Wastewater Engineering

Treatment and Reuse (Fourth Edition)

废水工程 处理与回用 （第4版）

本书为市政与环境工程专业废水处理方面的一本经典的、权威的教科书，并且是该专业人士的必备工具书。本书前3版分别于1972、1979、1991年出版。

本书主要内容包括：废水组分的确定、处理工艺的分析与选择、物理单元过程、化学单元过程、生物处理原理、悬浮生长和附着生长生物处理工艺、废水高级处理、消毒工艺、废水回用、生物固体的处理、处置及再利用、水处理厂运行的有关问题等。

在前3版内容的基础上，本书介绍了近十年来废水处理技术和法规方面的变化，并提供了该相关最新技术现状的信息，结合物理、化学和生物处理工艺阐述了废水处理的理论和设计问题，并扩充了废水生物处理的理论和设计部分。本书还对数据表进行了全面更新，并加入了新的设计实例，反映了工艺设计中的技术变化。

出版前言

在跨入21世纪之际，面临不断恶化的生存环境，人类清醒地认识到要走可持续发展之路。而发展环境教育是解决环境问题和实施可持续发展战略的根本。高等学校的环境教育，是提高新世纪建设者的环境意识，并向社会输送环境保护专门人才的重要途径。为了反映国外环境类教材的最新内容和编写风格，同时也为了提高学生阅读专业文献和获取信息的能力，我们精选了一些国外优秀的环境类教材，组成大学环境教育丛书(影印版)，本书即为其中的一册。所选教材均在国外被广泛采用，多数已再版，书中不仅介绍了有关概念、原理及技术方法，给出了丰富的数据，还反映了作者不同的学术观点。

我们希望这套丛书能对高等院校师生和广大科技人员有所帮助，同时对我国环境教育的发展作出贡献。

About the Authors

George Tchobanoglous is a professor emeritus of environmental engineering in the Department of Civil and Environmental Engineering at the University of California at Davis. He received a B S. degree in civil engineering from the University of the Pacific, an M.S. degree in sanitary engineering from the University of California at Berkeley, and a Ph.D. in environmental engineering from Stanford University. His principal research interests are in the areas of wastewater treatment, wastewater filtration, UV disinfection, aquatic wastewater management systems, solid waste management, and wastewater management for small systems. He has authored or coauthored over 350 technical publications, including 12 textbooks and two reference works. The textbooks are used in more than 200 colleges and universities throughout the United States. The textbooks and reference books are also used extensively by practicing engineers both in the United States and abroad. Professor Tchobanoglous serves nationally and internationally as consultant to both governmental agencies and private concerns. An active member of numerous professional societies, he is a past president of the Association of Environmental Engineering and Science Professors. He is a registered civil engineer in California.

Franklin L. Burton spent 30 years with Metcalf & Eddy serving as vice president and chief engineer in their western regional office in Palo Alto, CA. He received a B.S. degree in mechanical engineering from Lehigh University and an M.S. degree in civil engineering from the University of Michigan. He has been involved in the planning, design, and technical review of over 50 wastewater treatment plants. He was the coauthor of the third edition of this textbook. He retired from Metcalf & Eddy in 1986 and is in private practice in Los Altos, CA, specializing in treatment technology evaluation, energy management, facilities design review, and value engineering. He is a registered civil and mechanical engineer in California and is a life member of the American Society of Civil Engineers, Water Environment Federation, and the American Water Works Association.

H. David Stensel is a professor of civil and environmental engineering at the University of Washington, Seattle, WA. Prior to his academic positions, he spent 10 years in practice developing and applying industrial and municipal wastewater treatment processes. He received a B.S. degree in civil engineering from Union College, Schenectady, NY, and M.E. and Ph.D. degrees in environmental engineering from Cornell University. His principal research interests are in the areas of wastewater treatment, biological nutrient removal, sludge processing methods, biodegradation of hazardous substances, and stormwater treatment. He has authored or coauthored over 100 technical publications and a textbook on biological nutrient removal. He has received the ASCE Rudolf Hering Medal and twice received the Water Environment Federation Harrison

Prescott Eddy Medal for his research contributions. He is a member of numerous professional societies, and has served as chair of the ASCE Environmental Engineering Division, treasurer of the American Association of Environmental Engineering Professors, and associate editor of the *Water Environment Federation Research Journal.* He is a registered professional engineer and a diplomate in the American Academy of Environmental Engineers.

Preface

During the past 12 years since the publication of the third edition of this textbook, the number of new developments and changes that have occurred in the field of wastewater engineering has been dramatic, especially with respect to

(1) the characterization of the constituents found in wastewater, both in terms of the range of constituents and the detection limits;
(2) a greater fundamental understanding of the mechanisms of biological wastewater treatment;
(3) the application of advanced treatment methods for the removal of specific constituents;
(4) the increased emphasis on the management of the biosolids resulting from the treatment of wastewater; and
(5) the issuance of more comprehensive and restrictive permit requirements for the discharge and reuse of treated wastewater.

The fourth edition of this textbook has been prepared to address the significant new developments and changes that have occurred in the field and to correct other issues with the third edition to make the fourth edition more user friendly. For example, the theory and practice chapters, separated in the third edition, are now combined in the fourth edition to provide subject continuity and eliminate redundancy. Because of the importance of biological wastewater treatment, four separate chapters have been devoted to this subject. The chapter on advanced wastewater treatment has been expanded to include processes that are increasingly required to meet more stringent discharge requirements. A new chapter on disinfection has been added to deal with recent developments in the field. The chapter on reclamation and reuse has been revised completely and much new material has been added. Because of the importance of biosolids management, an entire chapter is devoted to this subject. The issues of process design and performance to meet more stringent permit requirements, including the upgrading of existing treatment plants, are considered in Chapter 15.

IMPORTANT FEATURES OF THIS BOOK

Following the practice in the third edition, more than 100 new example problems have been worked out in detail to enhance the readers' understanding of the basic concepts presented in the text. Wherever possible, spreadsheet solutions are presented. To aid in the planning, analysis, and design of wastewater management systems, design data and information are summarized and presented in more than 300 tables, most of which are new. To illustrate the principles and facilities involved in the field of wastewater management, over 570 illustrations, graphs, diagrams, and photographs are included. To help the readers of this textbook hone their analytical skills and mastery of the material,

problems and discussion topics are included at the end of each chapter. Selected references are also provided for each chapter.

The International System (SI) of Units is used in the fourth edition. The use of SI units is consistent with teaching practice in most U.S. universities and in many countries throughout the world. In general, dual sets of units (i.e., SI and U.S. customary) have been used for the data tables. Where the use of double units was not possible, conversion factors are included as a footnote to the table.

To further increase the utility of this textbook, several appendixes have been included. Conversion factors from International System (SI) of Units to U.S. Customary Units and the reverse are presented in Appendixes A–1 and A–2, respectively. Conversion factors commonly used for the analysis and design of wastewater management systems are presented in Appendix A–3. Abbreviations for SI and U.S. Customary units are presented in Appendixes A-4 and A–5, respectively. Physical characteristics of air and selected gases and water are presented in Appendixes B and C, respectively. Dissolved oxygen concentrations in water as a function of temperature are presented in Appendix D. Tables of most probable numbers (MPN) are presented in Appendix E, carbonate equilibrium is considered in Appendix F, and Moody diagrams for the analysis of flow in pipes are presented in Appendix G.

USE OF THIS BOOK

Enough material is presented in this textbook to support a variety of courses for one or two semesters or three quarters at either the undergraduate or graduate level. The specific topics to be covered will depend on the time available and the course objectives. Suggested course outlines follow.

For a one-semester introductory course on wastewater treatment, the following material is suggested:

Topic	Chapter	Sections
Introduction to wastewater treatment	1	All
Wastewater characteristics	2	All
Wastewater flowrates and constituent loadings	3	All
Introduction to process analysis	4	All
Physical unit operations	5	5–1 to 5–8
Chemical unit operations	6	6–1, 6–2,
Introduction to biological treatment of wastewater	7	All
Disinfection	12	12–1 to 12–5, 12–9
Water reuse	13	13–1 to 13–2
Biosolids management	14	All
Introduction to treatment plant performance	15	15–1 to 15–3

For a two-semester course on wastewater treatment, the following material is suggested:

Topic	Chapter	Sections
Introduction to wastewater treatment	1	All
Wastewater characteristics	2	All
Wastewater flowrates and constituent loadings	3	All
Introduction to process analysis	4	All
Introduction to treatment plant performance	15	15–1 to 15–3
Physical unit operations	5	All
Chemical unit operations	6	All
Introduction to biological treatment of wastewater	7	All
Suspended growth biological treatment processes	8	All
Attached growth and combined biological treatment processes	9	9–1 to 9–5
Anaerobic suspended and attached growth treatment processes	10	10–1, 10–2, 10–4
Disinfection	12	All
Water reuse	13	All
Biosolids management	14	All
Process control and upgrading treatment plant performance	15	15–3 to 15–7

For a one-semester course on biological wastewater treatment, the following material is suggested:

Topic	Chapter	Sections
Introduction to wastewater treatment	1	All
Wastewater characteristics	2	All
Introduction to process analysis	4	All
Introduction to treatment plant performance	15	15–1 to 15–3
Introduction to biological treatment of wastewater	7	All
Suspended growth biological treatment processes	8	All
Attached growth and combined biological treatment processes	9	All
Anaerobic suspended and attached growth treatment processes	10	All
Anaerobic and aerobic digestion and composting	14	14–9 to 14–11

For a one-semester course on wastewater reclamation and reuse, the following material is suggested:

Topic	Chapter	Sections
Introduction to wastewater treatment	1	All
Wastewater characteristics	2	All
Introduction to water reclamation and reuse	13	13–1
Introduction to risk assessment	13	13–3
Introduction to treatment plant performance	15	15–1 to 15–3
Advanced wastewater treatment (optional)	11	11–6
Disinfection	12	12–1 to 12–5, 12–7 to 12–9
Water reclamation technologies	13	13–4
Storage of reclaimed water	13	13–5
Reuse of reclaimed water	13	13–6 to 13–9
Planning consideration for reclamation and reuse	13	10

For a one-semester course on physical and chemical unit operations and processes, the following material is suggested. It should be noted that material listed below could be supplemented with additional examples from water treatment.

Topic	Chapter	Sections
Introduction to process analysis	4, 15	All
Introduction to treatment plant performance	15	15–1 to 15–3
Introduction to physical unit operations		
Mixing and flocculation	5	5–4
Sedimentation	5	5–5, 5–7, 5–8
Gas transfer	5	5–11 to 5–12
Filtration (conventional depth filtration)	11	11–3, 11–4
Membrane filtration	11	11–6
Adsorption	11	11–7
Gas stripping	5, 11	5–13, 11–8
UV disinfection	12	12–9
Introduction to chemical unit processes		6–2
Coagulation	6	6–2
Chemical precipitation	6	6–3 to 6–5
Ion exchange	11	11–9
Water stabilization	6	6–7
Chemical oxidation (conventional)	6	6–6
Advanced oxidation processes	11	11–9

ACKNOWLEDGMENTS

A book of this magnitude could not have been written without the assistance of numerous individuals. First and foremost, Mr. Harold Leverenz, a doctoral candidate at the University of California at Davis, provided exceptional assistance. He read and commented on all of the drafts, checked the problems, and prepared many of the new figures for this text. In addition, he helped review the page proofs. His devotion to the task of making this book student-friendly was beyond the call of duty.

Other individuals who contributed, arranged in alphabetical order, are: Mr. Mike Anderson of Nolte and Associates, reviewed portions of the text and worked several design examples; Professor Takashi Asano of the University of California at Davis, the 2001 Stockholm Water Prize recipient, revised Chap. 13, which he had contributed to the third edition; Dr. Keith Bourgeous of Carollo Engineers contributed and reviewed portions of Chap. 11; Mr. Max Burchett of Whitley Burchett & Associates in numerous discussions over many years has contributed valuable insights on the application of theory to practice; Ing. Ermanno Cacciari of Austep Environmental Protection, Milan, Italy, contributed to the section on anaerobic sludge blanket processes in Chap. 10; Dr. Robert Cooper of BioVir laboratories reviewed and provided valuable input for Chap. 2; Professor John C. Crittenden of Michigan Technological University reviewed Chap. 4 and the section on carbon adsorption in Chap. 11; Dr. Alex Ekster, of Ekster and Associates, contributed the sections on process control optimization in Chap. 15; Dr. Robert Emerick of Ecologic Engineers, contributed the section on UV disinfection in Chap. 11; Mr. William Hartnett of Montgomery/Watson contributed writeups on program logic controllers and piping and instrument diagrams in Chap. 15; Dr. Tim Haug of the City of Los Angeles reviewed and provided valuable insight on Chaps. 7 through 10 and 15; Professor David Jenkins of the University of California at Berkeley, provided photomicrographs of filamentous microorganisms; Ms. Sarah Mayhew printed most of the photographs; Ms. Margie Nellor of the County Sanitation Districts of Los Angeles County provided a photograph of the Rio Hondo spreading basins, Professor Kara Nelson of the University of California at Berkeley reviewed Chap. 2; Mr. Andrew Salveson of Whitley Burchett & Associates, reviewed Chaps. 2 and 4 and provided data for Chap. 11; Professor Edward D. Schroeder of the University of California at Davis reviewed an early draft of Chap. 7 and provided valuable organizational and technical comments and guidance, and as a colleague of 30 years, Professor Schroeder has contributed significantly to the education of the senior author; Dr. Richard E. Speece of Vanderbilt University reviewed the section on anaerobic digestion in Chap. 14 and provided valuable insight; Mr. Jeff Sollar of EOA, contributed to the probabilistic analysis of multiple processes in Chap. 13; Dr. Rhodes Trussell of Montgomery/Watson in numerous discussions offered valuable insights on disinfection, flocculation, and mixing processes; and Mr. Mike Weiner of the Orange County Water District provided a photograph of the water spreading basins in Orange County. The collective efforts of these individuals is invaluable.

Reviewers, selected by the publisher, who were asked to assess and comment on the prospectus for the fourth edition included Professor James J. Bisogni Jr. of Cornell University, Professor Alan R. Bowers of Vanderbilt University, Professor Jeff Kuo, of California State University at Fullerton, Professor Bruce Logan of Pennsylvania State University, Professor John A. Olofsson of the University of Alaska at Anchorage, and

Professor Tian C. Zhang of the University of Nebraska at Lincoln. Their input, early on, helped guide the development of the final format of the fourth edition. Their contributions are gratefully acknowledged.

The reviewers, selected by the publisher, who read the entire manuscript of the fourth edition, were Professor Syed A. Hashsham of Michigan State University; Professor Robert Lang of California Polytechnic University at San Luis Obispo; Professor John T. Novak of Virginia Polytechnic Institute and State University; and Professor Robert M. Sykes of Ohio State University. They provided valuable and timely comments that improved the content, organization, and readability of this textbook. Their contributions were significant and are acknowledged gratefully.

The assistance of the staff of Metcalf & Eddy in the preparation of this text is also acknowledged. The efforts of Mr. James Anderson were especially important in making this book possible and in managing the resources made available by Metcalf & Eddy to the authors. Mr. Jonathan Doane organized the team of staff reviewers and provided liaison between the authors and the reviewers. Valuable comments were provided that reflect current design practice in both the United States and overseas.

The McGraw-Hill staff was also critical to the production of this textbook. Mr. Eric Munson, formerly of McGraw-Hill, was instrumental in the early development of this project. Ms. Amy Hill, Developmental Editor, served as the overall project manager. Her organizational skills and tireless efforts on our behalf have made this book a reality. Her sunny personality was also a great help. Ms. Kay J. Brimeyer served as production coordinator and helped keep all of the loose ends together, while maintaining her sense of humor. Ms. Susan Sexton served as the technical editor. The publishers were Mr. Tom Casson and Ms. Betsy Jones.

Finally to Rosemary Tchobanoglous and Nancy Burton who suffered, supported, and encouraged us through the writing of this textbook, we are eternally grateful. Support for Dave Stensel by Carleen Clark and Pat Halikas was especially helpful.

Foreword

Almost 90 years have passed since Metcalf & Eddy first published *American Sewage Practice,* the legendary three-volume treatise that established design standards for sewerage facilities. Subsequently, the three volumes were combined into a single text, *Sewerage and Sewage Disposal,* in 1922 and a second edition was published in 1930 for class use in engineering schools. In 1972, a new version of the textbook was published, *Wastewater Engineering: Collection, Treatment, and Disposal,* followed in 1979 by a second edition, *Wastewater Engineering: Treatment, Disposal, Reuse.* A companion textbook, *Wastewater Engineering: Collection and Pumping of Wastewater,* was also published in 1981. The most recent publication was the third edition of *Wastewater Engineering* in 1991. Even though the wastewater practice has continued to evolve and grow during this period, no time period in the past can equal the last decade in terms of technological development.

In addition, the awareness of environmental issues among the U.S and world communities has reached a level not seen before. This active awareness is driving our industry to achieve levels of performance far beyond those envisioned even as recently as the last decade. This fourth edition of *Wastewater Engineering* incorporates these concepts as an essential part of a central theme. As a result, the fourth edition has been designed with a forward-looking focus. For example, emerging fields of biological process modeling and genetic engineering are addressed with some predictions on where these concepts may fit into future wastewater engineering activities.

Since the third edition was published in 1991, much focus in the wastewater practice has turned to nutrient removal, with particular emphasis on biological nutrient removal (BNR). Research in this field is being carried on worldwide, and new discoveries that challenge some of the conventional theory continue to be made. The chapters in the fourth edition that pertain to biological processes and BNR are therefore essentially new. They deal with both research results and their applications to wastewater engineering design.

Pressure for environmental compliance today is greater than ever. Regulatory requirements are, as always, present and forceful. Support from the community for environment-related programs is becoming a stronger driving force than ever before. *Stakeholders,* as they are often referred to, are quite demanding, well organized, and informed. They challenge wastewater engineers to stretch the performance of existing infrastructure through applied research programs. This concept, referred to by Metcalf & Eddy as "infrastretching," represents one of the most significant challenges to the practice of wastewater engineering in the new century.

ACKNOWLEDGMENTS

Metcalf & Eddy, Inc. has been privileged to have as our principal authors Dr. George Tchobanoglous of the University of California at Davis; Franklin L. Burton, a retired vice president of Metcalf & Eddy; and Dr. David Stensel of the University of Washington.

The principal authors were responsible for scope of the textbook, writing, editing, and coordination with the reviewers and the publisher. Two of our principal authors have enjoyed a long association with the textbook. The third principal author, Dr. Stensel, has joined the team for the fourth edition. Dr. Tchobanoglous was the principal author for the first three editions of this text and for the first two editions of the companion volume, *Wastewater Engineering: Collection and Pumping of Wastewater.* Mr. Burton was technical reviewer for the second edition of this text and the companion text and a principal author for the third edition.

The staff of Metcalf & Eddy played a significant role in the preparation of this edition. We acknowledge the contributions of the following members of the staff for their valuable efforts in review of manuscripts:

Kevin L. Anderson	Jonathan W. Doane
David P. Bova	Robert Gay
John G. Chalas	Charles E. Pound

We would also like to offer our sincere gratitude to Dr. Roger T. Haug for his review of the chapters that cover biological wastewater treatment processes. Dr. Haug's comments were very helpful with respect to achieving one of our goals: the presentation of wastewater engineering in a forward-looking fashion.

Special appreciation is extended to Jonathan W. Doane for his efforts in managing Metcalf & Eddy's efforts and to John G. Chalas, the former director of technology of Metcalf & Eddy, now retired, who served as special advisor.

An effort such as this fourth edition could not be successful without the professional encouragement and support of corporate management. We gratefully acknowledge the contributions of Robert H. Fisher, chairman and CEO of Metcalf & Eddy, Inc., and John Somerville, president of Metcalf & Eddy. We would also like to acknowledge the vision of our parent company, AECOM Technologies, Inc., acting through Richard Newman, chairman, and Raymond Holdsworth, president, for the commitment they made to complete this effort and to pave the way for future editions.

Metcalf & Eddy would like to make special note of the passing in 2001 of Harry L. Kinsel, a former president of Metcalf & Eddy. Harry Kinsel was known for his professionalism and commitment to education. Metcalf & Eddy established an internal competition for technical papers in 1973 in Harry Kinsel's honor and this competition will continue as an inspiration to Metcalf & Eddy staff and the industry.

Finally, I would like to personally express my appreciation to the entire team of authors, editors, and reviewers for their tireless effort, and the senior management of Metcalf & Eddy, Inc., and AECOM Technologies, Inc., for the opportunity to direct this effort for Metcalf & Eddy.

James Anderson
Senior Vice President
Chief Engineer
Metcalf & Eddy, Inc.

2 Constituents in Wastewater 27

2–1 Wastewater Constituents 29
Constituents Found in Wastewater 29
Constituents of Concern in Wastewater Treatment 29
2–2 Sampling and Analytical Procedures 29
Sampling 29
Methods of Analysis 34
Units of Measurement for Physical and Chemical Parameters 35
Useful Chemical Relationships 35
2–3 Physical Characteristics 42
Solids 42
Particle Size Distribution 48
Turbidity 51
Color 52
Absorption/Transmittance 52
Temperature 54
Conductivity 56
Density, Specific Gravity, and Specific Weight 56
2–4 Inorganic Nonmetallic Constituents 57
pH 57
Chlorides 59
Alkalinity 59
Nitrogen 60
Phosphorus 63
Sulfur 64
Gases 64
Odors 70
2–5 Metallic Constituents 77
Importance of Metals 77
Sources of Metals 77
Sampling and Methods of Analysis 77
Typical Effluent Discharge Limits for Metals 78
2–6 Aggregate Organic Constituents 80
Measurement of Organic Content 81
Biochemical Oxygen Demand (BOD) 81
Total and Soluble Chemical Oxygen Demand (COD and SCOD) 93
Total and Dissolved Organic Carbon (TOC and DTOC) 94
UV-Absorbing Organic Constituents 95

Theoretical Oxygen Demand (ThOD) 96
Interrelationships between BOD, COD, and TOC 96
Oil and Grease 98
Surfactants 98
2–7 Individual Organic Compounds 99
Priority Pollutants 99
Analysis of Individual Organic Compounds 100
Volatile Organic Compounds (VOCs) 100
Disinfection Byproducts 102
Pesticides and Agricultural Chemicals 102
Emerging Organic Compounds 102
2–8 Biological Characteristics 104
Microorganisms Found in Surface Waters and Wastewater 104
Pathogenic Organisms 109
Use of Indicator Organisms 115
Enumeration and Identification of Bacteria 118
Enumeration and Identification of Viruses 126
Polymerase Chain Reaction (PCR) 129
Development of Microorganisms Typing Techniques 130
New and Reemerging Microorganisms 130
2–9 Toxicity Tests 130
Toxicity Terminology 131
Toxicity Testing 133
Analysis of Toxicity Test Results 134
Application of Toxicity Test Results 136
Identification of Toxicity Components 137

3 Analysis and Selection of Wastewater Flowrates and Constituent Loadings 153
3–1 Components of Wastewater Flows 154
3–2 Wastewater Sources and Flowrates 154
Domestic Wastewater Sources and Flowrates 155
Strategies for Reducing Interior Water Use and Wastewater Flowrates 158
Water Use in Developing Countries 162
Sources and Rates of Industrial (Nondomestic) Wastewater Flows 162
Infiltration/Inflow 163
Exfiltration from Collection Systems 167
Combined System Flowrates 168
3–3 Statistical Analysis of Flowrates, Constituent Concentrations, and Mass Loadings 170
Common Statistical Parameters 170
Graphical Analysis of Data 171
3–4 Analysis of Wastewater Flowrate Data 178
Definition of Terms 178
Variations in Wastewater Flowrates 179
Wastewater Flowrate Factors 180
3–5 Analysis of Constituent Mass Loading Data 181
Wastewater Constituent Concentrations 181
Variations in Constituent Concentrations 185
Flow-Weighted Constituent Concentrations 192
Calculation of Mass Loadings 194
Effect of Mass Loading Variability on Treatment Plant Performance 197
3–6 Selection of Design Flowrates and Mass Loadings 197
Design Flowrates 199
Design Mass Loadings 205

4 Introduction to Process Analysis and Selection 215
4–1 Reactors Used for the Treatment of Wastewater 218
Types of Reactors 218
Application of Reactors 220
Hydraulic Characteristics of Reactors 220
4–2 Mass-Balance Analysis 222
The Mass-Balance Principle 222
Preparation of Mass Balances 224
Application of the Mass-Balance Analysis 224
Steady-State Simplification 225
4–3 Modeling Ideal Flow in Reactors 226
Ideal Flow in Complete-Mix Reactor 226
Ideal Flow in Plug-Flow Reactor 227

4–4 Analysis of Nonideal Flow in Reactors Using Tracers 229
Factors Leading to Nonideal Flow in Reactors 229
Need for Tracer Analysis 231
Types of Tracers 231
Conduct of Tracer Tests 231
Analysis of Tracer Response Curves 233
Practical Interpretation of Tracer Measurements 242
4–5 Modeling Nonideal Flow in Reactors 245
The Distinction between Molecular Diffusion, Turbulent Diffusion, and Dispersion 245
Plug-Flow Reactor with Axial Dispersion 246
Complete-Mix Reactors in Series 252
4–6 Reactions, Reaction Rates, and Reaction Rate Coefficients 257
Types of Reactions 257
Rate of Reaction 258
Reaction Order 259
Types of Rate Expressions 260
Rate Expressions Used in Environmental Modeling 261
Effects of Temperature on Reaction Rate Coefficients 261
Analysis of Reaction Rate Coefficients 264
4–7 Modeling Treatment Process Kinetics 269
Batch Reactor with Reaction 269
Complete-Mix Reactor with Reaction 270
Complete-Mix Reactors in Series with Reaction 271
Ideal Plug-Flow Reactor with Reaction 274
Comparison of Complete-Mix and Plug-Flow Reactors with Reaction 275
Ideal Plug-Flow Reactor with Retarded Reaction 277
Plug-Flow Reactor with Axial Dispersion and Reaction 279
Other Reactor Flow Regimes and Reactor Combinations 281
4–8 Treatment Processes Involving Mass Transfer 283
Basic Principle of Mass Transfer 283
Gas-Liquid Mass Transfer 284
Liquid-Solid Mass Transfer 293
4–9 Introduction to Process Selection 297
Important Factors in Process Selection 297
Process Selection Based on Reaction Kinetics 299
Process Selection Based on Mass Transfer 300
Process Design Based on Loading Criteria 301
Bench Tests and Pilot-Plant Studies 301
Reliability Considerations in Process Selection 301

5 Physical Unit Operations 311
5–1 Screening 315
Classification of Screens 315
Coarse Screens (Bar Racks) 316
Fine Screens 322
Microscreens 326
Screenings Characteristics and Quantities 327
5–2 Coarse Solids Reduction 330
Comminutors 331
Macerators 332
Grinders 333
Design Considerations 333
5–3 Flow Equalization 333
Description/Application 333
Design Considerations 335
5–4 Mixing and Flocculation 344
Continuous Rapid Mixing in Wastewater Treatment 345
Continuous Mixing in Wastewater Treatment 345
Energy Dissipation in Mixing and Flocculation 347
Timescale in Mixing 350
Types of Mixers Used for Rapid Mixing in Wastewater Treatment 350
Types of Mixers Used for Flocculation in Wastewater Treatment 355
Types of Mixers Used for Continuous Mixing in Wastewater Treatment 359

New Developments in Mixing Technology 361

5–5 Gravity Separation Theory 361
Description 362
Particle Settling Theory 363
Discrete Particle Settling 367
Flocculent Particle Settling 372
Inclined Plate and Tube Settling 374
Hindered (Zone) Settling 378
Compression Settling 383
Gravity Separation in an Accelerated Flow Field 383

5–6 Grit Removal 384
Types of Grit Chambers 385
Horizontal-Flow Grit Chambers 385
Aerated Grit Chambers 386
Vortex-Type Grit Chambers 392
Solids (Sludge) Degritting 392
Grit Characteristics, Quantities, Processing, and Disposal 394

5–7 Primary Sedimentation 396
Description 397
Sedimentation Tank Performance 405
Design Considerations 406
Characteristics and Quantities of Solids (Sludge) and Scum 411

5–8 High-Rate Clarification 411
Enhanced Particle Flocculation 412
Analysis of Ballasted Particle Flocculation and Settling 412
Process Application 414

5–9 Large-Scale Swirl and Vortex Separators for Combined Wastewater and Stormwater 417

5–10 Flotation 419
Description 419
Design Considerations for Dissolved-Air Flotation Systems 422

5–11 Oxygen Transfer 425
Description 425
Evaluation of Oxygen Transfer Coefficient 425

5–12 Aeration Systems 430
Types of Aeration Systems 430
Diffused-Air Aeration 430
Mechanical Aerators 443
Energy Requirement for Mixing in Aeration Systems 448
Generation and Dissolution of High-Purity Oxygen 448
Postaeration 452

5–13 Removal of Volatile Organic Compounds (VOCs) by Aeration 456
Emission of VOCs 456
Mass Transfer Rates for VOCs 457
Mass Transfer of VOCs from Surface and Diffused-Air Aeration Processes 459
Control Strategies for VOCs 463

6 Chemical Unit Processes 475

6–1 Role of Chemical Unit Processes in Wastewater Treatment 476
Application of Chemical Unit Processes 477
Considerations in the Use of Chemical Unit Processes 478

6–2 Fundamentals of Chemical Coagulation 478
Basic Definitions 479
Nature of Particles in Wastewater 480
Development and Measurement of Surface Charge 481
Particle-Particle Interactions 482
Particle Destabilization with Potential-Determining Ions and Electrolytes 483
Particle Destabilization and Aggregation with Polyelectrolytes 485
Particle Destabilization and Removal with Hydrolyzed Metal Ions 486

6–3 Chemical Precipitation for Improved Plant Performance 493
Chemical Reactions in Wastewater Precipitation Applications 493
Enhanced Removal of Suspended Solids in Primary Sedimentation 497
Independent Physical-Chemical Treatment 498
Estimation of Sludge Quantities from Chemical Precipitation 499

6–4 Chemical Precipitation for Phosphorus Removal 500

Chemistry of Phosphate Precipitation 501
Strategies for Phosphorus Removal 503
Phosphorus Removal Using Metal Salts and Polymers 505
Phosphorus Removal Using Lime 507
Phosphorus Removal with Effluent Filtration 508
Comparison of Chemical Phosphorus Removal Processes 508
Estimation of Sludge Quantities from Phosphorus Precipitation 509

6–5 Chemical Precipitation for Removal of Heavy Metals and Dissolved Inorganic Substances 514
Precipitation Reactions 514
Coprecipitation with Phosphorus 517

6–6 Chemical Oxidation 517
Fundamentals of Chemical Oxidation 517
Applications 522
Chemical Oxidation of BOD and COD 523
Chemical Oxidation of Ammonia 524

6–7 Chemical Neutralization, Scale Control, and Stabilization 526
pH Adjustment 526
Analysis of Scaling Potential 528
Scaling Control 532
Stabilization 532

6–8 Chemical Storage, Feeding, Piping, and Control Systems 532
Chemical Storage and Handling 533
Dry Chemical-Feed Systems 533
Liquid Chemical-Feed Systems 536
Gas Chemical-Feed Systems 537
Initial Chemical Mixing 540

7 Fundamentals of Biological Treatment 545

7-1 Overview of Biological Wastewater Treatment 547
Objectives of Biological Treatment 548
Some Useful Definitions 548
Role of Microorganisms in Wastewater Treatment 548
Types of Biological Processes for Wastewater Treatment 551

7-2 Composition and Classification of Microorganisms 555
Cell Components 555
Cell Composition 557
Environmental Factors 558
Microorganism Identification and Classification 559
Use of Molecular Tools 561

7-3 Introduction to Microbial Metabolism 563
Carbon and Energy Sources for Microbial Growth 563
Nutrient and Growth Factor Requirements 565

7-4 Bacterial Growth and Energetics 565
Bacterial Reproduction 566
Bacterial Growth Patterns in a Batch Reactor 566
Bacterial Growth and Biomass Yield 567
Measuring Biomass Growth 567
Estimating Biomass Yield and Oxygen Requirements from Stoichiometry 568
Estimating Biomass Yield from Bioenergetics 571
Stoichiometry of Biological Reactions 578
Biomass Synthesis Yields for Different Growth Conditions 579
Observed versus Synthesis Yield 580

7-5 Microbial Growth Kinetics 580
Microbial Growth Kinetics Terminology 581
Rate of Utilization of Soluble Substrates 581
Other Rate Expressions for the Utilization of Soluble Substrate 582
Rate of Soluble Substrate Production from Biodegradable Particulate Organic Matter 583
Rate of Biomass Growth with Soluble Substrates 584
Kinetic Coefficients for Substrate Utilization and Biomass Growth 584
Rate of Oxygen Uptake 585
Effects of Temperature 585
Total Volatile Suspended Solids and Active Biomass 586
Net Biomass Yield and Observed Yield 587

7-6 Modeling Suspended Growth Treatment Processes 588
Description of Suspended Growth Treatment Processes 589
Biomass Mass Balance 589
Substrate Mass Balance 592
Mixed Liquor Solids Concentration and Solids Production 592
The Observed Yield 595
Oxygen Requirements 595
Design and Operating Parameters 598
Process Performance and Stability 600
Modeling Plug-Flow Reactors 601

7-7 Substrate Removal in Attached Growth Treatment Processes 602
Substrate Flux in Biofilms 604
Substrate Mass Balance for Biofilm 605
Substrate Flux Limitations 606

7-8 Aerobic Biological Oxidation 607
Process Description 608
Microbiology 608

Stoichiometry of Aerobic Biological Oxidation 609
Growth Kinetics 610
Environmental Factors 610
7–9 Biological Nitrification 611
Process Description 611
Microbiology 611
Stoichiometry of Biological Nitrification 612
Growth Kinetics 614
Environmental Factors 615
7–10 Biological Denitrification 616
Process Description 616
Microbiology 618
Stoichiometry of Biological Denitrification 619
Growth Kinetics 621
Environmental Factors 623
7–11 Biological Phosphorus Removal 623
Process Description 624
Microbiology 625
Stoichiometry of Biological Phosphorus Removal 627
Growth Kinetics 629
Environmental Factors 629
7–12 Anaerobic Fermentation and Oxidation 629
Process Description 630
Microbiology 631
Stoichiometry of Anaerobic Fermentation and Oxidation 633
Growth Kinetics 634
Environmental Factors 635
7–13 Biological Removal of Toxic and Recalcitrant Organic Compounds 635
Development of Biological Treatment Methods 635
Anaerobic Degradation 637
Aerobic Biodegradation 638
Abiotic Losses 638
Modeling Biotic and Abiotic Losses 640
7–14 Biological Removal of Heavy Metals 644

8 Suspended Growth Biological Treatment Processes 659

8–1 Introduction to the Activated-Sludge Process 661
Historical Development 661
Description of Basic Process 661
Evolution of the Activated-Sludge Process 663
Recent Process Developments 664
8–2 Wastewater Characterization 666
Key Wastewater Constituents for Process Design 666
Measurement Methods for Wastewater Characterization 671
Recycle Flows and Loadings 676
8–3 Fundamentals of Process Analysis and Control 676
Process Design Considerations 677
Process Control 689
Operational Problems 694
Activated-Sludge Selector Processes 700
8–4 Processes for BOD Removal and Nitrification 703
Process Design Considerations 704
Complete-Mix Activated-Sludge Process 705
Sequencing Batch Reactor Process 720
Staged Activated-Sludge Process 734
Alternative Processes for BOD Removal and Nitrification 738
Process Design Parameters 740
Process Selection Considerations 740
8–5 Processes for Biological Nitrogen Removal 749
Overview of Biological Nitrogen-Removal Processes 750
Single-Sludge Biological Nitrogen-Removal Processes 750
Process Design Considerations 753
Anoxic/Aerobic Process Design 761
Step-Feed Anoxic/Aerobic Process Design 765
Intermittent Aeration Process Design 776
Postanoxic Endogenous Denitrification 780
Sequencing Batch Reactor Process Analysis 781
Postanoxic Denitrification with an External Carbon Source 784
Nitrogen Removal in Anaerobic Digestion Recycle Streams 788

Alternative Process Configurations for Biological Nitrogen Removal 789
Process Design Parameters 789
Process Selection Considerations 789

8–6 Processes for Biological Phosphorus Removal 799
Biological Phosphorus-Removal Processes 799
Process Design Considerations 801
Process Control 804
Solids Separation Facilities 805
Methods to Improve Phosphorus-Removal Efficiency in BPR Systems 805
Biological Phosphorus-Removal Process Performance 807
Alternative Processes for Biological Phosphorous Removal 809
Process Design Parameters 809
Process Selection Considerations 809

8–7 Selection and Design of Physical Facilities for Activated-Sludge Processes 816
Aeration System 816
Aeration Tanks and Appurtenances 816
Solids Separation 820
Design of Solids Separation Facilities 833

8–8 Suspended Growth Aerated Lagoons 840
Types of Suspended Growth Aerated Lagoons 841
Process Design Considerations for Flow-Through Lagoons 843
Dual-Powered Flow-Through Lagoon System 853

8–9 Biological Treatment with Membrane Separation 854
Overview of Membrane Biological Reactors 854
Process Description 855
Membrane Fouling Control 857
Process Capabilities 858

8–10 Simulation Design Models 859
Model Matrix Format, Components, and Reactions 860
Model Applications 861

9 Attached Growth and Combined Biological Treatment Processes 887

9–1 Background 888
Evolution of Attached Growth Processes 888
Mass Transfer Limitations 890

9–2 Trickling Filters 890
Trickling Filter Classification and Applications 893
Design of Physical Facilities 896
Process Design Considerations 909
Nitrification Design 922

9–3 Rotating Biological Contactors 930
Process Design Considerations 932
Physical Facilities for RBC Process 935
RBC Process Design 937

9–4 Combined Aerobic Treatment Processes 940
Trickling Filter/Solids Contact and Trickling Filter/Activated-Sludge Processes 940
Activated Biofilter and Biofilter Activated-Sludge Processes 943
Series Trickling Filter-Activated-Sludge Process 944
Design Considerations for Combined Trickling Filter Activated-Sludge Systems 944

9–5 Activated Sludge with Fixed-Film Packing 952
Processes with Internal Suspended Packing for Attached Growth 952
Processes with Internal Fixed Packing for Attached Growth 955

9–6 Submerged Attached Growth Processes 957
Downflow Submerged Attached Growth Processes 957
Upflow Submerged Attached Growth Processes 959
Fluidized-Bed Bioreactors (FBBR) 961

9–7 Attached Growth Denitrification Processes 962
Downflow Packed-Bed Postanoxic Denitrification Processes 962
Upflow Packed-Bed Postanoxic Denitrification Reactors 967
Fluidized-Bed Reactors for Postanoxic Denitrification 967
Submerged Rotating Biological Contactors 969
Attached Growth Preanoxic Denitrification Processes 969

10 Anaerobic Suspended and Attached Growth Biological Treatment Processes 983

10-1 The Rationale for Anaerobic Treatment 984
Advantages of Anaerobic Treatment Processes 984
Disadvantages of Anaerobic Treatment Processes 986
Summary Assessment 986

10-2 General Design Considerations for Anaerobic Treatment Processes 986
Characteristics of the Wastewater 987
Solids Retention Time 991
Expected Methane Gas Production 992
Treatment Efficiency Needed 994
Sulfide Production 994
Ammonia Toxicity 995
Liquid-Solids Separation 996

10-3 Anaerobic Suspended Growth Processes 996
Complete-Mix Process 997
Anaerobic Contact Process 997
Anaerobic Sequencing Batch Reactor 999
Design of Anaerobic Suspended Growth Processes 999

10-4 Anaerobic Sludge Blanket Processes 1005
Upflow Sludge Blanket Reactor Process 1005
Design Considerations for UASB Process 1007
Anaerobic Baffled Reactor 1016
Anaerobic Migrating Blanket Reactor 1017

10-5 Attached Growth Anaerobic Processes 1018
Upflow Packed-Bed Attached Growth Reactor 1019
Upflow Attached Growth Anaerobic Expanded-Bed Reactor 1020
Attached Growth Anaerobic Fluidized-Bed Reactor 1020
Downflow Attached Growth Processes 1022

10-6 Other Anaerobic Treatment Processes 1024
Covered Anaerobic Lagoon Process 1024
Membrane Separation Anaerobic Treatment Process 1026

11 Advanced Wastewater Treatment 1035

11-1 Need for Advanced Wastewater Treatment 1037

11-2 Technologies Used for Advanced Treatment 1038
Residual Constituents in Treated Wastewater 1038
Classification of Technologies 1038
Removal of Organic and Inorganic Colloidal and Suspended Solids 1038
Removal of Dissolved Organic Constituents 1040
Removal of Dissolved Inorganic Constituents 1041
Removal of Biological Constituents 1043
Process Selection and Performance Data 1044

11-3 Introduction to Depth Filtration 1044
Description of the Filtration Process 1044
Filter Hydraulics 1050
Analysis of the Filtration Process 1057

11-4 Selection and Design Considerations for Depth Filters 1069
Available Filtration Technologies 1069
Performance of Different Types of Filter Technologies 1078
Issues Related to Design and Operation of Treatment Facilities 1080
Importance of Influent Wastewater Characteristics 1081
Selection of Filtration Technology 1081
Filter-Bed Characteristics 1084
Filter Flowrate Control 1089
Filter Backwashing Systems 1091
Filter Appurtenances 1093
Filter Instrumentation and Control Systems 1093
Effluent Filtration with Chemical Addition 1095
Filter Problems 1096
Need for Pilot-Plant Studies 1096

11-5 Surface Filtration 1098
Discfilter® 1098
Cloth-Media Disk Filter® 1100
Performance Characteristics 1103

11–6 Membrane Filtration Processes 1104
Membrane Process Terminology 1104
Membrane Process Classification 1104
Membrane Configurations 1108
Membrane Operation 1111
Membrane Fouling 1117
Application of Membranes 1121
Electrodialysis 1131
Pilot Studies for Membrane Applications 1134
Disposal of Concentrated Waste Streams 1135

11–7 Adsorption 1138
Types of Adsorbents 1138
Fundamentals of Adsorption 1140
Activated Carbon Adsorption Kinetics 1146
Activated Carbon Treatment Process Applications 1149
Analysis and Design of Granular Activated Carbon Contactor 1152
Small-Scale Column Tests 1156
Analysis and Design of Powdered Activated Carbon Contactor 1159
Activated Sludge with Powdered Activated Carbon Treatment 1161

11–8 Gas Stripping 1162
Analysis of Gas Stripping 1163
Design of Stripping Towers 1174
Application 1178

11–9 Ion Exchange 1180
Ion-Exchange Materials 1181
Typical Ion-Exchange Reactions 1182
Exchange Capacity of Ion-Exchange Resins 1183
Ion-Exchange Chemistry 1185
Application of Ion Exchange 1189
Operational Considerations 1196

11–10 Advanced Oxidation Processes 1196
Theory of Advanced Oxidation 1196
Technologies Used to Produce Hydroxyl Radicals (HO˙) 1197
Applications 1200
Operational Problems 1202

11–11 Distillation 1202
Distillation Processes 1202
Performance Expectations in Reclamation Applications .s. Environmental standards in 1203
Operating Problems 1203
Disposal of Concentrated Waste 1205

Contents III

12 Disinfection Processes 1217

12-1 Regulatory Requirements for Wastewater Disinfection 1219

12-2 Disinfection Theory 1219
Characteristics of an Ideal Disinfectant 1220
Disinfection Methods and Means 1220
Mechanisms of Disinfectants 1223
Factors Influencing the Action of Disinfectants 1223

