature follows

$$(1/C_P)(dC_P/dT) \approx 3 \times 10^{-3}\,K^{-1} \quad (T < T_g) \tag{19.11}$$

to within about 5%. This empirical rule is particularly useful for estimating C_P at a desired temperature from a given value at another temperature e.g., at room temperature. For liquid polymers (above T_g) on the other hand, $(1/C_P)(dC_P/dT)$ is less ($\approx 1 \times 10^{-3}\,K^{-1}$) and has a large variability (more than 30%) from polymer to polymer. There are various empirical rules for predicting the heat capacity of a polymer based on the backbone chain structure and types of side groups, as discussed by *van Krevelen* and *Hoftyzer* [19.10]. The most popular is to simply sum heat capacity contributions per mole from each distinguishable molecular unit in the polymer structure's repeat unit. The heat capacity contribution from each type of identifiable molecular unit (e.g., $-CH_2-$ in the backbone or $-CH_3$ side group) in polymer structures are listed in various tables. For example, the molar heat capacity of polypropylene can be calculated approximately by adding contributions from three distinguishable units, CH_2, CH and CH_3 in the repeating unit that makes up the polypropylene structure, as illustrated schematically in Fig. 19.2. Once the contributions are added, the sum is 71.9 J/K mol. The molecular mass of the repeat unit corresponds to three C atoms and six H atoms, or to 42 g/mol so that the specific heat is 71.9 J/K mol/42 g/mol or 1.71 J/K g, which is close to the experimental value. (Polypropylene is normally semicrystalline and its specific heat also depends on the crystalline-to-amorphous phase ratio.) The term *heat capacity per mole* in polymers normally refers to a mole of repeat units or segments in the polymer.

More rigorous characterization of the heat capacity of polymers tends to be complicated by the fact that most polymers are a mixture of the crystalline and amorphous phases, which have different C_P versus T characteristics, and the exact volume fractions of the phases may not be readily available. There have been a number of examples where the heat capacity characteristics of semicrystalline polymers have been critically examined [19.11]. A comprehensive overview of the heat capacity of polymers has been given by *Wunderlich* [19.12], which is highly recommended.

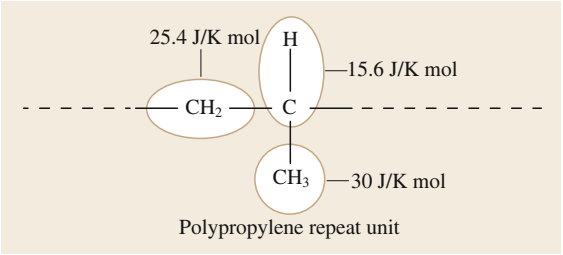

Fig. 19.2 Molar heat capacity of solid polypropylene calculated from various distinguishable units in the repeat unit

The overall or effective heat capacity of polymer blends can be usually calculated from the individual capacities and the volume fractions of the constituents. The simplest is a linear mixture rule in which individual capacities are weighted by the volume fraction and then summed.

The heat capacity of glasses depends on the composition and increases with temperature. There is a sharp change in the dependence of C_P on T through the glass-transition temperature T_g. For example, for zirconium, barium, lanthanum, aluminum, sodium (ZBLAN) glasses, C_m is 24 J/K mol below T_g and slightly less than $3R$. On the other hand, C_m is 38.8 J/K mol above T_g, and greater than $3R$. (The C_P change at T_g is discussed below.) The dependence of C_P on T below T_g has been modeled by a number of expressions dating back to the 1950s. For example, *Sharp* and *Ginther* [19.13] in 1951 proposed the following empirical expressions for the mean and true specific heat capacity c_m and c respectively, of oxide glasses in the range 0–1300 °C,

$$c_m = \frac{H_2 - H_1}{T_2 - T_1} = \frac{aT + c_o}{0.00146T + 1} \quad \text{and} \tag{19.12a}$$

$$c = \frac{dH}{dT} = \frac{aT + c_m}{0.00146T + 1} \tag{19.12b}$$

in which T is in °C, and a and c_o are calculated from the glass composition as described in the original paper [19.13]. The mean heat capacity in (19.12a) then predicts the heat capacity to within about 1%. More recently, for various oxide glasses from 300 K to T_g, *Inaba* and *Oda* [19.14] have proposed an exponential

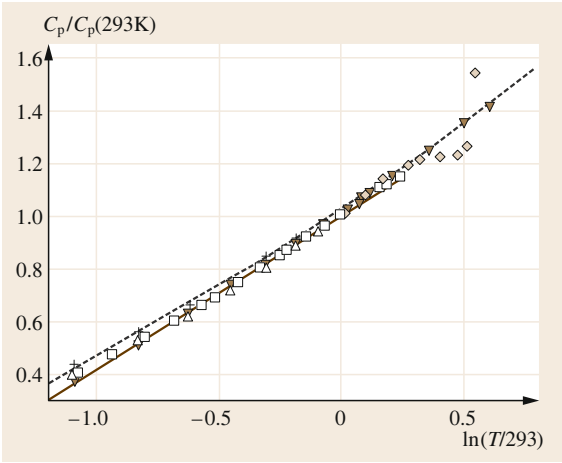

Fig. 19.3 Normalized heat capacity $C_P(T)/C_P(298)$ versus $\ln(T/298)$ for various glasses. *Open square:* $12.5Na_2O$, $12.5Al_2O_3$, $75SiO_2$; *solid circle:* 25MgO, 25CaO, $50SiO_2$; *open triangle:* $33Na_2O$, $67B_2O_3$; *solid triangle:* 24BaO, $1Fe_2O_3$, $75B_2O_3$; *open diamond:* B_2O_3 (includes T_g); $+30K_2O$, $70GeO_2$. Adapted from *Khalimovskaya-Churkina* and *Priven* [19.15]. The *solid straight line* is (19.14), whereas the *dashed line* is the experimental trend line

empirical expression of the form,

$$C_P = 3R\left[1-\exp\left(-1.5\frac{T}{T_D}\right)\right], \qquad (19.13)$$

where T_D is the Debye temperature. Equation (19.13) predicts a lower C_P than the Debye equation itself at the same temperature for the same T_D. There are also other empirical expressions for C_P (for example, a three-term polynomial in T) that typically involve at least three fitting parameters. *Khalimovskaya-Churkina* and *Priven* [19.15] have shown that a simple two-parameter empirical expression of the form

$$C_P = a + b\ln T\,, \qquad (19.14)$$

where a and b are composition-dependent parameters, can be fruitfully used to represent the dependence of C_P on T from 100 K to the lower boundary of T_g for various oxide glasses to within about 2.5% error as shown in Fig. 19.3. The authors further show that, to within about 4%,

$$C_P = C_P(293\,K)\,[1+0.52\ln(T/293)]\,. \qquad (19.15)$$

What is significant in this equation is that the composition dependence of C_P has been incorporated into $C_P(293\,K)$, and once the latter is calculated, the temperature dependence of C_P is then given by (19.15).

Various empirical rules have been proposed for approximately calculating the heat capacity of oxide glasses from its components. The simplest is the additive rule stated in (19.9), in which the overall heat capacity per mole is found from adding individual molar heat capacities of the constituents, so-called partial molar heat capacities, weighted by their molar fractions. However, for a heterogeneous mixture, that is for a solid in which there are two or more distinct phases present, the specific heat capacity may involve more complicated calculations.

The most common technique for heat capacity measurements is the heat-flow differential scanning calorimetry (DSC) – the instruments are relatively cheap and easy to operate, there is no specialized sample preparation, and the measurements are fast. Nonetheless, the lowest achieved uncertainties associated with the C_P values are approximately 1.5% even for standardized materials data obtained under ideal conditions using specialized DSC instruments [19.16] (typical uncertainties vary between 3 and 5%). Since the heat capacity belongs to the most important set of thermodynamic quantities (entropy, enthalpy, and free Gibbs energy can be calculated from the C_P–T dependences), often an increased need for maximum precision and accuracy arises. This is especially true for the low-temperature C_P data (0−100 K), where specialized experimental techniques like adiabatic calorimetry and relaxation calorimetry have to be used.

The most common and easy-to-apply methodology utilized for obtaining the C_P–T dependences by means of DSC measurements is the so-called *continuous method* [19.17]. This method is based on the comparison of two identical heating scans performed for the studied sample and referent material with known C_P–T dependence (sapphire). The heat-flow signal obtained for the studied sample can then be transformed to heat capacity according to the following equation (both measurements need to be corrected for a zero-line prior to the calculation)

$$C_P^{sample} = C_P^{ref}\frac{\Phi^{sample}m^{ref}}{\Phi^{ref}m^{sample}}\,, \qquad (19.16)$$

where C_P, Φ, and m correspond to the heat capacity, raw heat-flow gained from the DSC measurement, and mass of the measured material, respectively. The superscripts denote the sample and reference. Note that, while in this way the whole DSC curve can be easily transformed, true heat capacity is obtained only in the *thermodynamic regions*, where no overlapping kinetic effect (phase transformations or chemical reactions) occurs on the measured DSC curve.

In the case of a narrow temperature range, the obtained C_P–T dependence can be usually described

by means of a second-degree polynomial function, whereas for a wider temperature ranges more complicated functions need to be used. Below, an ultimate equation for description of the C_P–T dependences is shown

$$C_P = a + bT + cT^2 + dT^{-1} + eT^{-2} + f \ln T + gT \ln T \,. \quad (19.17)$$

The importance of the particular terms is usually determined by means of numerical optimization and consequent statistical analysis. The most commonly applied equations include the following combinations of the particular terms (denoted according to the corresponding composition-dependent parameters): $a+b+c$, $a+b+e$, $a+b+c+e$, $a+b+c+d+e$, and $a+b+c+f$.

19.2 Thermal Conductivity

19.2.1 Definition and Typical Values

Heat conduction in materials is generally described by *Fourier's heat conduction law*. Suppose that J_x is the heat flux in the x-direction, defined as the quantity of heat flowing in the x-direction per unit area per unit second: the thermal energy flux. Fourier's law states that the heat flux at a point in a solid is proportional to the temperature gradient at that point and the proportionality constant depends on the material,

$$J_x = -\kappa \frac{\mathrm{d}T}{\mathrm{d}x} \,, \quad (19.18)$$

where κ is a constant that depends on the material, called the thermal conductivity (W/m K or W/m °C), and $\mathrm{d}T/\mathrm{d}x$ is the temperature gradient. Equation (19.18) is called Fourier's law, and effectively defines the thermal conductivity of a medium. Table 19.2 provides an overview of typical values for the thermal conductivity of various classes of materials.

The thermal conductivity depends on how the atoms in the solid transfer the energy from the hot region to the cold region. In metals, the energy transfer involves the conduction electrons. In nonmetals, the energy transfer involves lattice vibrations, that is atomic vibrations of the crystal, which are described in terms of phonons.

The thermal conductivity, in general, depends on the temperature. Different classes of materials exhibit different κ values and dependence of κ on T, but we can generalize very roughly as follows:

- *Most pure metals*: $\kappa \approx 50$–400 W/m K. At sufficiently high T, e.g., above ≈ 100 K for copper, $\kappa \approx$ constant. In magnetic materials such as iron and nickel, κ decreases with T.
- *Most metal alloys*: κ lower than for pure metals; $\kappa \approx 10$–100 W/m K. κ increases with increasing T.
- *Most ceramics*: Large range of κ, typically 10–200 W/m K with diamond and beryllia being exceptions with high κ. At high T, typically above ≈ 100 K, κ decreases with increasing T.
- *Most glasses*: Small κ, typically less than $\approx$ 5 W/m K and increases with increasing T. Typical examples are borosilicate glasses, window glass, soda-lime glasses, fused silica etc. Fused silica is noncrystalline SiO_2 with $\kappa \approx 2$ W/m K.
- *Most polymers*: κ is very small and typically less than 2 W/m K and increases with increasing T. Good thermal insulators.

Table 19.2 Typical thermal conductivities of various classes of materials at 25 °C

19.2.2 Thermal Conductivity of Crystalline Insulators

In nonmetals heat transfer involves lattice vibrations, that is phonons. The heat absorbed in the hot region increases the amplitudes of the lattice vibrations which is the same as generating more phonons. These new phonons travel towards the cold regions and thereby transport the lattice energy from the the hot to cold region. The thermal conductivity κ measures the rate at which heat can be transported through a medium per unit area per unit temperature gradient. It is proportional to the rate at which a medium can absorb energy, that is, κ is proportional to the heat capacity. κ is also proportional to the rate at which phonons are transported which is determined by their mean velocity v_{ph}. In addition, of course, κ is proportional to the mean free path Λ_{ph} that a phonon has to travel before losing its momentum, just as the electrical conductivity is proportional to the electron's mean free path. A rigorous classical treatment gives κ as,

$$\kappa = \frac{1}{3} C_v v_{ph} \Lambda_{ph} \,, \tag{19.19}$$

where C_v is the heat capacity per unit volume. The mean phonon velocity v_{ph} is constant and approximately independent of temperature so that κ is governed primarily by C_v and Λ_{ph}. The mean free path Λ_{ph} depends on various processes that can scatter the phonons and hinder their propagation along the direction of heat flow. Phonons can collide with other phonons, crystal defects, impurities and crystal surfaces.