12-3 Disinfection with Chlorine 1231
Characteristics of Chlorine Compounds 1231
Chemistry of Chlorine Compounds 1234
Breakpoint Reaction with Chlorine 1237
Measurement and Reporting of Disinfection Process Variables 1241
Germicidal Efficiency of Chlorine and Various Chlorine Compounds 1242
Factors That Affect Disinfection Efficiency of Chlorine 1244
Modeling the Chlorine Disinfection Process 1248
Review of the $C_R t$ Concept 1252
Required Chlorine Dosage for Disinfection 1252
Formation and Control of Disinfection Byproducts 1255
Environmental Impacts 1257

12-4 Disinfection with Chlorine Dioxide 1258
Characteristics of Chlorine Dioxide 1258
Chlorine Dioxide Chemistry 1259
Effectiveness of Chlorine Dioxide as a Disinfectant 1259
Byproduct Formation and Control 1260
Environmental Impacts 1261

12-5 Dechlorination 1261
Need for Dechlorination 1261
Dechlorination of Wastewater Treated with Chlorine and Chlorine Compounds 1261
Dechlorination of Chlorine Dioxide with Sulfur Dioxide 1264

12-6 Design of Chlorination and Dechlorination Facilities 1264
Sizing Chlorination Facilities 1264
Application Flow Diagrams 1266
Dosage Control 1269
Injection and Initial Mixing 1270
Chlorine Contact Basin Design 1270
Chlorine Residual Measurement 1283
Chlorine Storage Facilities 1284
Chlorine Containment Facilities 1284
Dechlorination Facilities 1286

12-7 Disinfection with Ozone 1286
Ozone Properties 1287
Ozone Chemistry 1287
Ozone Disinfection Systems Components 1288
Effectiveness of Ozone as a Disinfectant 1290
Modeling the Ozone Disinfection Process 1290
Required Ozone Dosages for Disinfection 1293
Byproduct Formation and Control 1293
Environmental Impacts of Using Ozone 1295
Other Benefits of Using Ozone 1295

12-8 Other Chemical Disinfection Methods 1295
Peracetic Acid 1295
Ozone/Hydrogen Peroxide (Peroxone) 1297
Combined Chemical Disinfection Processes 1297

12-9 Ultraviolet (UV) Radiation Disinfection 1298
Source of UV Radiation 1298
UV Disinfection System Components and Configurations 1301

Germicidal Effectiveness of UV Radiation 1304
Modeling the UV Disinfection Process 1309
Estimating UV Dose 1311
Ultraviolet Disinfection Guidelines 1316
Selection and Sizing of a UV Disinfection System 1324
Troubleshooting UV Disinfection Systems 1326
Environmental Impacts of UV Radiation Disinfection 1329

12-10 Comparison of Alternative Disinfection Technologies 1329
Germicidal Effectiveness 1330
Advantages and Disadvantages 1330

13 Water Reuse 1345

13-1 Wastewater Reclamation and Reuse: An Introduction 1347
Definition of Terms 1347
The Role of Water Recycling in the Hydrologic Cycle 1347
Historical Perspective 1349
Wastewater Reuse Applications 1351
Need for Water Reuse 1354

13-2 Public Health and Environmental Issues in Water Reuse 1356
Constituents in Reclaimed Water 1356
Public Health Issues 1358
Environmental Issues 1358
The Evolution of Water Reuse Guidelines in the United States 1358
Water Reclamation Criteria in Other Countries 1362
What Level of Treatment Is Necessary? 1365

13-3 Introduction to Risk Assessment 1366
Risk Assessment 1366
Risk Management 1372
Ecological Risk Assessment 1373
Risk Assessment for Water Reuse 1373
Limitations in Risk Assessment for Water Reuse 1374

13-4 Water Reclamation Technologies 1376
Constituent Removal Technologies 1376
Conventional Wastewater Treatment Process Flow Diagrams for Water Reclamation 1377
Advanced Wastewater Treatment Process Flow Diagrams 1379
Performance Expectations for Water Reclamation Processes 1379
Predicting the Performance of Treatment Process Combinations 1387
Treatment Process Reliability 1391

13-5 Storage of Reclaimed Water 1391
Need for Storage 1392
Meeting Water Quality Discharge Requirements 1392
Operation of Storage Reservoirs 1393
Problems Involved with Storage of Reclaimed Water 1397
Management Strategies for Open and Enclosed Reservoirs 1399

13-6 Agricultural and Landscape Irrigation 1401
Evaluation of Irrigation Water Quality 1401
Other Problems 1410

13-7 Industrial Water Reuse 1412
Industrial Water Use 1413
Cooling Tower Makeup Water 1413
Water and Salt Balances in Cooling Tower 1414
Common Water Quality Problems in Cooling Tower Systems 1416

13-8 Groundwater Recharge with Reclaimed Water 1422
Groundwater Recharge Methods 1423
Pretreatment Requirements for Groundwater Recharge 1426
Fate of Contaminants in Groundwater 1427
Groundwater Recharge Guidelines 1429

13-9 Planned Indirect and Direct Potable Water Reuse 1429
Planned Indirect Potable Water Reuse 1431
Planned Direct Potable Water Reuse 1432
Planned Potable Water Reuse Criteria 1432
What Is the Ultimate Water Reuse Goal? 1433

13–10 Planning for Wastewater Reclamation and Reuse 1433
Planning Basis 1433
Market Assessment 1434
Monetary Analyses 1435
Other Planning Factors 1436
Planning Report 1437
13–11 Epilogue on Water Reuse Issues 1438

14 Treatment, Reuse, and Disposal of Solids and Biosolids 1447
14–1 Solids Sources, Characteristics, and Quantities 1451
Sources 1451
Characteristics 1451
Quantities 1454
14–2 Regulations for the Reuse and Disposal of Solids in the United States 1460
Land Application 1461
Surface Disposal 1461
Pathogen and Vector Attraction Reduction 1461
Incineration 1464
14–3 Solids Processing Flow Diagrams 1465
14–4 Sludge and Scum Pumping 1465
Pumps 1465
Headloss Determination 1475
Sludge Piping 1481
14–5 Preliminary Operations 1482
Grinding 1482
Screening 1482
Degritting 1484
Blending 1484
Storage 1485
14–6 Thickening 1488
Application 1488
Description and Design of Thickeners 1489
14–7 Introduction to Stabilization 1499
14–8 Alkaline Stabilization 1500
Chemical Reactions in Lime Stabilization 1500
Heat Generation 1502
Application of Alkaline Stabilization Processes 1502
14–9 Anaerobic Digestion 1505
Process Fundamentals 1506
Description of Mesophilic Anaerobic Digestion Processes 1507
Process Design for Mesophilic Anaerobic Digestion 1509
Selection of Tank Design and Mixing System 1516
Methods for Enhancing Solids Loading and Digester Performance 1522
Gas Production, Collection, and Use 1523
Digester Heating 1525
Thermophilic Anaerobic Digestion 1529
Two-Phased Anaerobic Digestion 1531
14–10 Aerobic Digestion 1533
Process Description 1534
Conventional Air Aerobic Digestion 1535
Dual Digestion 1541
Autothermal Thermophilic Aerobic Digestion (ATAD) 1541
High-Purity Oxygen Digestion 1545
14–11 Composting 1546
Process Microbiology 1547
Process Description 1547
Design Considerations 1550
Cocomposting with Municipal Solid Wastes 1551
Public Health and Environmental Issues 1554
14–12 Conditioning 1554
Chemical Conditioning 1555
Other Conditioning Methods 1557
14–13 Dewatering 1558
Centrifugation 1559
Belt-Filter Press 1563
Filter Presses 1565
Sludge Drying Beds 1570
Reed Beds 1578
Lagoons 1578
14–14 Heat Drying 1579
Heat-Transfer Methods 1579
Process Description 1580
Product Characteristics 1584
Product Transport and Storage 1585
Fire and Explosion Hazards 1585
Air Pollution and Odor Control 1585
14–15 Incineration 1586
Fundamental Aspects of Complete Combustion 1587
Multiple-Hearth Incineration 1588
Fluidized-Bed Incineration 1590

Coincineration with Municipal Solid Waste 1592
Air-Pollution Control 1592
14–16 Solids Mass Balances 1592
Preparation of Solids Mass Balances 1593
Performance Data for Solids-Processing Facilities 1593
Impact of Return Flows and Loads 1594
14–17 Application of Biosolids to Land 1608
Site Evaluation and Selection 1609
U.S. EPA Regulations for Beneficial Use and Disposal of Biosolids 1610
Design Loading Rates 1613
Application Methods 1617
Application to Dedicated Lands 1619
Landfilling 1621
14–18 Biosolids Conveyance and Storage 1621
Conveyance Methods 1622
Storage 1622

15 Issues Related to Treatment-Plant Performance 1633

15–1 Need for Upgrading Treatment-Plant Performance 1634
Meeting Current and Future Needs 1634
Meeting More Stringent Discharge Requirements 1635
Discharge Limits for Wastewater Treatment Plants 1635
15–2 Treatment Process Reliability and Selection of Design Values 1636
Variability in Wastewater Treatment 1636
Selection of Process Design Parameters to Meet Discharge Permit Limits 1640
Performance of Combined Processes 1647
Development of Input-Output Data 1649

REFERENCES 24

Every community produces both liquid and solid wastes and air emissions. The liquid waste—wastewater—is essentially the water supply of the community after it has been used in a variety of applications (see Fig. 1–1). From the standpoint of sources of generation, wastewater may be defined as a combination of the liquid or water-carried wastes removed from residences, institutions, and commercial and industrial establishments, together with such groundwater, surface water, and stormwater as may be present.

When untreated wastewater accumulates and is allowed to go septic, the decomposition of the organic matter it contains will lead to nuisance conditions including the production of malodorous gases. In addition, untreated wastewater contains numerous

Figure 1-1

Schematic diagram of a wastewater management infrastructure.

pathogenic microorganisms that dwell in the human intestinal tract. Wastewater also contains nutrients, which can stimulate the growth of aquatic plants, and may contain toxic compounds or compounds that potentially may be mutagenic or carcinogenic. For these reasons, the immediate and nuisance-free removal of wastewater from its sources of generation, followed by treatment, reuse, or dispersal into the environment is necessary to protect public health and the environment.

Wastewater engineering is that branch of environmental engineering in which the basic principles of science and engineering are applied to solving the issues associated with the treatment and reuse of wastewater. The ultimate goal of wastewater engineering is the protection of public health in a manner commensurate with environmental, economic, social, and political concerns. To protect public health and the environment, it is necessary to have knowledge of (1) constituents of concern in wastewater, (2) impacts of these constituents when wastewater is dispersed into the environment, (3) the transformation and long-term fate of these constituents in treatment processes, (4) treatment

methods that can be used to remove or modify the constituents found in wastewater, and (5) methods for beneficial use or disposal of solids generated by the treatment systems.

To provide an initial perspective on the field of wastewater engineering, common terminology is first defined followed by (1) a discussion of the issues that need to be addressed in the planning and design of wastewater management systems and (2) the current status and new directions in wastewater engineering.

1–1 TERMINOLOGY

In the literature, and in governmental regulations, a variety of terms have been used for individual constituents of concern in wastewater. The terminology used commonly for key concepts and terms in the field of wastewater management is summarized in Table 1–1. In some cases, confusion and undue negative perceptions arise with the use of the terms *contaminants, impurities,* and *pollutants,* which are often used interchangeably. To avoid confusion, the term *constituent* is used in this text in place of these terms to refer to an individual compound or element, such as ammonia nitrogen. The term *characteristic* is used to refer to a group of constituents, such as physical or biological characteristics.

The term "sludge" has been used for many years to signify the residuals produced in wastewater treatment. In 1994, the Water Environment Federation adopted a policy defining "biosolids" as a primarily organic, solid wastewater treatment product that can be recycled beneficially. In this policy, "solids" are defined as the residuals that are derived from the treatment of wastewater. Solids that have been treated to the point at which they are suitable for beneficial use are termed "biosolids." In this text, the terms of solids and biosolids are used extensively, but "sludge" continues to be used, especially in cases where untreated solid material and chemical residuals are referenced.

1–2 IMPACT OF REGULATIONS ON WASTEWATER ENGINEERING

From about 1900 to the early 1970s, treatment objectives were concerned primarily with (1) the removal of colloidal, suspended, and floatable material, (2) the treatment of biodegradable organics, and (3) the elimination of pathogenic organisms. Implementation in the United States of the Federal Water Pollution Control Act Amendments of 1972 (Public Law 92-500), also known as the Clean Water Act (CWA), stimulated substantial changes in wastewater treatment to achieve the objectives of "fishable and swimmable" waters. Unfortunately, these objectives were not uniformly met.

From the early 1970s to about 1980, wastewater treatment objectives were based primarily on aesthetic and environmental concerns. The earlier objectives involving the reduction of biological oxygen demand (BOD), total suspended solids (TSS), and pathogenic organisms continued but at higher levels. Removal of nutrients, such as nitrogen and phosphorus, also began to be addressed, particularly in some of the inland streams and lakes, and estuaries and bays such as Chesapeake Bay and Long Island Sound. Major programs were undertaken by both state and federal agencies to achieve more effective and widespread treatment of wastewater to improve the quality of the surface waters. These programs were based, in part, on (1) an increased understanding of the environmental effects caused by wastewater discharges; (2) a greater appreciation of the adverse long-term effects caused by the discharge of some of the specific constituents

Table 1-1
Terminology commonly used in the field of wastewater engineering[a]

Term	Definition
Biosolids	Primarily an organic, semisolid wastewater product that remains after solids are stabilized biologically or chemically and are suitable for beneficial use
Class A biosolids[b]	Biosolids in which the pathogens (including enteric viruses, pathogenic bacteria, and viable helminth ova) are reduced below current detectable levels
Class B biosolids[b]	Biosolids in which the pathogens are reduced to levels that are unlikely to pose a threat to public health and the environment under specific use conditions. Class B biosolids cannot be sold or given away in bags or other containers or applied on lawns or home gardens
Characteristics (wastewater)	General classes of wastewater constituents such as physical, chemical, biological, and biochemical
Composition	The makeup of wastewater, including the physical, chemical, and biological constituents
Constituents[c]	Individual components, elements, or biological entities such as suspended solids or ammonia nitrogen
Contaminants	Constituents added to the water supply through use
Disinfection	Reduction of disease-causing microorganisms by physical or chemical means
Effluent	The liquid discharged from a processing step
Impurities	Constituents added to the water supply through use
Nonpoint sources	Sources of pollution that originate from multiple sources over a relatively large area
Nutrient	An element that is essential for the growth of plants and animals. Nutrients in wastewater, usually nitrogen and phosphorus, may cause unwanted algal and plant growths in lakes and streams
Parameter	A measurable factor such as temperature
Point sources	Pollutional loads discharged at a specific location from pipes, outfalls, and conveyance methods from either municipal wastewater treatment plants or industrial waste treatment facilities
Pollutants	Constituents added to the water supply through use
Reclamation	Treatment of wastewater for subsequent reuse application or the act of reusing treated wastewater
Recycling	The reuse of treated wastewater and biosolids for beneficial purposes
Repurification	Treatment of wastewater to a level suitable for a variety of applications including indirect or direct potable reuse
Reuse	Beneficial use of reclaimed or repurified wastewater or stabilized biosolids
Sludge	Solids removed from wastewater during treatment. Solids that are treated further are termed biosolids
Solids	Material removed from wastewater by gravity separation (by clarifiers, thickeners, and lagoons) and is the solid residue from dewatering operations

[a] Adapted, in part, from Crites and Tchobanoglous (1998)

[b] U.S. EPA (1997*b*).

[c] To avoid confusion, the term "constituents" is used in this text in place of contaminants, impurities, and pollutants.

found in wastewater; and (3) the development of national concern for the protection of the environment. As a result of these programs, significant improvements have been made in the quality of the surface waters.

Since 1980, the water-quality improvement objectives of the 1970s have continued, but the emphasis has shifted to the definition and removal of constituents that may cause long-term health effects and environmental impacts. Health and environmental concerns are discussed in more detail in the following section. Consequently, while the early treatment objectives remain valid today, the required degree of treatment has increased significantly, and additional treatment objectives and goals have been added. Therefore, treatment objectives must go hand in hand with the water quality objectives or standards established by the federal, state, and regional regulatory authorities. Important federal regulations that have brought about changes in the planning and design of wastewater treatment facilities in the United States are summarized in Table 1–2. It is interesting to note that the clean air acts of 1970 and 1990 have had a significant impact on industrial and municipal wastewater programs, primarily through the implementation of treatment facilities for the control of emissions.

Table 1–2
Summary of significant U.S. federal regulations that affect wastewater management

Regulation	Description
Clean Water Act (CWA) (Federal Water Pollution Control Act Amendments of 1972)	Establishes the National Pollution Discharge Elimination System (NPDES), a permitting program based on uniform technological minimum standards for each discharger
Water Quality Act of 1987 (WQA) (Amendment of the CWA)	Strengthens federal water quality regulations by providing changes in permitting and adds substantial penalties for permit violations. Amends solids control program by emphasizing identification and regulation of toxic pollutants in sewage sludge
40 CFR Part 503 (1993) (Sewage Sludge Regulations)	Regulates the use and disposal of biosolids from wastewater treatment plants. Limitations are established for items such as contaminants (mainly metals), pathogen content, and vector attraction
National Combined Sewer Overflow (CSO) Policy (1994)	Coordinates planning, selection, design, and implementation of CSO management practices and controls to meet requirements of CWA. Nine minimum controls and development of long-term CSO control plans are required to be implemented immediately
Clean Air Act of 1970 and 1990 Amendments	Establishes limitations for specific air pollutants and institutes prevention of significant deterioration in air quality. Maximum achievable control technology is required for any of 189 listed chemicals from "major sources," i.e., plants emitting at least 60 kg/d
40 CFR Part 60	Establishes air emission limits for sludge incinerators with capacities larger than 1000 kg/d (2200 lb/d) dry basis
Total maximum daily load (TDML) (2000) Section 303(d) of the CWA	Requires states to develop prioritized lists of polluted or threatened water bodies and to establish the maximum amount of pollutant (TMDL) that a water body can receive and still meet water quality standards

Pursuant to Section 304(d) of Public Law 92-500 (see Table 1-2), the U.S. Environmental Protection Agency (U.S. EPA) published its definition of minimum requirements for secondary treatment. This definition, originally issued in 1973, was amended in 1985 to allow additional flexibility in applying the percent removal requirements of pollutants to treatment facilities serving separate sewer systems. The definition of secondary treatment is reported in Table 1-3 and includes three major effluent parameters, 5-day BOD, TSS, and pH. The substitution of 5-day carbonaceous BOD ($CBOD_5$) for BOD_5 may be made at the option of the permitting authority. These standards provided the basis for the design and operation of most treatment plants. Special interpretations of the definition of secondary treatment are permitted for publicly owned treatment works (1) served by combined sewer systems, (2) using waste stabilization ponds and trickling filters, (3) receiving industrial flows, or (4) receiving less concentrated influent wastewater from separate sewers. The secondary treatment regulations were amended further in 1989 to clarify the percent removal requirements during dry periods for treatment facilities served by combined sewers.

In 1987, Congress enacted the Water Quality Act of 1987 (WQA), the first major revision of the Clean Water Act. Important provisions of the WQA were: (1) strengthening federal water quality regulations by providing changes in permitting and adding substantial penalties for permit violations, (2) significantly amending the CWA's formal sludge control program by emphasizing the identification and regulation of toxic pollutants in sludge, (3) providing funding for state and U.S. EPA studies for defining nonpoint and toxic sources of pollution, (4) establishing new deadlines for compliance including priorities and permit requirements for stormwater, and (5) a phase-out of the construction grants program as a method of financing publicly owned treatment works (POTW).

Table 1-3
Minimum national standards for secondary treatment[a] [b]

Characteristic of discharge	Unit of measurement	Average 30-day concentration[c]	Average 7-day concentration[c]
BOD_5	mg/L	30[d]	45
Total suspended solids	mg/L	30[d]	45
Hydrogen-ion concentration	pH units	Within the range of 6.0 to 9.0 at all times[e]	
$CBOD_5$[f]	mg/L	25	40

[a] *Federal Register* (1988, 1989).

[b] Present standards allow stabilization ponds and trickling filters to have higher 30-day average concentrations (45 mg/L) and 7-day average concentrations (65 mg/L) of BOD/suspended solids performance levels as long as the water quality of the receiving water is not adversely affected. Exceptions are also permitted for combined sewers, certain industrial categories, and less concentrated wastewater from separate sewers. For precise requirements of exceptions, *Federal Register* (1988) should be consulted.

[c] Not to be exceeded

[d] Average removal shall not be less than 85 percent.

[e] Only enforced if caused by industrial wastewater or by in-plant inorganic chemical addition.

[f] May be substituted for BOD_5 at the option of the permitting authority.

Recent regulations that affect wastewater facilities design include those for the treatment, disposal, and beneficial use of biosolids (40 CFR Part 503). In the biosolids regulation promulgated in 1993, national standards were set for pathogen and heavy metal content and for the safe handling and use of biosolids. The standards are designed to protect human health and the environment where biosolids are applied beneficially to land. The rule also promotes the development of a "clean sludge" (U.S. EPA, 1999).

The total maximum daily load (TMDL) program was promulgated in 2000 but is not scheduled to be in effect until 2002. The TMDL rule is designed to protect ambient water quality. A TMDL represents the maximum amount of a pollutant that a water body can receive and still meet water quality standards. A TMDL is the sum of (1) the individual waste-load allocations for point sources, (2) load allocations for nonpoint sources, (3) natural background levels, and (4) a margin of safety (U.S. EPA, 2000). To implement the rule, a comprehensive watershed-based water quality management program must be undertaken to find and control nonpoint sources in addition to conventional point source discharges. With implementation of the TMDL rule, the focus on water quality shifts from technology-based controls to preservation of ambient water quality. The end result is an integrated planning approach that transcends jurisdictional boundaries and forces different sectors, such as agriculture, water and wastewater utilities, and urban runoff managers to cooperate. Implementation of the TMDL rule will vary depending on the specific water quality objectives established for each watershed and, in some cases, will require the installation of advanced levels of treatment.

1–3 HEALTH AND ENVIRONMENTAL CONCERNS IN WASTEWATER MANAGEMENT

As research into the characteristics of wastewater has become more extensive, and as the techniques for analyzing specific constituents and their potential health and environmental effects have become more comprehensive, the body of scientific knowledge has expanded significantly. Many of the new treatment methods being developed are designed to deal with health and environmental concerns associated with findings of recent research. However, the advancement in treatment technology effectiveness has not kept pace with the enhanced constituent detection capability. Pollutants can be detected at lower concentrations than can be attained by available treatment technology. Therefore, careful assessment of health and environment effects and community concerns about these effects becomes increasingly important in wastewater management. The need to establish a dialogue with the community is important to assure that health and environmental issues are being addressed.

Water quality issues arise when increasing amounts of treated wastewater are discharged to water bodies that are eventually used as water supplies. The waters of the Mississippi River and many rivers in the eastern United States are used for municipal and industrial water supplies and as repositories for the resulting treated wastewater. In southern California, a semiarid region, increasing amounts of reclaimed wastewater are being used or are planned to be used for groundwater recharge to augment existing potable water supplies. Significant questions remain about the testing and levels of treatment necessary to protect human health where the commingling of highly treated wastewater with drinking water sources results in indirect potable reuse. Some professionals

object in principle to the indirect reuse of treated wastewater for potable purposes; others express concern that current techniques are inadequate for detecting all microbial and chemical contaminants of health significance (Crook et al., 1999). Among the latter concerns are (1) the lack of sufficient information regarding the health risks posed by some microbial pathogens and chemical constituents in wastewater, (2) the nature of unknown or unidentified chemical constituents and potential pathogens, and (3) the effectiveness of treatment processes for their removal. Defining risks to public health based on sound science is an ongoing challenge.

Because new and more sensitive methods for detecting chemicals are available and methods have been developed that better determine biological effects, constituents that were undetected previously are now of concern (see Fig. 1–2). Examples of such chemical constituents found in both surface and groundwaters include: *n*-nitrosodimethylamine (NDMA), a principal ingredient in rocket fuel, methyl tertiary butyl ether (MTBE), a highly soluble gasoline additive, medically active substances including endocrine disruptors, pesticides, industrial chemicals, and phenolic compounds commonly found in nonionic surfactants. Endocrine-disrupting chemicals are a special health concern as they can mimic hormones produced in vertebrate animals by causing an exaggerated response, or they can block the effects of a hormone on the body (Trussell, 2000). These chemicals can cause problems with development, behavior, and reproduction in a variety of species. Increases in testicular, prostate, and breast cancers have been blamed on endocrine-disruptive chemicals (Roefer et al., 2000). Although treatment of these chemicals is not currently a mission of municipal wastewater treatment, wastewater treatment facilities may have to be designed to deal with these chemicals in the future.

Other health concerns relate to: (1) the release of volatile organic compounds (VOCs) and toxic air contaminants (TACs) from collection and treatment facilities, (2) chlorine disinfection, and (3) disinfection byproducts (DBPs). Odors are one of the most serious environmental concerns to the public. New techniques for odor measurement are used to quantify the development and movement of odors that may emanate from wastewater facilities, and special efforts are being made to design facilities that minimize the development of odors, contain them effectively, and provide proper treatment for their destruction (see Fig. 1–3).

Figure 1–2

Atomic adsorption spectrometer used for the detection of metals. Photo was taken in wastewater treatment plant laboratory. The use of such analytical instruments is now commonplace at wastewater treatment plants.

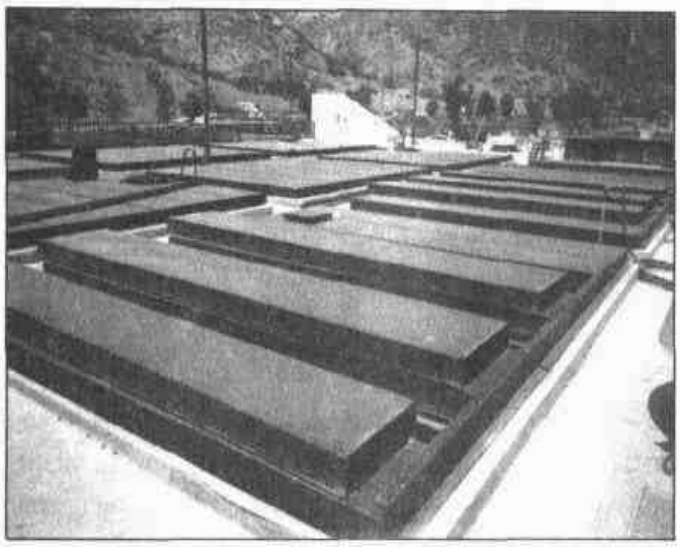

Figure 1-3
Covered treatment plant facilities for the control of odor emissions.

Many industrial wastes contain VOCs that may be flammable, toxic, and odorous, and may be contributors to photochemical smog and tropospheric ozone. Provisions of the Clean Air Act and local air quality management regulations are directed toward (1) minimizing VOC releases at the source, (2) containing wastewater and their VOC emissions (i.e., by adding enclosures), treating wastewater for VOC removal, and collecting and treating vapor emissions from wastewater. Many VOCs, classified as TACs, are discharged to the ambient atmosphere and transported to downwind receptors. Some air management districts are enforcing regulations based on excess cancer risks for lifetime exposures to chemicals such as benzene, trichloroethylene, chloroform, and methylene chloride (Card and Corsi, 1992). Strategies for controlling VOCs at wastewater treatment plants are reviewed in Chap. 5.

Effluents containing chlorine residuals are toxic to aquatic life, and, increasingly, provisions to eliminate chlorine residuals are being instituted. Other important health issues relate to the reduction of disinfection byproducts (DBPs) that are potential carcinogens and are formed when chlorine reacts with organic matter. To achieve higher and more consistent microorganism inactivation levels, improved performance of disinfection systems must be addressed. In many communities, the issues of safety in the transporting, storing, and handling of chlorine are also being examined.

1-4 WASTEWATER CHARACTERISTICS

Prior to about 1940, most municipal wastewater was generated from domestic sources. After 1940, as industrial development in the United States grew significantly, increasing amounts of industrial wastewater have been and continue to be discharged to municipal collection systems. The amounts of heavy metals and synthesized organic compounds generated by industrial activities have increased, and some 10,000 new organic compounds are added each year. Many of these compounds are now found in the wastewater from most municipalities and communities.

As technological changes take place in manufacturing, changes also occur in the compounds discharged and the resulting wastewater characteristics. Numerous compounds generated from industrial processes are difficult and costly to treat by conventional wastewater treatment processes. Therefore, effective industrial pretreatment

becomes an essential part of an overall water quality management program. Enforcement of an industrial pretreatment program is a daunting task, and some of the regulated pollutants still escape to the municipal wastewater collection system and must be treated. In the future with the objective of pollution prevention, every effort should be made by industrial dischargers to assess the environmental impacts of any new compounds that may enter the wastewater stream before being approved for use. If a compound cannot be treated effectively with existing technology, it should not be used.

Improved Analytical Techniques

Great strides in analytical techniques have been made with the development of new and more sophisticated instrumentation. While most constituent concentrations are reported in milligrams per liter (mg/L), measurements in micrograms per liter (μg/L) and nanograms per liter (ng/L) are now common. As detection methods become more sensitive and a broader range of compounds are monitored in water supplies, more contaminants that affect humans and the environment will be found. Many trace compounds and microorganisms, such as *Giardia lamblia* and *Cryptosporidium parvum*, have been identified that potentially may cause adverse health effects. Increased analytical sophistication also allows the scientist and engineer to gain greater knowledge of the behavior of wastewater constituents and how they affect process performance and effluent quality.

Importance of Improved Wastewater Characterization

Because of changing wastewater characteristics and the imposition of stricter limits on wastewater discharges and biosolids that are used beneficially, greater emphasis is being placed on wastewater characterization. Because process modeling is widely used in the design and optimization of biological treatment processes (e.g., activated sludge), thorough characterization of wastewater, particularly wastewaters containing industrial waste, is increasingly important. Process modeling for activated sludge as it is currently conceived requires experimental assessment of kinetic and stoichiometric constants. Fractionization of organic nitrogen, chemical oxygen demand (COD), and total organic carbon into soluble and particulate constituents is now used to optimize the performance of both existing and proposed new biological treatment plants designed to achieve nutrient removal. Techniques from the microbiological sciences, such as RNA and DNA typing, are being used to identify the active mass in biological treatment processes. Because an understanding of the nature of wastewater is fundamental to the design and operation of wastewater collection, treatment, and reuse facilities, a detailed discussion of wastewater constituents is provided in Chap. 2.

1–5 WASTEWATER TREATMENT

Wastewater collected from municipalities and communities must ultimately be returned to receiving waters or to the land or reused. The complex question facing the design engineer and public health officials is: What levels of treatment must be achieved in a given application—beyond those prescribed by discharge permits—to ensure protection of public health and the environment? The answer to this question requires detailed analy-

ses of local conditions and needs, application of scientific knowledge and engineering judgment based on past experience, and consideration of federal, state, and local regulations. In some cases, a detailed risk assessment may be required. An overview of wastewater treatment is provided in this section. The reuse and disposal of biosolids, vexing problems for some communities, are discussed in the following section.

Treatment Methods

Methods of treatment in which the application of physical forces predominate are known as *unit operations*. Methods of treatment in which the removal of contaminants is brought about by chemical or biological reactions are known as *unit processes*. At the present time, unit operations and processes are grouped together to provide various levels of treatment known as preliminary, primary, advanced primary, secondary (without or with nutrient removal), and advanced (or tertiary) treatment (see Table 1–4). In preliminary treatment, gross solids such as large objects, rags, and grit are removed that may damage equipment. In primary treatment, a physical operation, usually sedimentation, is used to remove the floating and settleable materials found in wastewater (see Fig. 1–4). For advanced primary treatment, chemicals are added to enhance the removal of suspended solids and, to a lesser extent, dissolved solids. In secondary treatment, biological and chemical processes are used to remove most of the organic matter. In advanced treatment, additional combinations of unit operations and processes are used to remove residual suspended solids and other constituents that are not reduced significantly by conventional secondary treatment. A listing of unit operations and processes used for

Table 1–4
Levels of wastewater treatment[a]

Treatment level	Description
Preliminary	Removal of wastewater constituents such as rags, sticks, floatables, grit, and grease that may cause maintenance or operational problems with the treatment operations, processes, and ancillary systems
Primary	Removal of a portion of the suspended solids and organic matter from the wastewater
Advanced primary	Enhanced removal of suspended solids and organic matter from the wastewater. Typically accomplished by chemical addition or filtration
Secondary	Removal of biodegradable organic matter (in solution or suspension) and suspended solids. Disinfection is also typically included in the definition of conventional secondary treatment
Secondary with nutrient removal	Removal of biodegradable organics, suspended solids, and nutrients (nitrogen, phosphorus, or both nitrogen and phosphorus)
Tertiary	Removal of residual suspended solids (after secondary treatment), usually by granular medium filtration or microscreens. Disinfection is also typically a part of tertiary treatment. Nutrient removal is often included in this definition
Advanced	Removal of dissolved and suspended materials remaining after normal biological treatment when required for various water reuse applications

[a]Adapted, in part, from Crites and Tchobanoglous (1998).

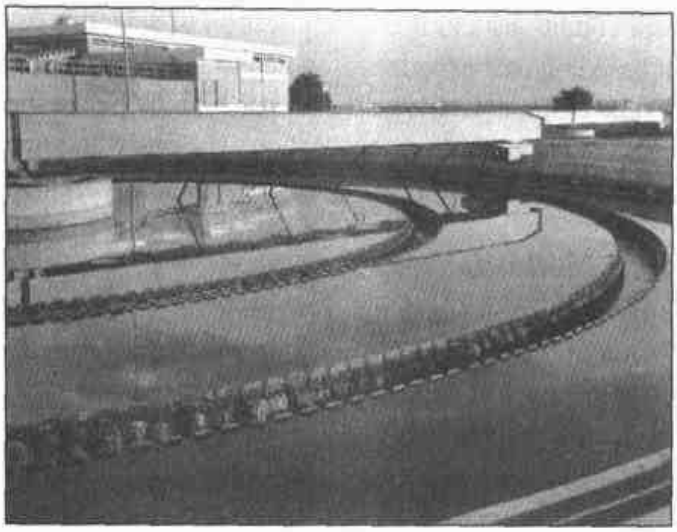

Figure 1–4
Typical primary sedimentation tanks used to remove floating and settleable material from wastewater.

the removal of major constituents found in wastewater and addressed in this text is presented in Table 1–5.

About 20 years ago, biological nutrient removal (BNR)—for the removal of nitrogen and phosphorus—was viewed as an innovative process for advanced wastewater treatment. Because of the extensive research into the mechanisms of BNR, the advantages of its use, and the number of BNR systems that have been placed into operation, nutrient removal, for all practical purposes, has become a part of conventional wastewater treatment. When compared to chemical treatment methods, BNR uses less chemical, reduces the production of waste solids, and has lower energy consumption. Because of the importance of BNR in wastewater treatment, BNR is integrated into the discussion of theory, application, and design of biological treatment systems.

Land treatment processes, commonly termed "natural systems," combine physical, chemical, and biological treatment mechanisms and produce water with quality similar to or better than that from advanced wastewater treatment. Natural systems are not covered in this text as they are used mainly with small treatment systems; descriptions may be found in the predecessor edition of this text (Metcalf & Eddy, 1991) and in Crites and Tchobanoglous (1998) and Crites et al. (2000).

Current Status

Up until the late 1980s, conventional secondary treatment was the most common method of treatment for the removal of BOD and TSS. In the United States, nutrient removal was used in special circumstances, such as in the Great Lakes area, Florida, and the Chesapeake Bay, where sensitive nutrient-related water quality conditions were identified. Because of nutrient enrichment that has led to eutrophication and water quality degradation (due in part to point source discharges), nutrient removal processes have evolved and now are used extensively in other areas as well.

As a result of implementation of the Federal Water Pollution Control Act Amendments, significant data have been obtained on the numbers and types of wastewater facilities used and needed in accomplishing the goals of the program. Surveys are conducted by U.S. EPA to track these data, and the results of the 1996 Needs Assessment Survey (U.S. EPA, 1997*a*) are reported in Tables 1–6 and 1–7. The number and types of

facilities needed in the future (~20 yr) are also shown in Table 1–7. These data are useful in forming an overall view of the current status of wastewater treatment in the United States.

The municipal wastewater treatment enterprise is composed of over 16,000 plants that are used to treat a total flow of about 1400 cubic meters per second (m^3/s) [32,000 million gallons per day (Mgal/d)]. Approximately 92 percent of the total existing flow is handled by plants having a capacity of 0.044 m^3/s [1 million gallons per day (Mgal/d)] and larger. Nearly one-half of the present design capacity is situated in plants

Table 1–6
Number of U.S. wastewater treatment facilities by flow range (1996)[a]

Flow ranges		Number of facilities	Total existing flowrate

providing greater than secondary treatment. Thus, the basic material presented in this text is directed toward the design of plants larger than 0.044 m^3/s (1 Mgal/d) with the consideration that many new designs will provide treatment greater than secondary.

In the last 10 years, many plants have been designed using BNR. Effluent filtration has also been installed where the removal of residual suspended solids is required. Filtration is especially effective in improving the effectiveness of disinfection, especially for ultraviolet (UV) disinfection systems, because (1) the removal of larger particles of suspended solids that harbor bacteria enhances the reduction in coliform bacteria and (2) the reduction of turbidity improves the transmittance of UV light. Effluent reuse systems, except for many that are used for agricultural irrigation, almost always employ filtration.

New Directions and Concerns

New directions and concerns in wastewater treatment are evident in various specific areas of wastewater treatment. The changing nature of the wastewater to be treated, emerging health and environmental concerns, the problem of industrial wastes, and the impact of new regulations, all of which have been discussed previously, are among the most important. Further, other important concerns include: (1) aging infrastructure, (2) new methods of process analysis and control, (3) treatment plant performance and reliability, (4) wastewater disinfection, (5) combined sewer overflows, (6) impacts of stormwater and sanitary overflows and nonpoint sources of pollution, (7) separate treatment of return flows, (8) odor control (see Fig. 1–5) and the control of VOC emissions, and (9) retrofitting and upgrading wastewater treatment plants.

Aging Infrastructure. Some of the problems that have to be addressed in the United States deal with renewal of the aging wastewater collection infrastructure and upgrading of treatment plants. Issues include repair and replacement of leaking and undersized sewers, control and treatment of overflows from sanitary and combined collection systems, control of nonpoint discharges, and upgrading treatment systems to achieve higher removal levels of specific constituents. Upgrading and retrofitting treatment plants is addressed later in this section.

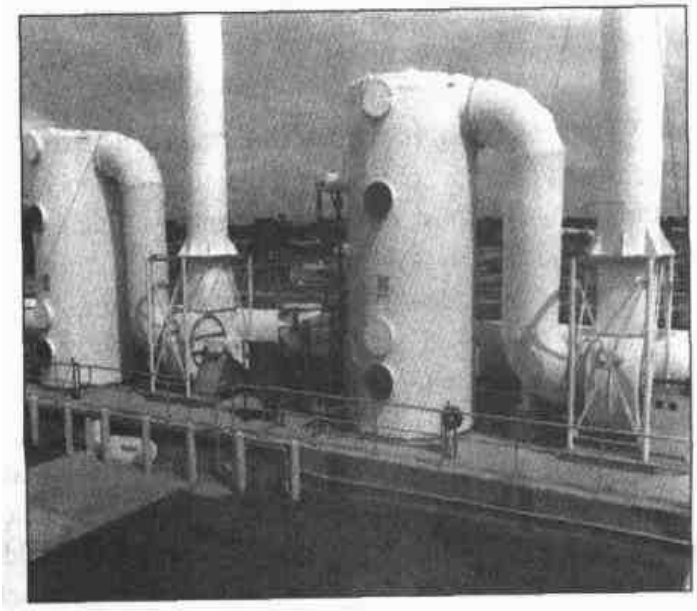

Figure 1–5

Facilities used for chemical treatment of odors from treatment facilities.

Portions of the collection systems, particularly those in the older cities in the eastern and midwestern United States, are older than the treatment plants. Sewers constructed of brick and vitrified clay with mortar joints, for example, are still used to carry sanitary wastewater and stormwater. Because of the age of the pipes and ancillary structures, the types of materials and methods of construction, and lack of repair, leakage is common. Leakage is in the form of both infiltration and inflow where water enters the collection system, and exfiltration where water leaves the pipe. In the former case, extraneous water has to be collected and treated, and oftentimes may overflow before treatment, especially during wet weather. In the latter case, exfiltration causes untreated wastewater to enter the groundwater and/or migrate to nearby surface water bodies. It is interesting to note that while the standards for treatment have increased significantly, comparatively little or no attention has been focused on the discharge of untreated wastewater from sewers through exfiltration. In the future, however, leaking sewers are expected to become a major concern and will require correction.

Process Analysis and Control. Because of the changing characteristics of the wastewater (discussed above), studies of wastewater treatability are increasing, especially with reference to the treatment of specific constituents. Such studies are especially important where new treatment processes are being considered. Therefore, the engineer must understand the general approach and methodology involved in: (1) assessing the treatability of a wastewater (domestic or industrial), (2) conducting laboratory and pilot plant studies, and (3) translating experimental data into design parameters.

Computational fluid dynamics (CFD), computer-based computational methods for solving the fundamental equations of fluid dynamics (i.e., continuity, momentum, and energy), is now being used to improve and optimize the hydraulic performance of wastewater treatment facilities. Applications of CFD include the design of new systems or the optimization of systems such as vortex separators, mixing tanks, sedimentation tanks, dissolved-air flotation units, and chlorine contact tanks to reduce or eliminate dead zones and short circuiting. Improved UV disinfection systems are being designed using CFD. One of the main advantages of CFD is simulating a range of operating conditions to evaluate performance before designs and operating changes are finalized. Another advantage is that dynamic models can be integrated with the process control system to optimize ongoing operation.

Treatment Process Performance and Reliability. Important factors in process selection and design are treatment plant performance and reliability in meeting permit requirements. In most discharge permits, effluent constituent requirements, based on 7-day and 30-day average concentrations, are specified (see Table 1–3). Because wastewater treatment effluent quality is variable because of varying organic loads, changing environmental conditions, and new industrial discharges, it is necessary to design the treatment system to produce effluent concentrations equal to or less than the limits prescribed by the discharge permit. Reliability is especially important where critical water quality parameters have to be maintained such as in reuse applications. On-line monitoring of critical parameters such as total organic carbon (TOC), transmissivity, turbidity, and dissolved oxygen is necessary for building a database and for improving process control. Chlorine residual monitoring is useful for dosage control, and pH monitoring assists in controlling nitrification systems.

Treatment plant reliability can be defined as the probability that a system can meet established performance criteria consistently over extended periods of time. Two components of reliability, the inherent reliability of the process and mechanical reliability, are discussed in Chap. 15. As improved microbiological techniques are developed, it will be possible to optimize the disinfection process.

The need to conserve energy and resources is fundamental to all aspects of wastewater collection, treatment, and reuse. Operation and maintenance costs are extremely important to operating agencies because these costs are funded totally with local moneys. Detailed energy analyses and audits are important parts of treatment plant design and operation as significant savings can be realized by selecting energy-efficient processes and equipment. Large amounts of electricity are used for aeration that is needed for biological treatment. Typically, about one-half of the entire plant electricity usage is for aeration. In the design of wastewater treatment plants power use can be minimized by paying more careful attention to plant siting, selecting energy-efficient equipment, and designing facilities to recover energy for in-plant use. Energy management in treatment plant design and operation is also considered in Chap. 15.

Wastewater Disinfection. Changes in regulations and the development of new technologies have affected the design of disinfection systems. Gene probes are now being used to identify where specific groups of organisms are found in treated secondary effluent (i.e., in suspension or particle-associated). Historically, chlorine has been the disinfectant of choice for wastewater. With the increasing number of permits requiring low or nondetectable amounts of chlorine residual in treated effluents, dechlorination facilities have had to be added, or chlorination systems have been replaced by alternative disinfection systems such as ultraviolet (UV) radiation (see Fig. 1-6). Concerns about chemical safety have also affected design considerations of chlorination and dechlorination systems. Improvements that have been made in UV lamp and ballast design within the past 10 years have improved significantly the performance and reliability of UV disinfection systems. Effective guidelines have also been developed for the application and design of UV systems (NWRI, 2000). Capital and operating costs have also been lowered. It is anticipated that the application of UV for treated drinking water and for stormwater will continue to increase in the future. Because UV produces essentially no troublesome byproducts and is also effective in the reduction of NDMA and other related compounds, its use for disinfection is further enhanced as compared to chlorine compounds.

Combined Sewer Overflows (CSOs), Sanitary Sewer Overflows (SSOs), and Nonpoint Sources. Overflows from combined sewer and sanitary sewer collection systems have been recognized as difficult problems requiring solution, especially for many of the older cities in the United States. The problem has become more critical as greater development changes the amount and characteristics of stormwater runoff and increases the channelization of runoff into storm, combined, and sanitary collection systems. Combined systems carry a mixture of wastewater and stormwater runoff and, when the capacity of the interceptors is reached, overflows occur to the receiving waters. Large overflows can impact receiving water quality and can prevent attainment of mandated standards. Recreational beach closings and shellfish

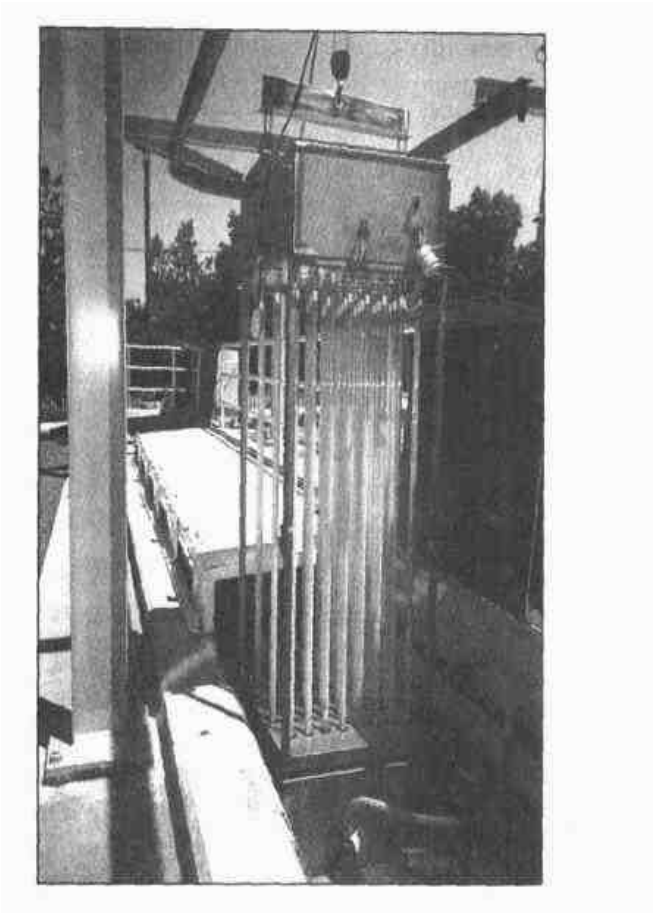

Figure 1-6
UV lamps used for the disinfection of wastewater.

bed closures have been attributed to CSOs (Lape and Dwyer, 1994). Federal regulations for CSOs are still under development and have not been issued at the time of writing this text (2001).

A combination of factors has resulted in the release of untreated wastewater from parts of sanitary collection systems. These releases are termed sanitary system overflows (SSOs). The SSOs may be caused by (1) the entrance of excessive amounts of stormwater, (2) blockages, or (3) structural, mechanical, or electrical failures. Many overflows result from aging collection systems that have not received adequate upgrades, maintenance, and repair. The U.S. EPA has estimated that at least 40,000 overflows per year occur from sanitary collection systems. The untreated wastewater from these overflows represents threats to public health and the environment. The U.S. EPA is proposing to clarify and expand permit requirements for municipal sanitary collection systems under the Clean Water Act that will result in reducing the frequency and occurrence of SSOs (U.S. EPA 2001). At the time of writing this text (2001) the proposed regulations are under review. The U.S. EPA estimates that nearly $45 billion is required for constructing facilities for controlling CSOs and SSOs in the United States (U.S. EPA, 1997*a*).

The effects of pollution from nonpoint sources are growing concerns as evidenced by the outbreak of gastrointestinal illness in Milwaukee traced to the oocysts of *Cryptosporidium parvum*, and the occurrence of *Pfiesteria piscicida* in the waters of Maryland and North Carolina. *Pfiesteria* is a form of algae that is very toxic to fish life. Runoff from pastures and feedlots has been attributed as a potential factor that triggers the effects of these microorganisms.

The extent of the measures that will be needed to control nonpoint sources is not known at this time of writing this text (2001). When studies for assessing TMDLs are completed (estimated to be in 2008), the remedial measures for controlling nonpoint sources may require financial resources rivaling those for CSO and SSO correction.

Treatment of Return Flows. Perhaps one of the significant future developments in wastewater treatment will be the provision of separate facilities for treating return flows from biosolids and other processing facilities. Treatment of return flows will be especially important where low levels of nitrogen are to be achieved in the treated effluent. Separate treatment facilities may include (1) steam stripping for removal of ammonia from biosolids return flows, now typically routed to the plant headworks; (2) high-rate sedimentation for removing fine and difficult-to-settle colloidal material that also shields bacteria from disinfection; (3) flotation and high-rate sedimentation for treating filter backwash water to reduce solids loading on the liquid treatment process; and (4) soluble heavy metals removal by chemical precipitation to meet more stringent discharge requirements. The specific treatment system used will depend on the constituents that will impact the wastewater treatment process.

Control of Odors and VOC Emissions. The control of odors and in particular the control of hydrogen sulfide generation is of concern in collection systems and at treatment facilities. The release of hydrogen sulfide to the atmosphere above sewers and at treatment plant headworks has occurred in a number of locations. The release of excess hydrogen sulfide has led to the accelerated corrosion of concrete sewers, headworks structures, and equipment, and to the release of odors. The control of odors is of increasing environmental concern as residential and commercial development continues to approach existing treatment plant locations. Odor control facilities including covers for process units, special ventilation equipment, and treatment of odorous gases need to be integrated with treatment plant design. Control of hydrogen sulfide is also fundamental to maintaining system reliability.

The presence of VOCs and VTOCs in wastewater has also necessitated the covering of treatment plant headworks and primary treatment facilities and the installation of special facilities to treat the compounds before they are released. In some cases, improved industrial pretreatment has been employed to eliminate these compounds.

Retrofitting and Upgrading Wastewater Treatment Plants. Large numbers of wastewater treatment plants were constructed in the United States during the 1970s and 1980s when large sums of federal money were available for implementation of the CWA. Much of the equipment, now over 20 years old, is reaching the end of its useful life and will need to be replaced. Process changes to improve performance, meet stricter permit requirements, and increase capacity will also be needed. For these reasons, significant future efforts in the planning and design of wastewater treatment plants in the United States will be directed to modifying, improving, and expanding existing treatment facilities. Fewer completely new treatment plants will be constructed. In developing countries, opportunities for designing and building completely new facilities may be somewhat greater. Upgrading and retrofitting treatment plants is addressed in Chap. 15.

Future Trends in Wastewater Treatment

In the U.S. EPA Needs Assessment Survey, the total treatment plant design capacity is projected to increase by about 15 percent over the next 20 to 30 years (see Table 1–7). During this period, the U.S. EPA estimates that approximately 2,300 new plants may have to be built, most of which will be providing a level of treatment greater than secondary. The design capacity of plants providing greater than secondary treatment is expected to increase by 40 percent in the future (U.S. EPA, 1997). Thus, it is clear that the future trends in wastewater treatment plant design will be for facilities providing higher levels of treatment.

Some of the innovative treatment methods being utilized in new and upgraded treatment facilities include vortex separators, high rate clarification, membrane bioreactors, pressure-driven membrane filtration (ultrafiltration and reverse osmosis—see Fig. 1–7), and ultraviolet radiation (low-pressure, low- and high-intensity UV lamps, and medium-pressure, high-intensity UV lamps). Some of the new technologies, especially those developed in Europe, are more compact and are particularly well suited for plants where available space for expansion is limited.

In recent years, numerous proprietary wastewater treatment processes have been developed that offer potential savings in construction and operation. This trend will likely continue, particularly where alternative treatment systems are evaluated or facilities are privatized. Privatization is generally defined as a public-private partnership in which the private partner arranges the financing, design, building, and operation of the treatment facilities. In some cases, the private partner may own the facilities. The reasons for privatization, however, go well beyond the possibility of installing proprietary processes. In the United States, the need for private financing appears to be the principal rationale for privatization; the need to preserve local control appears to be the leading pragmatic rationale against privatization (Dreese and Beecher, 1997).

1–6 WASTEWATER RECLAMATION AND REUSE

In many locations where the available supply of fresh water has become inadequate to meet water needs, it is clear that the once-used water collected from communities and municipalities must be viewed not as a waste to be disposed of but as a resource that

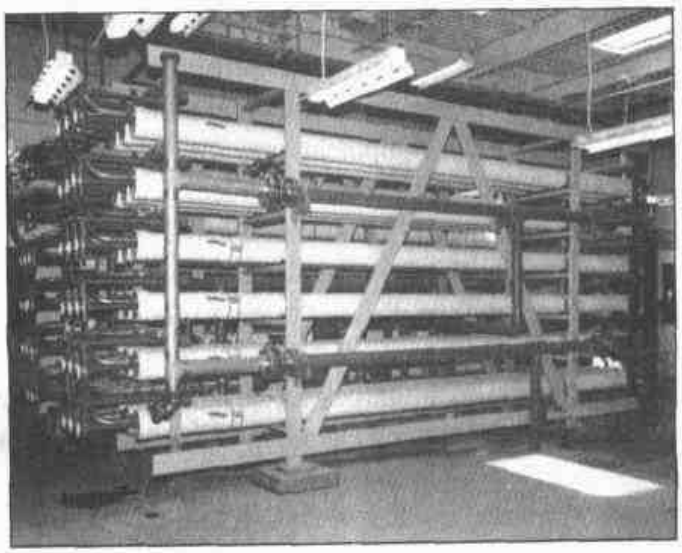

Figure 1–7

Reverse osmosis membrane system used for the removal of residual suspended solids remaining after conventional secondary treatment.

must be reused. The concept of reuse is becoming accepted more widely as other parts of the country experience water shortages. The use of dual water systems, such as now used in St. Petersburg in Florida and Rancho Viejo in California, is expected to increase in the future. In both locations, treated effluent is used for landscape watering and other nonpotable uses. Satellite reclamation systems such as those used in the Los Angeles basin, where wastewater flows are mined (withdrawn from collection systems) for local treatment and reuse, are examples where transportation and treatment costs of reclaimed water can be reduced significantly. Because water reuse is expected to become of even greater importance in the future, reuse applications are considered in Chap. 13.

Current Status

Most of the reuse of wastewater occurs in the arid and semiarid western and southwestern states of the United States; however, the number of reuse projects is increasing in the south especially in Florida and South Carolina. Because of health and safety concerns, water reuse applications are mostly restricted to nonpotable uses such as landscape and agricultural irrigation. In a report by the National Research Council (1998), it was concluded that indirect potable reuse of reclaimed water (introducing reclaimed water to augment a potable water source before treatment) is viable. The report also stated that direct potable reuse (introducing reclaimed water directly into a water distribution system) was not practicable. Because of the concerns about potential health effects associated with the reclaimed water reuse, plans are proceeding slowly about expanding reuse beyond agricultural and landscape irrigation, groundwater recharge for repelling saltwater intrusion, and nonpotable industrial uses (e.g., boiler water and cooling water).

New Directions and Concerns

Many of the concerns mentioned in the National Research Council (NRC, 1998) report regarding potential microbial and chemical contamination of water supplies also apply to water sources that receive incidental or unplanned wastewater discharges. A number of communities use water sources that contain a significant wastewater component. Even though these sources, after treatment, meet current drinking water standards, the growing knowledge of the potential impacts of new trace contaminants raises concern. Conventional technologies for both water and wastewater treatment may be incapable of reducing the levels of trace contaminants below where they are not considered as a potential threat to public health. Therefore, new technologies that offer significantly improved levels of treatment or constituent reduction need to be tested and evaluated. Where indirect potable reuse is considered, risk assessment also becomes an important component of a water reuse investigation. Risk assessment is addressed in Chap. 13.

Future Trends in Technology

Technologies that are suitable for water reuse applications include membranes (pressure-driven, electrically driven, and membrane bioreactors), carbon adsorption, advanced oxidation, ion exchange, and air stripping. Membranes are most significant developments as new products are now available for a number of treatment applications. Membranes had been limited previously to desalination, but they are being tested increasingly for wastewater applications to produce high-quality treated effluent suitable for reclamation. Increased levels of contaminant removal not only enhance the product for

reuse but also lessen health risks. As indirect potable reuse intensifies to augment existing water supplies, membranes are expected to be one of the predominant treatment technologies. Advanced wastewater treatment technologies are discussed in Chap. 11, and water reuse is considered in Chap. 13.

1–7 BIOSOLIDS AND RESIDUALS MANAGEMENT

The management of the solids and concentrated contaminants removed by treatment has been and continues to be one of the most difficult and expensive problems in the field of wastewater engineering. Wastewater solids are organic products that can be used beneficially after stabilization by processes such as anaerobic digestion and composting. With the advent of regulations that encourage biosolids use, significant efforts have been directed to producing a "clean sludge" (Class A biosolids—see definition in Table 1–1) that meets heavy metals and pathogen requirements and is suitable for land application. Regulations for Class B biosolids call for reduced density in pathogenic bacteria and enteric viruses, but not to the levels of Class A biosolids. Further, the application of Class B biosolids to land is strictly regulated, and distribution for home use is prohibited (see Table 1–1).

Other treatment plant residuals such as grit and screenings have to be rendered suitable for disposal, customarily in landfills. Landfills usually require some form of dewatering to limit moisture content. With the increased use of membranes, especially in wastewater reuse applications, a new type of residual, brine concentrate, requires further processing and disposal. Solar evaporation ponds and discharge to a saltwater environment are only viable in communities where suitable and environmental geographic conditions prevail; brine concentration and residuals solidification are generally too complex and costly to implement.

Current Status

Treatment technologies for solids processing have focused on traditional methods such as thickening, stabilization, dewatering, and drying. Evolution in the technologies has not occurred as rapidly as in liquid treatment processes, but some significant improvements have occurred. Centrifuges that produce a sludge cake with higher solids content, egg-shaped digesters that improve operation, and dryers that minimize water content are just a few examples of products that have come into use in recent years. These developments are largely driven by the need to produce biosolids that are clean, have less volume, and can be used beneficially.

Landfills still continue to be used extensively for the disposal of treatment plant solids, either in sludge-only monofills or with municipal solid waste. The number and capacity of landfills, however, have been reduced, and new landfill locations that meet public and regulatory acceptance and economic requirements are increasingly difficult to find. Incineration of solids by large municipalities continues to be practiced, but incineration operation and emission control are subject to greater regulatory restrictions and adverse public scrutiny. Alternatives to landfills and incineration include land application of liquid or dried biosolids and composting for distribution and marketing. Land application of biosolids is used extensively to reclaim marginal land for productive uses and to utilize nutrient content in the biosolids. Composting, although a more

expensive alternative, is a means of stabilizing and distributing biosolids for use as a soil amendment. Alkaline stabilization of biosolids for land application is also used but to a lesser extent.

New Directions and Concerns

Over the last 30 years, the principal focus in wastewater engineering has been on improving the quality of treated effluent through the construction of secondary and advanced wastewater treatment plants. With improved treatment methods, higher levels of treatment must be provided not only for conventional wastewater constituents but also for the removal of specific compounds such as nutrients and heavy metals. A byproduct of these efforts has been the increased generation of solids and biosolids per person served by a municipal wastewater system. In many cases, the increase in solids production clearly taxes the capacity of existing solids processing and disposal methods.

In addition to the shear volume of solids that has to be handled and processed, management options continue to be reduced through stricter regulations. Limitations that affect options are: (1) landfill sites are becoming more difficult to find and have permitted, (2) air emissions from incinerators are more closely regulated, and (3) new requirements for the land application of biosolids have been instituted. In large urban areas, haul distances to landfill or land application sites have significantly affected the cost of solids processing and disposal. Few new incinerators are being planned because of difficulties in finding suitable sites and obtaining permits. Emission control regulations of the Clean Air Act also require the installation of complex and expensive pollution control equipment.

More communities are looking toward (1) producing Class A biosolids to improve beneficial reuse opportunities or (2) implementing a form of volume reduction, thus lessening the requirements for disposal. The issue—"are Class A biosolids clean enough?"—will be of ongoing concern to the public. The continuing search for better methods of solids processing, disposal, and reuse will remain as one of the highest priorities in the future. Additionally, developing meaningful dialogue with the public about health and environmental effects will continue to be very important.

Future Trends in Biosolids Processing

New solids processing systems have not been developed as rapidly as liquid unit operations and processes. Anaerobic digestion remains the principal process for the stabilization of solids. Egg-shaped digesters, developed in Europe for anaerobic digestion, are being used more extensively in the United States because of advantages of easier operation, lower operation and maintenance costs, and, in some cases, increased volatile solids destruction (which also increases the production of reusable methane gas) (see Fig. 1–8). Other developments in anaerobic and aerobic digestion include temperature-phased anaerobic digestion and autothermal aerobic digestion (ATAD), another process developed in Europe. These processes offer advantages of improved volatile solids destruction and the production of stabilized biosolids that meet Class A requirements.

High solids centrifuges and heat dryers are expected to be used more extensively. High solids centrifuges extract a greater percentage of the water in liquid sludge, thus providing a dryer cake. Improved dewatering not only reduces the volume of solids

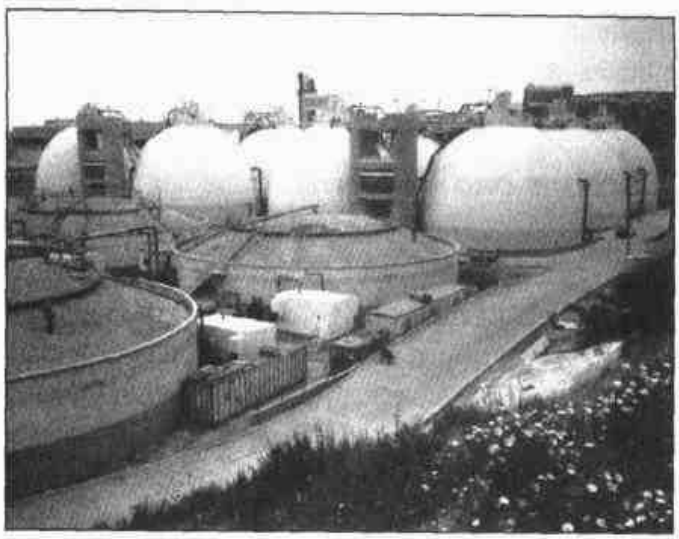

Figure 1–8
Egg-shaped digesters used for the anaerobic treatment of biosolids.

requiring further processing and disposal, but allows composting or subsequent drying to be performed more efficiently. Heat drying provides further volume reduction and improves the quality of the product for potential commercial marketing. Each of the newer methods of biosolids processing is described in Chap. 14.

PROBLEMS AND DISCUSSION TOPICS 139

REFERENCES 148

An understanding of the nature of wastewater is essential in the design and operation of collection, treatment, and reuse facilities, and in the engineering management of environmental quality. To promote this understanding, the information in this chapter is presented in nine sections dealing with (1) an introduction to the constituents found in wastewater, (2) sampling and analytical procedures, (3) physical characteristics, (4) inorganic nonmetallic constituents, (5) metallic constituents, (6) aggregate organic constituents, (7) individual organic constituents and compounds, (8) biological characteristics, and (9) toxicity tests. The material in this chapter has been organized in a manner similar to that used in Standard Methods (1998), the standard reference work for the characterization of wastewater in the field of environmental engineering.

2–1 WASTEWATER CONSTITUENTS

The physical, chemical, and biological constituents found in wastewater and the constituents of concern in wastewater are introduced briefly in the following discussion.

Constituents Found in Wastewater

Wastewater is characterized in terms of its physical, chemical, and biological composition. The principal physical properties and the chemical and biological constituents of wastewater, and their sources, are reported in Table 2–1. It should be noted that many of the physical properties and chemical and biological characteristics listed in Table 2–1 are interrelated. For example, temperature, a physical property, affects both the amounts of gases dissolved in the wastewater and the biological activity in the wastewater.

Constituents of Concern in Wastewater Treatment

The important constituents of concern in wastewater treatment are listed in Table 2–2. Secondary treatment standards for wastewater are concerned with the removal of biodegradable organics, total suspended solids, and pathogens. Many of the more stringent standards that have been developed recently deal with the removal of nutrients, heavy metals, and priority pollutants. When wastewater is to be reused, standards normally include additional requirements for the removal of refractory organics, heavy metals, and in some cases, dissolved inorganic solids.

2–2 SAMPLING AND ANALYTICAL PROCEDURES

Proper sampling and analytical techniques are of fundamental importance in the characterization of wastewater. Sampling techniques, the methods of analysis, the units of measurement for chemical constituents, and some useful concepts from chemistry are considered below.

Sampling

Sampling programs are undertaken for a variety of reasons such as to obtain (1) routine operating data on overall plant performance, (2) data that can be used to document the performance of a given treatment operation or process, (3) data that can be used to implement proposed new programs, and (4) data needed for reporting regulatory compliance. To meet the goals of the sampling program, the data collected must be:

1. *Representative*. The data must represent the wastewater or environment being sampled.
2. *Reproducible*. The data obtained must be reproducible by others following the same sampling and analytical protocols.
3. *Defensible*. Documentation must be available to validate the sampling procedures. The data must have a known degree of accuracy and precision.
4. *Useful*. The data can be used to meet the objectives of the monitoring plan (Pepper et al., 1996).

Because the data from the analysis of the samples will ultimately serve as a basis for implementing wastewater management facilities and programs, the techniques used in a wastewater sampling program must be such that representative samples are obtained.

Table 2-1
Common analyses used to assess the constituents found in wastewater[a]

Test[b]	Abbreviation/ definition	Use or significance of test results
Physical characteristics		
Total solids	TS	To assess the reuse potential of a wastewater and to determine the most suitable type of operations and processes for its treatment
Total volatile solids	TVS	
Total fixed solids	TFS	
Total suspended solids	TSS	
Volatile suspended solids	VSS	
Fixed suspended solids	FSS	
Total dissolved solids	TDS (TS − TSS)	
Volatile dissolved solids	VDS	
Total fixed dissolved solids	FDS	
Settleable solids		To determine those solids that will settle by gravity in a specified time period
Particle size distribution	PSD	To assess the performance of treatment processes
Turbidity	NTU[c]	Used to assess the quality of treated wastewater
Color	Light brown, gray, black	To assess the condition of wastewater (fresh or septic)
Transmittance	% T	Used to assess the suitability of treated effluent for UV disinfection
Odor	TON[d]	To determine if odors will be a problem
Temperature	°C or °F	Important in the design and operation of biological processes in treatment facilities
Density	ρ	
Conductivity	EC	Used to assess the suitability of treated effluent for agricultural applications
Inorganic chemical characteristics		
Free ammonia	NH_4^+	Used as a measure of the nutrients present and the degree of decomposition in the wastewater; the oxidized forms can be taken as a measure of the degree of oxidation
Organic nitrogen	Org N	
Total Kjeldahl nitrogen	TKN (Org N + NH_4^+)	
Nitrites	NO_2^-	
Nitrates	NO_3^-	
Total nitrogen	TN	
Inorganic phosphorus	Inorg P	
Total phosphorus	TP	
Organic phosphorus	Org P	

(continued)

Table 2–1 *(Continued)*

Test[b]	Abbreviation/ definition	Use or significance of test results
Inorganic chemical characteristics (continued)		
pH	$pH = -\log [H+]$	A measure of the acidity or basicity of an aqueous solution
Alkalinity	$\Sigma HCO_3^- + CO_3^{-2} + OH^- - H+$	A measure of the buffering capacity of the wastewater
Chloride	Cl^-	To assess the suitability of wastewater for agricultural reuse
Sulfate	SO_4^{-2}	To assess the potential for the formation of odors and may impact the treatability of the waste sludge
Metals	As, Cd, Ca, Cr, Co, Cu, Pb, Mg, Hg, Mo, Ni, Se, Na, Zn	To assess the suitability of the wastewater for reuse and for toxicity effects in treatment. Trace amounts of metals are important in biological treatment
Specific inorganic elements and compounds		To assess presence or absence of a specific constituent
Various gases	O_2, CO_2, NH_3, H_2S, CH_4	The presence or absence of specific gases
Organic chemical characteristics		
Five-day carbonaceous biochemical oxygen demand	$CBOD_5$	A measure of the amount of oxygen required to stabilize a waste biologically
Ultimate carbonaceous biochemical oxygen demand	UBOD (also BOD_u, BOD_L)	A measure of the amount of oxygen required to stabilize a waste biologically
Nitrogenous oxygen demand	NOD	A measure of the amount of oxygen required to oxidize biologically the nitrogen in the wastewater to nitrate
Chemical oxygen demand	COD	Often used as a substitute for the BOD test
Total organic carbon	TOC	Often used as a substitute for the BOD test
Specific organic compounds and classes of compounds	MBAS[e], CTAS[f]	To determine presence of specific organic compounds and to assess whether special design measures will be needed for removal
Biological characteristics		
Coliform organisms	MPN (most probable number)	To assess presence of pathogenic bacteria and effectiveness of disinfection process
Specific microorganisms	Bacteria, protozoa, helminths, viruses	To assess presence of specific organisms in connection with plant operation and for reuse
Toxicity	TU_a and TU_c	Toxic unit acute, Toxic unit chronic

[a] Adapted, in part, from Crites and Tchobanoglous (1998).

[b] Details on the various tests may be found in Standard Methods (1998).

[c] NTU = nephelometric turbidity unit

[d] TON = threshold odor number

[e] MBAS = methylene blue active substances

[f] CTAS = cobalt thiocyanate active substances

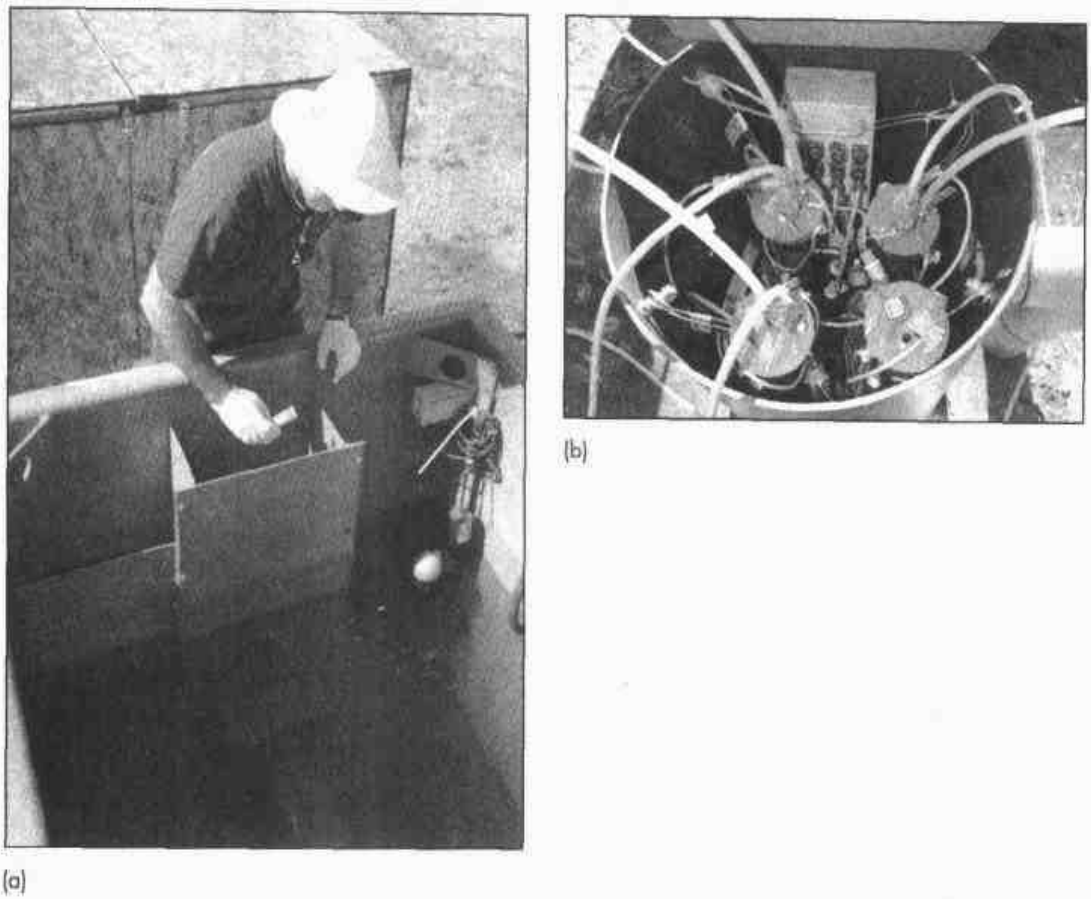

Table 2–2
Principal constituents of concern in wastewater treatment

Constituent	Reason for importance
Suspended solids	Suspended solids can lead to the development of sludge deposits and anaerobic conditions when untreated wastewater is discharged in the aquatic environment
Biodegradable organics	Composed principally of proteins, carbohydrates, and fats, biodegradable organics are measured most commonly in terms of BOD (biochemical oxygen demand) and COD (chemical oxygen demand). If discharged untreated to the environment, their biological stabilization can lead to the depletion of natural oxygen resources and to the development of septic conditions
Pathogens	Communicable diseases can be transmitted by the pathogenic organisms that may be present in wastewater
Nutrients	Both nitrogen and phosphorus, along with carbon, are essential nutrients for growth. When discharged to the aquatic environment, these nutrients can lead to the growth of undesirable aquatic life. When discharged in excessive amounts on land, they can also lead to the pollution of groundwater
Priority pollutants	Organic and inorganic compounds selected on the basis of their known or suspected carcinogenicity, mutagenicity, teratogenicity, or high acute toxicity. Many of these compounds are found in wastewater
Refractory organics	These organics tend to resist conventional methods of wastewater treatment. Typical examples include surfactants, phenols, and agricultural pesticides
Heavy metals	Heavy metals are usually added to wastewater from commercial and industrial activities and may have to be removed if the wastewater is to be reused
Dissolved inorganics	Inorganic constituents such as calcium, sodium, and sulfate are added to the original domestic water supply as a result of water use and may have to be removed if the wastewater is to be reused

There are no universal procedures for sampling; sampling programs must be tailored individually to fit each situation (see Fig. 2–1). Special procedures are necessary to handle sampling problems that arise when wastes vary considerably in composition.

Before a sampling program is undertaken, a detailed sampling protocol must be developed along with a quality assurance project plan (QAPP) (known previously as quality assurance/quality control, QA/QC). As a minimum, the following items must be specified in the QAPP (Pepper et al., 1996). Additional details on the subject of sampling may be found in Standard Methods (1998).

1. *Sampling plan.* Number of sampling locations, number (see homework problem 2–5) and type of samples, time intervals (e.g., real-time and/or time-delayed samples).
2. *Sample types and size.* Catch or grab samples, composite samples, or integrated samples, separate samples for different analyses (e.g., for metals). Sample size (i.e., volume) required

(a) (b)

Figure 2–1

Collection of samples for analysis: (*a*) collection of an effluent sample from a pilot plant treatment unit and (*b*) view of an uncapped monitoring well equipped with sampling outlets for four different well depths. Samples are collected from each depth to monitor a groundwater injection system.

3. *Sample labeling and chain of custody.* Sample labels, sample seals, field log book, chain of custody record, sample analysis request sheets, sample delivery to the laboratory, receipt and logging of sample, and assignment of sample for analysis.
4. *Sampling methods.* Specific techniques and equipment to be used (e.g., manual, automatic, or sorbent sampling).
5. *Sampling storage and preservation.* Type of containers (e.g., glass or plastic), preservation methods, maximum allowable holding times.
6. *Sample constituents.* A list of the parameters to be measured.
7. *Analytical methods.* A list of the field and laboratory test methods and procedures to be used, and the detection limits for the individual methods.

If the physical, chemical, and/or biological integrity of the samples is not maintained during interim periods between sample collection and sample analysis, a carefully performed sampling program will become worthless. Considerable research on the problem of sample preservation has failed to perfect a universal treatment or method, or to formulate a set of fixed rules applicable to samples of all types. Prompt analysis is undoubtedly the most positive assurance against error due to sample deterioration. When analytical and testing conditions dictate a lag between collection and analysis, such as when a 24-h composite sample is collected, provisions must be made for preserving samples (see Fig. 2–2). Current methods of sample preservation for the analysis of properties subject to deterioration must be used (Standard Methods, 1998). Probable errors due to deterioration of the sample should be noted in reporting analytical data.

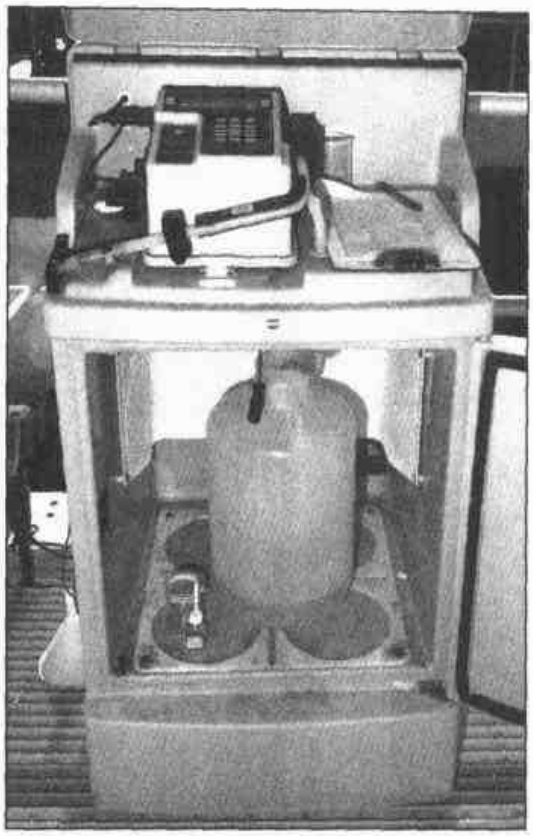

Figure 2-2

Typical automatic composite sampler used to collect and refrigerate samples over a 24-h period.

Methods of Analysis

The analyses used to characterize wastewater vary from precise quantitative chemical determinations to the more qualitative biological and physical determinations. The quantitative methods of analysis are either gravimetric, volumetric, or physicochemical. In the physicochemical methods, properties other than mass or volume are measured. Instrumental methods of analysis such as turbidimetry, colorimetry, potentiometry, polarography, adsorption spectrometry, fluorometry, spectroscopy, and nuclear radiation are representative of the physicochemical analyses. Details concerning the various analyses may be found in Standard Methods (1998), the accepted reference that details the conduct of water and wastewater analyses.

Regardless of the method of analysis used, the detection level must be specified. Several detection limits are defined and are listed below in order of increasing levels (Standard Methods, 1998).

1. *Instrumental detection level (IDL).* Constituent concentration that produces a signal greater than five times the signal/noise ratio of the instrument. The IDL is, in many respects, similar to "critical level" and "criterion of detection." The latter level is stated as 1.645 times the standard deviation s of blank analyses.
2. *Lower level of detection (LLD).* Constituent concentration in reagent water that produces a signal ($2 \times 1.645s$) above the mean of blank analyses, where s is the standard deviation. The value at $2 \times 1.645s$ sets both Type I and Type II errors at 5 percent. Type I and Type II errors are used to test the null hypothesis (Larson

and Farber, 2000). Other names for this level are "detection level" and "level of detection" (LOD).

3. *Method detection level (MDL).* Constituent concentration that, when processed through the complete method, produces a signal with a 99 percent probability that it is different from the blank. For seven replicates of the sample, the mean must be $3.14s$ above the blank, where s is the standard deviation of the seven replicates. Compute MDL from replicate measurements one to five times the actual MDL. The MDL will be larger than the LLD because of the few replications and the sample processing steps, and may vary with constituent and matrix.
4. *Level of quantification (LOQ).* Constituent concentration that produces a signal sufficiently greater than the blank that can be detected within specified levels by good laboratories during routine operating conditions. Typically it is the concentration that produces a signal $10s$ above the reagent blank signal.

Units of Measurement for Physical and Chemical Parameters

The results of the analysis of wastewater samples are expressed in terms of physical and chemical units of measurement. The most common units for these measurements are reported in Table 2–3. Measurements of chemical parameters are usually expressed in the physical unit of milligrams per liter (mg/L) or grams per cubic meter (g/m^3). The concentration of trace constituents is usually expressed as micrograms per liter ($\mu g/L$) or nanograms per liter (ng/L).

As noted in Table 2–3, the concentration can also be expressed as parts per million (ppm), which is a mass-to-mass ratio. The relationship between mg/L and ppm is:

$$\text{ppm} = \frac{\text{mg/L}}{\text{specific gravity of fluid}} \tag{2–1}$$

For dilute systems, such as those encountered in natural waters and wastewater, in which one liter of sample weighs approximately one kilogram, the units of mg/L or g/m^3 are interchangeable with ppm. The terms "parts per billion" (ppb) and "parts per trillion" (ppt) are used interchangeably with $\mu g/L$ and ng/L, respectively. Dissolved gases, considered to be chemical constituents, are expressed in parts per million by volume (ppm_v), $\mu g/m^3$, or mg/L. Conversion of gas concentrations between ppm_v and $\mu g/m^3$ is given by Eq. (2–44), the universal gas law. Gases that evolve as byproducts of wastewater treatment, such as carbon dioxide and methane (from anaerobic decomposition), are measured in terms of L or m^3 (ft^3). Parameters such as temperature, odor, hydrogen ion, and biological organisms are expressed in other units, as explained below.

Useful Chemical Relationships

Other useful relationships from chemistry used in the analysis and evaluation of wastewater test results and in the design of treatment facilities include mole fraction, electroneutrality, chemical equilibrium, activity coefficient, ionic strength, and solubility product.

Mole Fraction. The ratio of the number of moles of a given solute to the total number of moles of all components in solution is defined as the *mole fraction*. Along with

Table 2–3
Units commonly used to express analytical results

Basis	Application	Unit[a]
Physical analyses:		
Density	$\frac{\text{Mass of solution}}{\text{Unit of volume}}$	$\frac{kg}{m^3}$
Percent by volume	$\frac{\text{Volume of solution} \times 100}{\text{Total volume of solution}}$	% (by vol)
Percent by mass	$\frac{\text{Mass of solution} \times 100}{\text{Combined mass of solute + solvent}}$	% (by mass)
Volume ratio	$\frac{\text{Milliliters}}{\text{Liter}}$	$\frac{mL}{L}$
Mass per unit volume	$\frac{\text{Picograms}}{\text{Liter of solution}}$	$\frac{pg}{L}$
	$\frac{\text{Nanograms}}{\text{Liter of solution}}$	$\frac{ng}{L}$
	$\frac{\text{Micrograms}}{\text{Liter of solution}}$	$\frac{\mu g}{L}$
	$\frac{\text{Milligrams}}{\text{Liter of solution}}$	$\frac{mg}{L}$
	$\frac{\text{Grams}}{\text{Cubic meter of solution}}$	$\frac{g}{m^3}$
Mass ratio	$\frac{\text{Milligrams}}{10^9 \text{ milligrams}}$	ppb
	$\frac{\text{Milligrams}}{10^6 \text{ milligrams}}$	ppm
Chemical analyses:		
Molality	$\frac{\text{Moles of solute}}{\text{1000 grams solvent}}$	$\frac{mol}{kg}$
Molarity	$\frac{\text{Moles of solute}}{\text{Liter of solution}}$	$\frac{mol}{L}$
Normality	$\frac{\text{Equivalents of solute}}{\text{Liter of solution}}$	$\frac{eq}{L}$
	$\frac{\text{Milliequivalents of solute}}{\text{Liter of solution}}$	$\frac{meq}{L}$

[a]Note $1\ g = 10^3\ mg = 10^6\ \mu g = 10^9\ ng = 10^{12}\ pg$

$mg/L = g/m^3$

ppm = parts per million (by mass), ppb = parts per billion (by mass), ppt = parts per trillion (by mass)

its importance in solution chemistry, the mole fraction is of importance in the mass transfer of gases into and out of liquids. In equation form,

$$x_B = \frac{n_B}{n_A + n_B + n_C + \cdots + n_N} \tag{2-2}$$

where x_B = mole fraction of solute B
n_B = number of moles of solute B
n_A = number of moles of solute A
n_C = number of moles of solute C
n_N = number of moles of solute N

The application of Eq. (2–2) is illustrated in Example 2–1.

EXAMPLE 2–1 Determination of Mole Fraction Determine the mole fraction of oxygen in water if the concentration of dissolved oxygen is 10.0 mg/L.

Solution

1. Determine the mole fraction of oxygen using Eq. (2–2) written as follows:

$$x_{O_2} = \frac{n_{O_2}}{n_{O_2} + n_W}$$

   a. Determine the moles of oxygen.

$$n_{O_2} = \frac{(10 \text{ mg/L})}{(32 \times 10^3 \text{ mg/mole } O_2)} = 3.125 \times 10^{-4} \text{ mole/L}$$

   b. Determine the moles of water.

$$n_W = \frac{(1000 \text{ g/L})}{(18 \text{ g/mole of water})} = 55.556 \text{ mole/L}$$

   c. The mole fraction of oxygen is:

$$x_{O_2} = \frac{3.125 \times 10^{-4}}{3.125 \times 10^{-4} + 55.556} = 5.62 \times 10^{-6}$$

Electroneutrality. The principle of *electroneutrality* requires that the sum of the positive ions (cations) must equal the sum of negative ions (anions) in solution, thus:

$$\Sigma \text{ cations} = \Sigma \text{ anions} \tag{2-3}$$

where cations = positively charged species in solution expressed in terms of equivalent weight per liter, eq/L or milliequvalent weight per liter, meq/L
anions = negatively charged species in solution, eq/L or meq/L

The equivalent weight of a compound is defined as:

$$\text{Equivalent weight, g/eq} = \frac{\text{molecular weight, g}}{Z} \tag{2-4}$$

where Z = (1) the absolute value of the ion charge, (2) the number of H^+ or OH^- ions a species can react with or yield in an acid-base reaction, or (3) the absolute value of the change in valence occurring in an oxidation reduction reaction (Sawyer et al., 1994).