At high temperatures, κ is controlled by phonon–phonon scattering. The phonon–phonon collisions that are normally responsible for limiting the thermal conductivity, that is scattering the phonon momentum in the opposite direction to the heat flow, are due to the anharmonicity (asymmetry) of the interatomic potential energy curve. Stated differently, the net force F acting on an atom is not simply βx (where β is a spring constant) but also has an x^2 term, i. e., it is nonlinear. The greater the asymmetry or nonlinearity, the larger is the effect of such momentum-flipping collisions. The same asymmetry that is responsible for thermal expansion of solids is also responsible for determining the thermal conductivity. When two phonons 1 and 2 interact in a crystal region as in Fig. 19.4, the nonlinear behavior and the periodicity of the lattice, cause a new phonon 3 to be generated. This new phonon 3 has the same energy as the sum of 1 and 2 but it is traveling in the wrong direction. (The frequency of 3 is the sum of frequencies of 1 and 2.) The flipping of the phonon momentum is called an *Umklapp process* and is a result of the anharmonicity in the interatomic bond. Figure 19.5 shows the dependence of κ on T for three semiconductors. We can identify three types of behavior.

At low temperatures there are two factors that control κ. The phonon concentration is too low for phonon–phonon collisions to be significant. Instead, the mean free path Λ_{ph} is determined by phonon collisions with crystal imperfections, most significantly, crystal surfaces and grain boundaries. Thus, Λ_{ph} depends on the sample geometry and crystallinity. Further, as we expect from the Debye model, C_v depends on T^3 so that κ has the same temperature dependence as C_v, that is $\kappa \propto T^3$. Figure 19.5 shows the dependence of κ on T for Ge, Si and GaAs. Notice that κ increases with increasing T at low temperatures, and that κ also depends on the concentration of dopants (GaAs) or impurities in the crystal, which can scatter phonons. An extensive

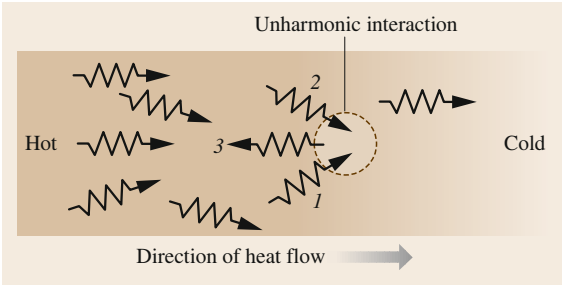

Fig. 19.4 Phonons generated in the hot region travel towards the cold region and thereby transport heat energy. Phonon–phonon anharmonic interaction generates a new phonon whose momentum is towards the hot region. (After [19.5])

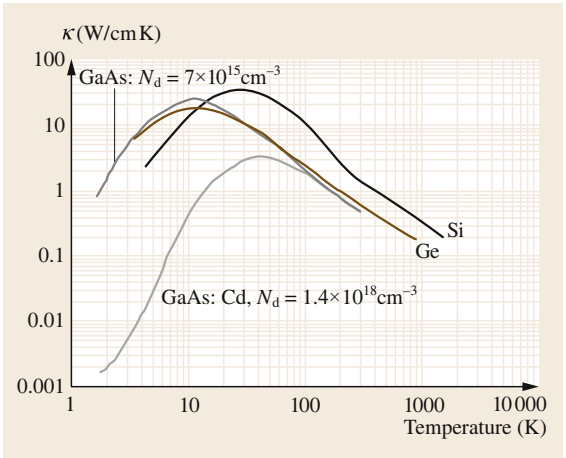

Fig. 19.5 Thermal conductivity of Si, Ge and GaAs. GaAs for two different levels of doping. Data extracted and replotted: Si [19.18]; Ge [19.19]; GaAs [19.20]

treatise on the thermal conductivity of semiconductors is given by *Bhandari* and *Rowe* [19.21].

As the temperature increases, the temperature dependence of κ becomes controlled by Λ_{ph} rather than C_v, which changes only slowly with T. The mean free path becomes limited by phonon–phonon collisions that obey the Umklapp process. These phonons have energies $\approx \frac{1}{2}k_B T_D$. The concentration of such phonons is therefore proportional to $\exp(T_D/2T)$. Since Λ_{ph} is inversely proportional to the Umklapp-obeying phonon concentration, κ decreases with increasing temperature, following a $\kappa \propto \exp(T_D/2T)$ type of behavior. At temperatures above the Debye temperature, C_v is, of course, constant, and the phonon concentration n_{ph} increases with temperature, $n_{ph} \propto T$. Thus, the mean free path decreases as $\Lambda_{ph} \propto 1/T$, which means that $\kappa \propto T^{-1}$, as observed for most crystals at sufficiently high temperatures. Figure 19.6 illustrates the expected dependence of κ on T for nonmetals, with three temperature regimes

$$\kappa \propto \begin{cases} T^3\,; & \text{Low } T \\ \exp\left(\dfrac{-T_D}{2T}\right)\,; & \text{Intermediate } T \\ T^{-1}\,; & \text{High } T\,. \end{cases} \qquad (19.20)$$

Most crystalline semiconductors tend to follow this type of behavior. The thermal conductivity of important semiconductors has been discussed by *Adachi* [19.3]. In the temperature range above the peak of κ with T, Adachi used a $\kappa = AT^n$ type of power law to model the κ–T data, and has provided an extensive table for A and n for various group IV, III–V and II–V semiconductors [19.3]. For example, for GaAs, over $150 \le T \le 1500$, $A = 750$ and $n = -1.28$ so that $\kappa\,(\mathrm{W/cm\,K}) = (750)T^{-1.28}$, where T is in Kelvin. Further, Adachi has been able to correlate κ with the lattice parameter a, mean atomic mass $\bar{M}$ in the unit cell and the Debye temperature T_D.

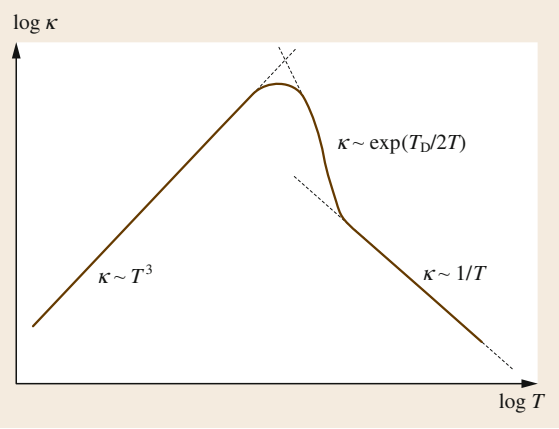

Fig. 19.6 Lattice thermal conductivity versus temperature on a log–log plot. κ is due to phonons

19.2.3 Thermal Conductivity of Noncrystalline Insulators

Glasses

The thermal conductivity of glasses tends to be substantially smaller than their crystalline counterparts, and tends to increase with the temperature almost monotonically. The most striking difference at room temperature is that, as the temperature is decreased, κ for a glass decreases whereas for a crystal it increases. This difference has been qualitatively attributed to the phonon mean free path Λ_{ph} in a glass remaining roughly constant as the temperature is lowered and being limited by the range of disorder in the structure, which is a few atomic spacings [19.23, 24]. While intuitively this explanation seems reasonable, a more rigorous derivation excludes (19.19) since concepts like phonon velocity and wavelength tend to become meaningless over very short distances [19.25]. Most of the theories that have been proposed for describing κ more rigorously in the noncrystalline state are quite mathematical, and beyond the scope of this review based on materials science. (These models include the Kubo transport equation [19.26], hopping of localized vibrations [19.27], simulations based on molecular dynamics [19.28] etc.) Figure 19.7 shows κ versus T for a few selected glasses [19.22, 29]. Other glasses

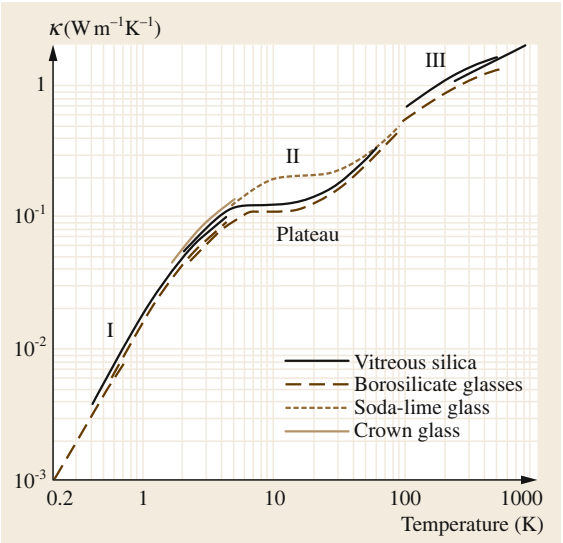

Fig. 19.7 The temperature dependence of κ for four types of glasses. Data in Figure 2 of *Zeller* and *Pohl* [19.22] replotted

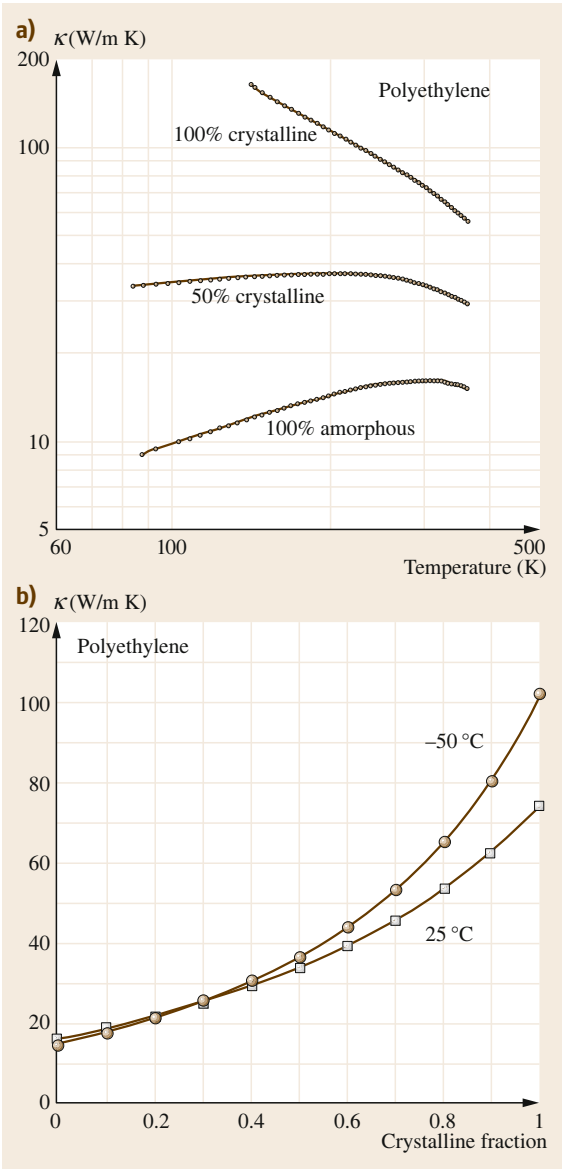

Fig. 19.8 **(a)** κ–T behavior for polyethylene for a fully crystalline, fully amorphous and 50% crystalline structures. **(b)** Dependence of κ on the crystallinity of polyethylene. Data extracted and replotted from [19.30]

tend to follow this type of behavior in which there are three regions of distinct behavior. At very low temperatures (I in Fig. 19.7), below 1–2 K, $\kappa \approx T^n$ where $n = 1.8$–2.0. In the intermediate temperature regime, from about 2 K to about 20–30 K, κ exhibits a plateau. At high temperatures, above 20–30 K, beyond the plateau, κ increases with T, with a decreasing slope.

Polymers

Crystalline polymers tend to follow the general predictions in Fig. 19.6 that at high temperatures κ decreases with the temperature. As the degree of crystallinity decreases, κ also decreases, and eventually for amorphous polymers κ is substantially smaller than the crystalline phase, and κ increases with increasing temperature. If ρ_c and ρ_a are the densities of a given polymer in the crystalline (c) and amorphous (a) phase, then various empirical rules have been proposed to relate the conductivities of c- and a-phases through the ratio ρ_c/ρ_a of their densities. For example, in one empirical rule [19.30]

$$\frac{\kappa_c}{\kappa_a} = 1 + 1.58\left[\frac{\rho_c}{\rho_a} - 1\right] .$$

This means that, if we know κ_c, and ρ_c/ρ_a, we can calculate κ_a. If we know the density ρ of the partially crystalline polymer or the volume fraction v_a of the amorphous phase, then we can use an appropriate mixture rule to find the overall κ. (A solved problem is given as an example in [19.10, Chap. 17].) Figure 19.8 shows the dependence of κ on T for three different degrees of crystallinity in the structure; clearly κ versus T is strongly influenced by the crystallinity of the structure.

Figure 19.9 shows the temperature dependence of κ when it has been normalized to its value $\kappa(T_g)$ at the glass-transition temperature T_g against the normalized temperature, T/T_g for a number of amorphous polymers. While there are marked differences between various polymers, there is nonetheless an overall trend in which κ increases up to T_g and thereafter decreases with T. The solid curve in Fig. 19.9 indicates an overall trend. Notice how similar the κ values are.

The overall or effective thermal conductivity of polymer blends can be usually estimated from the individual conductivities, the volume or weight fractions of the constituents, and the crystallinity of the structure; the problem can be quite complicated. A good example in which κ has been examined for a polymer blend as a function of blend composition has been given by *Agari* et al. [19.31], who also test various mixture rules.

The thermal conductivity of polymeric composite materials (as opposed to blends) can be estimated from various mixture rules [19.32, 33]. For example, if a matrix with κ_1 contains spherical particles with κ_2, then the composite has a thermal conductivity,

$$\kappa = \kappa_1 \frac{2\kappa_1 + \kappa_2 - 2v_2(\kappa_1 - \kappa_2)}{2\kappa_1 + \kappa_2 + v_2(\kappa_1 - \kappa_2)} , \qquad (19.21)$$

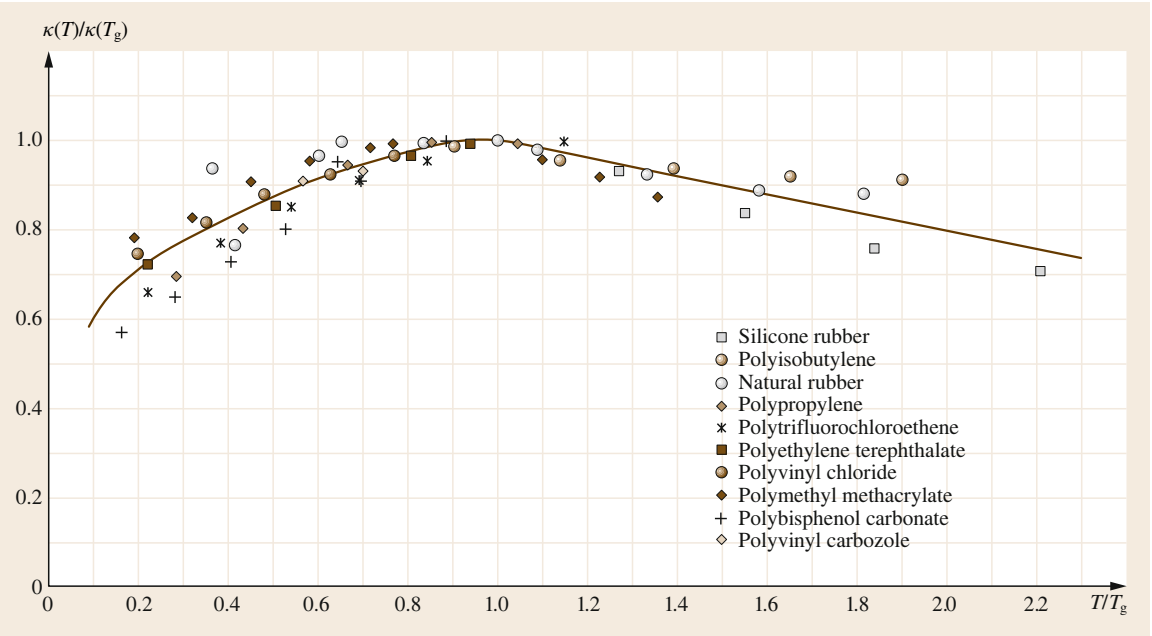

Fig. 19.9 Normalized thermal conductivity, $\kappa(T)/\kappa(T_g)$ versus normalized temperature, T/T_g, for various polymers. (After [19.10])

where v_2 is the volume fraction of the particles (with κ_2).

19.2.4 Thermal Conductivity of Metals

Although the heat capacity of metals is due the lattice vibrations, the thermal conductivity is due to the free conduction electrons. Both charge transport and heat transport are carried by the conduction electrons, and hence the electrical and thermal conductivity, σ and κ respectively, are related. Normally only electrons around the Fermi level contribute to conduction and energy transport. In general κ and σ can be written as

$$\kappa = \frac{1}{3} C_e v_F \ell_e \quad \text{and} \quad \sigma = \frac{1}{3} e^2 v_F \ell_e g(E_F) \,, \tag{19.22}$$

where C_e is the electronic heat capacity per unit volume, v_F is the Fermi velocity, $g(E_F)$ is the density of states at E_F (Fermi level), and ℓ_e is the electron mean free path. The scattering of electrons limits ℓ_e, which then limits κ and σ. If we then apply the free-electron theory to substitute for C_e and $g(E_F)$ then the ratio of κ to σT turns out to be a constant, which depends only on the constants k_B and e; ℓ_e cancels out in this ratio. A proper derivation involves solving the Boltzmann transport equation in the presence of a temperature gradient [19.34], and leads to the well-known *Wiedemann–Franz–Lorenz* (WFL) law

$$\frac{\kappa}{\sigma T} = C_{WFL} = \frac{\pi^2 k_B^2}{3e^2} = 2.44 \times 10^{-8} \frac{W\,\Omega}{K^2} \,, \tag{19.23}$$

where C_{WFL} is called the *Lorentz number*.

As shown in Fig. 19.10, the WFL law is well obeyed at room temperature for most pure metals and their alloys. The WFL law is normally well obeyed over a wide temperature range, and also by many liquid pure metals. Consequently the thermal conductivity κ of a metal or an alloy can be readily calculated given the conductivity or resistivity ρ. For example, we can easily calculate the resistivity of a solid solution alloy by using Matthiessen's and Nordheim's rules (as explained in this handbook by *Kasap* et al. in Chap. 2) and then simply calculate κ from (19.23). Figure 19.11 shows the typical dependence of κ on T for two pure metals (Cu and Al) and two alloys (brass and Al–14% Mg). Above the Debye temperature, for pure metals, $\sigma \propto 1/T$, so that the thermal conductivity remains almost constant, as in Fig. 19.11. For alloys, σ values are smaller than the corresponding pure metals and σ exhibits a weaker temperature dependence. Consequently κ is smaller and increases with the temperature, as shown in Fig. 19.11.

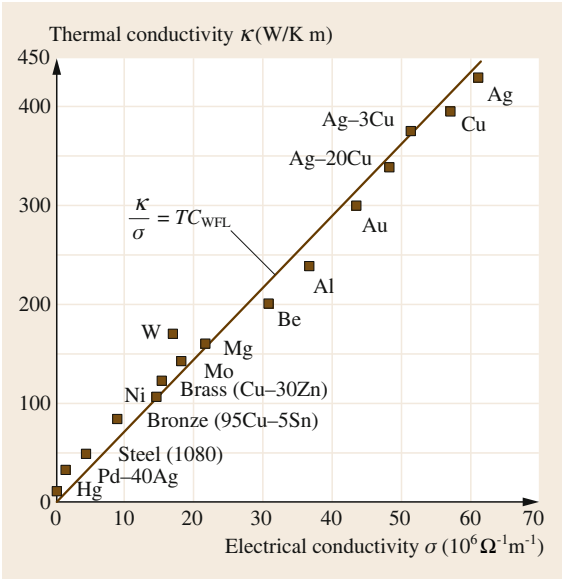

Fig. 19.10 Thermal conductivity versus electrical conductivity for various metals (both pure metals and alloys) at 20 °C. (After [19.5])

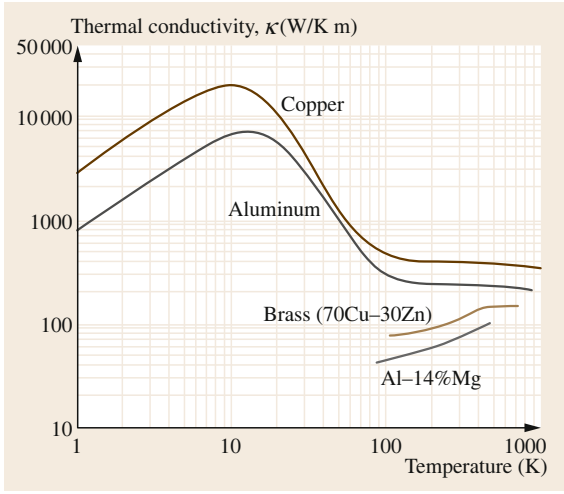

Fig. 19.11 Thermal conductivity versus temperature for two pure metals (Cu and Al) and two alloys (brass and Al–14% Mg). (After [19.5])

While for pure metals and many alloys κ is due to the conduction electrons, the phonon contribution can nonetheless become comparable to the electron contribution for those alloys that have substantial resistivity or at low temperatures. Glassy metals (or metallic glasses) usually have two or more elements alloyed; one of the elements is usually a nonmetal or a metalloid. Their resistivities tend to be higher than usual crystalline or polycrystalline alloys. Both conduction electrons and also phonons contribute to the thermal conductivity of these glassy metals. For example, for $Fe_{80}B_{20}$, $\rho = 1220\,\mathrm{n\Omega\,m}$ (compare with $17\,\mathrm{n\Omega\,m}$ for Cu), and the phonon contribution is about 15% at 273 K and 61% at 100 K [19.35].

19.3 Thermal Expansion

19.3.1 Grüneisen's Law and Anharmonicity

Nearly all materials expand as the temperature increases. The thermal coefficient of linear expansion, or simply, the thermal expansion coefficient α is defined as the fractional change in length per unit temperature increase, or

$$\alpha_\mathrm{L} = \frac{1}{L_0}\left(\frac{\mathrm{d}L}{\mathrm{d}T}\right)_{T_0}, \qquad (19.24)$$

where L_0 is the original length of the substance at temperature T_0, $\mathrm{d}L/\mathrm{d}T$ is the rate of change of length with temperature at the reference temperature T_0.

The principle of thermal expansion is illustrated in Fig. 19.12, which is the potential-energy curve $U(r)$ for two atoms separated by a distance r in a crystal. At temperature T_1, the atoms would be vibrating about their equilibrium positions between B and C; compressing (B) and stretching (C) the bond between them. The line BC corresponds to the total energy E of the pair of atoms. The average separation at T_1 is at A, halfway between B and C. The PE curve $U(r)$ is asymmetric, and it

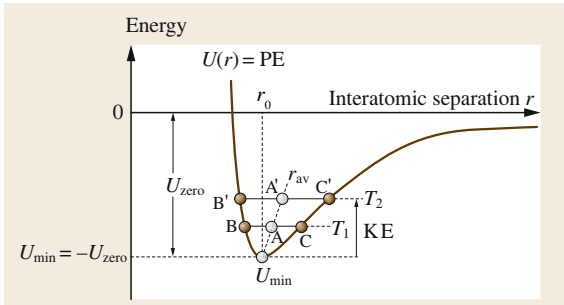

Fig. 19.12 Interatomic potential energy (PE) U curve, which has a minimum when the atoms in the solid attain the interatomic separation at $r = r_0$

Table 19.3 The Grüneisen parameter for some selected materials with different types of interatomic bonding. Only typical values are used; and for certain materials there can be significant variation in quoted data in the literature. Data extracted from [19.5]. (FCC is face-centered cubic and BCC is body-centered cubic crystal structures.)

Material	ρ (g/cm^{-3})	α_L ($\times 10^{-6}\,K^{-1}$)	K (GPa)	c_s (J/kg K)	γ
Iron (metallic, BCC)	7.9	12	170	450	1.7
Copper (metallic, FCC)	8.96	17	140	385	2.1
NaCl (ionic)	2.17	44	25	850	1.8
CsI (ionic)	4.51	48	13	201	2.1
Germanium (covalent)	5.32	6	77	322	0.81
Silicon (covalent)	2.32	2.6	99	703	0.47
Glass (covalent-ionic)	2.45	8	50	800	0.61
ZnSe (ionic/covalent)	5.27	7.4	62	350	0.75
Tellurium (covalent/van der Waals)	6.24	17	30	200	1.23
Polystyrene (van der Waals)	1.1	80	≈ 3	1300	0.50
Polyethylene terephthalate PET (van der Waals)	1.38	70	≈ 3	1200	0.38

is this asymmetry that leads to the phenomenon of thermal expansion. When the temperature increases from T_1 to T_2 the atoms vibrate between B' and C' and the average separation between the atoms also increases, from A to A', which is identified as thermal expansion. If the PE curve were symmetric, then there would be no thermal expansion. The extent of expansion (A to A') depends on the amount of increase from BC to $B'C'$ per degree of increase in the temperature. α must therefore also depend on the heat capacity. When the temperature increases by a small amount δT, the energy per atom increases by $(C_v \delta T)/N$, where C_v is the heat capacity per unit volume and N is the number of atoms per unit volume. If $C_v \delta T$ is large then the line $B'C'$ in Fig. 19.12 will be higher up on the energy curve and the average separation A' will therefore be larger. Thus, $\alpha \propto C_v$. Further, the average separation, point A, depends on how much the bonds are stretched and compressed. For large amounts of displacement from equilibrium, the average A will be greater as more asymmetry of the PE curve is used. Thus, smaller is the elastic modulus K, the greater is α_L; clearly $\alpha_L \propto C_v/K$.