Equation (2–3) can be used to check the accuracy of chemical analyses by taking into account the percentage difference defined as follows (Standard Methods, 1998):

$$\text{Percent difference} = 100 \times \left(\frac{\Sigma \text{ cations} - \Sigma \text{ anions}}{\Sigma \text{ cations} + \Sigma \text{ anions}} \right) \quad (2\text{–}5)$$

The acceptance criteria are as given below.

Σ Anions, meq/L	Acceptable difference
0–3.0	±0.2 meq/L
3.0–10.0	±2%
10–800	5%

The application of Eqs. (2–3) and (2–5) is illustrated in Example 2–2.

EXAMPLE 2–2 Checking the Accuracy of Analytical Measurements The following analysis has been completed on a filtered effluent, from an extended aeration wastewater-treatment plant, that is to be used for landscape watering. Check the accuracy of the analysis to determine if the analysis is sufficiently accurate, based on the criteria given above.

Cation	Conc., mg/L	Anion	Conc., mg/L
Ca^{2+}	82.2	HCO_3^-	220.0
Mg^{2+}	17.9	SO_4^{2-}	98.3
Na^+	46.4	Cl^-	78.0
K^+	15.5	NO_3^-	25.6

Solution

1. Prepare a cation-anion balance.

Cation	Conc., mg/L	mg/meq[a]	meq/L	Anion	Conc., mg/L	mg/meq[a]	meq/L
Ca^{2+}	82.2	20.04[b]	4.10	HCO_3^-	220	61.02	3.61
Mg^{2+}	17.9	12.15	1.47	SO_4^{2-}	98.3	48.03	2.05
Na^+	46.4	23.00	2.02	Cl^-	78.0	35.45	2.20
K^+	15.5	39.10	0.40	NO_3^-	25.6	62.01	0.41
		Σ cations	7.99			Σ anions	8.27

[a] Eq weight = molecular weight in grams/Z

[b] For calcium, eq wt = 40.08/2 = 20.04 g/eq or 20.04 mg/meq

2. Check the accuracy of the cation-anion balance using Eq. (2–5).

$$\text{Percent difference} = 100 \times \left(\frac{\Sigma \text{ cations} - \Sigma \text{ anions}}{\Sigma \text{ cations} + \Sigma \text{ anions}} \right)$$

$$\text{Percent difference} = 100 \times \left(\frac{7.99 - 8.27}{7.99 + 8.27} \right) = -1.72\%$$

For a total anion concentration between 3 and 10 meq/L, the acceptable difference must be equal to or less than 2 percent (see table given above); thus, the analysis is of sufficient accuracy.

Comment If the cation-anion balance is not of sufficient accuracy, the problem may be analytical or a constituent of significant concentration may be missing.

Chemical Equilibrium. A reversible chemical reaction in which reactants A and B combine to yield products C and D may be written as:

$$aA + bB \leftrightarrow cC + dD \tag{2–6}$$

Where the *stoichiometry* coefficients a, b, c, and d correspond to the number of moles of constituents A, B, C, and D, respectively. The *stoichiometry* of reaction refers to the definition of the quantities of chemical compounds involved in a reaction (e.g., a of A, b of B, etc.). When the chemical species come to a state of equilibrium, as governed by the law of mass action, the numerical value of the ratio of the products over the reactants is known as the *equilibrium constant* K and is written as:

$$\frac{[C]^c[D]^d}{[A]^a[B]^b} = K \tag{2–7}$$

For a given reaction, the value of the equilibrium constant will change with temperature and the ionic strength of the solution. It should also be noted that in Eq. (2–7) it is assumed that that activity of the individual ions is equal to 1.

Brackets are used in Eq. (2–7) to denote molar concentrations. The use of molal concentrations (see Table 2–3) is more correct theoretically, but for dilute solutions encountered in wastewater applications molar concentrations are used. Molal concentrations must be used for brine solutions and seawater. To account for nonideal conditions encountered due to ion-ion interactions, a new concentration term called "activity" is used. The activity of an ion is defined as follows.

$$a_i = \gamma[C_i] \tag{2–8}$$

where a_i = activity of ith ion, mol/L
γ = activity coefficient for the ith ion
C_i = concentration of ith ion in solution, mol/L

If Eq. (2–7) is written in terms of activity and activity coefficients rather than concentrations, the resulting expression is

$$\frac{[a_C]^c[a_D]^d}{[a_A]^a[a_B]^b} = \frac{[\gamma_C C]^c[\gamma_D D]^d}{[\gamma_A A]^a[\gamma_B B]^b} = K \tag{2–9}$$

Activity Coefficient. The activity coefficient can be estimated using the following expression, derived from the Debye-Huckel theory, and known as the Guntelberg approximation [see Snoeyink and Jenkins (1998); McMurry and Fay (1998) for discussion].

$$\log \gamma = -\frac{0.5(Z_i)^2\sqrt{I}}{1 + \sqrt{I}} \tag{2-10}$$

where Z_i = charge on ith ionic species
I = ionic strength

The above relationship is valid for solutions with an ionic strength that does not exceed 0.1 M. A number of other similar relationships will be found in the literature including those proposed by Davies (1962). The equation proposed by Davies, which can be used for higher ionic strengths (>0.1 M), is essentially the same as Eq. (2–10) with the exception that a factor of $0.3I$ is subtracted from the right-hand side of Eq. (2–10). The Davies equation is used in homework problem 2–3. Computation of the activity coefficient is illustrated in Example 2–3 following the discussion of ionic strength and solubility.

Ionic Strength. The ionic strength of a solution is a measure of the concentration of dissolved chemical constituents. The ionic strength of a solution can be estimated using the following expression:

$$I = \frac{1}{2} \sum C_i Z_i^2 \tag{2-11}$$

where I = ionic strength
C_i = concentration of the ith species, mole/L
Z_i = valence (or oxidation) number of the ith species [see Eq. (2–4)]

The ionic strength can also be estimated based on the total dissolved solids concentration using the following expression:

$$I = 2.5 \times 10^{-5} \times \text{TDS} \tag{2-12}$$

where TDS = total dissolved solids, mg/L or g/m^3

Equation (2–12) is often used to estimate the ionic strength of treated wastewater in groundwater recharge applications (see Chap. 13).

Solubility Product. The equilibrium constant for a reaction involving a precipitate and its constituent ions is known as the *solubility product*. For example, the reaction for calcium carbonate ($CaCO_3$) is

$$CaCO_3 \leftrightarrow Ca^{2+} + CO_3^{2-} \tag{2-13}$$

Because the activity of the solid phase is usually taken as 1, the solubility product is written as:

$$[Ca^{2+}]\,[CO_3^{2-}] = K_{sp} \tag{2-14}$$

where K_{sp} = solubility product constant.

It is important to note that the value of the equilibrium constant will change with temperature of the solution. Written in terms of activity coefficients, Eq. (2–14) becomes

$$\gamma_{Ca^{2+}}[Ca^{2+}]\gamma_{CO_3^{2-}}[CO_3^{2-}] = K_{sp} \tag{2–15}$$

The application of Eq. (2–15) is illustrated in Example 2–3.

EXAMPLE 2–3 Determine the Activity Coefficients and Solubility of Calcium Carbonate Determine the activity coefficients for the mono and divalent ions in the wastewater given in Example 2–2. Using the value of the activity coefficient for a divalent ion, estimate the equilibrium concentration of calcium in solution needed to satisfy the solubility product for calcium carbonate ($CaCO_3$) at 25°C. The value of the solubility product constant K_{sp} at 25°C is 5×10^{-9}.

Solution

1. Determine the ionic strength of the wastewater using Eq. (2–11).
   a. Prepare a computation table to determine the summation term in Eq. (2–10) using the data from Example 2–2.

Ion	Conc. C, mg/L	$C \times 10^3$, mole/L	Z^2	$CZ^2 \times 10^3$
Ca^{2+}	82.2	2.051	4	8.404
Mg^{2+}	17 9	0.736	4	2.944
Na^{+}	46.4	2.017	1	2.017
K^{+}	15.5	0.396	1	0.397
HCO_3^-	220	3.607	1	3.607
SO_4^{2-}	98.3	1.024	4	4.096
Cl^-	78.0	2.200	1	2.200
NO_3^-	25.6	0.413	1	0.413
Sum				23.876

   b. Determine the ionic strength for the concentration C.

$$I = \frac{1}{2}\sum C_i Z_i^2 = \frac{1}{2}(23.876 \times 10^{-3}) = 11.938 \times 10^{-3}$$

2. Determine the activity coefficients for Ca^{2+} and CO_3^{2-}. Because both species have a valence (charge) of 2, the activity of each will be the same.
   a. For monovalent ions

$$\log \gamma = -\frac{0.5(Z_i)^2\sqrt{I}}{1+\sqrt{I}} = \frac{0.5(1)^2\sqrt{11.938 \times 10^{-3}}}{1+\sqrt{11.938 \times 10^{-3}}} = 0.0492$$

$$\gamma = 0.893$$

b. For divalent ions

$$\log \gamma = -\frac{0.5(Z_i)^2\sqrt{I}}{1+\sqrt{I}} = -\frac{0.5(2)^2\sqrt{11.938 \times 10^{-3}}}{1+\sqrt{11.938 \times 10^{-3}}} = -0.1968$$

$$\gamma = 0.636$$

3. Determine the minimum solubility of calcium using Eq. (2–15).
   a. Because the molar concentrations of calcium and carbonate ions are the same, Eq (2–15) can be written as follows:

   $$\gamma^2[C]^2 = K_{sp}$$

   b. Solve for the concentration C.

   $$C = \sqrt{\frac{K_{sp}}{\gamma^2}} = \sqrt{\frac{5 \times 10^{-9}}{(0.636)^2}} = 11.1 \times 10^{-5} \text{ mole/L}$$

   c. Convert the molar concentration of calcium carbonate to mg/L.

   $$\text{Ca} = 11.1 \times 10^{-5} \text{ mole/L} \times 40{,}000 \text{ mg/mole} = 4.45 \text{ mg/L}$$

Comment The computed value represents the minimum concentration of calcium that would be required in solution to be in equilibrium with solid calcium carbonate.

2–3 PHYSICAL CHARACTERISTICS

The most important physical characteristic of wastewater is its total solids content, which is composed of floating matter, settleable matter, colloidal matter, and matter in solution. Other important physical characteristics include particle size distribution; turbidity; color; transmittance; temperature; conductivity; and density, specific gravity, and specific weight. Odor, sometimes considered a physical factor, is considered in the following section.

Solids

Wastewater contains a variety of solid materials varying from rags to colloidal material. In the characterization of wastewater, coarse materials are usually removed before the sample is analyzed for solids. The various solids classifications are identified in Table 2–4. The interrelationship between the various solids fractions found in wastewater is illustrated graphically on Fig. 2–3. The standard test for settleable solids consists of placing a wastewater sample in a 1-liter Imhoff cone (see Fig. 2–5) and noting the volume of solids in millimeters that settle after a specified time period (1 h). Typically, about 60 percent of the suspended solids in a municipal wastewater are settleable. Total solids (TS) are obtained by evaporating a sample of wastewater to dryness and measuring the mass of the residue. As shown on Fig. 2–3, a filtration step is used to separate the total suspended solids (TSS) from the total dissolved solids (TDS). The appa-

ratus used to determine TSS is shown on Fig. 2–4. The principal types of materials that comprise the filterable and nonfilterable solids in wastewater and their approximate size range are reported on Fig. 2–6

Total Suspended Solids. Because a filter is used to separate the TSS from the TDS, the TSS test is somewhat arbitrary, depending on the pore size of the filter paper used for the test. Filters with nominal pore sizes varying from 0.45 μm to about 2.0 μm have been used for the TSS test (see Fig. 2–7). More TSS will be measured as the pore size of the filter used is reduced. Thus, it is important to note the pore size of the filter paper used, when comparing reported TSS values. It is also important to note that the TSS test itself has no fundamental significance. The principal reasons that the test lacks a fundamental basis are as follows. First, the measured values of TSS are dependent on

Table 2–4 Definitions for solids found in wastewater[a]

Test[b]	Description
Total solids (TS)	The residue remaining after a wastewater sample has been evaporated and dried at a specified temperature (103 to 105°C)
Total volatile solids (TVS)	Those solids that can be volatilized and burned off when the TS are ignited (500 ± 50°C)
Total fixed solids (TFS)	The residue that remains after TS are ignited (500 ± 50°C)
Total suspended solids (TSS)	Portion of the TS retained on a filter (see Fig. 2–4) with a specified pore size, measured after being dried at a specified temperature (105°C). The filter used most commonly for the determination of TSS is the Whatman glass fiber filter, which has a nominal pore size of about 1.58 μm
Volatile suspended solids (VSS)	Those solids that can be volatilized and burned off when the TSS are ignited (500 ± 50°C)
Fixed suspended solids (FSS)	The residue that remains after TSS are ignited (500 ± 50°C)
Total dissolved solids (TDS) (TS − TSS)	Those solids that pass through the filter, and are then evaporated and dried at specified temperature. It should be noted that what is measured as TDS is comprised of colloidal and dissolved solids. Colloids are typically in the size range from 0.001 to 1 μm
Total volatile dissolved solids (VDS)	Those solids that can be volatilized and burned off when the TDS are ignited (500 ± 50°C)
Fixed dissolved solids (FDS)	The residue that remains after TDS are ignited (500 ± 50°C)
Settleable solids	Suspended solids, expressed as milliliters per liter, that will settle out of suspension within a specified period of time

[a] Adapted from Standard Methods (1998).

[b] With the exception of settleable solids, all solids values are expressed in mg/L.

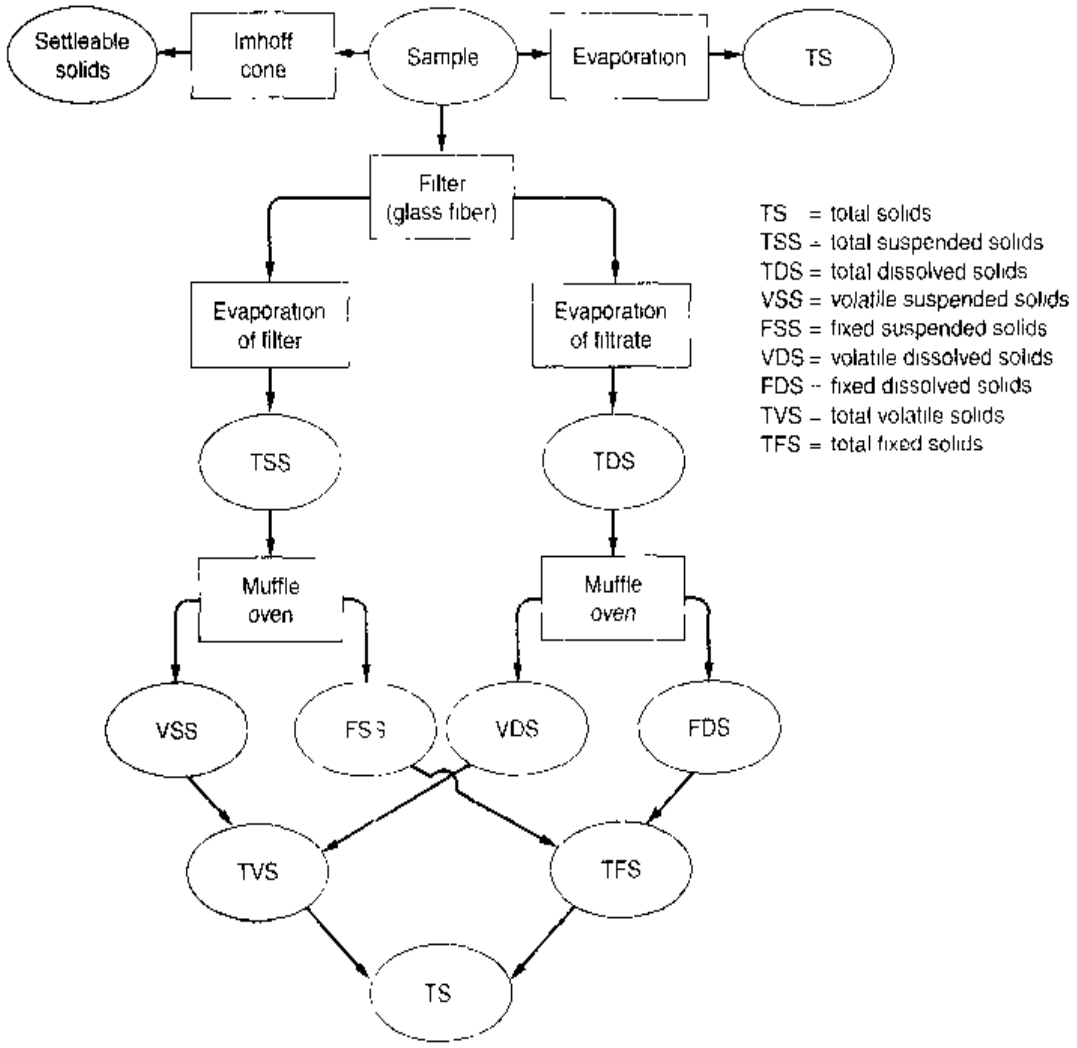

Figure 2–3

Interrelationships of solids found in water and wastewater. In much of the water quality literature, the solids passing through the filter are called dissolved solids. *(Tchobanoglous and Schroeder, 1985.)*

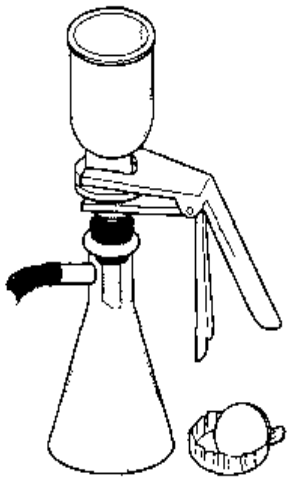

Figure 2–4

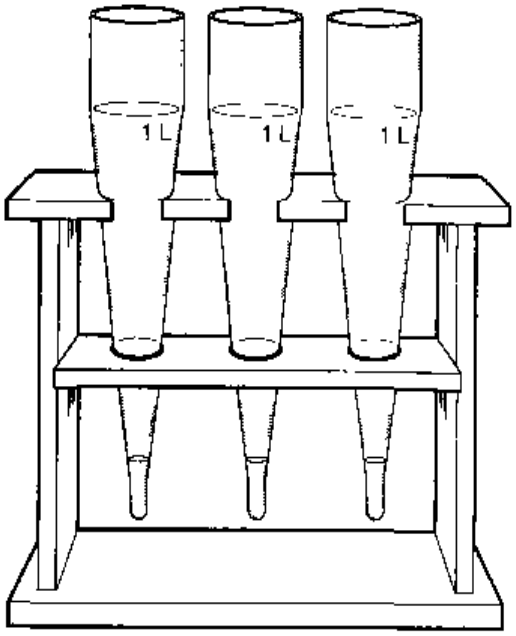
Apparatus used for the determination of total suspended solids. After wastewater sample has been filtered, the preweighted filter paper is placed in an aluminum dish for drying before weighing.

the type and pore size of the filter paper used in the analysis. Second, depending on the sample size used for the determination of TSS, autofiltration, where the suspended solids that have been intercepted by the filter also serve as a filter, can occur. Autofiltration will cause an apparent increase in the measured TSS value over the actual value. Third, depending on the characteristics of the particulate matter, small particles may be removed by adsorption to material already retained by the filter. Fourth, TSS is a lumped parameter, because the number and size distribution of the particles that comprise the measured value is unknown. Nevertheless, TSS test results are used routinely to assess the performance of conventional treatment processes and the need for effluent filtration in reuse applications. Finally, TSS is one of the two universally used effluent standards (along with BOD) by which the performance of treatment plants is judged for regulatory control purposes. The analysis of laboratory data is illustrated in Example 2–4.

Total Dissolved Solids. By definition, the solids contained in the filtrate that passes through a filter with a nominal pore size of 2.0 μm or less are classified as dissolved (Standard Methods, 1998). Yet it is known that wastewater contains a high fraction of colloidal solids. The size of colloidal particles in wastewater is typically in the range from 0.01 to 1.0 μm. It should be noted that some researchers have classified the



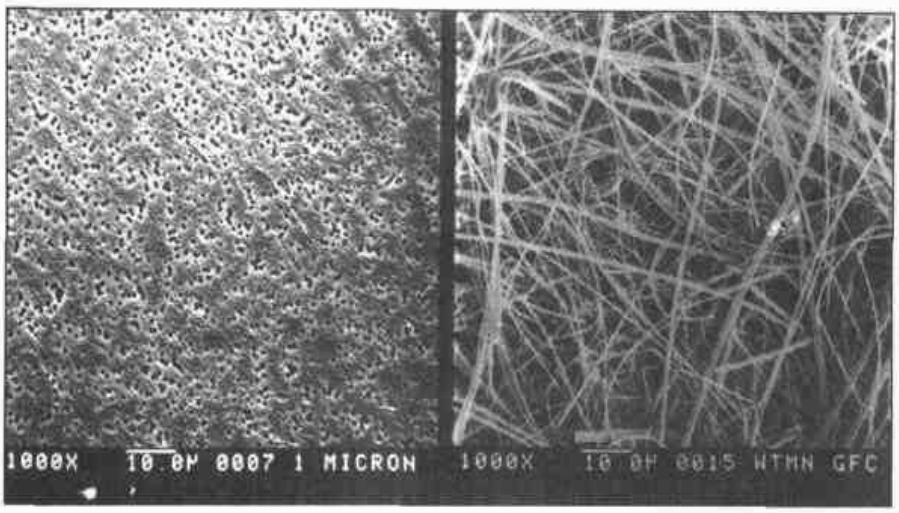


Figure 2–5

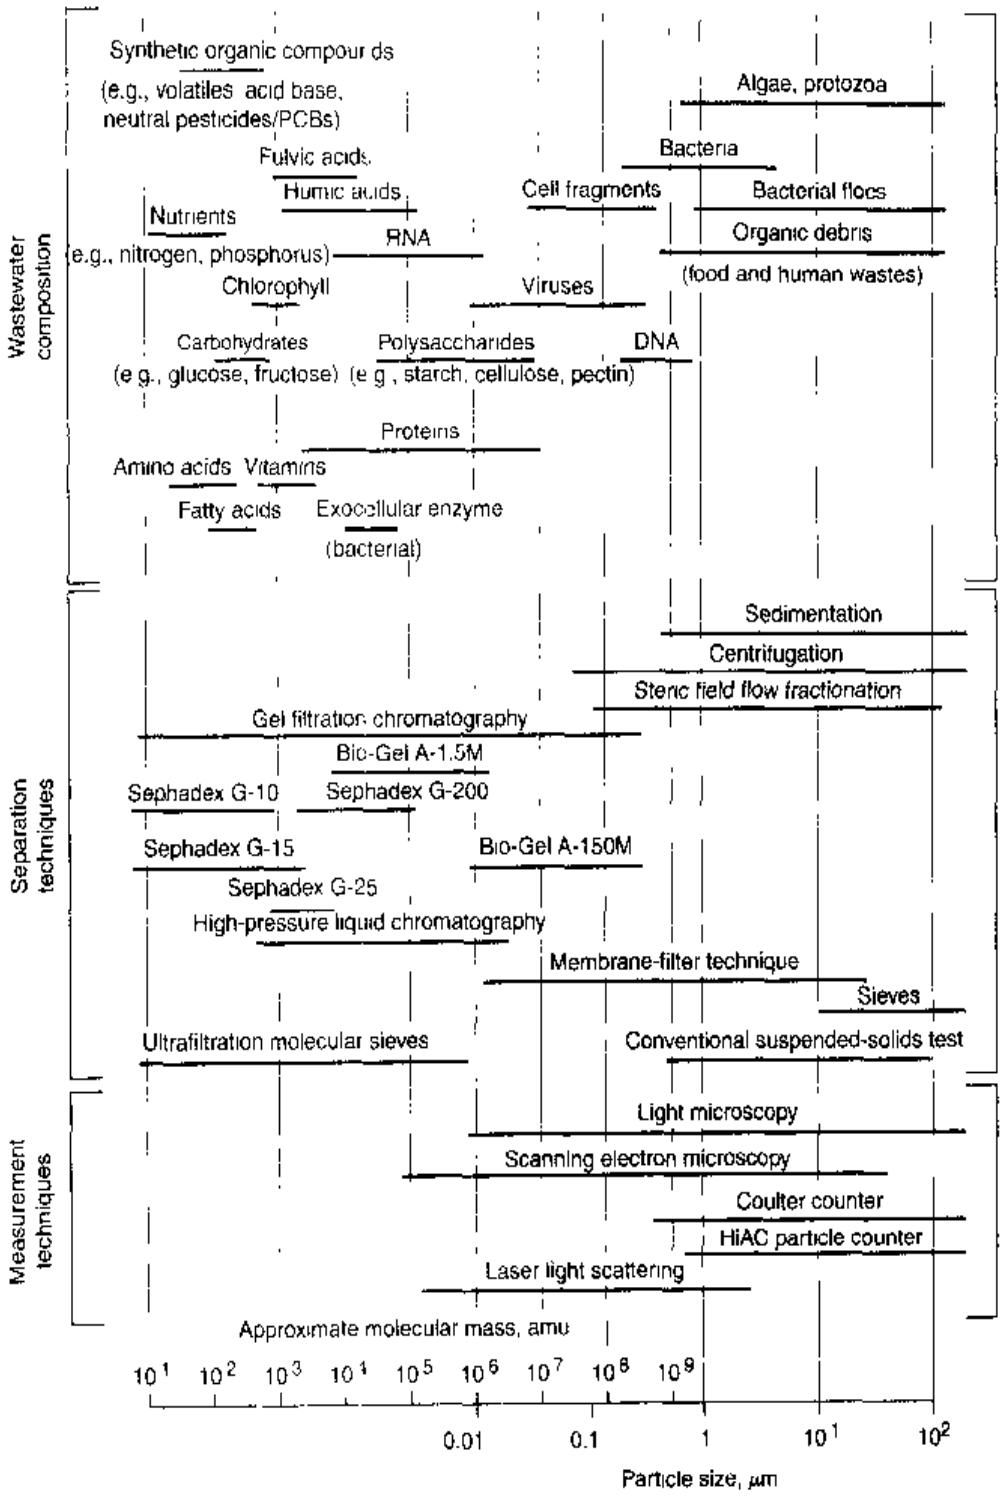
Imhoff cone used to determine settleable solids in wastewater. Solids that accumulate in the bottom of the cone after 60 min are reported as mL/L.

(a) (b)

Figure 2–6



Micrographs of two laboratory filters used for the measurement of suspended solids in wastewater. (a) Polycarbonate membrance filter with a nominal pore size of 1.0 μm and (b) glass fiber filter with a nominal pore size of 1.2 μm.

size range for colloidal particles as varying from 0.001 to 1.0 μm, others from 0.003 to 1.0 μm. The size range for colloidal particles considered in this text is from 0.01 to 1.0 μm. The number of colloidal particles in untreated wastewater and after primary sedimentation is typically in the range from 10^8 to 10^{12}/mL. The fact that the distinction between colloidal particles and truly dissolved material has not been made routinely has led to confusion in the analysis of treatment plant performance and in the design of treatment processes.

Volatile and Fixed Solids. Material that can be volatilized and burned off when ignited at 500 ± 50°C is classified as volatile. In general, volatile solids (VS) are presumed to be organic matter, although some organic matter will not burn and some inorganic solids break down at high temperatures. Fixed solids (FS) comprise the residue that remains after a sample has been ignited. Thus, TS, TSS, and TDS are comprised of both fixed solids and volatile solids. The ratio of the VS to FS is often used to characterize the wastewater with respect to amount of organic matter present.

Figure 2-7

Size ranges of organic contaminants in wastewater and size separation and measurement techniques used for their quantification.

EXAMPLE 2–4 Analysis of Solids Data The following test results were obtained for a wastewater sample taken at the headworks to a wastewater-treatment plant. All of the tests were performed using a sample size of 50 mL. Determine the concentration of total solids, total volatile solids, suspended solids, volatile suspended solids, total dissolved solids, and total volatile dissolved solids. The samples used in the solids analyses were all either evaporated, dried, or ignited to constant weight.

Tare mass of evaporating dish = 53.5433 g

Mass of evaporating dish plus residue after evaporation at 105°C = 53.5794 g

Mass of evaporating dish plus residue after ignition at 550°C = 53.5625 g

Tare mass of Whatman GF/C filter after drying at 105°C = 1.5433 g

Mass of Whatman GF/C filter and residue after drying at 105°C = 1.5554 g

Mass of Whatman GF/C filter and residue after ignition at 550°C = 1.5476 g

Solution

1. Determine total solids.

$$TS = \frac{\left(\begin{array}{c}\text{mass of evaporating}\\ \text{dish plus residue, g}\end{array}\right) - \left(\begin{array}{c}\text{mass of evaporating}\\ \text{dish, g}\end{array}\right)}{\text{sample size, L}}$$

$$TS = \frac{[(53.5794 - 53.5433)\ \text{g}](10^3\ \text{mg/g})}{0.050\ \text{L}} = 722\ \text{mg/L}$$

2. Determine total volatile solids.

$$TVS = \frac{\left(\begin{array}{c}\text{mass of evaporating}\\ \text{dish plus residue, g}\end{array}\right) - \left(\begin{array}{c}\text{mass of evaporating dish}\\ \text{plus residue after ignition, g}\end{array}\right)}{\text{sample size, L}}$$

$$TVS = \frac{[(53.5794 - 53.5625)\ \text{g}](10^3\ \text{mg/g})}{0.050\ \text{L}} = 338\ \text{mg/L}$$

3. Determine the total suspended solids.

$$TSS = \frac{\left(\begin{array}{c}\text{residue on filter}\\ \text{after drying, g}\end{array}\right) - \left(\begin{array}{c}\text{tare mass of filter}\\ \text{after drying, g}\end{array}\right)}{\text{sample size, L}}$$

$$TSS = \frac{[(1.5554 - 1.5433)\ \text{g}](10^3\ \text{mg/g})}{0.050\ \text{L}} = 242\ \text{mg/L}$$

4. Determine the volatile suspended solids.

$$VSS = \frac{\left(\begin{array}{c}\text{residue on filter}\\ \text{after drying, g}\end{array}\right) - \left(\begin{array}{c}\text{residue on filter}\\ \text{after ignition, g}\end{array}\right)}{\text{sample size, L}}$$

$$VSS = \frac{[(1.5554 - 1.5476)\ \text{g}](10^3\ \text{mg/g})}{0.050\ \text{L}} = 156\ \text{mg/L}$$

5. Determine the total dissolved solids.

   TDS = TS − TSS = 722 − 242 = 480 mg/L

6. Determine the volatile dissolved solids.

   VDS = TVS − VSS = 338 − 156 = 182 mg/L

Particle Size Distribution

As noted above, TSS is a lumped parameter. In an effort to understand more about the nature of the particles that comprise the TSS in wastewater, measurement of particle size is undertaken and an analysis of the distribution of particle sizes is conducted (Tchobanoglous, 1995). Information on particle size is of importance in assessing the effectiveness of treatment processes (e.g., secondary sedimentation, effluent filtration, and effluent disinfection). Because the effectiveness of both chlorine and UV disinfection is dependent on particle size, the determination of particle size has become more important, especially with the move toward greater effluent reuse in the western United States.

Information on the size of the biodegradable organic particles is significant from a treatment standpoint, as the biological conversion rate of these particles is dependent on size (see discussion in Sec. 2–6, which deals with biochemical oxygen demand). Methods that have been used to determine particle size are summarized in Table 2–5. As reported in Table 2–5, the methods can be divided into two general categories: (1) methods based on observation and measurement and (2) methods based on separation and analysis techniques. The methods used most commonly to study and quantify the particles in wastewater are: (1) serial filtration, (2) electronic particle counting, and (3) direct microscopic observation.

Serial Filtration. In the serial filtration method, a wastewater sample is passed sequentially through a series of membrane filters (see Fig. 2–8) with circular openings of known diameter (typically 12, 8, 5, 3, 1, and 0.1 μm), and the amount of suspended solids retained in each filter is measured. Typical results from such a measurement are reported in Table 2–6. What is interesting to note in Table 2–6 is the amount of colloidal material found between 0.1 and 1.0 μm. If a 0.1-μm filter had been used to determine TSS for the treated effluent at Monterey instead of a filter with a nominal pore size equal to or greater than 1.0 μm (2.0 μm as specified in Standard Methods for the TSS test), more than 20 mg/L of additional TSS would have been measured. Although some information is gained on the size and distribution of the particles in the wastewater sample, little information is gained on the nature of the individual particles. This method is useful in assessing the effectiveness of treatment methods (e.g., microfiltration) for the removal of residual TSS.

Electronic Particle Size Counting. In electronic particle size counting, particles in wastewater are counted by diluting a sample and then passing the diluted sample through a calibrated orifice or past laser beams. As the particles pass through the orifice,

the conductivity of the fluid changes, owing to the presence of the particle. The change in conductivity is correlated to the size of an equivalent sphere. In a similar fashion, as a particle passes by a laser beam, it reduces the intensity of the laser because of light scattering. The reduced intensity is correlated to the diameter of the particle. The particles that are counted are grouped into particle size ranges (e.g., 0.5 to 2, 2 to 5, 5 to 20 μm, etc.). In turn, the volume fraction corresponding to each particle size range can be computed.

Typical effluent volume fraction data from two activated sludge treatment plants are reported on Fig. 2–9. As shown, the particle size data for small particles are the same for both treatment plants. However, the particle size data for the large particles are quite different, owing primarily to the design and operation of the secondary clarifiers (see discussion in Chaps. 5 and 8). Particle size information, such as that shown on Fig. 2–9, is useful in assessing the performance of secondary sedimentation facilities, effluent filtration, and the potential for chlorine and ultraviolet radiation disinfection.

Microscopic Observation. Particles in wastewater can also be enumerated microscopically by placing a small sample in a particle counting chamber and counting the individual particles. To aid in differentiating different types of particles, various types of stains

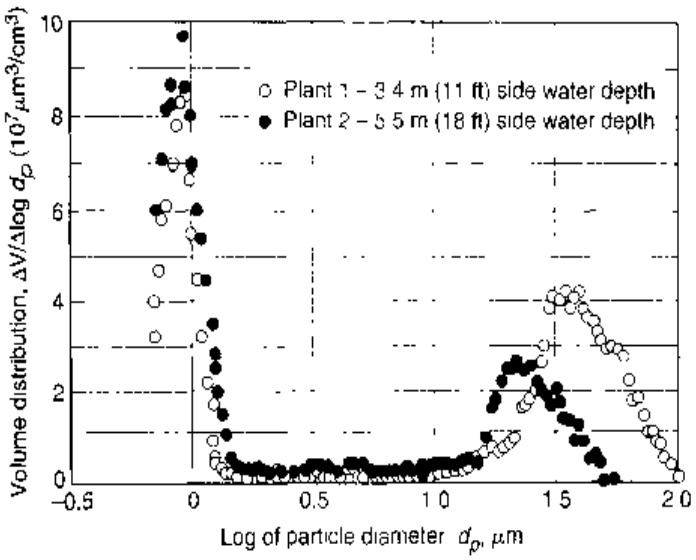

Figure 2–9

Volume fraction of particle sizes found in the effluent from two activated-sludge plants with clarifiers having different side water depths

can be used. In general, microscopic counting of particles is impractical on a routine basis, given the number of particles per milliliter of wastewater. Nevertheless, this method can be used to qualitatively assess the nature and size of the particles in wastewater.

A quantitative assessment of wastewater particles can be obtained with a microscope by means of a process called optical imaging. A small sample of wastewater is placed on a microscope slide. The images of the wastewater particles are collected with a video camera attached to a microscope and transmitted to a computer where various measurements of the wastewater particles can be assessed. The types of measurements that can be obtained are dependent on the computer software but typically include the mean, minimum, and maximum diameter, the aspect ratio (length to width ratio), the circumference, the surface area the volume, and the centroid of various particles. Particle imaging greatly reduces the time required to measure various characteristics of wastewater particles, but the cost of the software and equipment is often prohibitive for many small laboratories.

Turbidity

Turbidity, a measure of the light-transmitting properties of water, is another test used to indicate the quality of waste discharges and natural waters with respect to colloidal and residual suspended matter. The measurement of turbidity is based on comparison of the intensity of light scattered by a sample to the light scattered by a reference suspension under the same conditions (Standard Methods, 1998). Formazin suspensions are used as the primary reference standard. The results of turbidity measurements are reported as nephelometric turbidity units (NTU). Colloidal matter will scatter or absorb light and thus prevent its transmission. It should be noted that the presence of air bubbles in the fluid will cause erroneous turbidity readings. In general, there is no relationship between turbidity and the concentration of total suspended solids in untreated wastewater. There is, however, a reasonable relationship between turbidity and total suspended solids for the settled and filtered secondary effluent from the activated sludge process. The general form of the relationship is as follows:

$$\text{TSS, mg/L} \approx (\text{TSS}_f)\,(T) \qquad (2\text{–}16)$$

where TSS = total suspended solids, mg/L

TSS_f = factor used to convert turbidity readings to total suspended solids, (mg/L TSS)/NTU
T = turbidity, NTU

The specific value of the conversion factor will vary for each treatment plant, depending primarily on the operation of the biological treatment process. The conversion factors for settled secondary effluent and for secondary effluent filtered with a granular-medium depth filter will typically vary from 2.3 to 2.4 and 1.3 to 1.6, respectively.

One of the problems with the measurement of turbidity (especially low values in filtered effluent) is the high degree of variability observed, depending on the light source (incandescent light versus light-emitting diodes) and the method of measurement (reflected versus transmitted light). Another problem often encountered is the light-absorbing properties of the suspended material. For example, the turbidity of a solution of lampblack will essentially be equal to zero. As a result, it is almost impossible to compare turbidity values reported in the literature. However, turbidity readings at a given facility can be used for process control. Some on-line turbidity meters used to monitor the performance of microfiltration units are affected by the air used to clean the membranes.

Color

Historically, the term "condition" was used along with composition and concentration to describe wastewater. Condition refers to the age of the wastewater, which is determined qualitatively by its color and odor. Fresh wastewater is usually a light brownish-gray color. However, as the travel time in the collection system increases, and more anaerobic conditions develop, the color of the wastewater changes sequentially from gray to dark gray, and ultimately to black. When the color of the wastewater is black, the wastewater is often described as septic. Some industrial wastewaters may also add color to domestic wastewater. In most cases, the gray, dark gray, and black color of the wastewater is due to the formation of metallic sulfides, which form as the sulfide produced under anaerobic conditions reacts with the metals in the wastewater.

Absorption/Transmittance

The absorbance of a solution is a measure of the amount of light, of a specified wavelength, that is absorbed by the constituents in a solution. Absorbance, measured using a spectrophotometer and a fixed path length (usually 1.0 cm), is given by the following relationship:

$$A = \log\left(\frac{I_o}{I}\right) \tag{2-17}$$

where A = absorbance, absorbance units/centimeter, a.u./cm
I_o = initial detector reading for the blank (i.e., distilled water) after passing through a solution of known depth
I = final detector reading after passing through solution containing constituents of interest

Absorbance is measured with a spectrophotometer using a specified wavelength, typically 254 nm. Typical absorbance values for various wastewaters at 254 nm are:

1. Primary = 0.5 to 0.8 /cm
2. Secondary = 0.3 to 0.5/cm
3. Nitrified secondary = 0.25 to 0.45/cm
4. Filtered secondary = 0.02 to 0.40/cm
5. Microfiltration effluent = 0.15 to 0.3/cm
6. Reverse osmosis effluent = 0.05 to 0.2/cm

The transmittance of a solution is defined as

$$\text{Transmittance } T, \% = \left(\frac{I}{I_o}\right) \times 100 \tag{2-18}$$

Thus, the transmittance can also be derived from absorption measurements using the following relationship:

$$T = 10^{-(\text{a.u./cm})} \tag{2-19}$$

The term percent transmittance, commonly used in the literature, is

$$T, \% = 10^{-(\text{a.u./cm})} \times 100) \tag{2-20}$$

The extreme values of A and T are (Delahay, 1957)

For a perfectly transparent solution $A = 0$, $T = 1$

For a perfectly opaque solution $A \rightarrow \infty$, $T = 0$

Typical transmittance values for treated wastewater from several activated-sludge biological treatment plants and two lagoon systems are presented on Fig. 2–10. Percent transmittance is affected by all substances in wastewater that can absorb or scatter light. Unfiltered and filtered transmittance are measured in wastewater in connection with the evaluation and design of UV disinfection systems (see Chap. 12).

The principal wastewater characteristics that affect the percent transmission include selected inorganic compounds (e.g., copper, iron, etc.), organic compounds (e.g., organic dyes, humic substances, and conjugated ring compounds such as benzene and toluene), and TSS. Of the inorganic compounds which affect transmittance, iron is considered to be the most important with respect to UV absorbance because dissolved iron can absorb

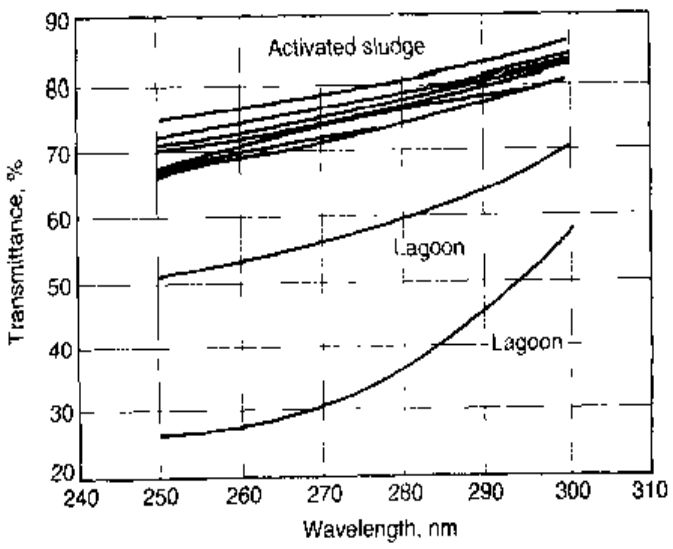

Figure 2–10
Transmittance measured at various wavelengths for activated-sludge effluents and lagoon effluents.

UV light directly and because iron will adsorb onto suspended solids, bacterial clumps, and other organic compounds. The sorbed iron can prevent the UV light from penetrating the particle and inactivating organisms that may be embedded within the particle. Where iron salts are added in the treatment process, dosage control is extremely important when UV disinfection is to be used. Organic constituents, identified as being absorbers of UV light, are compounds with six conjugated carbons or a five- or six-member conjugated ring. The reduction in transmittance observed during storm events is often ascribed to the presence of humic substances from stormwater flows.

Temperature

The temperature of wastewater is commonly higher than that of the local water supply, because of the addition of warm water from households and industrial activities. As the specific heat of water is much greater than that of air, the observed wastewater temperatures are higher than the local air temperatures during most of the year and are lower only during the hottest summer months. Depending on the geographic location, the mean annual temperature of wastewater in the United States varies from about 3 to 27°C (37 to 81°F); 15.6°C (60°F) is a representative value. Temperatures as high as 30 to 35°C (84 to 98°F) have been reported for countries in Africa and the Middle East. The variation that can be expected in influent wastewater temperatures is illustrated on Fig. 2–11. Depending on the location and time of year, the effluent temperatures can be either higher or lower than the corresponding influent values.

Effects of Temperature. The temperature of water is a very important parameter because of its effect on chemical reactions and reaction rates, aquatic life, and the suitability of the water for beneficial uses. Increased temperature, for example, can cause a change in the species of fish that can exist in the receiving water body. Industrial establishments that use surface water for cooling-water purposes are particularly concerned with the temperature of the intake water.