If we were to expand $U(r)$ about its minimum value U_{min} at $r = r_0$, we would obtain the Taylor expansion to the cubic term as,

$$U(r) = U_{min} + \frac{1}{2}\beta(r-r_0)^2 - \frac{1}{3}g(r-r_0)^3 \,, \quad (19.25)$$

where β and g are coefficients related to second and third derivatives of U at r_0. The term $(r-r_0)$ is missing because we are expanding a series about U_{min} where $dU/dr = 0$. The U_{min} and the $\beta_2(r-r_0)^2$ term give a parabola about U_{min} which is a symmetric curve around r_0 and therefore does not lead to thermal expansion. It is the cubic term that gives the expansion because it leads to asymmetry. Thus, the amount of expansion α also depends on the amount of asymmetry with respect to symmetry that is β/g. Thus, α is proportional to both C_v/K and g/β. The third term in (19.25) is called *anharmonicity* in the interatomic PE curve. The ratio of g to β depends on the nature of the bond. A simplified analytical treatment gives α_L as,

$$\alpha_L \approx \frac{\gamma}{3}\frac{C_v}{K} \,; \quad \gamma = \frac{r_0 g}{3\beta} \,, \quad (19.26)$$

where γ is a constant called the *Grüneisen parameter*, which represents the relative asymmetry of the energy curve, g/β. γ is of the order of unity for many materials; experimentally, $\gamma = 0.1{-}2$. We can also write the Grüneisen law in terms of the molar heat capacity C_m (heat capacity per mole or the specific heat capacity c_s (heat capacity per unit mass)). If ρ is the density, and M_{at} is the atomic mass of the constituent atoms of the crystal, then

$$\alpha_L = \frac{\gamma}{3}\frac{\rho C_m}{M_{at} K} = \frac{\gamma}{3}\frac{\rho c_s}{K} \,. \quad (19.27)$$

Given the experimental values for α_L, K, ρ and c_s, the Grüneisen parameters have been calculated from (19.27) and are listed in Table 19.3. An interesting feature is that the experimental γ values, within a factor of 2–3, are about the same, at least to an order of magnitude. Equation (19.26) also indicates that the dependence of α_L on T should resemble the dependence of C_v on T, which is borne out by experiments.

19.3.2 Thermal Expansion Coefficient α_L

The thermal expansion coefficient normally depends on the temperature, $\alpha_L = \alpha_L(T)$, and typically increases

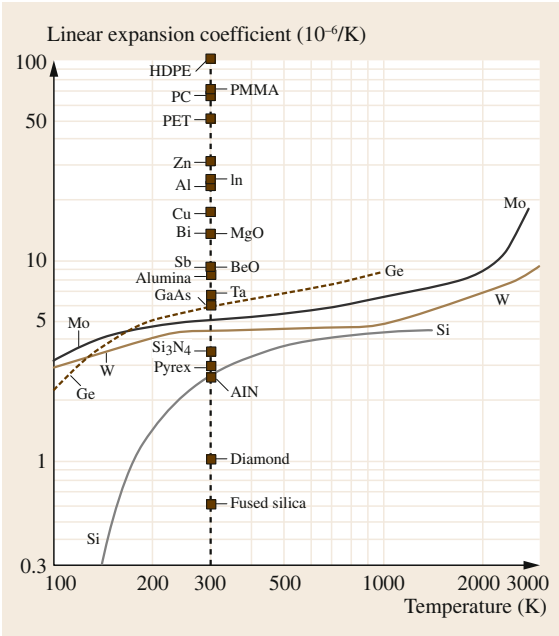

Fig. 19.13 α versus T for selected materials and comparison of α_L for a range of materials at 300 K. (After [19.5])

with increasing temperature, except at the lowest temperatures. Figure 19.13 shows α_L versus T for selected materials and also compares α_L for a wide range of materials at 300 K. In very general terms, except at very low (typically below 100 K) and very high temperatures (near the melting temperature), for most metals α_L does not depend strongly on the temperature; many engineers take α_L for a metal to be approximately temperature independent. Further, higher-melting-point temperature metals tend to have lower α_L.

To calculate the final length L from the original length L_0 that corresponds to the temperature increasing from T_0 to T, we have to integrate $\alpha_L(T)$ with respect to temperature from T_0 to T. If $\bar{\alpha}_L$ is the mean value for the expansion coefficient from T_0 to T, then

$$L = L_0[1 + \bar{\alpha}_L(T - T_0)] \text{ and} \tag{19.28}$$

$$\bar{\alpha}_L = \frac{1}{(T - T_0)} \int_{T_0}^{T} \alpha_L(T)\mathrm{d}T \tag{19.29}$$

For example, the expansion coefficient of silicon over the temperature range 120–1500 K is given by [19.36] as

$$\alpha_L = 3.725 \times 10^{-6} \left(1 - \mathrm{e}^{-5.88 \times 10^{-3}(T-124)}\right) + 5.548 \times 10^{-10} T\,, \tag{19.30}$$

where T is in Kelvin. At 20 °C, $\alpha_L = 2.51 \times 10^{-6}\,\mathrm{K}^{-1}$, whereas from 20 °C to 320 °C, $\bar{\alpha}_L = 3.35 \times 10^{-6}\,\mathrm{K}^{-1}$. Most $\alpha_L(T)$ expressions have exponential-type expressions as in (19.30) but they can always be expanded in terms of T or $(T - T_0)$ up to the third term, beyond which errors become insignificant.

19.4 Enthalpic Thermal Properties

19.4.1 Enthalpy, Heat Capacity and Phase Transformations

Consider the behavior of the enthalpy $H(T)$ versus temperature T of a typical material as it is cooled from a liquid state starting at O as shown in Fig. 19.14 (the sketch is idealized to highlight the fundamentals). For crystalline solids, at the melting or fusion temperature T_m, the liquid L solidifies to form a crystalline solid C. Some degree of undercooling is necessary to nucleate the crystals but we have ignored this fact in Fig. 19.14 so that T_m is the thermodynamic melting temperature where the Gibbs free energies of the liquid (L) and the crystal (C) are the same. The heat capacity $C_{liquid} = \mathrm{d}H_{liquid}/\mathrm{d}T$ for the liquid is greater than that for the crystal, $C_{crystal} = \mathrm{d}H_{crystal}/\mathrm{d}T$, as apparent from the H–T slopes in Fig. 19.14. The fusion enthalpy ΔH_f corresponds to the enthalpy change between the liquid and crystalline phases, L and C, in Fig. 19.14.

When a glass-forming liquid is cooled, it does not crystallize at T_m; its crystallization kinetics are too slow or negligible. Its enthalpy H continues to decrease along the liquid H versus T line with a slope C_{liquid} and it becomes a supercooled liquid. However, as the cooling proceeds, eventually, over a certain small temperature range around a temperature marked as T_g in Fig. 19.14, the atomic motions become too sluggish, and the viscosity becomes too high to follow the liquid-like behavior. The material cools along a solid-like H–T curve that is almost parallel to the crystalline or solid H–T line. This region where the slope or the heat capacity is similar to that of the solid or the crystal ($C_{crystal}$) is called the glass region, and the material is said to be in the *glassy state*. The intersection of the liquid-like (supercooled) and solid-like (glass) H–T lines defines

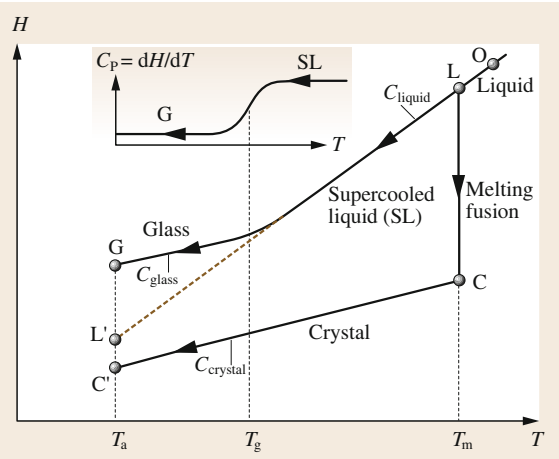

Fig. 19.14 Enthalpy H versus temperature T

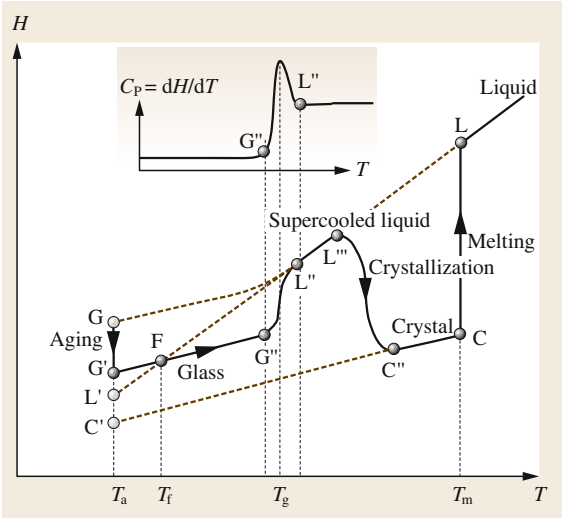

Fig. 19.15 Isothermal aging at T_a changes the glass enthalpy. When the glass is heated at a constant rate r, it undergoes glass transition at around T_g, and then ideally crystallization and then melting

a *glass-transition temperature* T_g as observed under cooling at a particular cooling rate q. T_g depends on the cooling rate (the slower the cooling, the lower the glass transition temperature), and obviously on the structure. C_P changes in a step-like fashion over a small interval around T_g during cooling as shown in Fig. 19.14. The shift in T_g with q can provide valuable information on the kinetics of the glass-transformation process as discussed below. The glass enthalpy is greater than the crystalline enthalpy due to the disorder in the glass structure.

It is apparent from Fig. 19.14 that, at least theoretically, if extremely slow cooling was applied, the enthalpy of the supercooled liquid could decrease at a pace suggested by the LL′ line in Fig. 19.14 without undergoing glass transition and eventually decrease below that of the crystal. This would, in consequence, mean that such massively undercooled liquid would have a negative entropy at 0 K, which is impossible. This scenario is called the *Kauzmann paradox* [19.37] and was, obviously, never truly observed in practice. There are two main theories of how to address the Kauzmann paradox – the first one states that the glass-transition kinetics would always intervene before enthalpy of the supercooled liquid would reach that of the crystal (i. e., no conditions exist under which supercooled liquid would be maintained to such low temperature). The second theory proposes the existence of a thermodynamic glass transition, which is overlapped by its kinetic manifestation. The question whether or not the glass transition is a true thermodynamic transition is still discussed in the literature [19.38]. For practical purposes it is, however, important to note that, regardless of the underlying thermodynamics, the experimentally observed glass transition is a kinetic phenomenon.

Suppose we stop the cooling at an ambient temperature T_a, corresponding to the glass state G. The glass enthalpy $H_{glass}(T_a)$ will relax via structural relaxations toward the enthalpy of the metastable liquid-like equilibrium state $H_{liquid}(T_a)$ at L′. This process is called aging or annealing. When we start heating a glass, its initial enthalpy can be anywhere between G and L′, depending on the thermal history (including aging) and the cooling rate.

When the sample at $H(T_a)$ at G′ is heated at a constant rate r, as shown in Fig. 19.15, the enthalpy of the system, as a result of long structural relaxation times at these low temperatures, follows the glass H–T curve until the atomic and molecular motions due to the increased temperature, are sufficiently rapid to overcome the kinetic barriers and allow the system to recover toward equilibrium $H_{liquid}(T)$; the transition is from G″ to L″. The sigmoidal-like change in $H(T)$ leads to the glass-transformation endotherm and the so-called overshoot in the C_P–T behavior observed for many glasses when they are heated through T_g. This endothermic heat, called the enthalpy of relaxation, depends on the duration of aging, and the structural relaxation processes, which in turn depend on the structure [19.39]. The observed glass-transition temperature T_g during heating depends not only on the heating rate r but also on the initial state $H(T_a)$ or G′. On the other hand, during cooling from the melt down to low temperatures, one observes only a change in the heat capacity. As we further heat the sample, the supercooled liquid state can crystallize, from L‴ to C″ and form a true solid, usu-

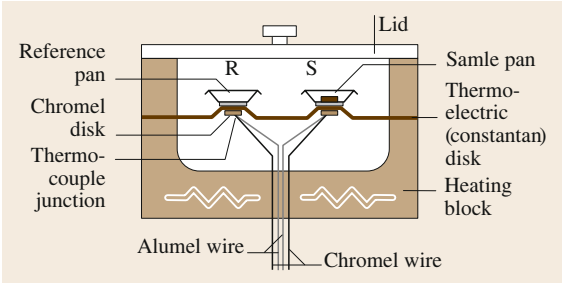

Fig. 19.16 Schematic illustration of heat-flux DSC cell. R and S refer to reference and sample pans

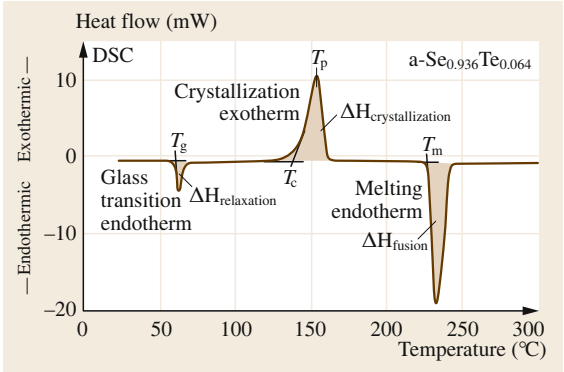

Fig. 19.17 Typical DSC signal for a chalcogenide $Se_{0.936}Te_{0.064}$ glass sample (well relaxed or aged). From left to right: the glass transition, crystallization and the melting temperatures, and the corresponding enthalpies of transitions for this material. $\Delta H_c = \Delta H_{crystallization}$; $\Delta H_f = \Delta H_{fusion}$

ally polycrystalline. This transformation from L‴ to C″ releases heat; it is exothermic. At T_m, the solid melts to form the liquid, C changes to L, which means that heat is absorbed.

It is apparent from the simple H–T behavior in Fig. 19.15 that there are at least several key parameters of interest in characterizing the thermal properties of materials: the heat capacity of the liquid, crystal, and glass phases, C_{liquid}, $C_{crystal}$, C_{glass}, their temperature dependences, melting or fusion temperature T_m, fusion enthalpy ΔH_f, crystallization onset temperature (L‴), exothermic enthalpy of crystallization (L‴ − C‴), T_g (which depends on various factors), and the endothermic glass-transformation enthalpy (L″ − G″). These properties are most conveniently examined using a *differential scanning calorimeter* (DSC).

19.4.2 Conventional Differential Scanning Calorimetry (DSC)

Principles

Differential scanning calorimetry (DSC) is a method that is extensively used to measure heat and temperatures of various transitions and has been recognized as a very useful tool for the interpretation of thermal events as discussed and reviewed by a number of authors (see, e.g., [19.40–46]). In essence, the DSC measures the net rate of heat flow $Q' = dQ/dT$, into a sample with respect to heat flow into a reference inert sample, as the sample temperature is ramped. Figure 19.16 shows a simplified schematic diagram of the heat-flux DSC cell. The constantan disk allows heat transfer to and from the reference and sample pans by thermal conduction. Due to symmetry, the thermal resistance of the heat paths from the heater to the reference and sample pans is approximately the same. The constantan disk has two slightly raised platforms on which the reference and sample pans are placed. Chromel disks fixed under these platforms form area thermocouple junctions with the constantan platforms. The constantan-chromel thermocouples are in series and read the temperature difference ΔT between the reference and sample pans. There are also alumel–chromel thermocouples attached to the chromel disks to measure the individual reference and sample temperatures.

The measured temperature difference ΔT corresponds to a differential heat flow $Q' = dQ/dt$ between the sample and the reference pans by virtue of Fourier's law of heat conduction

$$Q' = \Delta T/R\,, \tag{19.31}$$

where R is the effective thermal resistance of the heat flow path to the sample (or reference) through the constantan disk. In conventional thermal analysis, the sample temperature is either ramped linearly at a constant heating or cooling rate or kept constant (as in isothermal experiments).

A typical example of a heating scan performed for a glassy sample by means of a conventional DSC is shown in Fig. 19.17 where the thermogram evinces three distinct regions that correspond to the glass transition (T_g), crystallization and melting. T_g in DSC analysis is normally defined in terms of an onset temperature as in Fig. 19.17. The crystallization exotherm is normally used to obtain a crystallization onset temperature T_c and a peak crystallization rate temperature T_p that corresponds to the location of the peak crystallization. ΔH_c and fusion ΔH_f enthalpies are obtained by integrating the corresponding peaks as shown in Fig. 19.17 with an appropriate baseline. The base line represents the overall heat capacity of the sample, which changes during the transformation since the sample is gradually transformed into the new phase. Usually a simple sigmoidal, or even a straight line between the onset and the

end points, is sufficient for an accurate determination of the enthalpy.

Conventional DSC has been used to study and characterize a wide range of physical and chemical transformations. When the DSC is used in a heating or cooling scan, the temperature of the sample is ramped along $T = T_0 + rt$, where T_0 is the initial temperature. Consequently, the transformations in DSC are carried out under nonisothermal conditions, and well-known isothermal rate equations cannot be directly applied without some modification.

Glass Transition

Glass transition is one of the most intriguing phenomena in solid-state science. Despite extensive discussions in the literature (e.g., [19.47–52]), its nature is still not fully understood. Contrary to the simple thermally activated processes (crystallization, decomposition, etc.), the glass-transition kinetics exhibits a number of very complex features: hysteresis, nonlinearity, nonexponentiality, and thermorheological complexity [19.53]. Accordingly, special models had to be developed to properly account for these features – the *Tool–Narayanaswamy–Moynihan* (TNM) [19.54–56] and *Adam–Gibbs* (AG) [19.57] phenomenological models belong to the most successful and widespread. Both these models are based on the *Kohlrausch–Williams–Watts* (KWW) [19.58] stretch exponential relaxation function behavior combined with the concept of the so-called *reduced time integral*, which is explained below. For simplicity, we will consider the relaxation of the excess enthalpy $\Delta H(t)$ at any instant toward its equilibrium value, as shown in Fig 19.15. Within the relaxation description of glass transition, it is assumed that $\Delta H(t)$ at any time can be found from the relaxation function $F(t)$ given by the reduced time integral

$$F(t) = \exp\left[-\left(\int_0^t \frac{\mathrm{d}t}{\tau\,(T, T_\mathrm{f})}\right)^{\beta}\right], \qquad (19.32)$$

where the exponent β is a *nonexponentiality parameter*, which indicates the distribution of relaxation times associated with the particular structural cluster; ($\beta = 1$ corresponds to the fully exponential behavior, where all the clusters relax in a similar way and the overall relaxation response can be described by a single exponential function). Both TNM and AG models further utilize a quantity called the *fictive temperature* quantity T_f, which can be defined as the temperature of supercooled liquid with structure similar to that of the relaxing glass. Visualization of this definition can be made with the help of Fig. 19.15, where T_f can be determined as the intersection of the glass line passing through the starting enthalpic state G′ and the extended liquid H–T lines. It depends on the starting enthalpy G′ so that T_f is used as a convenient temperature parameter to identify the initial state of the amorphous structure at G′ (or at any other state reached, for example, by aging of or by application of a more complicated thermal history). The difference between the two models lies in the expression for the relaxation time τ, that is

$$\tau_\mathrm{TNM} = A \exp\left[x\frac{\Delta h^*}{RT} + (1-x)\frac{\Delta h^*}{RT_\mathrm{f}}\right], \qquad (19.33)$$

$$\tau_\mathrm{AG} = A \exp\left[\frac{B}{T\,(1 - T_2/T_\mathrm{f})}\right]. \qquad (19.34)$$

The following relaxation parameters can be identified for the TNM model: A is the pre-exponential constant, x is the nonlinearity parameter (which determines the relative contributions of temperature and structure to the relaxation process), and Δh^* is the apparent activation energy. B is a structure and material-dependent parameter discussed below. Notice that both expressions have T_f, which means that the relaxation times in (19.33) and (19.34) also depend on the initial state at G′. Although all these parameters are phenomenological and have no exact physical meaning, recently it was shown [19.59] that their qualitative interpretation can be used to explain the relaxation phenomena in terms of actual structural changes and movements at a molecular level. On the other hand, although the AG model is also denoted as phenomenological, its relaxation parameters have much clearer physical meaning: T_2 is the temperature at which the macroscopic configurational entropy extrapolates to zero (a quantity similar to the *Kauzmann temperature* introduced in Sect. 19.4.2) and B can be defined as

$$B = \frac{N_\mathrm{A}\Delta\mu S_\mathrm{c}^*}{k_\mathrm{B}\Delta C_\mathrm{P}\,(T_2)}, \qquad (19.35)$$

where k_B is the Boltzmann constant, $\Delta\mu$ is the potential barrier hindering structural rearrangement, S_c^* is the macroscopic configurational entropy, N_A is Avogadro's number, and ΔC_P is the T_g heat capacity change extrapolated to a given temperature (T_2).

In principle, both models can be accommodated within a curve-fitting procedure to the DSC data during which all the model parameters are determined; one of the most convenient algorithms can be found in [19.67]. In practice, in many engineering applications, it is usually sufficient to estimate the position of T_g for the given experimental conditions and/or material. Table 19.4 lists some of the most important empirical rules that can be used to estimate the position of T_g based on some

Table 19.4 Some selected examples of T_g dependences on various factors

Rule	Notation	Comment
$T_g \approx (2/3)T_m$	T_g and T_m in K. T_m = melting temperature of corresponding crystalline phase.	Kauzmman's empirical rule [19.37]. Most glass structures including many amorphous polymers [19.60]. Some highly symmetrical polymers with short repeat units follow $T_g \approx (1/2)T_m$ [19.10]
$\ln(q) \approx -\Delta h^*/RT_g + C$	q = cooling rate; Δh^* = activation energy (during colling); C = constant.	Dependence of T_g on the cooling rate. Δh^* may depend on the range of temperature accessed. Bartenev–Lukianov equation [19.61, 62]
$T_g \approx T_g(\infty) + C/M_n$	M_n = average molecular weight of polymer; C = constant; $T_g(\infty)$ is T_g for very large M_n	Dependence of T_g on the average molecular weight of a polymer [19.63, 64]. Tanaka's rule
$\ln(T_g) \approx 1.6Z + C$	Z = mean coordination number, C = constant (≈ 2.3)	Network glasses. Dependence of T_g on the mean coordination number. Neglects the heating rate dependence. [19.65]
$T_g(x) = T_g(0) - 626x$	T_g in K; x is atomic fraction in a : $(Na_2O + MgO)_x(Al_2O_3 + SiO_2)_{1-x}$ b : $(PbO)_x(SiO_2)_{1-x}$ c : $(Na_2O)_x(SiO_2)_{1-x}$ $T_g(0) = 1080$ K for a; 967 K for b; 895 K for c.	±5%. Silicate glasses [19.66]; x is network modifier. $0.01 < x < 0.6$

fundamental knowledge of the given material (composition, temperature of melting). Since T_g also depends on the heating or cooling rate, such rules should be used as an approximation; nonetheless, they are extremely useful in engineering as a guide to the selection and use of materials.

None of the two above-described approaches is, however, ideal in the sense that tedious time-consuming nonlinear optimizations of a large number of DSC measurements need to be performed to obtain a full description of the relaxation behavior by the two models (which may not be necessary). In certain cases, only a rough estimate of T_g is obtained, based on uncertain assumptions. Recently, a new approach has been introduced [19.68], extending the earlier works of *Kovacs* et al. [19.69] and *Hutchinson* et al. [19.70] in which a so-called constant ratio (CR) cyclic temperature history is introduced in the measurements in such a way that the ratio of the heating and cooling rates (r^+/r^-) is maintained constant. The sample is alternately cooled and heated through T_g at various rates while maintaining $(r^+/r^-) =$ constant. The shift in the peak temperature T_p, corresponding to the maximum of the relaxation overshoot in the heating DSC, is examined as a function of the heating rate r^+. The apparent activation energy Δh^* is then determined from these DSC scans through

$$\frac{\Delta h^*}{R} = -\left[\frac{\mathrm{d}\ln|r^+|}{\mathrm{d}\left(1/T_p\right)}\right]_{(r^-/r^+)=\text{const}}, \qquad (19.36)$$

where r^+ and r^- are the heating and cooling rates, respectively, as defined above. The peak temperature T_p can be replaced by the T_g midpoint introducing errors. Strength of this approach lies in the special design of the DSC experiment, which is performed as a series of alternating cooling and heating scans through T_g, where the cooling rates vary and heating rates are performed at the same rate as was that of the preceding cooling [19.68, 71]. The Δh^* value obtained in this way can be consequently used to calculate the position of T_g for a broad range of experimental conditions. Furthermore, this technique has been extensively tested for all types of structural relaxation behavior [19.71] and has been shown to be highly accurate and relatively insensitive to most data-distortive effects encountered in DSC experiments, including thermal lag, imprecise heating/cooling rates, or incomplete achievement of a true glassy state during cooling.