In addition, oxygen is less soluble in warm water than in cold water. The increase in the rate of biochemical reactions that accompanies an increase in temperature, combined with the decrease in the quantity of oxygen present in surface waters, can often cause serious depletions in dissolved oxygen concentrations in the summer months. When sig-

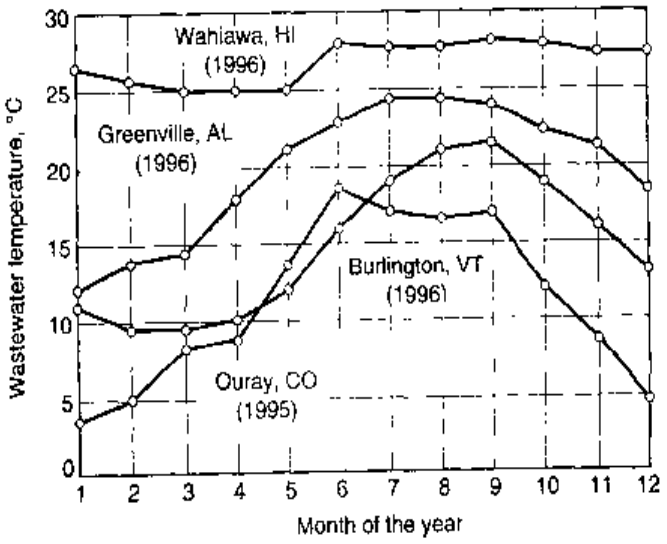

Figure 2–11
Typical variations in monthly wastewater temperatures.

nificantly large quantities of heated water are discharged to natural receiving waters, these effects are magnified. It should also be realized that a sudden change in temperature can result in a high rate of mortality of aquatic life. Moreover, abnormally high temperatures can foster the growth of undesirable water plants and wastewater fungus.

Optimum Temperatures for Biological Activity. Optimum temperatures for bacterial activity are in the range from 25 to 35°C. Aerobic digestion and nitrification stops when the temperature rises to 50°C. When the temperature drops to about 15°C, methane-producing bacteria become quite inactive, and at about 5°C, the autotrophic-nitrifying bacteria practically cease functioning. At 2°C, even the chemoheterotrophic bacteria acting on carbonaceous material become essentially dormant. The effects of temperature on the performance of biological treatment processes are considered in greater detail in Chaps. 7 and 8.

Estimation of Temperature Effects on Reaction Rates. Equilibrium constants, solubility product constants, and specific reaction-rate constants are all dependent on temperature. The temperature dependence of the rate and equilibrium constants can be estimated using the van't Hoff-Arrhenius relationship.

$$\frac{d(\ln k)}{dT} = \frac{E}{RT^2} \tag{2-21}$$

where k = reaction rate constant
T = temperature, K = 273.15 + °C
E = a constant characteristic of the reaction (e.g., activation energy), J/mol
R = ideal gas constant, 8.314 J/mol·K (1.99 cal/mol·K)

Integration of Eq. (2–21) between the limits T_1 and T_2 gives

$$\ln \frac{k_2}{k_1} = \frac{E(T_2 - T_1)}{RT_1T_2} = \frac{E}{RT_1T_2}(T_2 - T_1) \tag{2-22}$$

With k_1 known for a given temperature and with E known, k_2 can be estimated using Eq. (2–22). The activation energy E can be calculated by determining k values at two different temperatures. The application of the van't Hoff-Arrhenius temperature relationship will recur throughout this and the following chapters.

Because most wastewater-treatment operations and processes are carried out at or near the ambient temperature, the quantity $E/(RT_1T_2)$ in Eq. (2–22) may be assumed to be a constant for all practical purposes. If the value of the quantity $E/(RT_1T_2)$ is designated by C, then Eq. (2–22) can be rewritten as

$$\ln \frac{k_2}{k_1} = C(T_2 - T_1) \tag{2-23}$$

$$\frac{k_2}{k_1} = e^{C(T_2 - T_1)} \tag{2-24}$$

Replacing e^C in Eq. (2–23) with a temperature coefficient θ yields

$$\frac{k_2}{k_1} = \theta^{(T_2 - T_1)} \tag{2-25}$$

which is commonly used in environmental engineering to adjust the value of the operative rate constant to reflect the effect of temperature. An alternative form of the temperature correction equation may be obtained by expanding Eq. (2–21) as a series and dropping all but the first two terms. It should be noted, however, that although the value of θ is assumed to be constant, it will often vary considerably with temperature. Therefore, caution must be used in selecting appropriate values for θ for different temperature ranges. Typical values for various operations and processes for different temperature ranges are given, where available, in the sections in which the individual topics are discussed.

Conductivity

The electrical conductivity (EC) of a water is a measure of the ability of a solution to conduct an electrical current. Because the electrical current is transported by the ions in solution, the conductivity increases as the concentration of ions increases. In effect, the measured EC value is used as a surrogate measure of total dissolved solids (TDS) concentration. At present, the EC of a water is one of the important parameters used to determine the suitability of a water for irrigation. The salinity of treated wastewater to be used for irrigation is estimated by measuring its electrical conductivity.

The electrical conductivity in SI units is expressed as millisiemens per meter (mS/m) and in micromhos per centimeter (μmho/cm) in U.S. customary units. It should be noted that 1 mS/m is equivalent to 10 μmho/cm. Equation (2–26) can be used to estimate the TDS of a water sample based on the measured EC value (Standard Methods, 1998).

$$\text{TDS (mg/L)} \simeq \text{EC (dS/m or } \mu\text{mho/cm)} \times (0.55 - 0.70) \tag{2-26}$$

The above relationship does not necessarily apply to raw wastewater or high-strength industrial wastewater. The above relationship can also be used to check the acceptability of chemical analyses (see Standard Methods, 1998).

The electrical conductivity can also be used to estimate the ionic strength of a solution using the following relationship (Russell, 1976):

$$I = 1.6 \times 10^{-5} \times \text{EC (dS/m or } \mu\text{mho/cm)} \tag{2-27}$$

Equation (2–26) is used to estimate the ionic strength of treated wastewater in groundwater recharge applications (see Chap. 13).

Density, Specific Gravity, and Specific Weight

The density of wastewater ρ_w is defined as its mass per unit volume expressed as g/L or kg/m^3 in SI units and as lb_m/ft^3 in U.S. customary units. Density is an important physical characteristic of wastewater because of the potential for the formation of density currents in sedimentation tanks, chlorine contact tanks, and other treatment units. The density of domestic wastewater, which does not contain significant amounts of industrial waste, is essentially the same as that of water at the same temperature (see Appendix C).

In some cases the specific gravity of the wastewater s_w is used in place of the density. The specific gravity is defined as

$$s_w = \frac{\rho_w}{\rho_o} \tag{2-28}$$

where ρ_w = density of wastewater
ρ_o = density of water

Both the density and specific gravity of wastewater are temperature-dependent and will vary with the concentration of total solids in the wastewater.

The specific weight of a fluid γ is its weight per unit volume. In SI units the specific weight is expressed as kN/m^3 and as lb$_f$/ft^3 in U.S. customary units. The relationship between γ, ρ, and the acceleration due to gravity g is $\gamma = \rho g$. At normal temperatures γ is about 9.81 kN/m^3 (62.4 lb$_f$/ft^3). Values for both density and specific weight as a function of temperature in both SI and U.S. customary units are given in Appendix C.

2–4 INORGANIC NONMETALLIC CONSTITUENTS

The chemical constituents of wastewater are typically classified as inorganic and organic. Inorganic chemical constituents of concern include nutrients, nonmetallic constituents, metals, and gases. Organic constituents of interest in wastewater are classified as aggregate and individual. Aggregate organic constituents are comprised of a number of individual compounds that cannot be distinguished separately. Both aggregate and individual organic constituents are of great significance in the treatment, disposal, and reuse of wastewater. Aggregate organic constituents and individual organic compounds are considered in Secs. 2–6 and 2–7, respectively. Inorganic nonmetallic chemical constituents are considered in this section. Metallic constituents are considered in Sec. 2–5.

The sources of inorganic nonmetallic and metallic constituents in wastewater derive from the background levels in the water supply and from the additions resulting from domestic use, from the addition of highly mineralized water from private wells and groundwater, and from industrial use. Domestic and industrial water softeners also contribute significantly to the increase in mineral content and, in some areas, may represent the major source. Occasionally, water added from private wells and groundwater infiltration will (because of its high quality) serve to dilute the mineral concentration in the wastewater. Because concentrations of various inorganic constituents can greatly affect the beneficial uses made of the waters, the constituents in each wastewater must be considered separately. Inorganic nonmetallic constituents considered in this section include pH, nitrogen, phosphorus, alkalinity, chlorides, sulfur, other inorganic constituents, gases, and odors. Because the concentration of the species of most chemical constituents is dependent on the hydrogen-ion concentration in solution, pH is considered first in the following discussion.

pH

The hydrogen-ion concentration is an important quality parameter of both natural waters and wastewaters. The usual means of expressing the hydrogen-ion concentration is as pH, which is defined as the negative logarithm of the hydrogen-ion concentration.

$$\text{pH} = -\log_{10} [\text{H}^+] \tag{2-29}$$

The concentration range suitable for the existence of most biological life is quite narrow and critical (typically 6 to 9). Wastewater with an extreme concentration of hydrogen ion

is difficult to treat by biological means, and if the concentration is not altered before discharge, the wastewater effluent may alter the concentration in the natural waters. For treated effluents discharged to the environment the allowable pH range usually varies from 6.5 to 8.5.

The hydrogen-ion concentration in water is connected closely with the extent to which water molecules dissociate. Water will dissociate into hydrogen and hydroxyl ions as follows:

$$H_2O \leftrightarrow H^+ + OH^- \tag{2-30}$$

Applying the law of mass action [Eq. (2–7)] to Eq. (2–30) yields

$$\frac{[H^+][OH^-]}{H_2O} = K \tag{2-31}$$

where the brackets indicate concentration of the constituents in moles per liter. Because the concentration of water in a dilute aqueous system is essentially constant, this concentration can be incorporated into the equilibrium constant K to give

$$[H^+][OH^-] = K_w \tag{2-32}$$

K_w is known as the ionization constant or ion product of water and is approximately equal to 1×10^{-14} at a temperature of 25°C. Equation (2–32) can be used to calculate the hydroxyl-ion concentration when the hydrogen-ion concentration is known, and vice versa.

With pOH, which is defined as the negative logarithm of the hydroxyl-ion concentration, it can be seen from Eq. (2–32) that, for water at 25°C,

$$pH + pOH = 14 \tag{2-33}$$

The pH of aqueous systems typically is measured with a pH meter (see Fig. 2–12). Various pH papers and indicator solutions that change color at definite pH values are also used. The pH is determined by comparing the color of the paper or solution to a series of color standards.

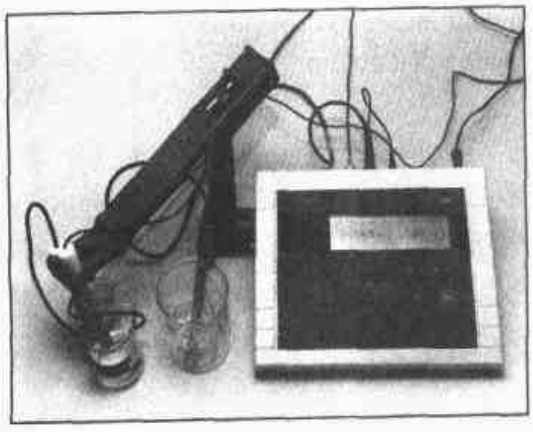

Figure 2–12
Typical meter used for the measurement of pH and specific ion concentrations.

Chlorides

Chloride is a constituent of concern in wastewater as it can impact the final reuse applications of treated wastewater. Chlorides in natural water result from the leaching of chloride-containing rocks and soils with which the water comes in contact, and in coastal areas from saltwater intrusion. In addition, agricultural, industrial, and domestic wastewaters discharged to surface waters are a source of chlorides.

Human excreta, for example, contain about 6 g of chlorides per person per day. In areas where the hardness of water is high, home regeneration type water softeners will also add large quantities of chlorides. Because conventional methods of waste treatment do not remove chloride to any significant extent, higher than usual chloride concentrations can be taken as an indication that a body of water is being used for waste disposal. Infiltration of groundwater into sewers adjacent to saltwater is also a potential source of high chlorides as well as sulfates.

Alkalinity

Alkalinity in wastewater results from the presence of the hydroxides [OH^-], carbonates [CO_3^{2-}], and bicarbonates [HCO_3^-] of elements such as calcium, magnesium, sodium, potassium, and ammonia. Of these, calcium and magnesium bicarbonates are most common. Borates, silicates, phosphates, and similar compounds can also contribute to the alkalinity. The alkalinity in wastewater helps to resist changes in pH caused by the addition of acids. Wastewater is normally alkaline, receiving its alkalinity from the water supply, the groundwater, and the materials added during domestic use. The concentration of alkalinity in wastewater is important where chemical and biological treatment is to be used (see Chaps. 6 and 7, respectively), in biological nutrient removal (see Chap. 8), and where ammonia is to be removed by air stripping (see Chap. 11).

Alkalinity is determined by titrating against a standard acid; the results are expressed in terms of calcium carbonate, mg/L as $CaCO_3$. For most practical purposes alkalinity can be defined in terms of molar quantities, as

$$\text{Alk, eq/m}^3 = \text{meq/L} = [HCO_3^-] + 2[CO_3^{2-}] + [OH^-] - [H^+] \tag{2-34}$$

The corresponding expression in terms of equivalents is

$$\text{Alk, eq/m}^3 = (HCO_3^-) + (CO_3^{2-}) + (OH^-) - (H^+) \tag{2-35}$$

In practice, alkalinity is expressed in terms of calcium carbonate. To convert from meq/L to mg/L as $CaCO_3$, it is helpful to remember that

$$\text{Milliequivalent mass of } CaCO_3 = \frac{100 \text{ mg/mmole}}{2 \text{ meq/mmole}} \tag{2-36}$$

$$= 50 \text{ mg/meq}$$

Thus 3 meq/L of alkalinity would be expressed as 150 mg/L as $CaCO_3$.

$$\text{Alkalinity, Alk as } CaCO_3 = \frac{3.0 \text{ meq}}{\text{L}} \times \frac{50 \text{ mg } CaCO_3}{\text{meq } CaCO_3}$$

$$= 150 \text{ mg/L as } CaCO_3$$

Nitrogen

The elements nitrogen and phosphorus, essential to the growth of microorganisms, plants, and animals, are known as nutrients or biostimulants. Trace quantities of other elements, such as iron, are also needed for biological growth, but nitrogen and phosphorus are, in most cases, the major nutrients of importance. Because nitrogen is an essential building block in the synthesis of protein, nitrogen data will be required to evaluate the treatability of wastewater by biological processes. Insufficient nitrogen can necessitate the addition of nitrogen to make the waste treatable. Nutrient requirements for biological waste treatment are discussed in Chaps. 7 and 8. Where control of algal growths in the receiving water is necessary, removal or reduction of nitrogen in wastewater prior to discharge may be desirable.

Sources of Nitrogen. The principal sources of nitrogen compounds are (1) the nitrogenous compounds of plant and animal origin, (2) sodium nitrate, and (3) atmospheric nitrogen. Ammonia derived from the distillation of bituminous coal is an example of nitrogen obtained from decayed plant material. Sodium nitrate ($NaNO_3$) is found principally in mineral deposits in Chile and in the manure found in seabird rookeries. The production of nitrogen from the atmosphere is termed *fixation*. Because fixation is a biologically mediated process and because $NaNO_3$ deposits are relatively scarce, most sources of nitrogen in soil/groundwater are of biological origin.

Forms of Nitrogen. The chemistry of nitrogen is complex, because of the several oxidation states that nitrogen can assume and the fact that changes in the oxidation state can be brought about by living organisms. To complicate matters further, the oxidation state changes brought about by bacteria can be either positive or negative depending upon whether aerobic or anaerobic conditions prevail. The oxidation states of nitrogen are summarized below (Sawyer et al., 1994).

$$\begin{array}{ccccccccc} -\text{III} & & 0 & & \text{I} & & \text{II} & \text{III} & \text{IV} & \text{V} \\ NH_3 & - & N_2 & - & N_2O & - & NO & - N_2O_3 & - NO_2 & - N_2O_5 \end{array} \qquad (2\text{–}37)$$

The most common and important forms of nitrogen in wastewater and their corresponding oxidation state in the water/soil environment are ammonia (NH_3, −III), ammonium (NH_4^+, −III), nitrogen gas (N_2, 0), nitrite ion (NO_2^-, +III), and nitrate ion (NO_3^-, +V). The oxidation state of nitrogen in most organic compounds is −III.

Total nitrogen, as reported in Table 2–7, is comprised of organic nitrogen, ammonia, nitrite, and nitrate. The organic fraction consists of a complex mixture of compounds including amino acids, amino sugars, and proteins (polymers of amino acids). The compounds that comprise the organic fraction can be soluble or particulate. The nitrogen in these compounds is readily converted to ammonium through the action of microorganisms in the aquatic or soil environment. Urea, readily converted to ammonium carbonate, is seldom found in untreated municipal wastewaters.

Organic nitrogen is determined analytically using the Kjeldahl method. The aqueous sample is first boiled to drive off the ammonia, and then it is digested. During digestion the organic nitrogen is converted to ammonium through the action of heat and acid. Total Kjeldahl nitrogen (TKN) is determined in the same manner as organic nitrogen, except that the ammonia is not driven off before the digestion step. Total Kjeldahl nitrogen is therefore the total of the organic and ammonia nitrogen.

Table 2-7
Definition of the various terms used to define various nitrogen species

Form of nitrogen	Abbrev.	Definition
Ammonia gas	NH_3	NH_3
Ammonium ion	NH_4^+	NH_4^+
Total ammonia nitrogen	TAN	$NH_3 + NH_4^+$
Nitrite	NO_2	NO_2^-
Nitrate	NO_3^-	NO_3
Total inorganic nitrogen	TIN	$NH_3 + NH_4^+ + NO_2^- + NO_3$
Total Kjeldahl nitrogen	TKN	Organic N + NH_3 + NH_4^+
Organic nitrogen	Organic N	TKN $(NH_3 + NH_4^+)$
Total nitrogen	TN	Organic N + NH_3 + NH_4^+ + NO_2^- + NO_3

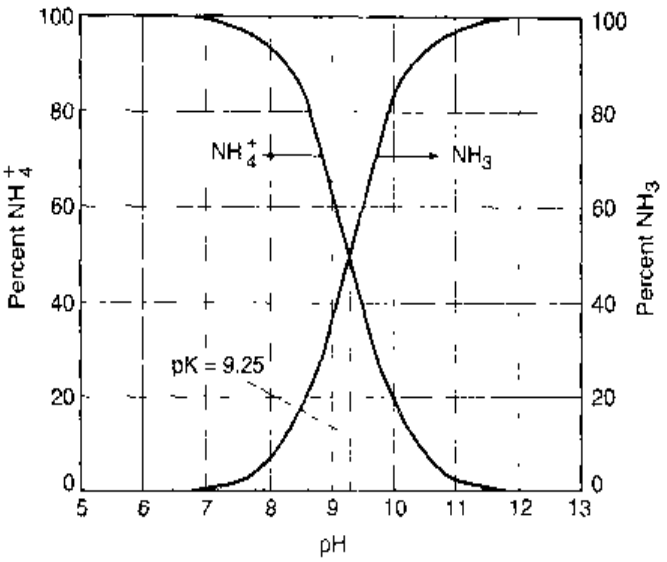
As biological nutrient removal has become more common, information on the various organic nitrogen fractions has become important. The principal fractions are particulate and soluble. In biological treatment studies, the particulate and soluble fractions of organic nitrogen are fractionated further to assess wastewater treatability (see discussion in Sec. 8–2 in Chap. 8). Fractions that have been used include (1) free ammonia, (2) biodegradable soluble organic nitrogen, (3) biodegradable particulate organic carbon, (4) nonbiodegradable soluble organic nitrogen, and (5) nonbiodegradable particulate organic nitrogen. Unfortunately, there is little standardization on the definition of soluble versus particulate organic nitrogen (see discussion of under Solids in Sec. 2–3). Where filtration is the technique used to fractionate the sample, the relative distribution between soluble and particulate organic nitrogen will vary depending on the pore size of the filter used. In many cases, colloidal organic nitrogen has been classified as soluble or dissolved. The lack of standardized definition will also affect other aggregate constituents (i.e., chemical oxygen demand and total organic carbon).

Ammonia nitrogen exists in aqueous solution as either the ammonium ion (NH_4^+) or ammonia gas (NH_3), depending on the pH of the solution, in accordance with the following equilibrium reaction:

$$NH_4^+ \leftrightarrow NH_3 + H^+ \tag{2-38}$$

Applying the law of mass action [Eq. (2–7)] to Eq. (2–38) and, assuming the activity of water is 1, yields

$$\frac{[NH_3][H^+]}{[NH_4^+]} = K_a \tag{2-39}$$



where K_a = acid ionization (dissociation) constant = $10^{-9.25}$ or 5.62×10^{-10}

Because the distribution of the ammonia species is a function of the pH, the percentage ammonia can be determined using the following relationship.

$$NH_3, \% = \frac{[NH_3] \times 100}{[NH_3] + [NH_4^+]} = \frac{100}{1 + [NH_4^+]/[NH_3]} = \frac{100}{1 + [H^+]/K_a} \tag{2-40}$$

Figure 2–13

Distribution of ammonia (NH_3) and ammonium ion (NH_4^+) as a function of pH.

Using Eq. (2-40) the distribution of the ammonia species as a function of pH is shown on Fig. 2–13. At pH levels above 7, the equilibrium is displaced to the right; at levels below pH 7, the ammonium ion is predominant. Ammonia is determined by raising the pH, distilling off the ammonia with the steam produced when the sample is boiled, and condensing the steam that absorbs the gaseous ammonia. The measurement is made colorimetrically, titrimetrically, or with specific-ion electrodes.

Nitrite nitrogen, determined colorimetrically, is relatively unstable and is easily oxidized to the nitrate form. It is an indicator of past pollution in the process of stabilization and seldom exceeds 1 mg/L in wastewater or 0.1 mg/L in surface waters or groundwaters. Although present in low concentrations, nitrite can be very important in wastewater or water pollution studies because it is extremely toxic to most fish and other aquatic species. Nitrites present in wastewater effluents are oxidized by chlorine and thus increase the chlorine dosage requirements and the cost of disinfection.

Nitrate nitrogen is the most oxidized form of nitrogen found in wastewaters. Where secondary effluent is to be reclaimed for groundwater recharge, the nitrate concentration is important. The U.S. EPA primary drinking water standards (U.S. EPA, 1977) limit nitrogen to 45 mg/L as NO_3^-, because of its serious and occasionally fatal effects on infants. Nitrates may vary in concentration from 0 to 20 mg/L as N in wastewater effluents. Assuming complete nitrification has taken place, the typical range found in treated effluents is from 15 to 20 mg/L as N. The nitrate concentration is typically determined by colorimetric methods or with specific-ion electrodes.

Nitrogen Pathways in Nature. The various forms of nitrogen that are present in nature and the pathways by which the forms are changed in an aquatic environment are depicted on Fig. 2–14. The nitrogen present in fresh wastewater is primarily combined in proteinaceous matter and urea. Decomposition by bacteria readily changes the organic form to ammonia. The age of wastewater is indicated by the relative amount of ammonia that is present. In an aerobic environment, bacteria can oxidize the ammonia nitrogen to nitrites and nitrates. The predominance of nitrate nitrogen in wastewater indicates that the waste has been stabilized with respect to oxygen demand. Nitrates, however, can be used by plants and animals to form protein. Death and decomposition

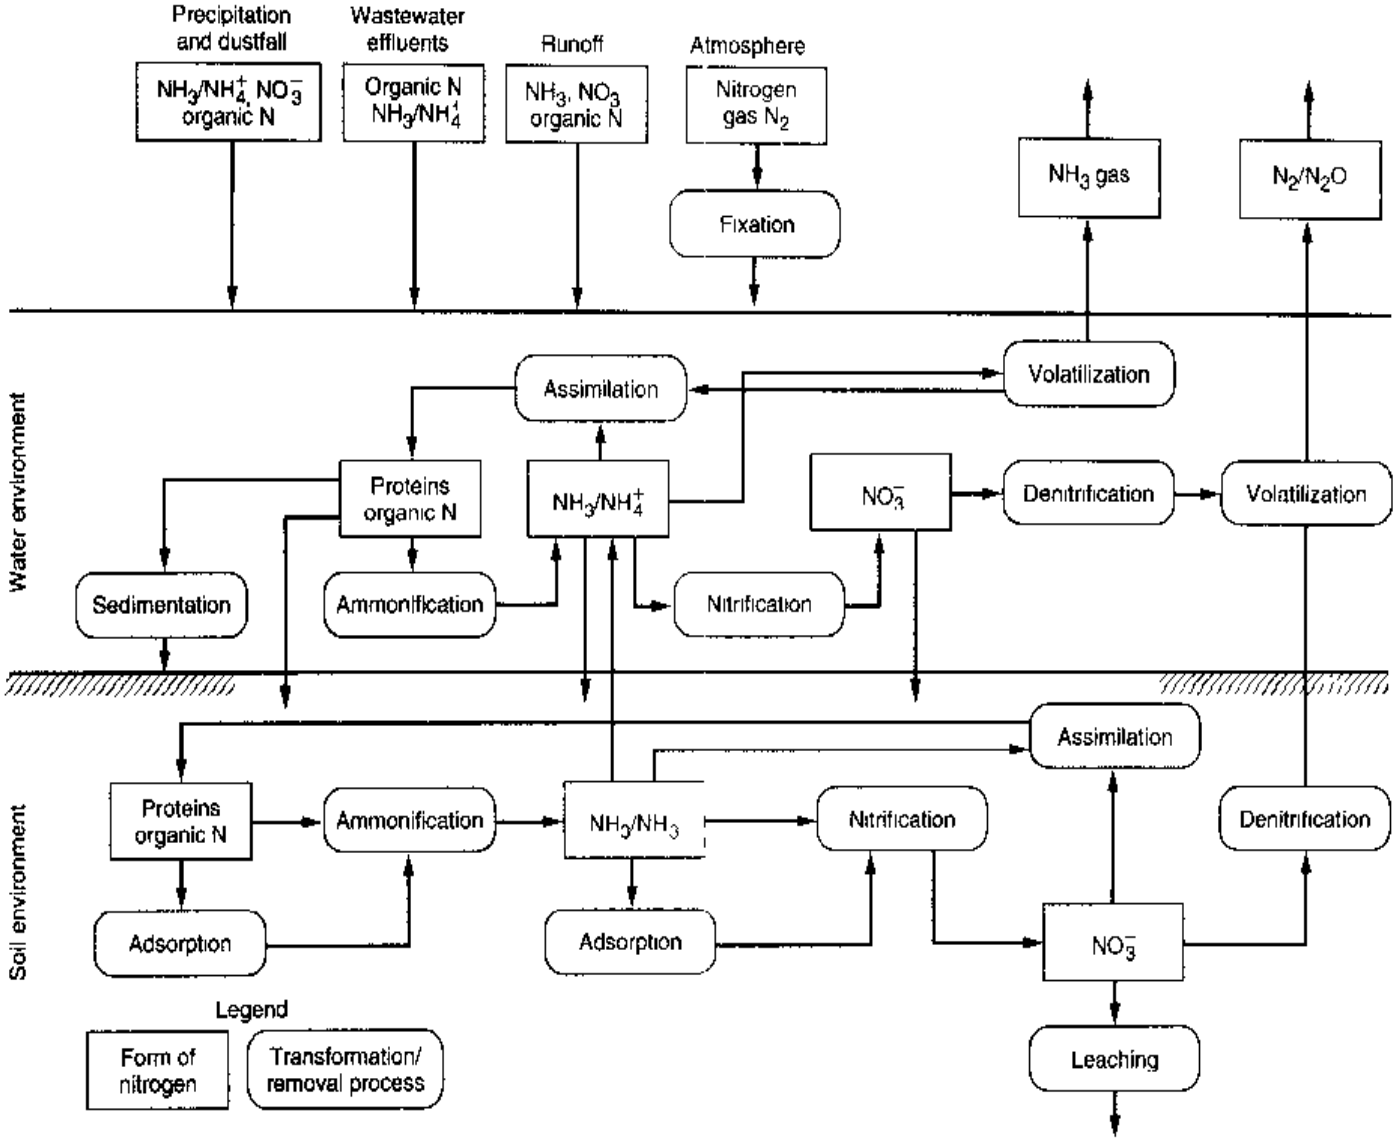


Figure 2–14

Generalized nitrogen cycle in the aquatic and soil environment.

of the plant and animal protein by bacteria again yields ammonia. Thus, if nitrogen in the form of nitrates can be reused to make protein by algae and other plants, it may be necessary to remove or reduce the nitrogen that is present to prevent these growths.

Phosphorus

Phosphorus is also essential to the growth of algae and other biological organisms. Because of noxious algal blooms that occur in surface waters, there is presently much interest in controlling the amount of phosphorus compounds that enter surface waters in domestic and industrial waste discharges and natural runoff. Municipal wastewaters, for example, may contain from 4 to 16 mg/L of phosphorus as P.

The usual forms of phosphorus that are found in aqueous solutions include the orthophosphate, polyphosphate, and organic phosphate. The orthophosphates, for example, PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^-$, H_3PO_4, are available for biological metabolism without further breakdown. The polyphosphates include those molecules with two or more

phosphorus atoms, oxygen atoms, and, in some cases, hydrogen atoms combined in a complex molecule. Polyphosphates undergo hydrolysis in aqueous solutions and revert to the orthophosphate forms; however, this hydrolysis is usually quite slow. The organically bound phosphorus is usually of minor importance in most domestic wastes, but it can be an important constituent of industrial wastes and wastewater sludges.

Orthophosphate can be determined by directly adding a substance such as ammonium molybdate which will form a colored complex with the phosphate. The polyphosphates and organic phosphates must be converted to orthophosphates using an acid digestion step before they can be determined in a similar manner.

Sulfur

The sulfate ion occurs naturally in most water supplies and is present in wastewater as well. Sulfur is required in the synthesis of proteins and is released in their degradation. Sulfate is reduced biologically under anaerobic conditions to sulfide which, in turn, can combine with hydrogen to form hydrogen sulfide (H_2S). The following generalized reactions are typical.

$$\text{Organic matter} + SO_4^{2-} \xrightarrow{\text{bacteria}} S^{2-} + H_2O + CO_2 \qquad (2\text{-}41)$$

$$S^{2-} + 2H^+ \rightarrow H_2S \qquad (2\text{-}42)$$

If lactic acid is used as the precursor organic compound, the reduction of sulfate to sulfide occurs as follows:

$$\underset{\text{lactic acid}}{2CH_3CH(OH)COOH} + \underset{\text{sulfate}}{SO_4^{2-}} \xrightarrow{\text{bacteria}} \underset{\text{acetate}}{2CH_3COOH} + \underset{\text{sulfide ion}}{S^{2-}} + 2H_2O + 2CO_2 \qquad (2\text{-}43)$$

Hydrogen sulfide gas, which will diffuse into the headspace above the wastewater in sewers that are not flowing full, tends to collect at the crown of the pipe. The accumulated H_2S can then be oxidized biologically to sulfuric acid, which is corrosive to concrete sewer pipes. This corrosive effect, known as "crown rot," can seriously threaten the structural integrity of the sewer pipe (ASCE, 1989; U.S. EPA, 1985e).

Sulfates are reduced to sulfides in sludge digesters and may upset the biological process if the sulfide concentration exceeds 200 mg/L. Fortunately, such concentrations are rare. The H_2S gas, which is evolved and mixed with the wastewater gas (CH_4 + CO_2), is corrosive to the gas piping and, if burned in gas engines, the products of combustion can damage the engine and severely corrode exhaust gas heat recovery equipment, especially if allowed to cool below the dew point.

Gases

Gases commonly found in untreated wastewater include nitrogen (N_2), oxygen (O_2), carbon dioxide (CO_2), hydrogen sulfide (H_2S), ammonia (NH_3), and methane (CH_4). The first three are common gases of the atmosphere and will be found in all waters exposed to air. The latter three are derived from the decomposition of the organic matter present in wastewater and are of concern with respect to worker health and safety. Although not found in untreated wastewater, other gases with which the environmental engineer must be familiar include chlorine (Cl_2) and ozone (O_3) (for disinfection and odor control), and the oxides of sulfur and nitrogen (in combustion processes). The fol-

lowing discussion is limited to those gases that are of interest in untreated wastewater. Under most circumstances, the ammonia in untreated wastewater will be present as the ammonium ion (see "Nitrogen"). However, before discussing the individual gases it will be useful to review the ideal gas law and to consider the solubility of gases in water and Henry's law as applied to the gases of interest.

Solubility of Gases in Water. The actual quantity of a gas that can be present in solution is governed by (1) the solubility of the gas as defined by Henry's law, (2) the partial pressure of the gas in the atmosphere, (3) the temperature, and (4) the concentration of the impurities in the water (e.g., salinity, suspended solids, etc.).

The Ideal Gas Law. The ideal gas law, derived from a consideration of Boyle's law (volume of a gas is inversely proportional to pressure at constant temperature) and Charles' law (volume of a gas is directly proportional to temperature at constant pressure) is

$$PV = nRT \tag{2-44}$$

where P = absolute pressure, atm
V = volume occupied by the gas, L, m^3
n = moles of gas, mole
R = universal gas law constant, 0.082057 atm·L/mole·K
= 0.000082057 atm·m^3/mole·K
T = temperature, K (273.15 + °C)

Using the universal gas law, it can be shown that the volume of gas occupied by one mole of a gas at standard temperature [0°C, (32°F)] and pressure (1.0 atm) is equal to 22.414 L.

$$V = \frac{nRT}{P}$$

$$V = \frac{(1 \text{ mole})(0.082057 \text{ atm·L/mole·K})[(273.15 + 0)\text{K}]}{1.0 \text{ atm}} = 22.414 \text{ L}$$

The following relationship, based on the ideal gas law, is used to convert between gas concentrations expressed in ppm_v and $\mu g/m^3$:

$$\mu g/m^3 = \frac{(\text{concentration, } ppm_v)(\text{mw, g/mole of gas})(10^6 \mu g/g)}{(22.414 \times 10^{-3} m^3/\text{mole of gas})} \tag{2-45}$$

The application of Eq. (2-45) is illustrated in Example 2–5.

EXAMPLE 2–5 Conversion of Gas Concentration Units The off gas from a wastewater force main (i.e., pressure sewer) was found to contain 9 ppm_v (by volume) of hydrogen sulfide (H_2S). Determine the concentration in $\mu g/m^3$ and in mg/L at standard conditions (0°C, 101.325 kPa).

Solution

1. Compute the concentration in μg/L using Eq. (2–45). The molecular weight of $H_2S = 34.08$ [2(1.01) + 32.06]

$$9\ \text{ppm}_v = \left(\frac{9\ \text{m}^3}{10^6\ \text{m}^3}\right)\left(\frac{(34.08\ \text{g/mole}\ H_2S)}{(22.4 \times 10^3\ \text{m}^3/\text{mole of}\ H_2S)}\right)\left(\frac{10^6\ \mu\text{g}}{\text{g}}\right) = 13{,}693\ \mu\text{g/m}^3$$

2. The concentration in mg/L is

$$13{,}693\ \mu\text{g/m}^3 = \left(\frac{13{,}693\ \mu\text{g}}{\text{m}^3}\right)\left(\frac{1\ \text{mg}}{10^3\ \mu\text{g}}\right)\left(\frac{1\ \text{m}^3}{10^3\ \text{L}}\right) = 0.0137\ \text{mg/L}$$

Comment If gas measurements, expressed in μg/L, are made at other than standard conditions, the concentration must be corrected to standard conditions, using the ideal gas law, before converting to ppm.

Henry's Law for Dissolved Gases. The equilibrium or saturation concentration of gas dissolved in a liquid is a function of the type of gas and the partial pressure of the gas in contact with the liquid. The relationship between the mole fraction of the gas in the atmosphere above the liquid and the mole fraction of the gas in the liquid is given by the following form of Henry's law:

$$p_g = \frac{H}{P_T} x_g \qquad (2\text{–}46)$$

where p_g = mole fraction of gas in air, mole gas /mole of air

H = Henry's law constant, $\dfrac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}$

P_T = total pressure, usually 1.0 atm

x_g = mole fraction of gas in water, mole gas/mole water

$$= \frac{\text{mole gas}\,(n_g)}{\text{mole gas}\,(n_g) + \text{mole water}\,(n_w)}$$

In Eq. (2–46) it is helpful to remember that the mole fraction of a gas corresponds to the partial pressure of the gas. If the partial pressure of the gas is used, Eq. (2–46) is written as follows:

$$P_g = Hx_g \qquad (2\text{–}47)$$

where P_g = partial pressure of gas, atm
other terms are as defined above.

In practice and in the literature, the Henry's law constant is often reported as atm, with the mole fraction being implied. Henry's law constant is a function of the type of

Table 2-8 Henry's law constants at 20°C, unitless Henry's law constants at 20°C, and temperature-dependent coefficients[a]

Parameter	Henry's constant, atm	Henry's constant, unitless	Temperature coefficients	
			A	B
Air	66,400	49.68	557.60	6.724
Ammonia	0.75	5.61×10^{-4}	1887.12	6.315
Carbon dioxide	1420	1.06	1012.40	6.606
Carbon monoxide	53,600	40.11	554.52	6.621
Chlorine	579	0.43	875.69	5.75
Chlorine dioxide	1500	1.12	1041.77	6.73
Hydrogen	68,300	51.10	187.04	5.473
Hydrogen sulfide	483	0.36	884.94	5.703
Methane	37,600	28.13	675.74	6.880
Nitrogen	80,400	60.16	537.62	6.739
Oxygen	41,100	30.75	595.27	6.644
Ozone	5,300	3.97	1268.24	8.05
Sulfur dioxide	36	2.69×10^{-2}	1207.85	5.68

[a] Adapted in part from Montgomery (1985) Cornwell (1990), and Hand et al. (1998).

gas, temperature, and nature of the liquid. Values of Henry's law constants for various gases in water at 20°C are given in Table 2–8. It is important to note that reported values of the Henry's law constant found in the literature will vary depending on the date of the reference and the specific method used to estimate the constant. Use of the data in Table 2–8 is illustrated in Example 2–6.

EXAMPLE 2–6 Saturation Concentration of Oxygen in Water What is the saturation of oxygen in water in contact with dry air at 1 atm and 20°C?

Solution

1. Dry air contains about 21 percent oxygen by volume (see Appendix D). Therefore, $p_g = 0.21$ mole O_2/mole air.
2. Determine x_g.
   a. From Table 2–8, at 20°C, Henry's constant is

$$H = 4.11 \times 10^4 \frac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}$$

b. Using Eq (2–46), the value of x_g is

$$x_g = \frac{P_T}{H} p_g$$

$$= \frac{1.0 \text{ atm}}{4.11 \times 10^4 \dfrac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}} (0.21 \text{ mole gas/mole air})$$

$$= 5.11 \times 10^{-6} \text{ mole gas/mole water}$$

3. One liter of water contains 1000 g/(18 g/mole) = 55.6 mole, thus

$$\frac{n_g}{n_g + n_w} = 5.11 \times 10^{-6}$$

$$\frac{n_g}{n_g + 55.6} = 5.11 \times 10^{-6}$$

Because the number of moles of dissolved gas in a liter of water is much less than the number of moles of water,

$n_g + 55.6 \approx 55.6$

and $n_g \approx (55.6)\ 5.11 \times 10^{-6}$

$n_g \approx 2.84 \times 10^{-4}$ mole O_2/L

4. Determine the saturation concentration of oxygen.

$$C_s \approx \frac{(2.84 \times 10^{-4} \text{ mole } O_2/\text{L})(32 \text{ g/mole } O_2)}{(1 \text{ g}/10^3 \text{ mg})}$$

$$\approx 9.09 \text{ mg/L}$$

Comment The computed value (9.09 mg/L) compares well with the value given in Appendix D (9.08 mg/L). It should be noted that the values for the Henry's law constant given in Table 2–8 will vary depending on the source and the method used to derive them.

The change in the Henry's law constant with temperature can be estimated using the following modified form of the van't Hoff-Arrhenius relationship [see Eq. (2–20)].

$$\log_{10} H = \frac{-A}{T} + B \qquad [2\text{–}48]$$

where H = Henry's law constant at temperature T, atm
A = empirical constant that takes into account the enthalpy change in water due to the dissolution of a component in water and the universal gas law constant
T = temperature, K = 273.15 + °C
B = empirical constant

Values of A and B for various gases of interest in wastewater treatment are presented in Table 2–8. It should be noted that the values given in Table 2–8 for A and B are approximate and will vary depending on the source and the method used to derive them.

Unitless Form of Henry's Law. In the literature, the unitless form of Henry's law is often used to compute the solubility of trace gases in water or wastewater. The unitless form is usually written as

$$\frac{C_g}{C_s} = H_u \tag{2-49}$$

where C_g = concentration of constituent in gas phase, $\mu g/m^3$, mg/L
C_s = saturation concentration of constituent in liquid, $\mu g/m^3$, mg/L
H_u = Henry's law constant, unitless

The unitless form is obtained by noting that at 1.0 atm pressure and 0°C, the volume occupied by 1.0 mole of air is 22.414 L. At other temperatures, 1.0 mole of air is equal to 0.082 T L of air, where T is temperature in Kelvin, K (273.15 + °C). Using these conversions, the unitless form of Henry's law is (Cornwell, 1990)

$$H_u = \left[H \frac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}\right]\left(\frac{\text{mole air}}{0.082\ T\ \text{L}}\right)\left(\frac{\text{L}}{55.6\ \text{mole water}}\right)$$

$$H_u = \left(\frac{H}{4.559\ T}\right) \tag{2-50}$$

For example, at 20°C, H_u equals

$$H_u = \left[\frac{H}{4.559(273.15 + 20)}\right] = H \times (7.49 \times 10^{-4}) \text{ at } 20°C$$

If atmospheric conditions prevail and Henry's constant is expressed in terms of atm·m³/mole (another form of Henry's law used commonly in the literature), the unitless form of Henry's law is obtained as follows:

$$H_u = \frac{H}{RT} \tag{2-51}$$

where H_u = Henry's law constant, unitless as used in Eq. (2–49)
H = Henry's law constant values expressed in atm·m³/mole
R = universal gas law constant, 0.000082057 atm·m³/mole·K
T = temperature, K = 273.15 + °C

Dissolved Oxygen. Dissolved oxygen is required for the respiration of aerobic microorganisms as well as all other aerobic life forms. However, oxygen is only slightly soluble in water. The actual quantity of oxygen (other gases too) that can be present in solution is governed by (1) the solubility of the gas, (2) the partial pressure of the gas in the atmosphere, (3) the temperature, and (4) the concentration of the impurities in the water (e.g., salinity, suspended solids, etc.). The interrelationship of these variables is

delineated in Chap. 6 and is illustrated in Appendix D, where the effect of temperature and salinity on dissolved oxygen concentration is presented.

Because the rate of biochemical reactions that use oxygen increases with increasing temperature, dissolved oxygen levels tend to be more critical in the summer months. The problem is compounded in summer months because stream flows are usually lower, and thus the total quantity of oxygen available is also lower. The presence of dissolved oxygen in wastewater is desirable because it prevents the formation of noxious odors. The role of oxygen in wastewater treatment is discussed in Chaps. 7, 8, and 9.