Very good example of how the results of conventional DSC enthalpy relaxation measurements correlate with the relaxation parameters obtained by means of other commonly used experimental techniques can be shown for the case of amorphous As_2Se_3, which is one of the best glass-formers from the family of chalcogenide glasses and was one of the first extensively studied inorganic glasses with respect to the glass transition kinetics. In [19.72], the enthalpy relaxation of As_2Se_3 glass was studied by means of conventional and temperature-modulated DSC – the TMDSC technique will be described in detail later in Sect. 19.5. For the conventional DSC, the apparent activation en-

Table 19.5 Activation energy (Δh^*) from DSC cooling rate (q) scans (inflection and onset T_g data), from TMDSC modulation frequency (ω) scans (inflection and onset T_g data) [19.72], and Δh_η calculated from *Henderson* and *Ast* viscosity data [19.73] using an average for T_g value that represents the T_g range of interest

	$\ln(q)$ versus $1/T_g$ (inflection T_g)	$\ln(q)$ versus $1/T_g$ (onset T_g)	$\ln(\omega)$ versus $1/T_g$ (inflection T_g)	$\ln(\omega)$ versus $1/T_g$ (onset T_g)
Activation energy (Δh^*)	407.4 kJ mol^{-1}	322.9 kJ mol^{-1}	243.5 kJ mol^{-1}	231.1 kJ mol^{-1}
Activation energy (Δh_η) of viscosity	385.2 kJ mol^{-1}	317.7 kJ mol^{-1}	287.5 kJ mol^{-1}	265.3 kJ mol^{-1}
T_g average	447.8 K	463.6 K	472.9 K	481 K
Difference between Δh^* and Δh_η	5.5%	1.6%	18%	15%

ergies were evaluated from the dependence of T_g on the cooling rate (the methodology was originally developed by *Moynihan* et al. [19.74]); in the case of the TMDSC technique, the activation energies were evaluated from the dependence of T_g on angular frequency of temperature modulation. The resulting Δh^* values were then compared with the activation energies of viscous flow Δh_η determined in the same temperature ranges (viscosity data by *Henderson* and *Ast* [19.73] were used). All determined Δh^* and Δh_η values are listed in Table 19.5 together with the average T_g values for the given combination of used experimental technique (DSC/TMDSC) and T_g evaluation method (onset/inflection). It is apparent that the activation energy decreases as the glass transition (indicated by the mean T_g value) increases, due to different measurement conditions. Nonetheless, good agreement was found between the Δh^* and Δh_η values within the respective temperature ranges, confirming that both the enthalpy relaxation and viscosity processes are closely interconnected and exhibit similar apparent activation energies. In addition, it was also found [19.75] that the volume relaxation measured by means of thermomechanical analysis provides comparable values of apparent activation energy ($\Delta h^*_{TMA} = 319\,\mathrm{kJ\,mol^{-1}}$), which are in excellent agreement with the viscosity data obtained in the given temperature range ($\Delta h_\eta = 316\,\mathrm{kJ\,mol^{-1}}$). The above example clearly demonstrates that the glass transition behavior is universal and manifests similarly across a large variety of physical properties.

Crystallization

The crystallization-phase transformation takes place in many amorphous and glassy materials. This process can be followed directly by microscopy or indirectly by macroscopic methods, such as DSC, x-ray diffraction, electrical conductivity measurements, etc. Microscopic techniques are time consuming and often also experimentally difficult. Therefore, it is not surprising that they are frequently replaced by macroscopic methods and especially by DSC. Despite the high universality of DSC, there are also some shortcomings. Two most important ones are related to the detection limit and instrumental time constant. The sensitivity of modern DSC instruments is very high. However, for a slow process associated with rather small heat evolution, the signal-to-noise ratio might be well below the detection limit and the uncertainty of baseline subtraction may cause substantial errors. On the other hand, for very fast crystallization where the rate constant becomes comparable to the instrumental time constant, a significant part of the signal might be distorted due to transient effects.

For crystallization in the glassy state or in glass-forming supercooled liquids, the overall rate of transformation usually involves the nucleation of the new phase followed by its growth. Theoretical description of nucleation-growth processes is based on the classical nucleation theory that has been developed some 80 years ago. The growth proceeds until the whole or substantial part of the sample has been transformed. Consequently, the crystallization process is a typical sigmoidal time-transformation curve. The shape of this typical curve has been described in 1939 by *Johnson* and *Mehl* [19.76] and *Avrami* [19.77–79]. In general, the equation for volume fraction α transformed as a function of time under isothermal conditions can be written in the following form

$$\alpha = 1 - \exp\left[-(Kt)^m\right] , \qquad (19.37)$$

where the parameter m is known as the Avrami exponent and K is a constant. For some simple cases of crystallization, it is possible to find a characteristic value of the kinetic exponent m whose value depends on nucleation and crystal growth mechanism. A detailed summary of possible m values has been given by *Christian* [19.80]. Equation (19.37) and its differential form expressed by (19.39) and (19.40) are usually referred to as the *Johnson–Mehl–Avrami (JMA) equation*. The parameter K in (19.37) is defined as an effective overall crystallization rate that depends on both the nucleation and growth rates. It should be emphasized that the va-

lidity of the JMA equation is based on the following assumptions [19.81, 82]:

1. Isothermal crystallization conditions
2. Homogeneous nucleation or heterogeneous nucleation at randomly dispersed second-phase particles
3. Growth rate of new crystalline phase is controlled by temperature and it is independent of time
4. Low anisotropy of growing crystals.

Henderson [19.81, 82] has shown that the validity of the JMA equation expressed by (19.37), (19.39), and (19.40), can be extended to nonisothermal conditions if the entire nucleation process takes place during the early stages of the transformation, and it becomes negligible afterward. The crystallization rate is then defined only by temperature and does not depend on the previous thermal history. Similar kinetic equations for nonisothermal crystal growth from preexisting nuclei have also been developed by *Ozawa* [19.83].

It is known that JMA equation must be modified for certain types of isothermal crystallization processes. Examples of such situations are given by systems where finite size effects are of importance, where multiple crystallization mechanisms occur, where inert inclusions are present in the matrix, and where the second-phase particles are anisotropic. *Shepilov* and *Baik* [19.84] have examined the behavior of the Avrami exponent in three dimensions, using computer simulations of the crystallization of randomly oriented ellipsoidal crystals. They found that shielding effects (such as blocking due to anisotropic growth) tend to reduce the value of the Avrami exponent as the crystallization process progresses. However, their analyses were limited to the case of site saturation (prenucleation). *Weinberg* [19.85] examined the behavior of Avrami exponent for anisotropic particle formation in systems exhibiting continuous nucleation and site saturation concluding that for the case studied, blocking effect (stronger impingement) causes a reduction in the Avrami exponent, but the unblocked values are reestablished at infinite times. These features should be taken into account when attempting to determine reaction mechanisms from crystallization data from which anisotropic particles form. The relative reduction in the Avrami exponent as a function of $\alpha(t)$ is larger for the prenucleated samples due to more efficient blocking which occurs in this case. More mechanisms that cause deviations from (19.37) were reported by *Starink* [19.86].

The conditions of validity of the JMA equation concerning the nucleation process and crystal growth morphology are essential for practical application of this equation in the analysis of DSC data. Nevertheless, there are some additional assumptions inherent to any calorimetric measurement that should also be fulfilled. These assumptions can be formulated as follows [19.87]:

1. It is assumed that the rate of the crystallization process $\mathrm{d}\alpha/\mathrm{d}t$ is proportional to the net rate of heat flow, Q', normalized per sample mass

$$\left(\frac{\mathrm{d}\alpha}{\mathrm{d}t}\right) = \frac{1}{\Delta H_\mathrm{c}} Q' \,, \tag{19.38}$$

   where ΔH_c is the total enthalpy change associated with the crystallization process. The fraction transformed, α, can easily be obtained by partial integration of isothermal or nonisothermal crystallization curve. The total peak area then corresponds to ΔH_c.
2. The rate of the crystallization process can be expressed as a product of temperature-dependent crystallization rate constant $K(T)$ and a function $f(\alpha)$ that depends on the fraction transformed,

$$\left(\frac{\mathrm{d}\alpha}{\mathrm{d}t}\right) = K(T) f(\alpha) \,. \tag{19.39}$$

By differentiation of (19.37) with respect to time, we obtain the $f(\alpha)$ function that corresponds to the JMA nucleation-growth equation,

$$f(\alpha) = m\,(1-\alpha)\,[-\ln\,(1-\alpha)]^{1-1/m} \,. \tag{19.40a}$$

The crystallization rate constant in (19.37) is usually assumed to follow an Arrhenius-type temperature dependence, that is, $K(T) = A\exp(-E_\mathrm{a}/RT)$, where A is pre-exponential factor and E_a is an apparent activation energy describing the overall crystallization process. This assumption is appropriate when the nucleation and growth processes vary in an Arrhenian way with temperature, which is fulfilled over a sufficiently narrow range of temperature (such as in the range of DSC crystallization peaks). If the nucleation frequency is negligible over the limited temperature range then the apparent activation energy is approximately equal to activation energy of crystal growth [19.88]. The value of E_a can be determined from the shift of the crystallization peak temperature T_p with the heating rate r. The plot of $\ln(r/T_\mathrm{p}^2)$ versus $1/T_\mathrm{p}$ is called a *Kissinger plot* [19.89, 90], and gives the activation energy E_a. Thus,

$$\ln\left(\frac{r}{T_\mathrm{p}^2}\right) = -\frac{E_\mathrm{a}}{RT_\mathrm{p}} + \text{constant} \,. \tag{19.40b}$$

Combining (19.38) and (19.39), we can write for the heat flow rate corresponding to the crystallization

process

$$Q' = \Delta H_c A \exp\left(-E_a/RT\right) f(\alpha)\,, \tag{19.41}$$

where the $f(\alpha)$ function following the JMA model is expressed by (19.40a). This function should be invariable with respect to the experimental conditions such as sample mass and heating rate (nonisothermal conditions) or temperature (isothermal conditions).

Any direct comparison of the isothermal $Q'(t)$ and nonisothermal $Q'(T)$ DSC crystallization curves is complicated by the fact that they strongly depend on the temperature and heating rate, respectively. Moreover, the shape and symmetry of these curves that correspond to the same kinetic model may be quite different in isothermal and nonisothermal conditions. However, there are two functions $y(\alpha)$ and $z(\alpha)$ that can easily be obtained by a simple transformation of DSC data [19.87]. In isothermal conditions, these functions are defined as

$$y\left(\alpha\right) = Q' \tag{19.42a}$$

$$z\left(\alpha\right) = Q' t\,. \tag{19.42b}$$

In nonisothermal conditions these functions are defined as follows

$$y\left(\alpha\right) = Q' \exp\left(E_a/RT\right)\,, \tag{19.43a}$$

$$z\left(\alpha\right) = Q' T^2\,. \tag{19.43b}$$

For practical reasons, the $y(\alpha)$ and $z(\alpha)$ functions are normalized within the (0, 1) range. From (19.42a) and (19.42b), it is evident that both the $y(\alpha)$ and $z(\alpha)$ functions in isothermal conditions directly follow from the experimental data. Similarly, the $z(\alpha)$ function in nonisothermal conditions is obtained by a simple transformation of experimental data. However, the value of apparent activation energy E_a is needed to calculate the $y(\alpha)$ function in nonisothermal conditions.

The validity of the assumptions (1) and (2) can easily be verified by checking the invariance of the $y(\alpha)$ and $z(\alpha)$ plots with respect to procedural variables such as heating rate (nonisothermal conditions) and temperature (isothermal conditions). These functions should be identical for both isothermal and nonisothermal DSC data provided that the kinetic model $f(\alpha)$ does not change. In case that there are considerable differences or pronounced influence of the procedural parameters affecting the shape of the $y(\alpha)$ and $z(\alpha)$ functions then, probably, these assumptions are not fulfilled. Such behavior can be a consequence of many different factors. One possibility is that the baseline has not been drawn correctly due to substantial change in the sample heat capacity during the measurement. Another possible explanation is that the measured data corresponds to a complex process (parallel or consecutive processes, branching, etc.) featuring different reaction scheme than expressed by (19.42). Thermal inertia effects caused by lower thermal contact between the sample and temperature sensor or low thermal conductivity of amorphous materials can also play an important role [19.91].