Hydrogen Sulfide. Hydrogen sulfide is formed, as mentioned previously, from the anaerobic decomposition of organic matter containing sulfur or from the reduction of mineral sulfites and sulfates. It is not formed in the presence of an abundant supply of oxygen. This gas is a colorless, inflammable compound having the characteristic odor of rotten eggs. Hydrogen sulfide is also toxic, and great care must be taken in its presence. High concentrations can overwhelm olfactory glands, resulting in a loss of smell. This loss of smell can lead to a false sense of security that is very dangerous. The blackening of wastewater and sludge usually results from the formation of hydrogen sulfide that has combined with the iron present to form ferrous sulfide (FeS). Various other metallic sulfides are also formed. Although hydrogen sulfide is the most important gas formed from the standpoint of odors, other volatile compounds such as indol, skatol, and mercaptans, which may also be formed during anaerobic decomposition, may cause odors far more offensive than that of hydrogen sulfide.

Methane. The principal byproduct from the anaerobic decomposition of the organic matter in wastewater is methane gas (see Chaps. 10 and 14). Methane is a colorless, odorless, combustible hydrocarbon of high fuel value. Normally, large quantities are not encountered in untreated wastewater because even small amounts of oxygen tend to be toxic to the organisms responsible for the production of methane. Occasionally, however, as a result of anaerobic decay in accumulated bottom deposits, methane has been produced. Because methane is highly combustible and the explosion hazard is high, access ports (manholes) and sewer junctions or junction chambers where there is an opportunity for gas to collect should be ventilated with a portable blower during and before the time required for operating personnel to work in them for inspection, renewals, or repairs. In treatment plants, methane is produced from the anaerobic treatment process used to stabilize wastewater sludges (see Chap. 14). In treatment plants where methane is produced, notices should be posted about the plant warning of explosion hazards, and plant employees should be instructed in safety measures to be maintained while working in and about the structures where gas may be present.

Odors

Odors in domestic wastewater usually are caused by gases produced by the decomposition of organic matter or by substances added to the wastewater. Fresh wastewater has a distinctive, somewhat disagreeable odor, which is less objectionable than the odor of wastewater which has undergone anaerobic (devoid of oxygen) decomposition. The most characteristic odor of stale or septic wastewater is that of hydrogen sulfide, which, as discussed previously, is produced by anaerobic microorganisms that reduce sulfate

to sulfide. Industrial wastewater may contain either odorous compounds or compounds that produce odors during the process of wastewater treatment.

Odors have been rated as the foremost concern of the public relative to the implementation of wastewater-treatment facilities. Within the past few years, the control of odors has become a major consideration in the design and operation of wastewater-collection, treatment, and disposal facilities, especially with respect to the public acceptance of these facilities. In many areas, projects have been rejected because of the concern over the potential for odors. In view of the importance of odors in the field of wastewater management, it is appropriate to consider the effects they produce, how they are detected, and their characterization and measurement.

Effects of Odors. The importance of odors at low concentrations in human terms is related primarily to the psychological stress they produce rather than to the harm they do to the body. Offensive odors can cause poor appetite for food, lowered water consumption, impaired respiration, nausea and vomiting, and mental perturbation. In extreme situations, offensive odors can lead to the deterioration of personal and community pride, interfere with human relations, discourage capital investment, lower socioeconomic status, and deter growth. Also, some odorous compounds (e.g., H_2S) are toxic at elevated concentrations. These problems can result in a decline in market and rental property values, tax revenues, payrolls, and sales.

Detection of Odors. The malodorous compounds responsible for producing psychological stress in humans are detected by the olfactory system, but the precise mechanism involved is at present not well understood. Since 1870, more than 30 theories have been proposed to explain olfaction. One of the difficulties in developing a universal theory has been the inadequate explanation of why compounds with similar structures may have different odors and why compounds with very different structures may have similar odors. At present, there appears to be some general agreement that the odor of a molecule must be related to the molecule as a whole.

Over the years, a number of attempts have been made to classify odors in a systematic fashion. The major categories of offensive odors and the compounds involved are listed in Table 2-9. All these compounds may be found or may develop in domestic wastewater, depending on local conditions. The odor thresholds for specific malodorous compounds associated with untreated wastewater are listed in Table 2–10.

Odor Characterization and Measurement. It has been suggested that four independent factors are required for the complete characterization of an odor: intensity, character, hedonics, and detectability (see Table 2–11). To date, detectability is the only factor that has been used in the development of statutory regulations for nuisance odors. As shown on Fig. 2-15, odor can be measured by sensory methods, and specific odorant concentrations can be measured by instrumental methods. It has been shown that, under carefully controlled conditions, the sensory (organoleptic) measurement of odors by the human olfactory system can provide meaningful and reliable information. Therefore, the sensory method is often used to measure the odors emanating from wastewater-treatment facilities. The availability of a direct reading meter for hydrogen sulfide (see Fig. 2–16) which can be used to detect concentrations as low as 1 ppb is a significant development.

Table 2-9
Major categories of odorous compounds associated with untreated wastewater

Odorous compound	Chemical formula	Odor quality
Amines	CH_3NH_2, $(CH_3)_3H$	Fishy
Ammonia	NH_3	Ammoniacal
Diamines	$NH_2(CH_2)_4NH_2$, $NH_2(CH_2)_5NH_2$	Decayed flesh
Hydrogen sulfide	H_2S	Rotten eggs
Mercaptans (e.g., methyl and ethyl)	CH_3SH, $CH_3(CH_2)SH$	Decayed cabbage
Mercaptans (e.g., T = butyl and crotyl)	$(CH_3)_3CSH$, $CH_3(CH_2)_3SH$	Skunk
Organic sulfides	$(CH_3)_2S$, $(C_6H_5)_2S$	Rotten cabbage
Skatole	C_9H_9N	Fecal matter

Table 2-10
Odor thresholds of odorous compounds associated with untreated wastewater[a]

Odorous compound	Chemical formula	Molecular weight	Odor threshold, ppm_v[b]	Characteristic odor
Ammonia	NH_3	17.0	46.8	Ammoniacal, pungent
Chlorine	Cl_2	71.0	0.314	Pungent, suffocating
Crotyl mercaptan	$CH_3-CH=CH-CH_2-SH$	90.19	0.000029	Skunklike
Dimethyl sulfide	CH_3-S-CH_3	62	0.0001	Decayed vegetables
Diphenyl sulfide	$(C_6H_5)_2S$	186	0.0047	Unpleasant
Ethyl mercaptan	CH_3CH_2-SH	62	0.00019	Decayed cabbage
Hydrogen sulfide	H_2S	34	0.00047	Rotten eggs
Indole	C_8H_6NH	117	0.0001	Fecal, nauseating
Methyl amine	CH_3NH_2	31	21.0	Putrid, fishy
Methyl mercaptan	CH_3SH	48	0.0021	Decayed cabbage
Skatole	C_9H_9N	131	0.019	Fecal, nauseating
Sulfur dioxide	SO_2	64.07	0.009	Pungent, irritating
Thiocresol	$CH_3-C_6H_4-SH$	124	0.000062	Skunk, rancid

[a] Adapted from Patterson et al. (1984) and U.S. EPA (1985c).

[b] Parts per million by volume.

In the sensory method, human subjects (often a panel of subjects) are exposed to odors that have been diluted with odor-free air, and the number of dilutions required to reduce an odor to its minimum detectable threshold odor concentration (MDTOC) is noted. The detectable odor concentration is reported as the dilutions to the MDTOC, commonly called D/T (dilutions to threshold). Thus, if four volumes of diluted air must be added to one unit volume of sampled air to reduce the odorant to its MDTOC, the

Table 2-11
Factors that must be considered for the complete characterization of an odor

Factor	Description
Character	Relates to the mental associations made by the subject in sensing the odor. Determination can be quite subjective
Detectability	The number of dilutions required to reduce an odor to its minimum detectable threshold odor concentration (MDTOC)
Hedonics	The relative pleasantness or unpleasantness of the odor sensed by the subject
Intensity	The perceived strength of the odor. Usually measured by the butanol olfactometer or calculated from the D/T (dilutions to threshold ratio) when the relationship is established

Figure 2-15
Classification of methods used to detect odors.

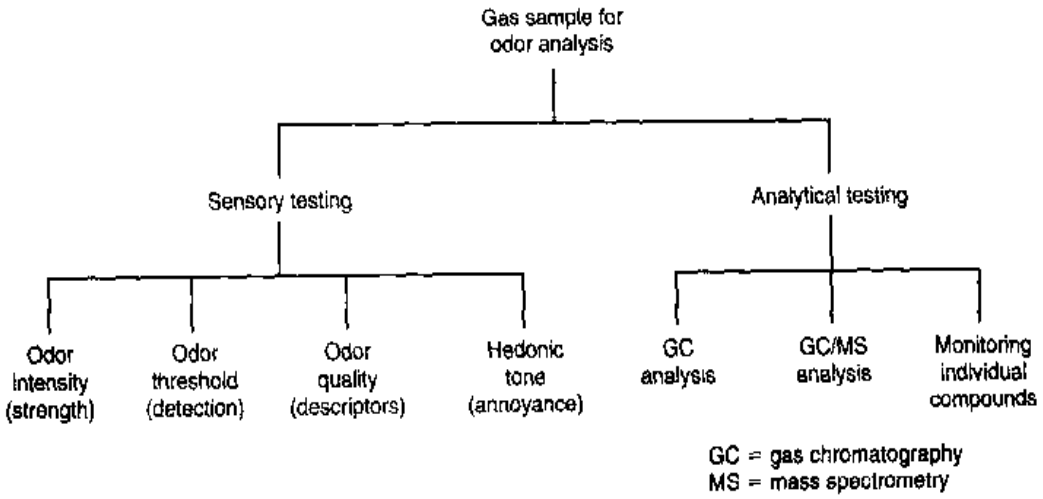

Figure 2-16
Portable H_2S meter used for field odor studies. *(From Arizona Instrument Corporation, Jerome Instrument Division.)*

odor concentration would be reported as four dilutions to MDTOC. Other terminology commonly used to measure odor strength is ED_{50}. The ED_{50} value represents the number of times an odorous air sample must be diluted before the average person (50 percentile) can barely detect an odor in the diluted sample. Details of the test procedure are provided in ASTM (1979). However, the sensory determination of this minimum threshold concentration can be subject to a number of errors. Adaptation and cross adaptation, synergism, subjectivity, and sample modification (see Table 2–12) are the principal errors. To avoid errors in sample modification during storage in sample collection containers, direct-reading olfactometers have been developed to measure odors at their source without using sampling containers.

The threshold odor of a water or wastewater sample is determined by diluting the sample with odor-free water. The "threshold odor number" (TON) corresponds to the greatest dilution of the sample with odor-free water at which an odor is just perceptible. The recommended sample size is 200 mL. The numerical value of the TON is determined as follows:

$$\text{TON} = \frac{A + B}{A} \tag{2–52}$$

where TON = threshold odor number
A = mL of sample
B = mL of odor-free water

Table 2–12
Types of errors in the sensory detection of odors[a]

Description	Type of error
Adaptation and cross adaptation	When exposed continually to a background concentration of an odor, the subject is unable to detect the presence of that odor at low concentrations. When removed from the background odor concentration, the subject's olfactory system will recover quickly. Ultimately, subjects with an adapted olfactory system will be unable to detect the presence of an odor to which their system has adapted
Sample modification	Both the concentration and composition of odorous gases and vapors can be modified in sample-collection containers and in odor-detection devices. To minimize problems associated with sample modification, the period of odor containment should be minimized or eliminated, and minimum contact should be allowed with any reactive surfaces
Subjectivity	When the subject has knowledge of the presence of an odor, random error can be introduced in sensory measurements. Often, knowledge of the odor may be inferred from other sensory signals such as sound, sight, or touch
Synergism	When more than one odorant is present in a sample, it has been observed that it is possible for a subject to exhibit increased sensitivity to a given odor because of the presence of another odor

[a]Wilson (1975).

The odor emanating from the liquid sample is determined as discussed above with human subjects (often a panel of subjects). Details for this procedure may be found in Standard Methods (1998). The application of Eq. (2–52) is illustrated in Example 2–7.

EXAMPLE 2–7 Determination of Threshold Odor Number A 25-mL sample of treated wastewater requires 175 mL of distilled water to reduce the odor to a level that is just perceptible. What is the threshold odor number (TON)?

Solution

1. Determine the TON using Eq. (2–52).

$$\text{TON} = \frac{A + B}{A} = \frac{25\ \text{mL} + 175\ \text{mL}}{25\ \text{mL}} = 8.0$$

Comment The value of the threshold number will depend on the nature of the odor compound. Also, depending on the odor compound, different persons will respond differently in assessing when an odor is just perceptible.

With regard to the instrumental measurement of odors, air-dilution olfactometry provides a reproducible method for measuring threshold odor concentrations. Equipment used to analyze odors includes (1) the triangle olfactometer, (2) the butanol wheel, and (3) the scentometer. The triangle olfactometer enables the operator to introduce the sample at different concentrations at six different cups (see Fig. 2–17). At each cup, two ports contain purified air, and one port contains diluted sample. Each odor panel member (usually six) then sniffs each of the three ports and selects the port which he or she believes to contain the sample. The butanol wheel is a device used to measure the intensity of the odor against a butanol scale containing various concentrations of butanol. A scentometer (see Fig. 2–18) is a hand-held device in which malodorous air passes through graduated orifices and is mixed with air that has been purified by passing through activated-carbon beds. The dilution ratios are determined by the ratio of the size of the malodorous to purified inlets. The scentometer is very useful in the field for making odor determinations over a large area surrounding a treatment plant. Often a mobile odor laboratory, which contains several types of olfactory and analytical equipment in a single van-type vehicle, is used for field sites.

It is often desirable to know the specific compounds responsible for odor. Although gas chromatography has been used successfully for this purpose, it has not been used as successfully in the detection and quantification of odors derived from wastewater-collection, treatment, and disposal facilities. Equipment developed and found useful in the chemical analysis of odors is the triple-stage quadrupole mass spectrometer. The spectrometer can be used as a conventional mass spectrometer to produce simple mass spectra or as a triple-stage quadrupole to produce collesionally activated disassociation spectra. The former operating mode provides the masses of molecular or parent ions present in samples, while the latter provides positive identification of compounds. Types of compounds that can be identified include ammonia, amino acids, and volatile organic compounds.

2-5 METALLIC CONSTITUENTS

Trace quantities of many metals, such as cadmium (Cd), chromium (Cr), copper (Cu), iron (Fe), lead (Pb), manganese (Mn), mercury (Hg), nickel (Ni), and zinc (Zn) are important constituents of most waters. Many of these metals are also classified as priority pollutants. However, most of these metals are necessary for growth of biological life, and absence of sufficient quantities of them could limit growth of algae, for example. The presence of any of these metals in excessive quantities will interfere with many beneficial uses of the water because of their toxicity; therefore, it is frequently desirable to measure and control the concentrations of these substances.

Importance of Metals

Metals of importance in the treatment, reuse, and disposal of treated effluents and biosolids are summarized in Table 2–13. All living organisms require varying amounts (macro and micro) of metallic elements, such as iron, chromium, copper, zinc, and cobalt, for proper growth. Although macro and micro amounts of metals are required for proper growth, the same metals can be toxic when present in elevated concentrations. As more use is made of treated wastewater effluent for irrigation and landscape watering, a variety of metals must be determined to assess any adverse effects that may occur. Calcium, magnesium, and sodium are of importance in determining the sodium adsorption ratio (SAR), which is used to assess the suitability of treated effluent for agricultural use (see Chap. 13). Where composted sludge is applied in agricultural applications, arsenic, cadmium, copper, lead, mercury, molybdenum, nickel, selenium, and zinc must be determined.

Sources of Metals

The sources of trace metals in wastewater include the discharges from residential dwellings, groundwater infiltration, and commercial and industrial discharges. Many of the sources of heavy metals are identified in Table 2–14. For example, cadmium, chromates, lead, and mercury are often present in industrial wastes. These are found particularly in metal-plating wastes and should be removed by pretreatment at the site of the industry rather than be mixed with the municipal wastewater. Fluoride, a toxic anion, is found commonly in wastewater from electronics manufacturing facilities.

Sampling and Methods of Analysis

Methods for determining the concentrations of these substances vary in complexity according to the interfering substances that may be present (Standard Methods, 1998). Metals are determined typically by flame atomic absorption, electrothermal atomic absorption, inductively coupled plasma, or IPC/mass spectrometry. Various classes of metals are defined as: (1) *dissolved metals* are those metals present in unacidified samples that pass through a 0.45-μm membrane filter, (2) *suspended metals* are those metals present in unacidified samples that are retained on a 0.45-μm membrane filter, (3) *total metals* is the total of the dissolved and suspended metals or the concentration of metals determined on an unfiltered sample after digestion, and (4) *acid extractable metals* are those metals in solution after an unfiltered sample is treated with a hot dilute mineral acid (Standard Methods, 1998).

Table 2–13
Metals of importance in wastewater management[a]

Metal	Symbol	Nutrients necessary for biological growth		Concentration threshold of inhibitory effect on heterotrophic organisms, mg/L	Used to determine SAR for land application of effluent	Used to determine if biosolids are suitable for land application

Typical Effluent Discharge Limits for Metals

Increasingly, metallic constituents in effluent discharges and in biosolids are being regulated. Typical discharge requirements for metals and other toxic constituents are reported in Table 2–15. In addition to complying with existing U.S. EPA requirements, many states have adopted more restrictive standards to protect specific beneficial uses.

Table 2–14
Typical waste compounds produced by commercial, industrial, and agricultural activities that have been classified as priority pollutants

Name	Formula	Use	Concern
Arsenic	As	Alloying additive for metals, especially lead and copper as shot, battery grids, cable sheaths, boiler tubes. High-purity (semiconductor) grade	Carcinogen and mutagen. *Long-term*—sometimes can cause fatigue and loss of energy; dermatitis
Barium	Ba	Getter alloys in vacuum tubes, deoxidizer for copper, Frary' s metal, lubricant for anode rotors in x-ray tubes, spark-plug alloys	Flammable at room temperature in powder form. *Long-term*—Increased blood pressure and nerve block
Cadmium	Cd	Electrodeposited and dipped coatings on metals, bearing and low-melting alloys, brazing alloys, fire protection system, nickel-cadmium storage batteries power transmission wire, TV phosphors, basis of pigments used in ceramic glazes, machinery enamels, fungicide, photography and lithography, selenium rectifiers, electrodes for cadmium-vapor lamps and photoelectric cells	Flammable in powder form. Toxic by inhalation of dust or fume. A carcinogen. Soluble compounds of cadmium are highly toxic. *Long-term*—concentrates in the liver, kidneys, pancreas, and thyroid; hypertension suspected effect
Chromium	Cr	Alloying and plating element on metal and plastic substrates for corrosion resistance, chromium-containing and stainless steels, protective coating for automotive and equipment accessories, nuclear and high-temperature research, constituent of inorganic pigments	Hexavalent chromium compounds are carcinogenic and corrosive on tissue. *Long-term*—skin sensitization and kidney damage
Lead	Pb	Storage batteries, gasoline additive, cable covering, ammunition, piping, tank linings, solder and fusible alloys, vibration damping in heavy construction, foil, babbitt and other bearing alloys	Toxic by ingestion or inhalation of dust or fumes. *Long-term*—brain and kidney damage; birth defects
Mercury	Hg	Amalgams, catalyst electrical apparatus, cathodes for production of chlorine and caustic soda, instruments, mercury vapor lamps, mirror coating, arc lamps, boilers	Highly toxic by skin absorption and inhalation of fume or vapor. *Long-term*—toxic to central nervous system, may cause birth defects
Selenium	Se	Electronics, xerographic plates, TV cameras, photocells, magnetic computer cores, solar batteries (rectifiers, relays), ceramics (colorant for glass), steel and copper, rubber accelerator, catalyst, trace element in animal feeds	*Long-term*—red staining of fingers, teeth, and hair; general weakness; depression; irritation of nose and mouth
Silver	Ag	Manufacture of silver nitrate, silver bromide, photochemicals; lining vats and other equipment for chemical reaction vessels, water distillation, etc.; mirrors, electric conductors, silver plating electronic equipment; sterilant, water purification, surgical cements, hydration and oxidation catalyst, special batteries, solar cells, reflectors for solar towers, low-temperature brazing alloys, table cutlery, jewelry, dental, medical, and scientific equipment, electrical contacts, bearing metal, magnet windings, dental amalgams, colloidal silver used as a nucleating agent in photography and medicine, often combined with protein	Toxic metal. *Long-term*—permanent gray discoloration of skin, eyes, and mucous membranes

Table 2-15
Typical discharge limits for toxic constituents found in secondary effluent

Constituent	Units	Average value[a]	
		Daily	Monthly
Arsenic	μg/L	20	
Cadmium	μg/L	1.1	
Chromium	μg/L	11	
Copper	μg/L	4.9	
Lead[b]	μg/L	5.6	
Mercury	μg/L	2.1	0.012
Nickel[b]	μg/L	7.1	
Selenium[b]	μg/L	5.0	
Silver	μg/L	2.3	
Zinc[b]	μg/L	58	
Dieldrin[c]	μg/L	0.0019	0.00014
Lindane	μg/L	0.16	0.063
Tributylin	μg/L	0.01	0.005
PAHs[d,e]	μg/L	0.049	

[a] Limits apply to the average concentration of all samples collected during the averaging period (daily—24-h period; monthly—calendar month).

[b] Effluent limitation may be met as a 4-d average. If compliance is to be determined based on a 4-d average, then concentrations of four 24-h composite samples must be reported as well as the average of four.

[c] Compliance will be based on the practical quantification level (PQL), 0.07 μg/L.

[d] PAHs = polynuclear aromatic hydrocarbons.

[e] Compliance will be based on the practical quantification level (PQL) for each PAH, 4 μg/L.

2-6 AGGREGATE ORGANIC CONSTITUENTS

Organic compounds are normally composed of a combination of carbon, hydrogen, and oxygen, together with nitrogen in some cases. The organic matter in wastewater typically consists of proteins (40 to 60 percent), carbohydrates (25 to 50 percent), and oils and fats (8 to 12 percent). Urea, the major constituent of urine, is another important organic compound contributing to fresh wastewater. Because urea decomposes rapidly, it is seldom found in other than very fresh wastewater. Along with the proteins, carbohydrates, fats and oils, and urea, wastewater typically contains small quantities of a very large number of different synthetic organic molecules, with structures ranging from simple to extremely complex.

Over the years, a number of different analyses have been developed to determine the organic content of wastewaters. In general, the analyses may be classified into those used to measure aggregate organic matter comprising a number of organic constituents

with similar characteristics that cannot be distinguished separately, and those analyses used to quantify individual organic compounds (Standard Methods, 1998). Aggregate organic compounds are considered in this section. Individual organic compounds are considered in the following section.

Measurement of Organic Content

In general, the analyses used to measure aggregate organic material may be divided into those used to measure gross concentrations of organic matter greater than about 1.0 mg/L and those used to measure trace concentrations in the range of 10^{-12} to 10^{0} mg/L. Laboratory methods commonly used today to measure gross amounts of organic matter (typically greater than 1 mg/L) in wastewater include: (1) biochemical oxygen demand (BOD), (2) chemical oxygen demand (COD), and (3) total organic carbon (TOC). Complementing these laboratory tests is the theoretical oxygen demand (ThOD), which is determined from the chemical formula of the organic matter.

Other methods used in the past included: (1) total, albuminoid, organic, and ammonia nitrogen, and (2) oxygen consumed. These determinations, with the exception of albuminoid nitrogen and oxygen consumed, are still included in complete wastewater analyses. Their significance, however, has changed. Whereas formerly they were used almost exclusively to indicate organic matter, they are now used to determine the availability of nitrogen to sustain biological activity in industrial waste-treatment processes and to determine whether undesirable algal growths will occur in receiving waters.

Trace organics in the range of 10^{-12} to 10^{-3} mg/L are determined using instrumental methods including gas chromotography and mass spectroscopy. Within the past 10 years, the sensitivity of the methods used for the detection of trace organic compounds has improved significantly, and detection of concentrations in the range of 10^{-9} mg/L is now almost a routine matter.

Biochemical Oxygen Demand (BOD)

The most widely used parameter of organic pollution applied to both wastewater and surface water is the 5-day BOD (BOD_5). This determination involves the measurement of the dissolved oxygen used by microorganisms in the biochemical oxidation of organic matter. Despite the widespread use of the BOD test, it has a number of limitations, as discussed later in this section. It is hoped that, through the continued efforts of workers in the field, one of the other measures of organic content, or perhaps a new measure, will ultimately be used in its place. Why, then, if the test suffers from serious limitations, is further space devoted to it in this text? The reason is that BOD test results are now used (1) to determine the approximate quantity of oxygen that will be required to biologically stabilize the organic matter present, (2) to determine the size of waste-treatment facilities, (3) to measure the efficiency of some treatment processes, and (4) to determine compliance with wastewater discharge permits. Because it is likely that the BOD test will continue to be used for some time, it is important to know the details of the test and its limitations.

Basis for BOD Test. If sufficient oxygen is available, the aerobic biological decomposition of an organic waste will continue until all of the waste is consumed. Three more or less distinct activities occur. First, a portion of the waste is oxidized to end products to obtain energy for cell maintenance and the synthesis of new cell tissue.

Simultaneously, some of the waste is converted into new cell tissue using part of the energy released during oxidation. Finally, when the organic matter is used up, the new cells begin to consume their own cell tissue to obtain energy for cell maintenance. This third process is called endogenous respiration. Using the term COHNS (which represents the elements carbon, oxygen, hydrogen, nitrogen, and sulfur) to represent the organic waste and the term $C_5H_7NO_2$ [first proposed by Hoover and Porges (1952)] to represent cell tissue, the three processes are defined by the following generalized chemical reactions:

Oxidation:

$$\text{COHNS} + O_2 + \text{bacteria} \rightarrow CO_2 + H_2O + NH_3 + \text{other end products} + \text{energy} \quad (2\text{–}53)$$

Synthesis:

$$\text{COHNS} + O_2 + \text{bacteria} + \text{energy} \rightarrow \underset{\text{New cell tissue}}{C_5H_7NO_2} \quad (2\text{–}54)$$

Endogenous respiration:

$$C_5H_7NO_2 + 5O_2 \rightarrow 5CO_2 + NH_3 + 2H_2O \quad (2\text{–}55)$$

If only the oxidation of the organic carbon that is present in the waste is considered, the ultimate BOD is the oxygen required to complete the three reactions given above. This oxygen demand is known as the ultimate carbonaceous or first-stage BOD, and is usually denoted as UBOD.

BOD Test Procedure. In the standard BOD test (see Fig. 2–19*a*), a small sample of the wastewater to be tested is placed in a BOD bottle (volume = 300 mL). The bottle is then filled with dilution water saturated in oxygen and containing the nutrients required for biological growth. To ensure that meaningful results are obtained, the sample must be suitably diluted with a specially prepared dilution water so that adequate nutrients and oxygen will be available during the incubation period. Normally, several dilutions are prepared to cover the complete range of possible values. The ranges of BOD that can be measured with various dilutions based on percentage mixtures and direct pipetting are reported in Table 2–16. Before the bottle is stoppered, the oxygen concentration in the bottle is measured (see Fig. 2–20).

After the bottle is incubated for 5 days at 20°C, the dissolved oxygen concentration is measured again. The BOD of the sample is the difference in the dissolved oxygen concentration values, expressed in milligrams per liter, divided by the decimal fraction of sample used. The computed BOD value is known as the 5-day, 20°C biochemical oxygen demand. When testing waters with low concentrations of microorganisms, a seeded BOD test is conducted (see Fig. 2–19*b*). The organisms contained in the effluent from primary sedimentation facilities are used commonly as the seed for the BOD test. Seed organisms can also be obtained commercially. When the sample contains a large population of microorganisms (e.g., untreated wastewater), seeding is not necessary.

The standard incubation period is usually 5 days at 20°C, but other lengths of time and temperatures can be used. Longer time periods (typically 7 days), which correspond to work schedules, are often used, especially in small plants where the laboratory

staff is not available on the weekends. The temperature, however, should be constant throughout the test. The 20°C temperature used is an average value for slow-moving streams in temperate climates and is easily duplicated in an incubator. Different results would be obtained at different temperatures, because biochemical reaction rates are

Table 2-16
Measurable BOD using various dilutions of samples

By using percent mixtures		By direct pipetting into 300-mL bottles	
% mixture	**Range of BOD, mg/L**	**mL**	**Range of BOD, mg/L**

temperature-dependent. After incubation, the dissolved oxygen of the sample is measured (see Fig. 2–20) and the BOD is calculated using Eq. (2–56) or (2–57).

When the dilution water is not seeded:

$$\text{BOD, mg/L} = \frac{D_1 - D_2}{P} \tag{2-56}$$

When the dilution water is seeded:

$$\text{BOD, mg/L} = \frac{(D_1 - D_2) - (B_1 - B_2)f}{P} \tag{2-57}$$

where D_1 = dissolved oxygen of diluted sample immediately after preparation, mg/L
D_2 = dissolved oxygen of diluted sample after 5-day incubation at 20°C, mg/L
B_1 = dissolved oxygen of seed control before incubation, mg/L
B_2 = dissolved oxygen of seed control after incubation, mg/L
f = fraction of seeded dilution water volume in sample to volume of seeded dilution water in seed control
P = fraction of wastewater sample volume to total combined volume

Biochemical oxidation theoretically takes an infinite time to go to completion because the rate of oxidation is assumed to be proportional to the amount of organic matter remaining. Within a 20-day period, the oxidation of the carbonaceous organic matter is about 95 to 99 percent complete, and in the 5-day period used for the BOD test, oxidation is from 60 to 70 percent complete.

EXAMPLE 2–8 Determination of BOD from Laboratory Data The following information is available for a seeded 5-day BOD test conducted on a wastewater sample. Fifteen mL of the waste sample was added directly into a 300-mL BOD incubation bottle. The initial DO of the diluted sample was 8.8 mg/L and the final DO after 5 days was 1.9 mg/L. The corresponding initial and final DO of the seeded dilution water was 9.1 and 7.9, respectively. What is the 5-day BOD (BOD_5) of the wastewater sample?

Solution

1. Determine the 5-day BOD using Eq. (2–57).

$$BOD_5, \text{mg/L} = \frac{(D_1 - D_2) - (B_1 - B_2)f}{P}$$

$$f = [(300 - 15)/300] = 0.95$$

$$P = 15/300 = 0.05$$

$$BOD_5, \text{mg/L} = \frac{(8.8 - 1.9) - (9.1 - 7.9)0.95}{0.05} = 115.2 \text{ mg/L}$$

Modeling of BOD Reaction. The rate of BOD oxidation ("exertion") is modeled based on the assumption that the amount of organic material remaining at any time t is governed by a first-order function (see Chap. 4), as given below.

$$\frac{dBOD_r}{dt} = -k_1 BOD_r \tag{2–58}$$

Integrating between the limits of UBOD and BOD_t and $t = 0$ and $t = t$ yields

$$BOD_r = UBOD(e^{-k_1 t}) \tag{2–59}$$

where BOD_r = amount of waste remaining at time t (days) expressed in oxygen equivalents, mg/L.
k_1 = first-order reaction rate constant, $1/d$
UBOD = total or ultimate carbonaceous BOD, mg/L
t = time, d

Thus the BOD exerted up to time t is given by

$$BOD_t = UBOD - BOD_r = UBOD - UBOD(e^{-k_1 t}) = UBOD(1 - e^{-k_1 t}) \tag{2–60}$$

Equation (2–60) is the standard expression used to define the BOD for wastewater. The basis for this equation is discussed in Sec. 4–3 in conjunction with the analysis of a batch reactor. It should be noted that in the literature dealing with the characterization of wastewater, the terms "L" and "BOD_u" are often used to denote ultimate carbonaceous BOD (UBOD).

The value of k_1 for untreated wastewater is generally about 0.12 to 0.46 d^{-1} (base e), with a typical value of about 0.23 d^{-1}. The range of k_1 values for effluents from

biological treatment processes is from 0.12 to 0.23 d^{-1}. For a given wastewater, the value of k_1 at 20°C can be determined experimentally by observing the variation with time of the dissolved oxygen in a series of incubated samples. If k_1 at 20°C is equal to 0.23 d^{-1}, the 5-day oxygen demand is about 68 percent of the ultimate first-stage demand. Occasionally, the first-order reaction rate constant will be expressed in log (base 10) units. The relationship between k_1 (base e) and K_1 (base 10) is as follows:

$$K_1(\text{base } 10) = \frac{k_1(\text{base } e)}{2.303} \tag{2-61}$$

As discussed above, the temperature at which the BOD of a wastewater sample is determined is usually 20°C. It is possible, however, to determine the reaction constant k at a temperature other than 20°C using the following relationship developed in the discussion on temperature in Sec. 2–2.

$$k_{1_T} = k_{1_{20}}\theta^{T-20} \tag{2-25}$$

The value of θ has been found to vary from 1.056 in the temperature range between 20 and 30°C to 1.135 in the temperature range between 4 and 20°C (Schroepfer et al., 1964). A value of θ often quoted in the literature is 1.047 (Phelps, 1944), but it has been observed that this value does not apply at cold temperatures (e.g., below 20°C). Equation (2–60), along with Eq. (2–25), makes it possible to convert test results from different time periods and temperatures to the standard 5-day 20°C test, as illustrated in Example 2–9.

EXAMPLE 2–9 Calculation of BOD Determine the 1-day BOD and ultimate first-stage BOD for a wastewater whose 5-day 20°C BOD is 200 mg/L. The reaction constant k (base e) = 0.23 d^{-1}. What would have been the 5-day BOD if the test had been conducted at 25°C?

Solution

1. Determine the ultimate carbonaceous BOD.

   $$BOD_5 = UBOD - BOD_r = UBOD(1 - e^{-k_1 t})$$

   $$200 = UBOD\,(1 - e^{-5\times 0.23}) = UBOD\,(1 - 0.316)$$

   $$UBOD = 293 \text{ mg/L}$$

2. Determine the 1-day BOD.

   $$BOD_t = UBOD\,(1 - e^{-k_1 t})$$

   $$BOD_1 = 293(1 - e^{-0.23\times 1}) = 293(1 - 0.795) = 60.1 \text{ mg/L}$$

3. Determine the 5-day BOD at 25°C.

   $$k_{1_T} = k_{1_{20}}(1.047)^{T-20}$$

   $$k_{1_{25}} = 0.23(1.047)^{25-20} = 0.29 \text{ d}^{-1}$$

   $$BOD_5 = UBOD\,(1 - e^{-k_1 t}) = 293(1 - e^{-0.29\times 5}) = 224 \text{ mg/L}$$

Figure 2-21

Effect of the rate constant k_1 on BOD (for a unit UBOD value).

For polluted water and wastewater, a typical value of k_1 (base e at 20°C) is 0.23 d^{-1} (K_1, base 10, = 0.10 d^{-1}). The value of reaction rate constant varies significantly, however, with the type of waste. The range may be from 0.05 to 0.3 d^{-1} (base e) or more. For the same ultimate BOD, the oxygen uptake will vary with time and with different reaction rate constant values (see Fig. 2–21).

Nitrification in the BOD Test. Noncarbonaceous matter, such as ammonia, is produced during the hydrolysis of proteins. It is now known that a number of bacteria are capable of oxidizing ammonia to nitrite and subsequently to nitrate. The generalized reactions are as follows:

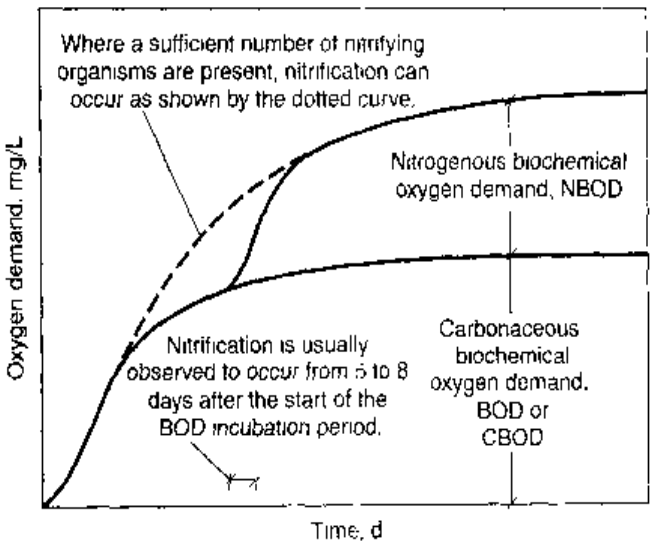
Conversion of ammonia to nitrite (as typified by *Nitrosomonas*):

$$NH_3 + 3/2O_2 \rightarrow HNO_2 + H_2O \quad [2\text{–}62]$$

Conversion of nitrite to nitrate (as typified by *Nitrobacter*):

$$HNO_2 + 1/2O_2 \rightarrow HNO_3 \quad [2\text{–}63]$$

Overall conversion of ammonia to nitrate:



$$NH_3 + 2O_2 \rightarrow HNO_3 + H_2O \quad [2\text{–}64]$$

The oxygen demand associated with the oxidation of ammonia to nitrate is called the nitrogenous biochemical oxygen demand (NBOD). The normal exertion of the oxygen demand in a BOD test for a domestic wastewater is shown on Fig. 2–22. Because the reproductive rate of the nitrifying bacteria is slow, it normally takes from 6 to 10 days for them to reach significant numbers to exert a measurable oxygen demand. However, if a sufficient number of nitrifying bacteria is present initially, the interference caused by nitrification can be significant.

When nitrification occurs in the BOD test, erroneous interpretations of treatment operating data are possible. For example, assume the effluent BOD from a biological treatment process is 20 mg/L without nitrification and 40 mg/L with nitrification. If the influent BOD to the treatment process is 200 mg/L, then the corresponding BOD removal efficiency would be reported as 90 and 80 percent without and with nitrification, respectively. Thus, if nitrification is occurring but is not suspected, it might be concluded

Figure 2-22

Definition sketch for the exertion of the carbonaceous and nitrogenous biochemical oxygen demand in a waste sample.

that the treatment process is not performing well, when in actuality it is performing quite well.

Carbonaceous Biochemical Oxygen Demand. When nitrification occurs, the measured BOD value will be higher than the true value due to the oxidation of carbonaceous material (see Fig. 2–22). If a given percentage of carbonaceous biochemical oxygen demand (CBOD) removal must be achieved to meet regulatory permit limits, early nitrification can pose a serious problem. The effects of nitrification can be overcome either by using various chemicals to suppress the nitrification reactions, or by treating the sample to eliminate the nitrifying organisms (Young, 1973). Pasteurization and chlorination/dechlorination are two methods that have also been used to suppress the nitrifying organisms.

When the nitrification reaction is suppressed, the resulting BOD is known as the carbonaceous biochemical oxygen demand (CBOD). In effect, the CBOD is a measure of the oxygen demand exerted by the oxidizable carbon in the sample. The CBOD test, in which the nitrification reaction is suppressed chemically, should be used only on samples that contain small amounts of organic carbon (e.g., treated effluent). Large errors will occur in the measured BOD values (up to 20 percent) when the CBOD test is used on wastewater containing significant amounts of organic matter such as untreated wastewater (Albertson, 1995).

Analysis of BOD Data. The value of k is needed if the BOD_5 is to be used to obtain UBOD, the ultimate or 20-day BOD. The usual procedure followed when these values are unknown is to determine k_1 and UBOD from a series of BOD measurements. There are several ways of determining k_1 and UBOD from the results of a series of BOD measurements, including the method of least squares, the method of moments (Moore et al., 1950), the daily-difference method (Tsivoglou, 1958), the rapid-ratio method (Sheehy, 1960), the Thomas method (Thomas, 1950), and the Fujimoto method (Fujimoto, 1961). The least-squares method and the Fujimoto method are illustrated in the following discussion.

The least-squares method involves fitting a curve through a set of data points, so that the sum of the squares of the residuals (the difference between the observed value

and the value of the fitted curve) must be a minimum. Using this method, a variety of different types of curves can be fitted through a set of data points. For example, for a time series of BOD measurements on the same sample, the following equation may be written for each of the various n data points:

$$\left.\frac{dy}{dt}\right|_{t=n} = k_1(\text{UBOD} - y) \tag{2–65}$$

where k_1 = first-order reaction rate constant
y = BOD at $t = n$

In the above equation both k_1 and UBOD are unknown. If it is assumed that dy/dt represents the value of the slope of the curve to be fitted through all the data points for a given k_1 and UBOD value, then because of experimental error, the two sides of Eq. (2–65) will not be equal but will differ by an amount R. Rewriting Eq. (2–65) in terms of R for the general case yields

$$R = k_1(\text{UBOD} - y) - \frac{dy}{dt} \tag{2–66}$$

Simplifying and using the notation y' for dy/dt gives

$$R = k_1\text{UBOD} - k_1 y - y' \tag{2–67}$$

Substituting a for k_1 UBOD and $-b$ for k_1 gives

$$R = a + by - y' \tag{2–68}$$

Now, if the sum of the squares of the residuals R is to be a minimum, the following equations must hold:

$$\frac{\partial}{\partial b}\Sigma R^2 = \Sigma\frac{\partial R}{\partial a} \tag{2–69}$$

$$\frac{\partial}{\partial b}\Sigma R^2 = \Sigma 2R\frac{\partial R}{\partial b} \tag{2–70}$$

If the indicated operations in Eqs. (2–69) and (2–70) are carried out using the value of the residual R defined by Eq. (2–68), the following set of equations result:

$$na + b\Sigma y - \Sigma y' = 0 \tag{2–71}$$

$$a\Sigma y + b\Sigma y^2 - \Sigma yy' = 0 \tag{2–72}$$

where n = number of data points
$a = -$ bUBOD
$b = -k_1$(base e)
UBOD $= -a/b$
$y = y_t$, mg/L

$$y' = \frac{y_{n+1} - y_{n-1}}{2\Delta t}$$

Application of the least-squares method in the analysis of BOD data is illustrated in Example 2–9 following the discussion of the Fujimoto method.

In the Fujimoto method an arithmetic plot is prepared of BOD_{t+1} versus BOD_t (Fujimoto, 1961). The value at the intersection of the plot with a line of slope 1 corresponds to the ultimate BOD. After the UBOD has been determined, the rate constant is determined using Eq. (2–59) and one of the BOD values. The application of the Fujimoto method is illustrated in Example 2–10.

EXAMPLE 2–10 Calculation of BOD Constants Using the Least-Squares and the Fujimoto Methods Compute k_1 and UBOD using the least-squares and Fujimoto methods for the following BOD data reported for a stream receiving some treated effluent:

t, d	2	4	6	8	10
y, mg/L	11	18	22	24	26

Solution

1. Determine k_1 and UBOD using the method of least squares.
   a. Set up a computation table and perform the indicated steps.

Time, d	y	y^2	y'	yy'
0	0			
2	11	121	4.50	49.5
4	18	324	2.75	49.5
6	22	484	1.50	33.0
8	24	576	1.00	24.0
10	26[a]			
Sums	75	1505	9.75	156.0

[a]Value not included in total.

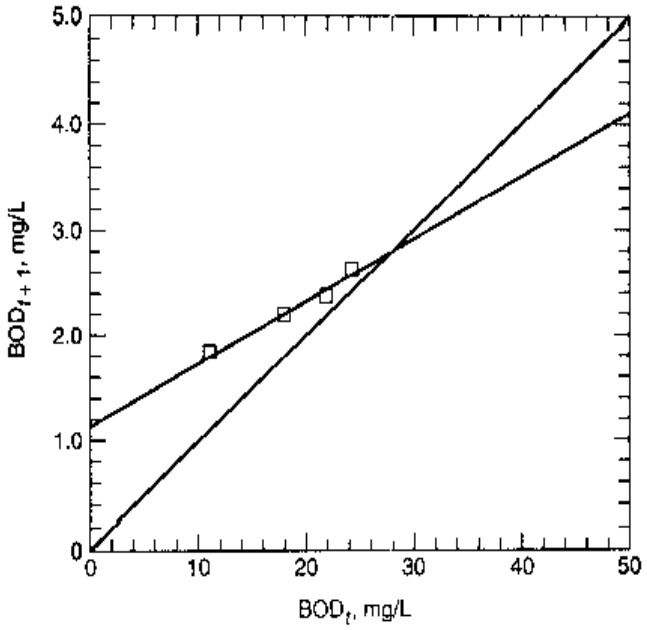
   b. The slope y' is computed as follows:

$$\frac{dy}{dt} = y' = \frac{y_{n+1} - y_{n-1}}{2\Delta t}$$

   c. Substituting the values computed in Step 1 in Eqs. (2–71) and (2–72), solve for a and b.

$$4a + 75b - 9.75 = 0$$

$$75a + 1505b - 156.0 = 0$$



$$a = 7.5 \text{ and } b = -0.271$$

   d. Determine the values of k_1 and UBOD.

$$k_1 = -b = -(-0.271) = 0.271 \text{ (base } e\text{)}$$

$$\text{UBOD} = -\frac{a}{b} = -\frac{7.5}{(-0.271)} = 27.7$$

2. Determine k_1 and UBOD using the Fujimoto method.
   a. Prepare an arithmetic plot of BOD_{t+1} versus BOD_t and on the same plot draw a line with a slope of 1. The value at the intersection of the two lines (BOD = 27.8 mg/L) corresponds to the ultimate BOD.

   b. Determine the k_1 value using Eq. (2–59).

$$y_6 = \text{UBOD} - \text{BOD}_6 = \text{UBOD}(1 - e^{-6k_1})$$

$$22 = \text{UBOD} - \text{BOD}_6 = 27.8(1 - e^{-6k_1})$$

$$k_1 = 0.261 \text{ d}^{-1}$$

Respirometric Determination of BOD. Determination of the BOD value and the corresponding rate constant k_1 can be accomplished more effectively in the laboratory using an instrumented large-volume (1.0-L) electrolysis cell respirometer. An electrolysis cell may also be used to obtain a continuous BOD (Young and Baumann, 1976a, 1976b). Within the cell, oxygen pressure over the sample is maintained constant by continuously replacing the oxygen used by the micoorganisms. Oxygen replacement is accomplished by means of an electrolysis reaction in which oxygen is produced in response to changes in the pressure. The BOD readings are determined by noting the length of time that the oxygen was generated and correlating it to the amount of oxygen produced by the electrolysis reaction. The modern electrolysis cell respirometer has replaced the Gilson and Warburg respirometer, used previously, in which the oxygen consumed was calculated from pressure drop measurements made with a manometer (Tchobanoglous and Burton, 1991). The principal advantages of the electrolysis cell over the Gilson and Warburg respirometers are that (1) the use of a large (1-L) sample minimizes the errors of grab sampling and pipetting in dilutions, and (2) the value of the BOD

Figure 2-23
Commercial electrolytic respirometer apparatus. *(Courtesy Challenge Environmental Systems, Inc.)*

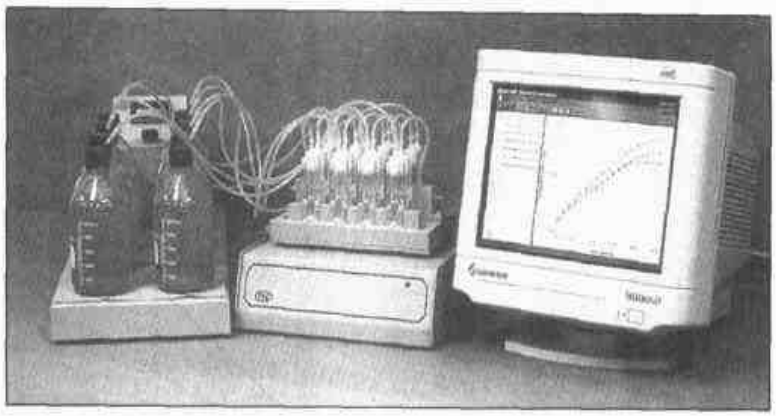


Table 2-17
Effect of the size of the biodegradable particles found in wastewater on observed BOD reaction rates[a]

Fraction	Size range, μm	*k* (base 10), d^{-1}
Settleable	>100	0.08
Supracolloidal	1–100	0.09
Colloidal	0.1–1.0	0.22
Soluble	<0.1	0.39

is available directly. A typical example of a commercially available electrolytic respirometer with multiple electrolysis cells is also shown on Fig. 2–23.

Effect of Particle Size on BOD Reaction Rates. If a separation and analysis technique, such as membrane filtration (see Figs. 2–4 and 2–8), is used to quantify the size distribution of the solids in the influent wastewater, the various size fractions can be correlated to observed oxygen (BOD) uptake rates, determined using a respirometer. As reported in Table 2–17, the observed BOD reaction rate coefficients are affected significantly by the size of the particles in wastewater. Based on the data given in Table 2–17, it is clear that the treatment of a wastewater can be effected by modifying the particle size distribution. Further, wastewaters with significantly different particle size distributions will respond differently, depending on the method of treatment (e.g., in constructed wetlands).

Limitations in the BOD Test. The limitations of the BOD test are as follows: (1) a high concentration of active, acclimated seed bacteria is required; (2) pretreatment is needed when dealing with toxic wastes, and the effects of nitrifying organisms must be reduced; (3) only the biodegradable organics are measured; (4) the test does not have stoichiometric validity after the soluble organic matter present in solution has been used (see Fig. 2–24); and (5) the relatively long period of time required to obtain test results (originally chosen to minimize variance). Of the above, perhaps the most serious limitation is that the 5-day period may or may not correspond to the point where the solu-

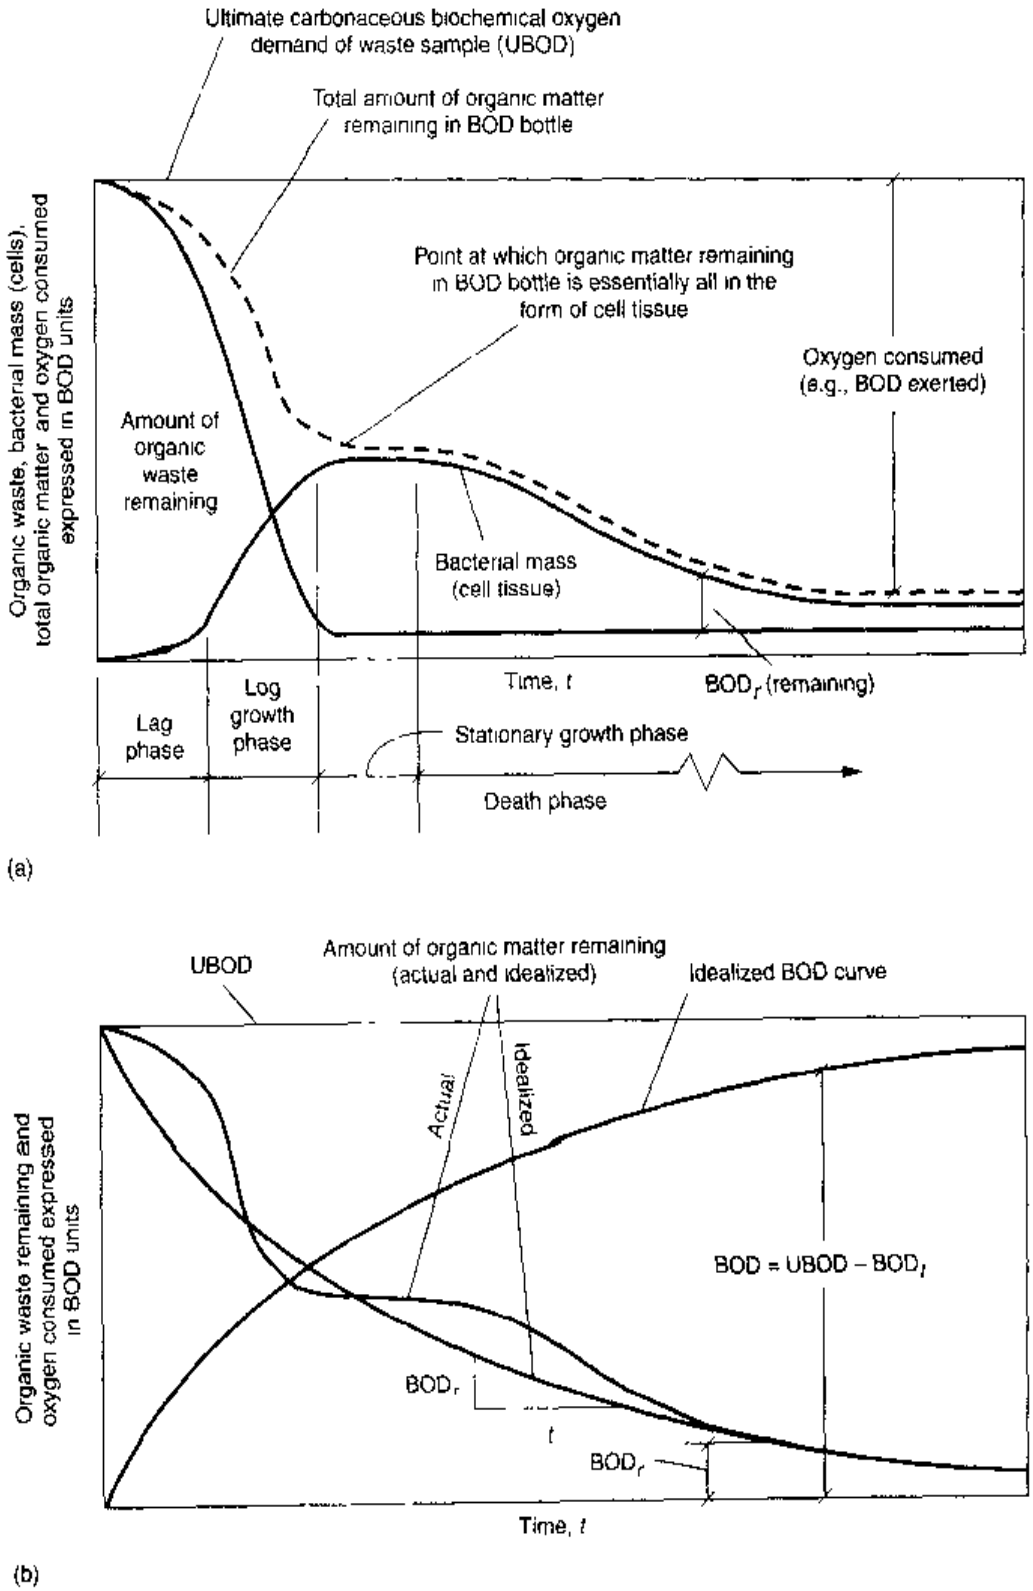

Figure 2–24

Functional analysis of the BOD test: (a) Interrelationship of organic waste, bacterial mass (cell tissue, total organic waste, and oxygen consumed in BOD test) and (b) idealized representation of the BOD test. *(Tchobanoglous and Schroeder, 1985.)*

ble organic matter that is present has been used. The lack of stoichiometric validity at all times reduces the usefulness of the test results.

Total and Soluble Chemical Oxygen Demand (COD and SCOD)

The COD test is used to measure the oxygen equivalent of the organic material in wastewater that can be oxidized chemically using dichromate in an acid solution, as

illustrated in the following equation, when the organic nitrogen is in the reduced state (oxidation number = −3) (Sawyer et al., 1994).

$$C_nH_aO_bN_c + dCr_2O_7^{2-} + (8d + c)H^+ \rightarrow$$

$$nCO_2 + \frac{a + 8d - 3c}{2} H_2O + cNH_4^+ + 2d\,Cr^{3+} \quad (2\text{–}73)$$

where $d = \frac{2n}{3} - \frac{a}{6} - \frac{b}{3} - \frac{c}{2}$

Although it would be expected that the value of the ultimate carbonaceous BOD would be as high as the COD, this is seldom the case. Some of the reasons for the observed differences are as follows: (1) many organic substances which are difficult to oxidize biologically, such as lignin, can be oxidized chemically, (2) inorganic substances that are oxidized by the dichromate increase the apparent organic content of the sample, (3) certain organic substances may be toxic to the microorganisms used in the BOD test, and (4) high COD values may occur because of the presence of inorganic substances with which the dichromate can react. From an operational standpoint, one of the main advantages of the COD test is that it can be completed in about 2.5 h, compared to 5 or more days for the BOD test. To reduce the time further, a rapid COD test that takes only about 15 min has been developed.

As new methods of biological treatment have been developed, especially with respect to biological nutrient removal, it has become more important to fractionate the COD. The principal fractions are particulate and soluble COD. In biological treatment studies, the particulate and soluble fractions are fractionated further to assess wastewater treatability (see discussion in Chap. 8, Sec. 8–2). Fractions that have been used include: (1) readily biodegradable soluble COD, (2) slowly biodegradable colloidal and particulate (enmeshed) COD, (3) nonbiodegradable soluble COD, and (4) nonbiodegradable colloidal and particulate COD. The readily biodegradable soluble COD is often fractionated further into complex COD that can be fermented to volatile fatty acids (VFAs) and short chain VFAs (see Fig. 8–31 in Chap. 8). Unfortunately, as noted previously, there is little standardization on the definition of soluble versus particulate COD. Where filtration is the technique used to fractionate the sample, the relative distribution between soluble and particulate COD will vary greatly depending on the pore size of the filter. An alternative method used to determine the soluble COD involves precipitation of the suspended solids and a portion of the colloidal material. The COD of the clarified liquid corresponds to the soluble COD.

Total and Dissolved Organic Carbon (TOC and DTOC)

The TOC test, done instrumentally, is used to determine the total organic carbon in an aqueous sample. The test methods for TOC utilize heat and oxygen, ultraviolet radiation, chemical oxidants, or some combination of these methods to convert organic carbon to carbon dioxide which is measured with an infrared analyzer or by other means. The TOC of a wastewater can be used as a measure of its pollutional characteristics, and in some cases it has been possible to relate TOC to BOD and COD values. The TOC test is also gaining in favor because it takes only 5 to 10 min to complete. If a valid relationship can

be established between results obtained with the TOC test and the results of the BOD test for a given wastewater, use of the TOC test for process control is recommended.

More recently, a continuous on-line TOC analyzer has been developed, in conjunction with the space program, that can be used to detect TOC concentrations in the ppb (parts per billion) range. Such instruments are currently being used to detect the residual TOC in the treated effluent from microfiltration and reverse osmosis (RO) treatment units. Continuous TOC measurements may be used to monitor the performance of the full-scale RO units, to be used in conjunction with repurification projects in which repurified effluent is proposed to be blended with other waters.

Along with COD, it has also become more important to fractionate the TOC. The principal fractions are particulate TOC and dissolved (soluble) DTOC. As with COD, the particulate and soluble TOC fractions are fractionated further to assess treatability. It should be noted that the pore size of the filter paper recommended in Standard Methods (1998) for differentiating between dissolved and particulate TOC is 0.45 μm, in contrast to the pore size (2.0 μm or less) used to define TSS and TDS. Again, because of the pore size of the filter paper used, the colloidal material that passes through the filter will be classified as dissolved. Because of the interest in the chemical constituents that make up the DTOC, advanced methods of analysis have been developed to quantify the constituent groupings as illustrated on Fig. 2–25.

UV-Absorbing Organic Constituents

A number of organic compounds are found in wastewater, including humic substances, lignin, tannin, and various aromatic compounds, that strongly absorb ultraviolet (UV) radiation. As a result, UV absorption has been used as a surrogate measure for the organic compounds cited above. The UV wavelengths at which adsorption is determined are typically in the range from 200 to 400 nm, with the value of 254 nm being reported most commonly. The results of UV absorption measurements are reported in units of cm^{-1}, along with the pH and the UV wavelength (e.g., UV_{λ}^{pH} where λ is the UV wavelength). This method has proved useful in assessing the aggregate presence of UV absorbing compounds in wastewater, although interfering compounds can render the test invalid.

The results of UV absorption measurements at a wavelength of 254 nm are also correlated to the amount of dissolved organic carbon (DOC) present in a sample which

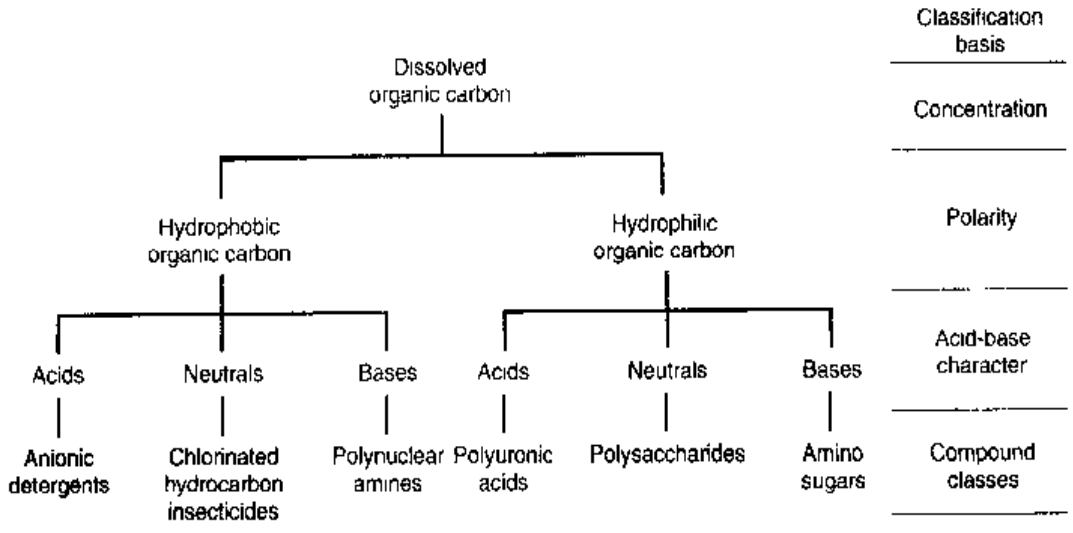

Figure 2–25

Procedure for the characterization of the organic fractions that comprise the TOC (see also Fig. 2–29). *(From Jerry Leenheer, U.S. Geologic Survey.)*

has been filtered through a filter with a pore size of 0.45 μm. The results are reported as the *specific ultraviolet adsorption* (SUVA) per mg/L of DOC. It should be noted that although the UV measurement is correlated to the DOC, SUVA is in fact a measure of the nature of the carbon in the sample being analyzed, more specifically the extent to which the carbon is aromatic. Thus, the SUVA test is used most commonly to distinguish between different water samples. The SUVA test has also been used to assess the potential for the formation of trihalomethanes (THMs) (see Sec. 2–7).

Theoretical Oxygen Demand (ThOD)

Organic matter of animal or vegetable origin in wastewater is generally a combination of carbon, hydrogen, oxygen, and nitrogen. The principal groups of these elements present in wastewater are, as previously noted, carbohydrates, proteins, oils and grease, and products of their decomposition. The biological decomposition of the substances is discussed in Chap. 7. If the chemical formula of the organic matter is known, the ThOD may be computed as illustrated in Example 2–11.

EXAMPLE 2–11 Calculation of ThOD Determine the ThOD for glycine ($CH_2(NH_2)COOH$) using the following assumptions:

1. In the first step, the organic carbon and nitrogen are converted to carbon dioxide (CO_2) and ammonia (NH_3), respectively.
2. In the second and third steps, the ammonia is oxidized sequentially to nitrite and nitrate.
3. The ThOD is the sum of the oxygen required for all three steps.

Solution

1. Write a balanced reaction for the carbonaceous oxygen demand.

   $$CH_2(NH_2)COOH + 3/2O_2 \rightarrow NH_3 + 2CO_2 + H_2O$$

2. Write balanced reactions for the nitrogenous oxygen demand.
   a. $NH_3 + 3/2O_2 \rightarrow HNO_2 + H_2O$
   b. $HNO_2 + 1/2O_2 \rightarrow HNO_3$

   $$NH_3 + 2O_2 \rightarrow HNO_3 + H_2O$$

3. Determine the ThOD.

   $$\text{ThOD} = (3/2 + 4/2) \text{ mol } O_2/\text{mol glycine}$$
   $$= 7/2 \text{ mol } O_2/\text{mol glycine} \times 32 \text{ g/mol } O_2$$
   $$= 112 \text{ g } O_2/\text{mol glycine}$$

Interrelationships between BOD, COD, and TOC

Typical values for the ratio of BOD/COD for untreated municipal wastewater are in the range from 0.3 to 0.8 (see Table 2–18). If the BOD/COD ratio for untreated wastewater is 0.5 or greater, the waste is considered to be easily treatable by biological means. If the ratio is below about 0.3, either the waste may have some toxic components or accli-

Table 2-18 Comparison of ratios of various parameters used to characterize wastewater

Type of wastewater	BOD/COD	BOD/TOC
Untreated	0.3–0.8	1.2–2.0
After primary settling	0.4–0.6	0.8–1.2
Final effluent	0.1–0.3[a]	0.2–0.5[b]

[a] CBOD/COD
[b] CBOD/TOC.

mated microorganisms may be required in its stabilization. The corresponding BOD/TOC ratio for untreated wastewater varies from 1.2 to 2.0. In using these ratios it important to remember that they will change significantly with the degree of treatment the waste has undergone, as reported in Table 2–18. The theoretical basis for these ratios is explored in the following example.

EXAMPLE 2-12 Determination of BOD/COD, BOD/TOC, and TOC/COD Ratios Determine the theoretical BOD/COD, BOD/TOC, and TOC/COD ratios for the following compound $C_5H_7NO_2$. Assume the value of the BOD first-order reaction rate constant is 0.23/*d* (base *e*) (0.10/*d* base 10).

Solution

1. Determine the COD of the compound using Eq. (2–55).

   $$C_5H_7NO_2 + 5O_2 \rightarrow 5CO_2 + NH_3 + 2H_2O$$
   $$\text{mw} = 113 \quad \text{mw} = 160$$

   $$\text{COD} = 160/113 = 1.42 \text{ mg } O_2/\text{mg } C_5H_7NO_2$$

2. Determine the BOD of the compound.

   $$\frac{\text{BOD}}{\text{UBOD}} = (1 - e^{-k\,t}) = (1 - e^{-0.23 \times 5}) = 1 - 0.32 = 0.68$$

   $$\text{BOD} = 0.68 \times 1.42 \text{ mg } O_2/\text{mg } C_5H_7NO_2 = 0.97 \text{ mg BOD/mg } C_5H_7NO_2$$

3. Determine the TOC of the compound.

   $$\text{TOC} = (5 \times 12)/113 = 0.53 \text{ mg TOC/mg } C_5H_7NO_2$$

4. Determine BOD/COD, BOD/TOC, and TOC/COD ratios.

   $$\frac{\text{BOD}}{\text{COD}} = \frac{0.68 \times 1.42}{1.42} = 0.68$$

   $$\frac{\text{BOD}}{\text{TOC}} = \frac{0.68 \times 1.42}{0.53} = 1.82$$

   $$\frac{\text{TOC}}{\text{COD}} = \frac{0.53}{1.42} = 0.37$$

Oil and Grease

The term *oil and grease*, as commonly used, includes the fats, oils, waxes, and other related constituents found in wastewater. The term *fats, oil, and grease* (FOG) used previously in the literature has been replaced by the term *oil and grease*. The oil and grease content of a wastewater is determined by extraction of the waste sample with trichlorotrifluoroethane (oil and grease are soluble in trichlorotrifluoroethane). Other extractable substances include mineral oils, such as kerosene and lubricating and road oils. Oil and grease are quite similar chemically; they are compounds (esters) of alcohol or glycerol (glycerin) with fatty acids. The glycerides of fatty acids that are liquid at ordinary temperatures are called oils, and those that are solids are called grease (or fats).

If grease is not removed before discharge of treated wastewater, it can interfere with the biological life in the surface waters and create unsightly films. The thickness of oil required to form a translucent film on the surface of a water body is about 0.0003048 mm (0.0000120 in), as given below.

	Film thickness		Quantity spread	
Appearance	**in**	**mm**	**gal/mi²**	**L/ha**
Barely visible	0.0000015	0.0000381	25	0.365
Silvery sheen	0.0000030	0.0000762	50	0.731
First trace of color	0.0000060	0.0001524	100	1.461
Bright bands of color	0.0000120	0.0003048	200	2.922
Colors begin to dull	0.0000400	0.0010160	666	9.731
Colors are much darker	0.0000800	0.0020320	1332	19.463

Source: Eldridge (1942)

Fats and oils are contributed to domestic wastewater in butter, lard, margarine, and vegetable fats and oils. Fats are also commonly found in meats, in the germinal area of cereals, in seeds, in nuts, and in certain fruits. The low solubility of fats and oils reduces their rate of microbial degradation. Mineral acids attack them, however, resulting in the formation of glycerin and fatty acid. In the presence of alkalies, such as sodium hydroxide, glycerin is liberated, and alkali salts of the fatty acids are formed. These alkali salts are known as soaps. Common soaps are made by saponification of fats with sodium hydroxide. They are soluble in water, but in the presence of hardness constituents, the sodium salts are changed to calcium and magnesium salts of the fatty acids, or so-called mineral soaps. These are insoluble and are precipitated.

Kerosene, lubricating, and road oils are derived from petroleum and coal tar and contain essentially carbon and hydrogen. These oils sometimes reach the sewers in considerable volume from shops, garages, and streets. For the most part, they float on the wastewater, although a portion is carried into the sludge on settling solids. To an even greater extent than fats, oils, and soaps, the mineral oils tend to coat surfaces. The particles interfere with biological action and cause maintenance problems.

Surfactants

Surfactants, or surface-active agents, are large organic molecules that are slightly soluble in water and cause foaming in wastewater treatment plants and in the surface waters

into which the waste effluent is discharged. Surfactants are most commonly composed of a strongly hydrophobic group combined with a strongly hydrophilic group. Typically, the hydrophobic group is a hydrocarbon radical (R) made up of 10 to 20 carbon atoms. Two types of hydrophobic groups are used: those that will and those that will not ionize in water. Anionic surfactants are negatively charged [e.g., $(RSO_3N)^-Na^+$]; whereas cationic surfactants are positively charged [e.g., $(RMe_3N)^+Cl^-$]. Nonionizing (nonionic) surfactants commonly contain a polyoxyethylene hydrophilic group ($ROCH_2CH_2OCH_2CH_2 \ldots OCH_2CH_2OH$, often abbreviated Re_n, where n is the average number of $-OCH_2CH_2-$ units in the hydrophilic group). Hybrids of these types also exist. In the United States, ionic surfactants amount to about two-thirds of the total surfactants used and nonionics to about one-third (Standard Methods, 1998).

Surfactants tend to collect at the air-water interface with the hydrophilic in the water and the hydrophobic group in the air. During aeration of wastewater, these compounds collect on the surface of the air bubbles and thus create a very stable foam. Before 1965, the type of surfactant present in synthetic detergents, called alkyl-benzene-sulfonate (ABS), was especially troublesome because it resisted breakdown by biological means. As a result of legislation in 1965, ABS has been replaced in detergents by linear-alkyl-sulfonate (LAS), which is biodegradable. Because surfactants come primarily from synthetic detergents, the foaming problem has been greatly reduced. It should be noted that so-called "hard" synthetic detergents are still used extensively in many foreign countries.

Two tests are now used to determine the presence of surfactants in water and wastewater. The MBAS (methylene blue active substances) test is used for anionic surfactants. The determination of surfactants is accomplished by measuring the color change in a standard solution of methylene blue dye. Nonionic surfactants are measured using the CTAS (cobalt thiocyanate active substances) test. Nonionic surfactants will react with the CTAS to produce a cobalt-containing product which can be extracted into a organic liquid and then measured. It should be noted that the CTAS method requires sublimation to remove nonionic surfactants and ion exchange to remove the cationic and anionic surfactants (Standard Methods, 1998).

2-7 INDIVIDUAL ORGANIC COMPOUNDS

Individual organic compounds are determined to assess the presence of priority pollutants identified by the U.S. Environmental Protection Agency (U.S. EPA) and a number of new emerging compounds of concern. Priority pollutants (both inorganic and organic) have been and are continuing to be selected on the basis of their known or suspected carcinogenicity, mutagenicity, teratogenicity, or high acute toxicity. As the techniques used to identify specific compounds continue to improve, a number of other organic compounds have been detected in public water supplies and in treated wastewater effluents.

Priority Pollutants

The Environmental Protection Agency has identified approximately 129 priority pollutants in 65 classes to be regulated by categorical discharge standards (*Federal Register*, 1981). Priority pollutants (both inorganic and organic) were selected on the basis of their known or suspected carcinogenicity, mutagenicity, teratogenicity, or high acute

toxicity. Many of the organic priority pollutants are also classified as volatile organic compounds (VOCs).

Two types of standards are used to control pollutant discharges to publicly owned treatment works (POTWs). The first, "prohibited discharge standards," applies to all commercial and industrial establishments which discharge to POTWs. Prohibited standards restrict the discharge of pollutants that may create a fire or explosion hazard in sewers or treatment works, are corrosive (pH < 5.0), obstruct flow, upset treatment processes, or increase the temperature of the wastewater entering the plant to above 40°C. "Categorical standards" apply to industrial and commercial discharges in 25 industrial categories ("categorical industries"), and are intended to restrict the discharge of the 129 priority pollutants. It is anticipated that this list will continue to be expanded in the future.

Analysis of Individual Organic Compounds

The analytical methods used to determine individual organic compounds require the use of sophisticated instrumentation capable of measuring trace concentrations in the range of 10^{-12} to 10^{-3} mg/L. Gas chromatographic (GC) and high-performance liquid chromatographic (HPLC) methods are most commonly used to detect individual organic compounds. Different types of detectors are used with each method, depending on the nature of the compound being analyzed. Typical detectors used in conjunction with gas chromatography include electrolytic conductivity, electron capture (ECD), flame ionization (FID), photoionization (PID), and mass spectrometer (GCMS). Typical detectors for high-performance liquid chromatography include photodiode array (PDAD) and post column reactor (PCR). It should also be noted that many of the individual organic constituents can be determined by two or more of the above methods (Standard Methods, 1998).

Over 180 individual organic compounds can be determined using one or more of the methods cited above. The principal categories containing the individual organic compounds are reported in Table 2–19. As instrumental methods of analysis have improved, the detection limits for these compounds have become increasingly small, typically below 10 ng/L. The specific organic compounds that are analyzed will depend on the application. For example, for indirect reuse applications scans of disinfection byproducts may be required where chlorine is used for disinfection.

Volatile Organic Compounds (VOCs)

Organic compounds that have a boiling point less than or equal to 100°C and/or a vapor pressure greater than 1 mm Hg at 25°C are generally considered to be volatile organic compounds (VOCs). For example, vinyl chloride, which has a boiling point of −13.9°C and a vapor pressure of 2548 mm Hg at 20°C, is an example of an extremely volatile organic compound. Volatile organic compounds are of great concern because (1) once such compounds are in the vapor state they are much more mobile and therefore more likely to be released to the environment, (2) the presence of some of these compounds in the atmosphere may pose a significant public health risk, and (3) they contribute to a general increase in reactive hydrocarbons in the atmosphere, which can lead to the formation of photochemical oxidants. The release of these compounds in sewers and at treatment plants, especially at the headworks, is of particular concern with respect to the health of collection system and treatment plant workers. The physical phenomena involved in the release and control of VOCs are considered in more detail in Chap. 5.

Table 2–19
Typical classes of organic compounds whose members are identified as individual compounds

Name	Occurrence/source	Concern
Volatile organic compounds	Found in ground- and surface waters	Potential for tetratogenesis or carcinogenesis in humans
1,2-Dibromoethane (EDB) and 1,2-dibromo-3-chloropropane (DBCP)	Found in groundwater supplies, especially where these compounds have been used as fumigants	Detrimental effects on human health
Trihalomethanes (THMs)	Found in most chlorinated water supplies	Disinfection byproduct. Potential human carcinogen
Chlorinated organic solvents	Found in raw water supplies resulting from industrial contamination	Potential human carcinogen
Haloacetic acids (HAAs)	Formed from the chlorination of natural organic matter (humic and fulvic acids)	Disinfection byproduct. Potential human carcinogen
Trichlorophenol	Formed from the chlorination of natural organic matter (humic and fulvic acids)	Disinfection byproduct. Dichloroacetic acid and trichloroacetic acid are animal carcinogens
Aldehydes	Formed from the application of ozone to water containing organic matter	Disinfection byproduct
Extractable base/neutral and acids	Many semivolatile compounds including polynuclear aromatic hydrocarbons, phthalates, phenolics, organochlorine pesticides, and PCBs	Many of the listed compounds are toxic or carcinogenic
Phenols	Generally traceable to industrial discharges or landfills	Impart a taste to water at low levels. May have detrimental impact on human health at higher levels
Polychlorinated biphenyls (PCB)	Found in water supplies contaminated by transformer oils	These compounds are toxic, bioaccumulative, and extremely stable in water
Polynuclear aromatic hydrocarbons (PAHs)	Byproducts of petroleum processing or combustion	Many compounds in this group are highly carcinogenic at relatively low levels
Carbamate pesticides	Found in water supplies contaminated by pesticides	
Organochlorine pesticides	Found in water supplies contaminated by pesticides	Many compounds in this group are bioaccumulative, and relatively stable, as well as toxic or carcinogenic
Acidic herbicide compounds	Used for weed control, these compounds are found in aquatic systems	
Glyphosphate herbicide	Broad spectrum nonselective postemergence herbicide Water supplies can become contaminated through runoff and spray drift	

Disinfection Byproducts

It has been found that when chlorine is added to water containing organic matter a variety of organic compounds containing chlorine are formed. Collectively, these compounds, along with others, are known as disinfection byproducts (DBPs). Although generally present in low concentrations, they are of concern because many of them are known or suspected potential human carcinogens. Typical classes of compounds include trihalomethanes (THMs), haloacetic acids (HAAs), trichlorophenol, and aldehydes.

More recently, *N*-nitrosodimethylamine (NDMA) has been found in the effluent from wastewater-treatment plants. The reason for concern over this compound is that as a group of compounds nitrosamines are among the most powerful carcinogens known (Snyder, 1995). These compounds are also known to be strongly carcinogenic to various fish species at low concentrations. The U.S. EPA action limit for NDMA is 2 parts per trillion. Based on the results of recent studies, NDMA appears to be formed during the chlorination process. In treated effluent, the nitrite ion can react with hydrochloric acid, present as a result of the use of chlorine for disinfection, to form nitrous acid. In turn, nitrous acid can react with dimethylamine to form NDMA (Hill, 1988). The compound dimethylamine is common in wastewater and surface waters, and is found in urine, feces, algae, and plant tissues. Dimethylamine is also part of some polymers used for water treatment (such as polydiallyl dimethylamine) and for ion-exchange resins. The formation of NDMA under basic and alkaline conditions has been reported by Wainwright (1986).

Because of the concern over the formation of DBPs and NDMA, considerable attention has been focused over the past five years on the use of ultraviolet (UV) disinfection as a possible replacement for chlorine. In addition, considerable attention has been focused on the modifications to conventional treatment processes to improve the treatment of these compounds and to advanced treatment processes for the removal of these substances. The use of UV radiation for disinfection and the destruction of NDMA is considered in Chaps. 11 and 12.

Pesticides and Agricultural Chemicals

Pesticides, herbicides, and other agricultural chemicals are toxic to many organisms and therefore can be significant contaminants of surface waters. These chemicals are not common constituents of domestic wastewater but result primarily from surface runoff from agricultural, vacant, and park lands. Concentrations of these chemicals can result in fish kills, in contamination of the flesh of fish that decreases their value as a source of food, and in impairment of water supplies.

Emerging Organic Compounds

In addition to the compounds discussed above, for which requirements have been established, a variety of new (emerging) compounds have been identified in many of the nation's water supplies and in treated wastewater effluents. The compounds in question are derived, in large part, from (1) veterinary and human antibiotics, (2) human prescription and nonprescription drugs, (3) industrial and household wastewater products, and (4) sex and steroidal hormones. Typical examples of the types of compounds involved are reported in Table 2-20. As more becomes known about the health impacts of these compounds, it is anticipated that discharge limits may be developed for a number of

Table 2–20
Emerging organic compounds found in the stream waters[a]

Veterinary and human antibiotics

Carbadox	Norfloxacin	Sulfamethazine
Chlortetracycline	Oxytetracycline	Sulfamethiazole
Ciprofloxacin	Roxarsone	Sulfamethoxazole
Doxycycline	Roxithromycin	Sulfathiazole
Enrofloxacin	Sarafloxacin	Tetracycline
Erythromycin	Spectinomycin	Trimethoprim
Erythromycin-H_2O	Sulfachlorpyridazine	Tylosin
Ivermectin	Sulfadimethoxine	Virginiamycin
Lincomycin	Sulfomerazine	

Human prescription and nonprescription drugs

Acetaminophen (antipyretic)
Amoxicillin (antibiotic)
Caffeine (stimulant)
Cimetidine (antacid)
Cotinine (nicotine metabolite)
Dehydronifedipine (antianginal)
Digoxigenin (digoxin metabolite)
Diltiazem (antihypertensive)
Enalaprillat (antihypertensive)
Fluoxetine (antidepressant)
Gemfibrozil (lipotropic agent)
Ibuprofen (anti-inflammatory)
Metformin (antidiabetic agent)
Paraxanthine (caffeine metabolite)
Paroxetine (paxil metabolite)
Ranitidine (antacid)
Salbutamol (antiasthmatic)
Sulfamethoxazole (antibiotic)
Trimethoprim (antibiotic)

Industrial and household wastewater products

Acetophenone (fragrance)
Anthracene (PAH)
Benzo(a)pyrene (PAH)
2,6-di-tert-para-benzoquinone (antioxidant)
5-methyl 1 H benzotriazole (antioxidant)
Bisphenol A (used in palymers)
Bis(2-ethylhexyl)phthalate (plasticizer)
2,6-di-tert-butylphenol (antioxidant)
Butylated hydroxyanisole (BHA)
Butylated hydroxytoluene (BHT) (antioxidant)
Caffeine (stimulant)
Chlorpyrifos (pesticide)
Cholesterol (fecal indicator)
Cis-chlordane (pesticide)
Coarbaryl (pesticide)
Codeine (analgesic)
3b-coprostanol (carnivore fecal indicator)
Cotinine (nicotine metabolite)
Para-cresol (wood preservative)
Diazinan (pesticide)
1,4-dichlorobenzene (fumigant)
Dieldrin (pesticide)
Diethylphthalate (plasticizer)
N,N-diethyltoluamide (DEET) (insecticide)

(continued)

Table 2-20 (*Continued*)

Industrial and household wastewater products (continued)

Ethanol, 2-butoxy-, phosphate (plasticizer)	Phenol (disinfectant)
Fluoranthene (PAH)	Para-nonylphenol-total (detergent metabolite)
Lindane (pesticide)	Phthalic anhydride (used in plastics)
Methyl parathion (pesticide)	Pyrene (PAH)
Naphthalene (PAH)	Stigmastanol (plant sterol)
NPEO1-total (detergent metabolite)	Tetrachloroethylene (solvent)
NPEO2-total (detergent metabolite)	Triclosan (antimicrobial disinfectant)
OPEO1	Tri(2-chloroethyl)phosphate (fire retardant)
OPEO2	Tri(dichlorisopropyl)phosphate (fire retardant)
Phenanthrene (PAH)	Triphenyl phosphate (plasticizer)

Sex and steroidal hormones

Cis-androsterone	17a-estradiol	Mestranol
3b-coprostanol	17b-estradiol	19-norethisterone
Cholesterol	Estriol	Progesterone
Equilenin	Estrone	Testosterone
Equilin	17a-ethynylestradiol	

[a] From U.S. GS (2000).

these compounds. Given that over 30 million organic compounds are known to exist, it is clear that the list of emerging compounds will continue to grow as analytical techniques continue to improve.

2–8 BIOLOGICAL CHARACTERISTICS

The biological characteristics of wastewater are of fundamental importance in the control of diseases caused by pathogenic organisms of human origin, and because of the extensive and fundamental role played by bacteria and other microorganisms in the decomposition and stabilization of organic matter, both in nature and in wastewater-treatment plants. The purpose of this section is to introduce (1) the microorganisms found in surface waters and wastewater, (2) the pathogenic microorganisms associated with human disease, (3) the use of indicator organisms, (4) the methods and techniques used for the enumeration of bacteria, (5) the method of enumerating viruses, and (6) a brief discussion of newly recognized or emerging organisms. The organisms responsible for the treatment of wastewater are considered further in Chap. 7.

Microorganisms Found in Surface Waters and Wastewater

Organisms found in surface water and wastewater include bacteria, fungi, algae, protozoa, plants and animals, and viruses. Bacteria, fungi, algae, protozoa, and viruses can

only be observed microscopically. The general classification of these organisms and a general description of the organisms found in wastewater are considered in the following discussion. The growth and metabolic and environmental requirements of microorganisms are considered in detail in Chap. 7.

General Classification. Living single-cell microorganisms that can only be seen with a microscope are responsible for the activity in biological wastewater treatment. The basic functional and structural unit of all living matter is the cell. Living organisms are divided into either prokaryote or eukaryote cells as a function of their genetic information and cell complexity. The prokaryotes have the simplest cell structure and include bacteria, blue-green algae (cyanobacter), and archaea. The archaea are separated from bacteria due to their DNA composition and unique cellular chemistry, such as differences in the cell wall and ribosome structure. Many archaea are bacteria that can grow under extreme conditions of temperature and salinity, and also include methanogenic methane-producing bacteria, important in anaerobic treatment processes. In contrast to the prokaryotes, the eukaryotes are much more complex and contain plants and animals and single-celled organisms of importance in wastewater treatment including protozoa, fungi, and green algae.

Some of the key differences between prokaryote and eukaryote microorganisms are summarized in Table 2-21, and a schematic of their cell structures is shown on Fig. 2–26. The prokaryote organisms are generally much smaller compared to eukaryote organisms. The absence of a nuclear membrane to contain the cell DNA is also a distinguishing feature of the prokaryote organisms. The eukaryotic organisms have much more complex internal structures. These include the endoplasmic reticulum, which is a distinct organelle that contains the sites of ribosomes with internal membranes. The golgi bodies are also distinct membrane structures and contain sites for the secretion of enzymes and other macromolecules. The mitochondrion is a complex internal membrane structure where respiration occurs for eukaryotic cells, and is lacking in prokaryotic cells. While the prokaryotes can have photosynthetic pigments, they do not contain chloroplasts, which are used in photosynthesis by green algae. Additional information on prokaryote cell structure and composition and the role and importance of DNA and ribonucleic acid (RNA) is discussed in Chap. 7.

Viruses are obligate *intracellular parasites* that require the machinery of a host cell to support their growth. Although viruses contain the genetic information (either DNA or RNA) needed to replicate themselves, they are unable to reproduce outside of a host cell. Viruses are composed of a nucleic acid core (RNA or DNA) surrounded by an outer coat of protein and glycoprotein. Viruses are classified separately according to the host infected. Bacteriophage, as the name implies, are viruses that infect bacteria.

General Description. A general description of the microorganisms found in wastewater is given in Table 2–22 using the terminology introduced in the previous paragraphs. Data on the shape, resistant form, and size of the microorganisms found in wastewater are presented in Table 2–23. Information on the size of the microorganisms, especially the resistant form, is needed to determine the type of treatment that will be required to treat and/or remove them.