The $y(\alpha)$ and $z(\alpha)$ plots exhibit maxima at α_y^* and α_z^*, respectively. The maximum of the $y(\alpha)$ function for the JMA model depends on the value of the kinetic exponent. For $m \leq 1$, it is $\alpha_y^* = 0$ and for $m > 1$ it can be expressed as

$$\alpha_y^* = 1 - \exp\left(m^{-1} - 1\right)\,. \tag{19.44}$$

This equation can be used to estimate the value of the kinetic exponent. The maximum of the $z(\alpha)$ function α_z^* that is a characteristic constant for the JMA model: $\alpha_z^* = 0.632$. Therefore, it can be used as a simple test of the applicability of this model [19.87]. Taking into account a typical error limit of α_z^*, determined from calorimetric data (± 0.02) then the maximum of the $z(\alpha)$ function can be expected within the interval $0.61 \leq \alpha_z^* \leq 0.65$ for the JMA model. Higher or lower values indicate increasing complexity and the JMA model can hardly be applied. This can be caused, for example, by the non-negligible influence of heterogeneous nucleation. However, a complex behavior can also be observed when the temperature distribution within the sample is nonuniform due to the heat liberated by crystallization process at the crystal–liquid interface [19.82]. Such local overheating can lead to an autocatalytic behavior of the crystallization kinetics that has been observed in several noncrystalline systems. In this case, the crystallization can be described by means of an empirical two-parameter autocatalytic (AC) model [19.91]

$$f(\alpha) = \alpha^M \left(1-\alpha\right)^N\,, \tag{19.45}$$

where the parameters M and N define relative contributions of acceleratory and decelerating parts of the crystallization process, respectively. It has been shown [19.92] that (19.45) is meaningful only for $M < 1$. The maxima of the $y(\alpha)$ and $z(\alpha)$ functions depend on the value of the kinetic exponents M and N. The maximum α_y^* of the $y(\alpha)$ function can be expressed as [19.87]

$$\alpha_y^* = \frac{M}{M+N}\,. \tag{19.46}$$

However, the maximum α_z^* of the $z(\alpha)$ function cannot be expressed in an analytical form and has to be obtained by a numerical solution [19.87].

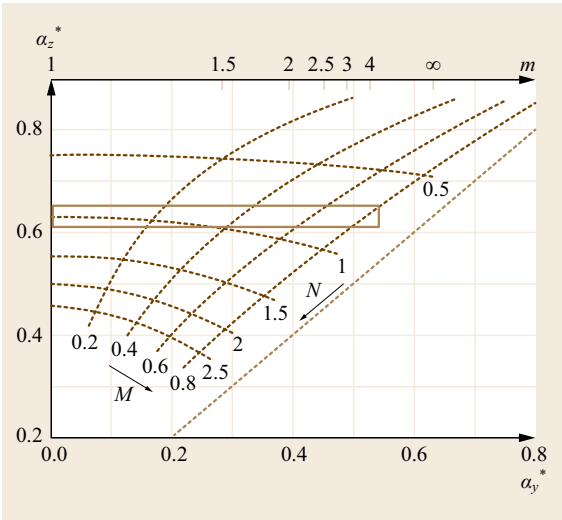

Fig. 19.18 The α_y^* versus α_z^* diagram for the JMA and AC model [19.91]. Numbers mark the values of the kinetic exponents M and N for the AC model and the Avrami exponent m. The area marked by full lines corresponds to the applicability range of the JMA model. The broken line shows the theoretical limit for $\alpha_y^* = \alpha_z^*$

Figure 19.18 shows the α_y^* versus α_z^* diagram for the JMA and AC models. The dotted lines were calculated for a constant values of the parameters M and N. The whole area of this diagram, restricted by a broken line defined as $\alpha_y^* = \alpha_z^*$ (i. e., theoretical limit [19.24, 87] for any $f(\alpha)$ function defined by (19.40) corresponds to the AC model. The JMA model is restricted to the small area where the condition of $0.61 \leq \alpha_z^* \leq 0.65$ is fulfilled. Therefore, the JMA model is a special case of the two-parameter AC model; it is a plausible description for the nucleation-growth processes in non-crystalline solids. A similar conclusion was also found by the shape analysis of DSC curve for the JMA and AC models [19.93]. The increasing value of the kinetic exponent M indicates a more important role of the crystallized phase on the overall kinetics. It also seems that a higher value of the kinetic exponent $N > 1$ means increasing complexity. However, the temptation to associate parameters M and N with a particular crystallization mechanism should be avoided, and too much physical significance should not be attached to the numerical values of what is essentially a phenomenological convenience. In particular, this advice applies to processes exhibiting a complex behavior. Any meaningful conclusions on the mechanism of the crystallization process should always be based on direct experimental evidence, such as microscopic observation of the crystal growth [19.91].

Probably the most popular method for analysis of isothermal data is an inspection of the linearity of the Avrami plot; that is, the dependence of $\ln[-\ln(1-\alpha)]$ as a function of logarithm of time. The kinetic exponent m is obtained from the slope of this plot [19.87]

$$\frac{\mathrm{d}\ln[-\ln(1-\alpha)]}{\mathrm{d}\ln t} = m\,. \tag{19.47}$$

A similar method known as the *Coats–Redfern–Sestak plot* [19.94, 95] has been developed for nonisothermal DSC data. The slope of $\ln[-\ln(1-x)]$ versus $1/T$ dependence obtained from a single scan DSC experiment then provides the product of m and the activation energy E_a,

$$\frac{\mathrm{d}\ln[-\ln(1-\alpha)]}{\mathrm{d}\,(1/T)} \cong -\frac{mE_\mathrm{a}}{R}\,. \tag{19.48}$$

The value of the kinetic exponent m can then be calculated if E_a is known. The latter can be extracted from multiscan DSC measurements by using (19.40b), so in principle, one can determine both m and E_a. However, it is well known that a double logarithmic function, in general, is not very sensitive to subtle changes to its argument. One can expect that the plots of $\ln[-\ln(1-\alpha)]$ versus $\ln t$ or $1/T$ may appear linear even in the case that the JMA model is not fulfilled. Consequently the value of the parameter m estimated in this way may not necessarily correspond to the true m that describes the crystallization kinetics. Therefore, it seems that better way to estimate the Avrami exponent is (19.44) [19.87].

19.5 Temperature-Modulated DSC (TMDSC)

19.5.1 TMDSC Principles

In the early 1990s, a greatly enhanced version of the DSC method called temperature-modulated differential scanning calorimetry (MDSC) was introduced by the efforts of *Reading* and coworkers [19.96–98]. The MDSC method incorporates not only the ability of conventional DSC but it also provides significant and distinct advantages over traditional DSC. The benefits of the MDSC technique have been documented in several recent papers, and include the following: separation of complex transitions, e.g., glass transition, into eas-

ily interpreted components; measurement of heat flow and heat capacity in a single experiment; ability to determine more accurately the initial crystallinity of the studied material; increased sensitivity for the detection of weak transitions; increased resolution without the loss of sensitivity; measurement of thermal conductivity [19.99, 100]. One of the most important benefits is the separation of complex transitions such as the glass transition into more easily interpreted components. Recent applications of MDSC to glasses has shown that it can be very useful for the interpretation of thermal properties, such as the heat capacity, in relation to the structure as, for example, in the case of chalcogenide glasses (e.g., [19.101–103]).

The MDSC that is currently commercialized by TA Instruments uses a conventional heat-flux DSC cell whose heating block temperature is sinusoidally modulated. In MDSC, the sample temperature is modulated sinusoidally about a constant ramp so that the temperature T at time t is,

$$T = T_0 + rt + A\sin(\omega t)\,, \tag{19.49}$$

where T_0 is the initial (or starting) temperature, r is the heating rate (which may also be a cooling ramp q), A is the amplitude of the temperature modulation, $\omega = 2\pi/P$ is the angular frequency of modulation and P is the modulation period. It should be emphasized that (19.49) is a simplified statement of the fact that the cell has reached a steady-state operation and that the initial temperature transients have died out. The resulting instantaneous heating rate, $\mathrm{d}T/\mathrm{d}t$, therefore varies sinusoidally about the average heating rate r, and is given by

$$\frac{\mathrm{d}T}{\mathrm{d}t} = r + A\omega\sin(\omega t)\,. \tag{19.50}$$

At any time, the apparatus measures the sample temperature and the amplitude of the instantaneous heat flow (by measuring ΔT) and then, by carrying out a suitable Fourier deconvolution of the measured quantities, it determines two quantities (which have been termed by TA Instruments):

1. Reversing heat flow (RHF).
2. Nonreversing heat flow (NHF).

Fourier transforms are made on one full cycle of temperature variation, which means that the average quantities refer to moving averages. The average heat flow, which corresponds to the average heating rate (r), is called the total heat flow (HF). Total heat flow is the only quantity that is available and hence it is the only quantity that is always measured in conventional DSC experiments. MDSC determines the heat capacity using the magnitudes of heat flow and heating rate obtained by averaging over one full temperature cycle. If triangular brackets are used for averages over one period P, then $\langle Q'\rangle$ is the average heat flow per temperature cycle. The heat capacity per cycle is then calculated from

$$mC_\mathrm{P} = \frac{\langle\text{Heat flow}\rangle}{\langle\text{Heating rate}\rangle}\,, \tag{19.51}$$

where m is the mass of the sample. This C_P has been called the *reversing heat capacity*, though Schawe has defined as the complex heat capacity [19.104]. The reversing in this context refers to a heat flow that is reversing over the time scale of the modulation period. Furthermore, it is assumed that C_P is constant, that is, it does not change with time or temperature over the modulation period. The reversing heat flow is then obtained by

$$\mathrm{RHF} = C_\mathrm{P}\left\langle\frac{\mathrm{d}T}{\mathrm{d}t}\right\rangle\,. \tag{19.52}$$

The nonreversing heat flow (NHF) is the difference between the total heat flow and the reversing heat flow and represents heat flow due to a kinetically hindered process such as crystallization. There are a few subtle issues in the above condensed qualitative explanation. First is that the method requires several temperature cycles during a phase transition to obtain RHF and NHF components, which sets certain requirements on r, A and ω. The second is that the phase difference between the heat flow and the heating rate oscillations is assumed to be small as it would be the case through a glass-transition region or crystallization; but not through a melting process. There are a number of useful discussions and reviews on the MDSC technique and its applications in the literature [19.105–109].

19.5.2 TMDSC Applications

There has been considerable scientific interest in applying TMDSC measurements to the study of glass-transformation kinetics in glasses and polymers (e.g., [19.101, 102, 110–114]). The interpretation of TMDSC measurements in the glass-transition region has been discussed and reviewed by *Hutchinson* and *Montserrat* [19.115–118]. The reversing heat flow (RHF) through the T_g region exhibits a step-like change and represents the change in the heat capacity. The hysteresis effects associated with thermal history seem to be less important in the RHF but present in the NHF. The measurement of T_g from the RHF in TMDSC

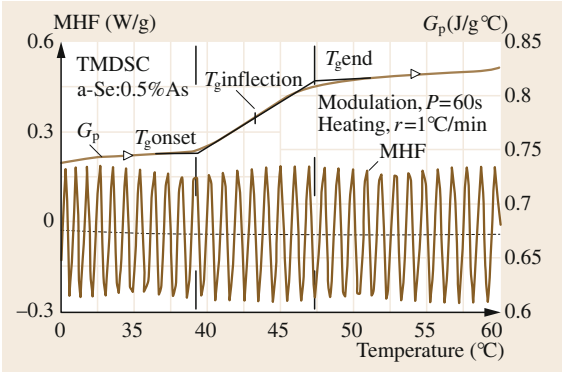

Fig. 19.19 A typical TMDSC scan

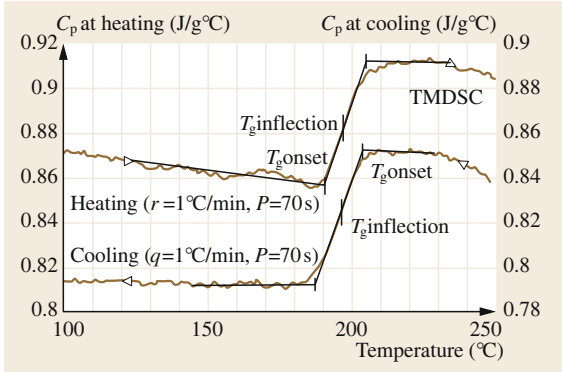

Fig. 19.20 Typical TMDSC heating and cooling scans on As_2Se_3 glass

experiments shows only a weak dependence on glass aging and thermal history [19.119–121], which is a distinct advantage of this technique. The interpretation of the NHF has been more difficult but it is believed that it provides a qualitative indication of the enthalpy loss during the annealing period below T_g [19.105] though more research is needed to clarify its interpretation. Figure 19.19 shows a typical MDSC result through the glass-transition region of $Se_{99.5}As_{0.5}$ glass.

It is important to emphasize that ideally the underlying heating rate in TMDSC experiments should be as small as possible. In this way we can separate the conventional DSC experiment, which also takes place during TMDSC measurements, from the dynamic, frequency-controlled TMDSC experiment. The oscillation amplitude A in the TMDSC must be properly chosen so that the C_P measurements do not depend on A; typically $A = \pm 1.0\,^{\circ}\mathrm{C}$ [19.72]. The oscillation period P should be chosen to ensure that there are at least four full modulations within the half width of the temperature transition, that is, a minimum of eight oscillations over the T_g range, as can be seen in the example in Fig. 19.19 which has a particularly narrow glass-transition range and required a $P = 60\,\mathrm{s}$. The difference between the average specific capacity, as determined from the conventional DSC heat flow, and the complex heat capacity, as determined from TMDSC RHF, in the T_g region is substantial [19.117]. The influence of experimental conditions on TMDSC measurements have been well discussed in the literature [19.104].

The glass transition T_g as observed in DSC scans is well known to depend on thermal history. The classical well-known example is the fact that the T_g value determined by DSC under a heating scan at a given rate r is different from that determined under a cooling scan at a rate $q = r$. Further, T_g determined in a DSC heating scan also depends on aging. The case for As_2Se_3 is well documented [19.122]. Figure 19.20 shows an example in which the T_g values for vitreous As_2Se_3 determined in TMDSC heating and cooling scans are approximately the same for a given modulation period P, within experimental errors. T_g depends only on the modulation frequency $\omega\,(= 2\pi/P)$ provided that the underlying heating or cooling scan is sufficiently slow, usually less than $1\,^{\circ}\mathrm{C/min}$. Other examples are also available in the literature for both glasses and polymers [19.123, 124]. The T_g measurement in the TMDSC experiments represents the relaxation processes associated with the temperature modulation, and not the underlying heating rate as in the conventional DSC. For example, T_g in TMDSC represents a temperature where the relaxation time τ is comparable with the modulation period P. Above T_g, $\tau \ll P$ and below T_g, $\tau \gg P$, and in the T_g region $\tau \approx P$. As P (or ω) is varied, from experiment to experiment, different values of τ satisfy $\tau \approx P$ and hence T_g depends on ω. It is possible to examine the shift in T_g with ω, and then plot $\ln\omega$ versus $1/T_g$ to extract the activation energy of the relaxation time τ, as shown for As_2Se_3 [19.72]. T_g that is observed in conventional DSC experiments is associated with the devitrification (on heating) and vitrification (on cooling) of the structure, whereas T_g in TMDSC experiments represents a dynamic glass-transition temperature; it is important to arrange the experimental conditions so that the two processes are separated in the measurement [19.125].

While a single phenomenological relaxation time provides a convenient description of the overall glass-transformation behavior, a more complete description necessarily involves incorporating a distribution of relaxation times, as discussed in [19.118].

19.5.3 Tzero Technology

It is well known that there is a thermal lag between the sample and temperature-control sensors in the DSC and

most DSCs require calibration at the heating rate to be used. Alternatively, calibration at multiple rates is required to correct for the heating rate dependence of the thermal lag. Without this calibration, there is considerable error in the temperature data in changing from one heating rate to another. This problem is especially acute in cooling experiments due to the thermal lag being in the opposite direction to that of heating, thereby doubling the lag effect. The lag problem has been solved in a recent DSC technique called the *Tzero technology*, as developed by TA Instruments [19.126, 127]. With the Q-series DSC system, an additional thermocouple on the DSC sensor allows a complete calibration of the DSC cell and compensation for all thermal lags, including those caused by the encapsulated sample. This means that, for all practical purposes, the DSC can be calibrated at any reasonable heating rate, and the DSC temperature data will be correct within a few tenths of a Celsius degree for data taken at other heating or cooling rates. Inasmuch as advanced Tzero compensates for the effect of pan thermal mass and coupling, it is possible to calibrate using one pan type and then use another pan type without incurring substantial errors. In summary, since the Tzero technology uses more information in the DSC measurement, it is more accurate under a wider range of conditions compared with the ordinary DSC without calibration under those specific conditions.

The thermal lag error is proportional to heat flow, heating rate, and to the mass of the sample/pan system. Hence, this error becomes greatest with fast scanning rates, large sample masses, massive sample pans, or sample specimens with an especially high heat capacity. The thermal lag error is also proportional to the thermal resistance between the sample and sensors so it is made worse by using pans made of poor thermal conductivity or pans making poor thermal contact. However, even in ordinary polymer samples, using optimally coupled aluminum pans, the error produced could be more than two Celsius degrees because of poor thermal conductivity; for other samples it could be several times larger. In summary, the Tzero technology has enabled better DSC experiments to be carried out.

Acknowledgments. The authors thank Dr. Dancho Tonchev for many helpful discussions on thermal properties, and his invaluable contributions to the first edition of this chapter.

20. Electrical Characterization of Semiconductor Materials and Devices

M. Jamal Deen, Fabien Pascal

Semiconductor materials and devices continue to occupy a preeminent technological position due to their importance when building integrated electronic systems used in a wide range of applications from computers, cell-phones, personal digital assistants, digital cameras and electronic entertainment systems, to electronic instrumentation for medical diagnositics and environmental monitoring. Key ingredients of this technological dominance have been the rapid advances made in the quality and processing of materials – semiconductors, conductors and dielectrics – which have given metal oxide semiconductor device technology its important characteristics of negligible standby power dissipation, good input–output isolation, surface potential control and reliable operation. However, when assessing material quality and device reliability, it is important to have fast, nondestructive, accurate and easy-to-use electrical characterization techniques available, so that important parameters such as carrier doping density, type and mobility of carriers, interface quality, oxide trap density, semiconductor bulk defect density, contact and other parasitic resistances and oxide electrical integrity can be determined. This chapter describes some of the more widely employed and popular techniques that are used to determine these important parameters. The techniques presented in this chapter range in both complexity and test structure requirements from simple current–voltage measurements to more sophisticated low-frequency noise, charge pumping and deep-level transient spectroscopy techniques.

The continued evolution of semiconductor devices to smaller dimensions in order to improve performance – speed, functionality, integration density and reduced cost – requires layers or films of semiconductors, insulators and metals with increasingly high quality that are well-characterized and that can be deposited and patterned to very high precision. However, it is not always the case that improvements in the quality of materials have kept pace with the evolution of integrated circuit down-scaling. An important aspect of assessing the material quality and device reliability is the development and use of fast, nondestructive and accurate electrical characterization techniques to determine important parameters such as carrier doping density, type and mo-

bility of carriers, interface quality, oxide trap density, semiconductor bulk defect density, contact and other parasitic resistances and oxide electrical integrity. This chapter will discuss several techniques that are used to determine these important parameters. However, it is not an extensive compilation of the electrical techniques currently used by the research and development community; rather, it presents a discussion of some of the more widely used and popular ones [20.1–4].

An important aspect of electrical characterization is the availability of appropriate test components [20.1–4]. In this chapter, we concentrate on discussing techniques that use standard test devices and structures. In addition, we will use the metal–oxide–semiconductor field-effect transistor (MOSFET) whenever possible because they are widely available on test chips. This is also motivated by the fact that MOSFETs continue to dominate the semiconductor industry for a wide range of applications from memories and microprocessors to signal and imaging processing systems [20.5]. A key reason for this dominance is the excellent quality of the silicon wafers and the silicon–silicon dioxide interface, both of which play critical roles in the performance and reliability of the device. For example, if the interface has many defects or interface states, or it is rough, then the device's carrier mobility decreases, low-frequency noise increases and its performance and reliability degrades. In particular, it is not only the interface that is important, but also the quality of the oxide; good-quality oxide prevents currents from flowing between the gate and substrate electrodes through the gate oxide. Both interface and oxide quality allows for excellent isolation between the input and output terminals of the MOSFETs, causing it to behave as an almost ideal switch. Therefore, it is important to have good experimental tools to study the interface properties and the quality of the gate dielectric.

Electrical characterization of semiconductors and the semiconductor–dielectric interface is important for a variety of reasons. For example, the defects at and in the interfacial oxide layer in silicon–silicon dioxide (Si–SiO_2) systems and in the bulk semiconductor play critical roles in their low-frequency noise, independent of whether the device is surface-controlled such as a MOSFET, or a bulk transport device such as a polysilicon emitter bipolar junction transistor (PE BJT). These defects can affect the charge transfer efficiency in charge coupled devices (CCDs), p–n photodiodes or complementary metal-oxide-semiconductor (CMOS) imagers, and can be the initiation point of catastrophic failure of oxides. Interface and bulk states can act as scattering centers to reduce the mobility in MOSFETs, thus affecting their performance parameters such as switching speed, transconductance and noise. This chapter is devoted to the electrical characterization of semiconductors, insulators and interfaces. In the first part (Sects. 20.1 and 20.2), the basic electrical properties of materials (such as resistivity, concentration and mobility of carriers) are studied. The main measurement techniques used to determine these electrical parameters are presented. Due to its increasing importance in modern ultrasmall geometry devices, electrical contacts are also studied. All of the characterization techniques presented in this first part are associated with specially designed test structures. In the second part (Sects. 20.4–20.7), we use active components such as capacitors, diodes and transistors (mainly MOSFETs) in order to determine more specific electrical parameters such as traps, oxide quality and noise level that are associated with material or devices. Of course this involves specific measurement techniques that are often more sophisticated than those discussed in the previous two sections.

20.1 Resistivity

Resistivity is one of the most important electrical parameters of semiconductors [20.1–4]. First, we present the basic physical relations concerning the bulk resistivity. The main electrical measurement techniques are then described: the two oldest ones that are still relevant today – the *four-point-probe* technique and the *van der Pauw* technique – and then the *spreading resistance* technique. Second, because it is closely linked with bulk resistivity measurement techniques and it is increasingly important in modern ultrasmall geometry devices, contact resistivity will be presented. Special attention will be given to *Kelvin contact resistance* (*KCR*) *measurement* and the *transmission line measurement* (*TLM*) techniques.

20.1.1 Bulk Resistivity

Physical Approach, Background and Basics

The bulk resistivity ρ is an intrinsic electrical property related to carrier drift in materials such as metals and semiconductors [20.6]. From a macroscopic point of view, the resistivity ρ can be viewed as the normalization of the bulk resistance (R) by its geometrical dimensions – the cross-sectional area ($A = Wt$) through

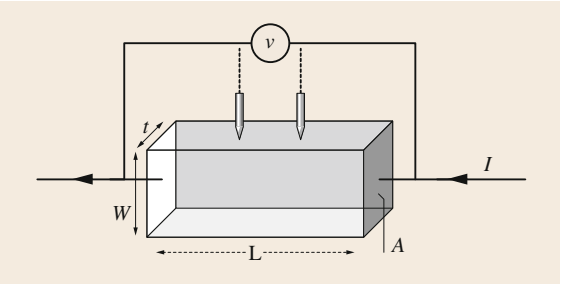

Fig. 20.1 Bulk resistance and its geometrical dimensions

which the current flows, and the distance between the two ideal contacts L, as shown in Fig. 20.1. The resistivity is given by

$$\rho = \frac{RA}{L} \quad \text{in } \Omega\,\text{m or commonly } \Omega\,\text{cm}. \tag{20.1}$$

For thin semiconductor layers, the sheet resistivity ρ_s is often used instead of the bulk resistivity ρ. The sheet resistivity ρ_s is the bulk resistivity divided by the sample's thickness t. This normalized parameter is related to the resistance of a square of side L. For this particular geometry in Fig. 20.1, since $A = Wt$, then $\rho_s = R_\square$, the sheet resistance. The unit of sheet resistance is Ω/square or $\Omega/\square$. The parameter $R_\square$ is convenient for integrated circuit designers because it allows them to quickly design the geometry for a specific value of resistance using very thin implanted or diffused semiconductor regions or polycrystalline layers. Resistivity (or its inverse, the conductivity σ in $\Omega^{-1}\,\text{cm}^{-1}$ or S/cm) and its variation with temperature is often used to classify material into metals, semiconductors and insulators.

Since different semiconductors can have the same resistivity, and also different values of resistivity can be found for a given semiconductor, depending on how it is processed for example, then resistivity is not a fundamental material parameter. From solid state theory, in the case of homogeneous semiconductor materials, the resistivity expresses the proportionality between the applied electric field E and the drift current density J; that is, $J = (1/\rho)\,E$. It can be defined by the microscopic relation

$$\rho = \frac{1}{q(n\mu_n + p\mu_p)}\,, \tag{20.2}$$

where q is the electronic charge, n and p are the free electron and hole concentrations, and μ_n and μ_p are the electron and hole drift mobilities, respectively. In this way, the resistivity is related to fundamental semiconductor parameters: the number of free carriers, and their ability to move in the lattice when an electric field is applied.

In n-type or donor (N_D)-doped, or p-type or acceptor (N_A)-doped semiconductors, the free carrier densities are determined by the ionized impurities (N_D or $N_A \gg$ the intrinsic carrier concentration n_i), then (20.2) can be simplified to

$$\rho \approx \frac{1}{qn\mu_n}\,, \text{ for an n-type semiconductor}\,, \tag{20.3}$$

$$\text{and } \rho \approx \frac{1}{qp\mu_p}\,, \text{ for a p-type semiconductor}\,. \tag{20.4}$$

In the following sections, only single-type semiconductors will be studied. This corresponds to most semiconductor materials used in electronic and optoelectronic devices because either $N_D \gg N_A$ or $N_A \gg N_D$ in a typical semiconductor layer.

Measurement Techniques