Table 2-21
Comparison of prokaryote and eukaryote cells[a]

Cell characteristic	Prokaryote	Eukaryote (Eukarya)
Phylogenetic group	Bacteria, blue-green algae (cyanobacter), archaea	Single cell: algae, fungi, protozoan; multicell: plants, animals
Size[b]	Small, 0.2–3.0 μm	2–100 μm for single-cell organisms
Cell wall	Composed of peptidoglycan (bacteria), other polysaccharides, protein, glycoprotein (archaea)	Absent in animals and most protozoan; present in plants, algae, fungi: usually polysaccharide
Nuclear structure:		
Nuclear membrane	Absent	Present
DNA	Single molecular, plasmids	Several chromosomes
Internal membranes	Simple, limited	Complex, endoplasmic reticulum, golgi, mitochondria; several present
Membrane organelles	Absent	Several present
Photosynthetic pigments	In internal membranes; chloroplasts absent	In chloroplasts
Respiratory system	Part of cytoplasmic membrane	Mitochondria

Figure 2-26
Typical structure of microorganism cells: (a) prokaryotic and (b) eukaryotic.

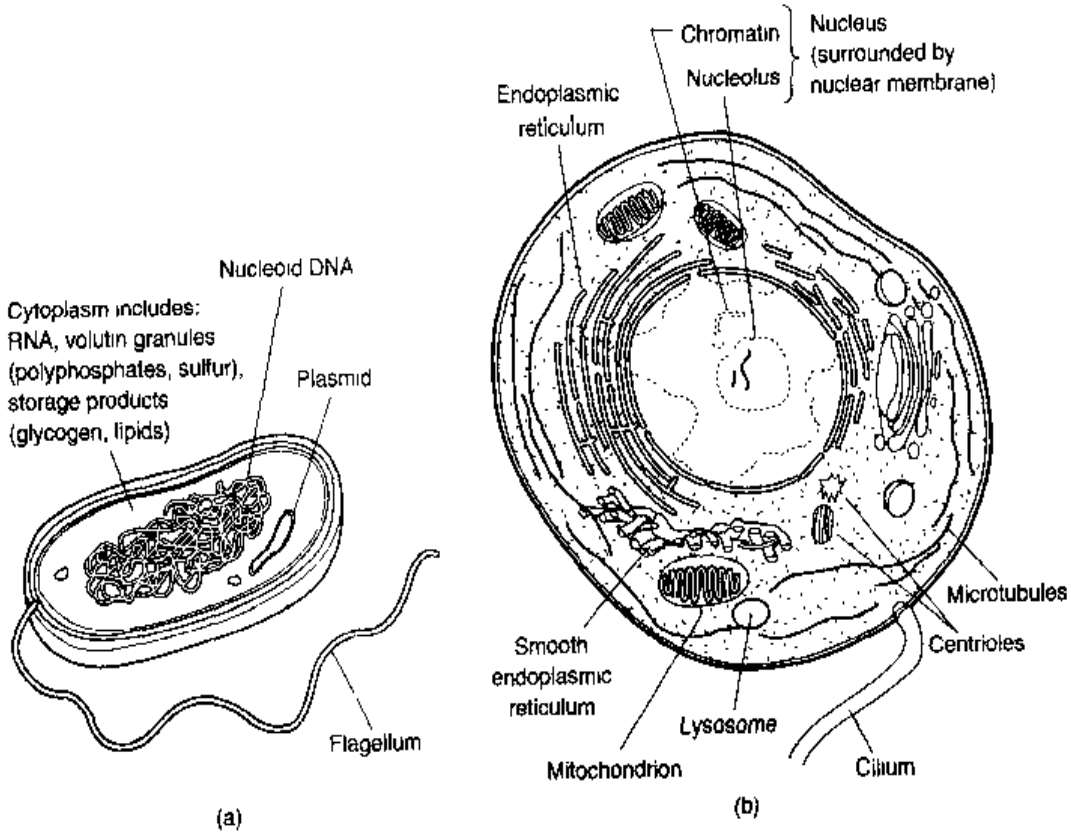

Table 2-22
Typical descriptions of the microorganisms found in natural waters, wastewater, and wastewater-treatment processes

Organism	Description
Bacteria	Bacteria are single-cell prokaryotic organisms. The interior of the cell contains a colloidal suspension of proteins, carbohydrates, and other complex organic compounds, called the cytoplasm. The cytoplasmic area contains ribonucleic acid (RNA), whose major role is in the synthesis of proteins. Also within the cytoplasm is deoxyribonucleic acid (DNA). DNA contains all the information necessary for the reproduction of all the cell components and may be considered to be the blueprint of the cell. Their usual mode of reproduction is by binary fission, although some species reproduce sexually or by budding
Archaea	Similar to bacteria in size and basic cell components. Their cell wall, cell material, and RNA composition are different. Important in anaerobic processes and also found under extreme conditions of temperature and chemical composition
Fungi/yeast	Fungi are multicellular, nonphotosynthetic, heterotrophic eukaryotes. Most fungi are either strict or facultative aerobes which reproduce sexually or asexually, by fission, budding, or spore formation. Molds, or "true fungi," produce microscopic units (hyphae), which collectively form a filamentous mass called the mycelium. Yeasts are fungi that cannot form a mycelium and are therefore unicellular. Fungi have the ability to grow under low-moisture, low-nitrogen conditions and can tolerate an environment with a relatively low pH. The ability of the fungi to survive under low-pH and nitrogen-limiting conditions, coupled with their ability to degrade cellulose, makes them very important in the composting of sludge
Protozoa	Protozoa are motile, microscopic eukaryotes that are usually single cells. The majority of protozoa are aerobic heterotrophs, some are aerotolerant anaerobes, and a few are anaerobic. Protozoa are generally an order of magnitude larger than bacteria and often consume bacteria as an energy source. In effect, the protozoa act as polishers of the effluents from biological waste-treatment processes by consuming bacteria and particulate organic matter
Rotifers	Rotifers are aerobic heterotrophic animal eukaryotes. The name is derived from the fact that they have two sets of rotating cilia on their head which are used for motility and capturing food. Rotifers are very effective in consuming dispersed and flocculated bacteria and small particles of organic matter. Their presence in an effluent indicates a highly efficient aerobic biological purification process
Algae	Algae are unicellular or multicellular, autotrophic, photosynthetic eukaryotes. They are of importance in biological treatment processes. In wastewater-treatment lagoons, the ability of algae to produce oxygen by photosynthesis is vital to the ecology of the water environment. The blue-green algo cyanobacter is a prokaryotic organism
Viruses	Viruses are composed of a nucleic acid core (either DNA or RNA) surrounded by an outer shell of protein called a capsid. Viruses are obligate intracellular parasites that multiply only within a host cell, where they redirect the cell's biochemical system to reproduce themselves. Viruses can also exist in an extracellular state in which the virus particle (known as a viron) is metabolically inert. Bacteriophages are viruses that infect bacteria as the host; they have not been implicated in human infections

An important feature of microorganisms is their ability to form resistant forms. For example, selected species of bacteria can form endospores (formed within the cell), the structure of which is extremely complex. The endospore which contains all of the information necessary for reproduction is coated with several layers of proteins. Endospores are extremely resistant to heat and disinfecting chemicals. It has been speculated that endospores may remain dormant for decades, and perhaps even centuries. A spore can

Table 2-23
Typical data on the shape, size, and resistant forms of classes of microorganisms and selected species found in wastewater[a]

Microorganism	Shape	Size, μm[b]	Envionmentally resistant form
Bacteria:			
Bacilli	Rod	0.3–1.5 *D* × 1–10 *L*	Endospores or dormant cells
Bacillus (*E. coli*)	Rod	0.6–1.2 *D* × 2–3 *L*	Endospores or dormant cells
Cocci	Spherical	0.5–4	Endospores or dormant cells
Spirilla	Spiral	0.6–2 *D* × 20–50 *L*	Endospores or dormant cells
Vibrio	Rod, curved	0.4–2 *D* × 1–10 *L*	Endospores or dormant cells
Protozoa:			
Cryptosporidium[c]			
Oocysts	Spherical	3–6	Oocysts
Sporozoite	Teardrop	1–3 *W* × 6–8 *L*	
Entamoeba histolytica			
Cysts	Spherical	10–15	Cysts
Trophozoite	Semispherical	10–20	
Giardia lamblia[d]			
Cysts	Ovid	6–8 *W* × 8–14 *L*	Cysts
Trophozoite	Pear or kite	6–8 *W* × 12–16 *L*	
Helminths:			
Ancylostoma duodenale (hookworm) eggs	Elliptical or egg	36–40 *W* × 55–70 *L*	Filariform larva
Ascaris lumbricoides (roundworm) eggs	Lemon or egg	35–50 *W* × 45–70 *L*	Embryonated egg
Trichuris trichiura (whipworm) eggs	Elliptical or egg	20–24 *W* × 50–55 *L*	Embryonated egg
Viruses:			
MS2	Spherical	0.022–0.026	Virion
Enterovirus	Spherical	0.020–0.030	Virion
Norwalk	Spherical	0.020–0.035	Virion
Polio	Spherical	0.025–0.030	Virion
Rotavirus	Spherical	0.070–0.080	Virion

[d] Member of the phylum Sarcomastigophora, order Diplomonadida

become viable in a suitable environment in a three-step process: activation, germination, and outgrowth (Madigan et al., 2000). The resistant forms in protozoans are known as cysts or oocysts. Resistant forms in helminths are eggs and oocysts.

The term *parasite* is used to describe an organism that lives at the expense of another. Parasites that live on the surface of a host organism are *ectoparasites*. Parasites that live internally within the host are known as *endoparasites* (Roberts and Janovy, 1996).

Pathogenic Organisms

Pathogenic organisms found in wastewater may be excreted by human beings and animals who are infected with disease or who are carriers of a particular infectious disease. The pathogenic organisms found in wastewater can be classified into four broad categories, bacteria, protozoa, helminths, and viruses. The principal pathogenic organisms found in untreated wastewater are reported in Table 2–24, along with the diseases and disease symptoms associated with each pathogen. Bacterial pathogenic organisms of human origin typically cause diseases of the gastrointestinal tract, such as typhoid and paratyphoid fever, dysentery, diarrhea, and cholera. Because these organisms are highly infectious, they are responsible for many thousands of deaths each year in areas with poor sanitation, especially in the tropics. It has been estimated that up to 4.5 billion people are or have been infected with some parasite (Madigan et al., 2000). Typical data on the quantity of selected pathogenic organisms found in wastewater and the corresponding concentration needed for an infectious dose are reported in Table 2–25.

Bacteria. Many types of harmless bacteria colonize the human intestinal tract and are routinely shed in the feces. Because pathogenic bacteria are present in the feces of infected individuals, domestic wastewater contains a wide variety and concentration range of nonpathogenic and pathogenic bacteria. One of the most common bacterial pathogens found in domestic wastewater is the genus *Salmonella*. The *Salmonella* group contains a wide variety of species that can cause disease in humans and animals. Typhoid fever, caused by *Salmonella typhi*, is the most severe and serious. The most common disease associated with *Salmonella* is food poisoning identified as salmonellosis. *Shigella*, a less common genus of bacteria, is responsible for an intestinal disease known as bacillary dysentery or shigellosis. Waterborne outbreaks of shigellosis have been reported from recreational swimming areas and where wastewater has contaminated wells used for drinking water (Crook, 1998; Maier et al., 2000).

Other bacteria isolated from raw wastewater include *Vibrio*, *Mycobacterium*, *Clostridium*, *Leptospira*, and *Yersinia* species. *Vibrio cholerae* is the disease agent for cholera, which is not common in the United States but is still prevalent in other parts of the world. Humans are the only known hosts, and the most frequent mode of transmission is through water. *Mycobacterium tuberculosis* has been found in municipal wastewater, and outbreaks have been reported among persons swimming in water contaminated with wastewater (Crook, 1998; Maier et al., 2000).

Waterborne gastroenteritis of unknown cause is frequently reported, with the suspected agent being bacterial. One potential source of this disease is certain gram-negative bacteria normally considered to be nonpathogenic. These include the enteropathogenic *Escherichia coli* and certain strains of *Pseudomonas*, which may affect the newborn and have been implicated in gastrointestinal disease outbreaks. *Campylobacter jejuni* has

Table 2-24
Infectious agents potentially present in untreated domestic wastewater[a]

Organism	Disease	Remarks/symptoms
Bacteria:		
Campylobacter jejuni	Gastroenteritis	Diarrhea
Escherichia coli (enteropathogenic)	Gastroenteritis	Diarrhea
Legionella pneumophila	Legionnaires' disease	Malaise, myalgia, fever, headache, respiratory illness
Leptospira (spp.)	Leptospirosis	Jaundice, fever (Weil's disease)
Salmonella (≈2100 serotypes)	Salmonellosis	Food poisoning
Salmonella typhi	Typhoid fever	High fever, diarrhea, ulceration of small intestine
Shigella (4 spp.)	Shigellosis	Bacillary dysentery
Vibrio cholerae	Cholera	Extremely heavy diarrhea, dehydration
Yersinia enterocolitica	Yersiniosis	Diarrhea
Protozoa:		
Balantidium coli	Balantidiasis	Diarrhea, dysentery
Cryptosporidium parvum	Cryptosporidiosis	Diarrhea
Cyclospora cayetanensis	Cyclosporasis	Severe diarrhea, stomach cramps, nausea, and vomiting lasting for extended periods
Entamoeba histolytica	Amebiasis (amoebic dysentery)	Prolonged diarrhea with bleeding, abscesses of the liver and small intestine
Giardia lamblia	Giardiasis	Mild to severe diarrhea, nausea, indigestion
Helminths:[b]		
Ascaris lumbricoides	Ascariasis	Roundworm infestation
Enterobius vermicularis	Enterobiasis	Pinworm
Fasciola hepotica	Fascioliasis	Sheep liver fluke
Hymenolepis nana	Hymenolepiasis	Dwarf tapeworm
Taenia saginata	Taeniasis	Beef tapeworm
T. solium	Taeniasis	Pork tapeworm
Trichuris trichiura	Trichuriasis	Whipworm
Viruses:		
Adenovirus (31 types)	Respiratory disease	
Enteroviruses (more than 100 types, e.g., polio, echo, and coxsackie viruses)	Gastroenteritis, heart anomalies, meningitis	
Hepatitis A virus	Infectious hepatitis	Jaundice, fever
Norwalk agent	Gastroenteritis	Vomiting
Parvovirus (2 types)	Gastroenteritis	
Rotavirus	Gastroenteritis	

[a] Adapted from Feachem et al. (1983), Madigan et al. (2000), and Crook (1998).

[b] The helminths listed are those with a worldwide distribution.

Table 2-25
Microorganism concentrations found in untreated wastewater and the corresponding infectious dose[a]

Organism	Concentration in raw wastewater,[b] MPN/100 mL	Infectious dose, number of organisms[c]
Bacteria:		
Bacterioides	10^7–10^{10}	
Coliform, total	10^7–10^9	
Coliform, fecal[d]	10^6–10^8	10^6–10^{10}
Clostridium perfringens	10^3–10^5	1–10^{10}
Enterococci	10^4–10^5	
Fecal streptococci	10^4–10^7	
Pseudomonas aeruginosa	10^3–10^6	
Shigella	10^0–10^3	10–20
Salmonella	10^2–10^4	10^1–10^8
Protozoa:		
Cryptosporidium parvum oocysts	10^1–10^3	1–10
Entamoeba histolytica cysts	10^{-1}–10^1	10–20
Giardia lamblia cysts	10^3–10^4	<20
Helminth:		
Ova	10^1–10^3	
Ascaris lumbricoides	10^{-2}–10^0	1–10
Viruses:		
Enteric virus	10^3–10^4	1–10
Coliphage	10^3–10^4

[b] Value will vary with portion of population shedding at any given time.

[c] Infectious dose will vary with serotype or strain of organism, and the individual's general health.

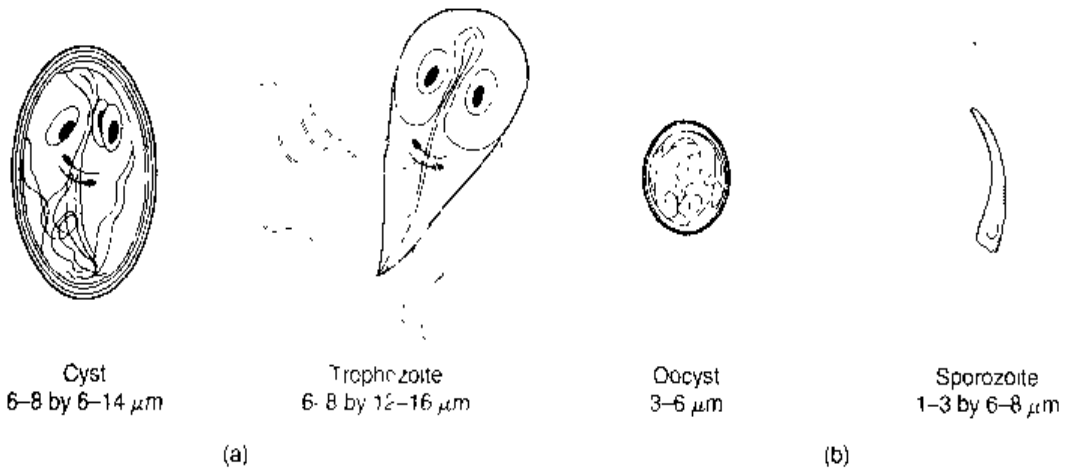
[d] *Escherichia coli* (enteropathogenic).

been identified as the cause of a form of bacterial diarrhea in humans. While it has been well established that this organism causes disease in animals, it has also been implicated as the etiologic agent in human waterborne disease outbreaks (Crook, 1998).

Protozoa. Of the disease causing organisms reported in Table 2–24, the protozoans *Cryptosporidium parvum, Cyclospora,* and *Giardia lamblia* (see Fig. 2–27) are of great concern because of their significant impact on individuals with compromised immune systems, including very young children, the elderly, persons undergoing treatment for cancer, and individuals with acquired immune deficiency syndrome (AIDS). The life cycle of *Cryptosporidium parvum* and *Giardia lamblia* is illustrated on Fig. 2–28. As shown, infection is caused by the ingestion of water contaminated with oocysts and cysts. It is also important to note that numerous nonhuman sources of

Figure 2–27

Defintion sketch for (a) *Giardia lamblia* cyst and trophozoite and (b) *Cryptosporidium parvum* oocyst and sporozoite.



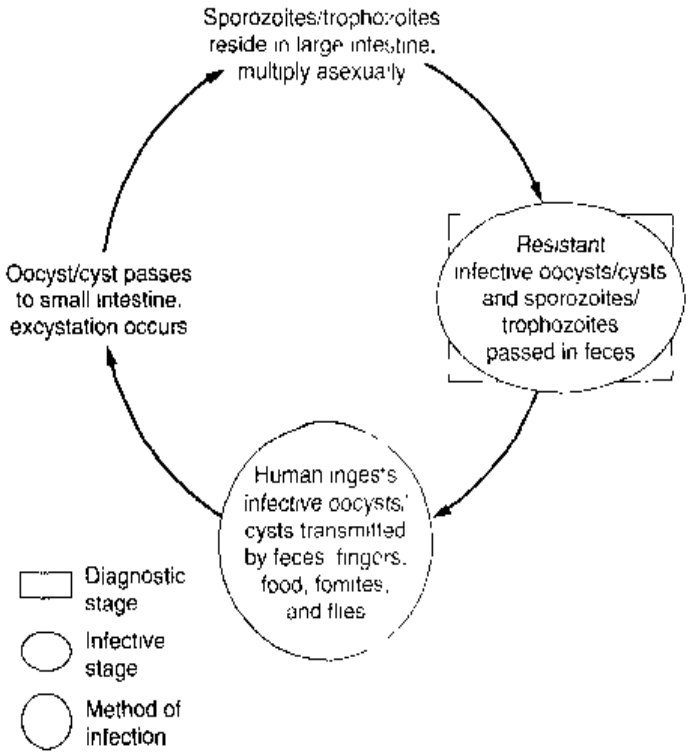


Figure 2–28

Life cycle of *Cryptosporidium parvum* and *Giardia lamblia*.

Cryptosporidium parvum and *Giardia lamblia* are present in the environment. Further, not all of the oocysts and cysts that are present are viable in terms of their ability to cause disease. To determine the potential risk from these microorganisms, infectivity studies must be conducted.

Pathogenic protozoan disease outbreaks have been significant, highlighted by the 1993 outbreak of cryptosporidiosis in Milwaukee in which 400,000 persons became ill and outbreaks of cyclosporiasis in ten states. As noted in Table 2–24, these protozoan organisms may cause symptoms which can include severe diarrhea, stomach cramps, nausea, and vomiting lasting for extended periods. Despite intensive trials in humans and animals, no effective treatment has been found for cryptosporidiosis (Roberts and Janovy, 1996). The oocysts of *Cryptosporidium parvum* and the cysts of *Giardia lamblia* are the most resistant forms (see Table 2–23). These organisms are of particular concern because they are found in almost all wastewaters, and because conventional

disinfection techniques using chlorine have not proved to be effective in their inactivation or destruction. However, in recent studies, it has been found that UV disinfection is extremely effective in the inactivation of oocysts of *Cryptosporidium parvum* and the cysts of *Giardia lamblia*.

Helminths. The term *helminths* is used to describe worms collectively. In the United States, as a result of the improvements in the provision of sanitation and wastewater treatment facilities and in food-handling practices, the prevalence of helminth infections has decreased dramatically over the last century. Nevertheless, owing to increased levels of immigration to the United States of persons from countries where worms are endemic, the transmission of helminthes by wastewater and particularly by biosolids remains a concern. In fact, the eggs of worms are found in wastewater throughout the United States. In particular, small nonparasitic nematodes are universally present, even in finished drinking water at the tap (Cooper, 2001). Worldwide, worms are one of the principal causative agents of human disease. It is estimated that the number of human infections caused by helminths collectively is on the order of 4.5 billion (Roberts and Janovy, 1996).

Most of the helminths fall into three major phyla: Nematoda (roundworms), Platyhelminthes (flatworms), and Annelida (segmented worms). Most human infections are associated with nematodes and flatworms, while the segmented worms are primarily ectoparasitic, such as leaches. The phylum Nematoda collectively represents one of the most abundant animal groups on earth, most of which are harmless to humans. Included among its members are the large roundworm *Ascaris lumbricoides*, the whipworm *Trichuris trichiura*, the hookworms *Necator americanus* and *Ancylostoma duodenale*, and the threadworm *Strongyloides stercoralis*. *Ascaris lumbricoides* is considered to be the most prevalent parasitic infection worldwide with over one and a half billion persons infected (Crompton, 1999; Maier et al., 2000; Roberts and Janovy, 1996). It has been estimated that there are on the order of 4 million cases in the United States (Khuroo, 1996).

The phylum platyhelminthes includes the tapeworms *Taenia saginata* (beef tapeworm) and *Taenia solium* (pork tapeworm) and *Schistosoma* species. *Taenia saginata*, transmitted primarily by infected beef products, is the most common tapeworm found in humans. The trematodes *Schistosoma mansoni*, *S. haematobium*, and *S. japonicum*, also known as blood flukes, are medically important members of the trematoda class. More than 200 million infections are ascribed to these worms worldwide. It is estimated that more than 400,000 infected individuals, most of whom were infected outside of the United States, live in the United States (West and Olds, 1992).

The human infective stage of helminths varies; in some species it is either the adult organism or larvae, while in other species it is the eggs, but it is primarily the eggs that are present in wastewater. Helminth eggs, which range in size from about 10 μm to more than 100 μm, can be removed by many commonly used wastewater-treatment processes such as sedimentation, filtration, and stabilization ponds. However, some helminth eggs are extremely resistant to environmental stresses and may survive usual wastewater and sludge disinfection procedures. Chlorine disinfection and mesophilic anaerobic digestion, for example, are not effective at inactivating many helminth eggs. In a recent study, it has been found that the eggs of *Ascaris* can survive for up to 10 years in the sediments of oxidation ponds (Nelson, 2001). The long survival times of

Ascaris and other worm eggs is of particular importance in the management of biosolids.

Viruses. More than 100 different types of enteric viruses capable of producing infection or disease are excreted by humans. Enteric viruses multiply in the intestinal tract and are released in the fecal matter of infected persons. From the standpoint of health, the most important human enteric viruses are the enteroviruses (polio, echo, and coxsackie), Norwalk viruses, rotaviruses, reoviruses, caliciviruses, adenoviruses, and hepatitis A virus. Of the viruses that cause diarrheal disease, only the Norwalk virus and rotavirus have been shown to be major waterborne pathogens. The reoviruses and adenoviruses, known to cause respiratory illness, gastroenteritis, and eye infections, have been isolated from wastewater. There is no evidence that the human immunodeficiency virus (HIV), the pathogen that causes the acquired immunodeficiency syndrome (AIDS), can be transmitted via the waterborne route (Crook, 1998; Madigan et al., 2000; Maier et al., 2000; Rose and Gerba, 1991). The biology of viruses is delineated in Voyles (1993).

Survival of Pathogenic Organisms. Of great concern in the management of disease-causing organisms is the survival of these organisms in the environment. Typical data on the survival of microorganisms in the environment are presented in Table 2–26. Although the data given in Table 2–26 can be used as a rough guide, numerous

Table 2–26
Typical pathogen survival times at 20–30°C in various environments[a]

Pathogen	Survival time, days		
	Fresh water and wastewater	Crops	Soil
Bacteria:			
Fecal coliforms[b]	<60 but usually <30	<30 but usually <15	<120 but usually <50

[b] In seawater, viral survival is less, and bacterial survival is very much less than in fresh water.
[c] *V. cholerae* survival in aqueous environments is a subject of current uncertainty.
[d] Includes polio, echo, and coxsackie viruses.

exceptions have been reported in the literature. Additional data on the effect of temperature on the survival of microorganisms are given in Chap 13.

Use of Indicator Organisms

Because the numbers of pathogenic organisms present in wastes and polluted waters are usually few and difficult to isolate and identify, microorganisms, which are more numerous and more easily tested for, are commonly used as surrogate (i.e., an indicator) organisms for the target pathogen(s). The general features of an ideal indicator organism and the use of bacterial and other indicators are considered briefly in the following discussion.

Characteristics of an Ideal Indicator Organism. An ideal organism should have the following characteristics (adapted from Cooper, 2001; Maier et al., 2000):

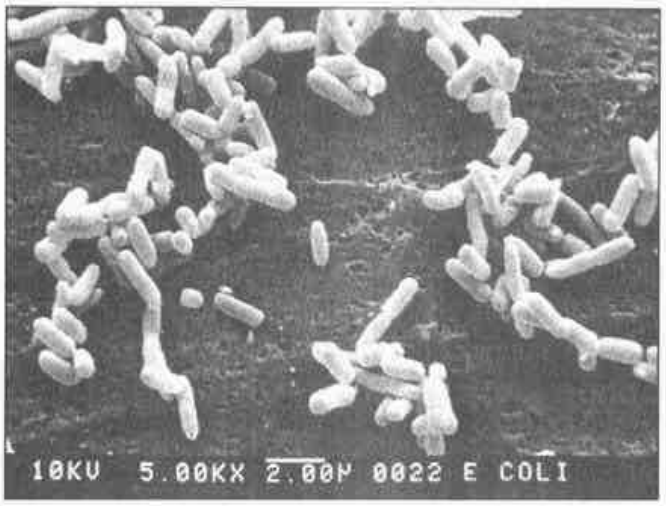
1. The indicator organism must be present when fecal contamination is present.
2. The numbers of indicator organisms present should be equal to or greater than those of the target pathogenic organism (e.g., pathogenic viruses).
3. The indicator organism must exhibit the same greater survival characteristics in the environment as the target pathogen organism for which it is a surrogate.
4. The indicator organism must not reproduce outside of the host organism (i.e., the culturing procedure itself should not produce a serious health threat to laboratory workers).
5. The isolation and quantification of the indicator organism must be faster than that of the target pathogen (i.e, the procedure must be cheaper and easier for cultivating the indicator organisms than for the target pathogen).
6. The organism should be a member of the intestinal microflora of warmblooded animals.

Some authors have stated the first characteristic as "The indicator organism must be present when the target pathogen is present." Unfortunately, the target pathogen(s) may not be present during the entire year, because the shedding of pathogenic organisms is not uniform throughout the year. Thus, it is important that the indicator organism be present when fecal contamination is present, if public health is to be protected. To date, no ideal indicator organism has been found.

Bacterial Indicators. The intestinal tract of humans contains a large population of rod-shaped bacteria known collectively as coliform bacteria. Each person discharges from 100 to 400 billion coliform bacteria per day, in addition to other kinds of bacteria. Thus, the presence of coliform bacteria in environmental samples has, over the years, been taken as an indication that pathogenic organisms associated with feces (e.g., viruses) may also be present. The absence of coliform bacteria is taken as an indication that the water is free from disease-producing organisms. Microorganisms that have been proposed for use as indicators of fecal contamination are summarized in Table 2–27. Indicator organisms that have been used to establish performance criteria for various water uses are reported in Table 2–28.

The coliform bacteria include a number of genera and species of bacteria that have common biochemical and morphological attributes. Typically, these organisms are gram-negative (a staining procedure, non-spore-forming rod-shaped organisms (see Fig. 2–29) that ferment lactose in 24 to 48 h at 35 ± 0.5°C (BioVir, 2001). The term

Table 2-27 Specific organisms that have been used or proposed for use as indicators of fecal contamination



Indicator organism	Characteristics
Total coliform bacteria	Species of gram-negative rods that may ferment lactose with gas production (or produce a distinctive colony within 24 ± 2 h to 48 ± 3 h incubation on a suitable medium) at 35 ± 0.5°C. There are strains that do not conform to the definition. The total coliform group includes four genera in the Enterobacteriaceae family. These are *Escherichia, Citrobacter, Enterobacter,* and *Klebsiella.* Of the group, the *Escherichia* genus (*E. coli* species) appears to be most representative of fecal contamination
Fecal coliform bacteria	A fecal coliform bacteria group was established based on the ability to produce gas (or colonies) at an elevated incubation temperature (44.5 ± 0.2°C for 24 ± 2 h)
Klebsiella	The total coliform population includes the genera *Klebsiella.* The thermotolerant *Klebsiella* are also included in the fecal coliform group. This group is cultured at 35 ± 0.5°C for 24 ± 2 h
E. coli	The *E. coli* is one of the coliform bacteria population and is more representative of fecal sources than other coliform genera
Bacteroides	Bacteroides, an anaerobic organism, has been proposed as a human specific indicator
Fecal streptococci	This group had been used in conjunction with fecal coliforms to determine the source of recent fecal contamination (man or farm animals). Several strains appear to be ubiquitous and cannot be distinguished from the true fecal streptococci under usual analytical procedures, which detract from their use as an indicator organism
Enterococci	Two strains of fecal streptococci, *S. faecalis* and *S. faecium,* are the most human-specific members of the fecal streptococcus group. By eliminating the other strains through the analytical procedures, the two strains known as enterococci can be isolated and enumerated. The enterococci are generally found in lower numbers than other indicator organisms; however, they exhibit better survival in seawater
Clostridium perfringens	This organism is a spore-forming anaerobic persistent bacteria, and the characteristics make it a desirable indicator where disinfection is employed, where pollution may have occurred in the past, or where the interval before analysis is protracted
P. aeruginosa and *A. hydrophila*	These organisms may be present in domestic wastewater in large numbers. Both can be considered aquatic organisms and can be recovered in water in the absence of immediate sources of fecal pollution

gram-negative refers to a staining procedure used to differentiate groups of organisms. The organism *Escherichia coli* (*E. coli*), found in the feces of warmblooded animals, has historically been the target organism tested for with the *total coliform test.* Unfortunately, it was found early on that the coliform test was not specific for *E. coli* and that a variety of other coliform organisms were included in the test results. For example,

Table 2–28
Indicator organisms used in establishing performance criteria for various water uses

Water use	Indicator organism
Drinking water	Total coliform
Freshwater recreation	Fecal coliform
	E. coli
	Enterococci

	Enterococci
Shellfish-growing areas	Total coliform
	Fecal coliform
Agricultural irrigation (for reclaimed water)	Total coliform
Wastewater effluent disinfection	Total coliform
	Fecal coliform
	MS2 coliphage

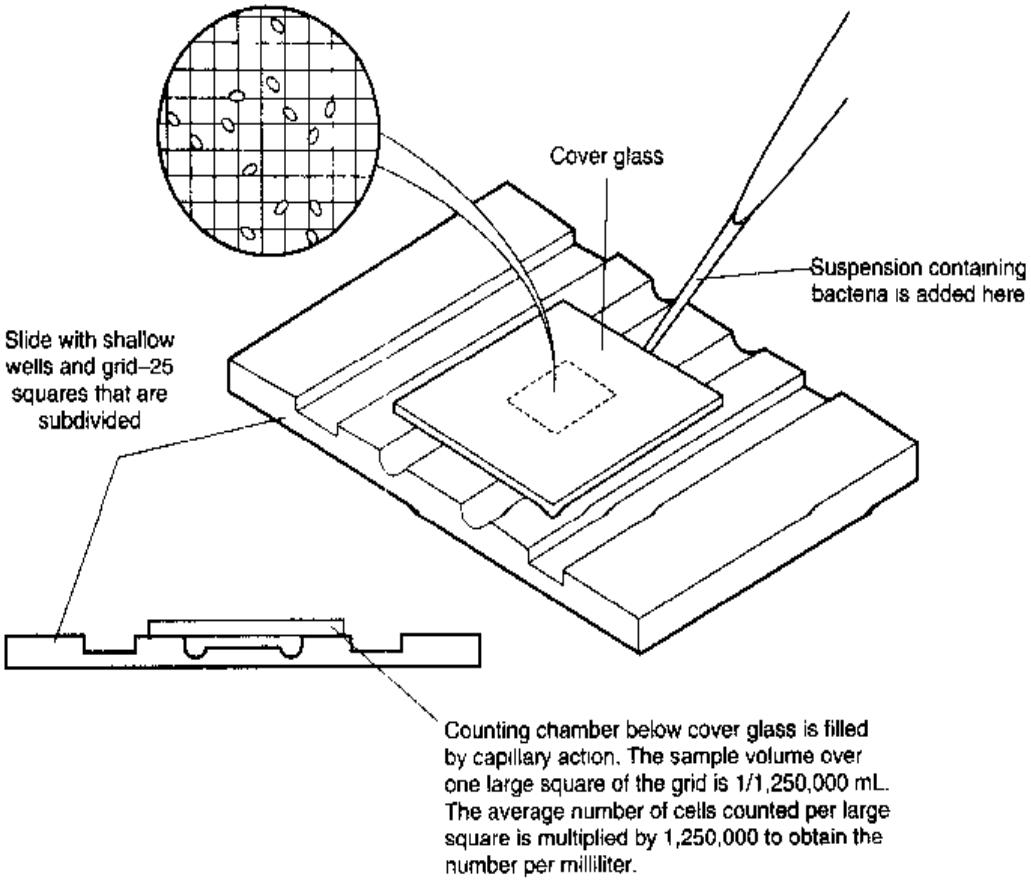
Figure 2–29
Micrograph of a pure culture of *E. coli*.

some of the coliform organisms of the genus *Escherichia* can grow in soil. Thus, the presence of coliforms does not always mean contamination with human wastes. In recent years, tests have been developed that distinguish among total coliforms, fecal coliforms, and *E. coli*, and all three are being reported in the literature.

One of the most recent and important developments in the evolution of the coliform test is the ability to identify and quantify *E. coli* through the use of elevated temperatures and a specific growth medium (MUG). When *E. coli* are present, they are able to cleave the fluorogenic substrate MUG (4-methylumbelliferyl-β-D–glucuronide) from the growth medium, because they possess a specific enzyme (β-glucuronidase). The presence of a bright blue fluorescence is taken as a positive response for *E. coli*. In turn, the occurrence of *E. coli* is taken as a specific indicator of fecal contamination and the possible presence of enteric pathogens (Standard Methods, 1998).

Other Indicator Organisms. While total and fecal coliform organisms and *E. coli* may be present, it has not been demonstrated that they are indicators of the presence of enteric viruses and protozoa. Further, concerns for newly emerging pathogenic organisms which may arise from nonhuman reservoirs (e.g., pathogenic *E. coli, Cryptosporidium parvum,* and *Giardia lamblia*) have led to the questioning of the use of indicators that arise primarily from fecal inputs. In a recently completed study, it was concluded that coliform bacteria are adequate indicators for the potential presence of pathogenic bacteria and viruses, but are inadequate as an indicator of the presence of waterborne protozoa. It was also found that waterborne disease outbreaks have occurred in water systems that have not violated their microbial water quality standards (Craun et al., 1997).

Given the limitations in using coliform organisms as indicators of potential contamination by wastewater, attention has now focused on the use of bacteriophages as an indicator organism and more specifically as indicators of enteric viruses. Bacteriophages are viruses that can infect prokaryotic cells. There are six major families of bacteriophages, five of which are DNA-based and one of which is RNA-based. Of the five DNA-based bacteriophages, three are double-stranded and two are single-stranded. Bacteriophages that infect *E. coli* are known as coliphages. Coliphages that attach directly to the cell wall are known as *somatic*. Coliphages that infect only male strains of *E. coli* (possess pili) are known as male-specific (F+) coliphages. Male-specific phages are thought to only be found in feces. Within the male-specific family there are four serotypes. Groups II and III are primarily of human origin whereas groups I and IV are of animal origin, with the exception of pigs, which may harbor groups II and III. Analytically, somatic coliphages are determined using *E. coli* as the host organism whereas F+ coliphages are determined using *E. coli* with pilli. Interest in using coliphages as indicators of enterovirses is based on the fact that the phages are approximately the same size as pathogenic viruses of interest (e.g., polio), are of fecal origin, and are always present in raw municipal wastewater. Coliphages have been used extensively in disinfection studies (see Sec. 12–8 in Chap. 12).



Enumeration and Identification of Bacteria

Individual bacteria are typically enumerated by one of four methods: (1) direct microscopic count, (2) pour and spread plate counts, (3) membrane filtration, and (4) multiple tube fermentation. Colonies of bacteria are often enumerated but not identified using the heterotrophic plate count (HPC) method. In addition, a number of staining and fluorescent methods have been developed for the identification of specific bacteria. These tests are considered in the following discussion.

Direct Counts. Direct counts can be obtained by microscopically using a Petroff-Hauser counting chamber (see Fig. 2–30). Counting cells, as shown on Fig. 2–30, are designed so that each square in the counting chamber corresponds to a given volume (depth is known). Because it is difficult to differentiate between live and dead cells, the measured counts are total counts. Acridine orange (vital) stain is often used to differentiate between live and dead cells, but questions have been raised about the accuracy of this method of identification. Another technique for obtaining direct counts is with an electronic particle counter in which a sample containing bacteria is passed though an

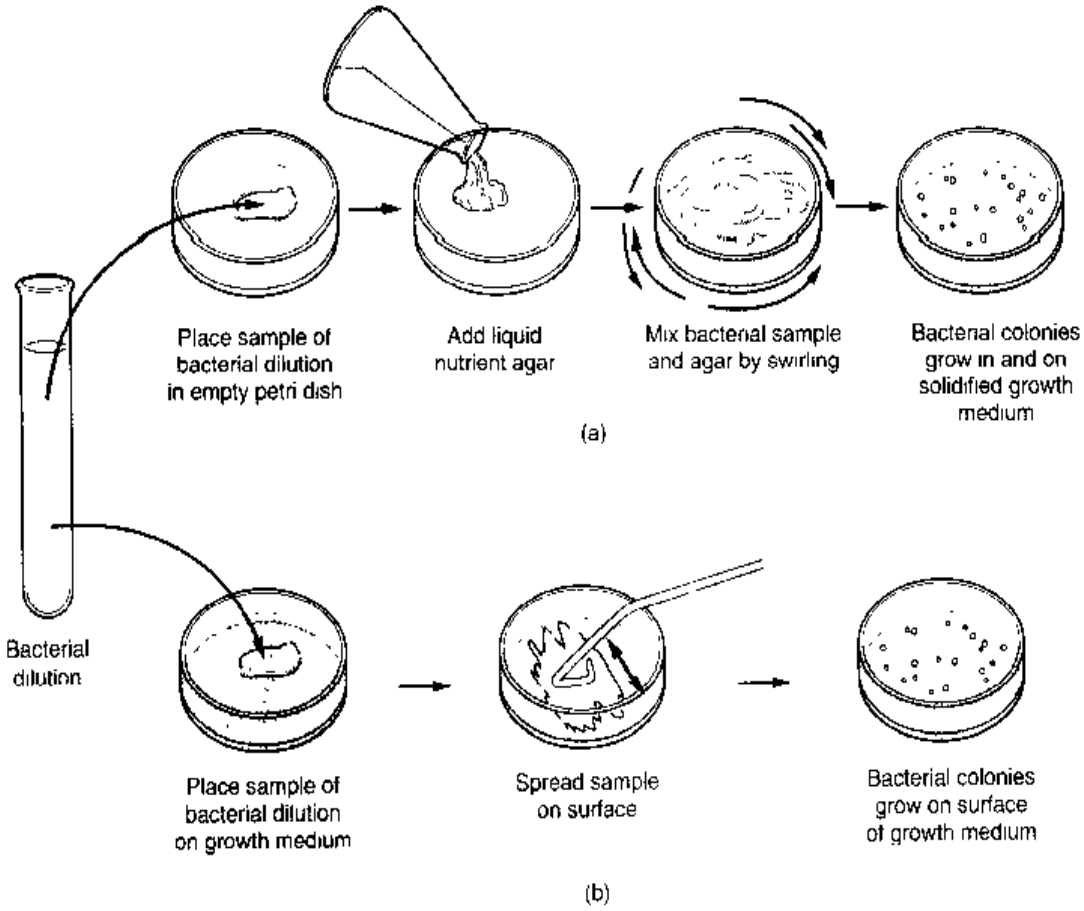
Figure 2–30

Schematic of Petroff-Hauser counting chamber for bacteria. *(From Crites and Tchobanoglous, 1998.)*

orifice. As each bacteria passes through the orifice, the electrical conductivity of the fluid in the orifice decreases. The number of times the conductivity is reduced and the values to which it is reduced are correlated to the number of bacteria. Unfortunately the electronic particle counter cannot differentiate between bacteria (whether live or dead) and inert particles, both of which are counted as particles. Also, orifice clogging is a serious problem with this method.

Pour and Spread Plate Method. The pour and spread plate count methods are used to culture, identify, and enumerate bacteria. In the pour plate method (see Fig. 2–31*a*), a sample of wastewater to be tested is diluted serially. A small amount of each dilution is then mixed with a warmed liquid (agar) culture medium, poured into a culture dish, allowed to solidify, and incubated under controlled conditions. The separate distinct bacterial colonies formed on the plates after incubation are counted, and the results reported as colony-forming units (cfu) per unit volume of sample (typically cfu/mL). In the past, it was assumed that each colony developed from a single bacterium, but use of the term cfu does not assume that one bacteria formed each colony. The total number of bacteria are determined using the appropriate dilutions. In the spread plate method (see Fig. 2–31*b*), a small amount of the diluted wastewater is placed and spread on the surface of a prepared culture dish containing a suitable solid medium.

Membrane-Filter Technique. In the membrane-filter (MF) technique (see Fig. 2–32) a known volume of water sample is passed through a membrane filter that has a small pore size (typically 0.45 μm). Bacteria are retained on the filter because they are



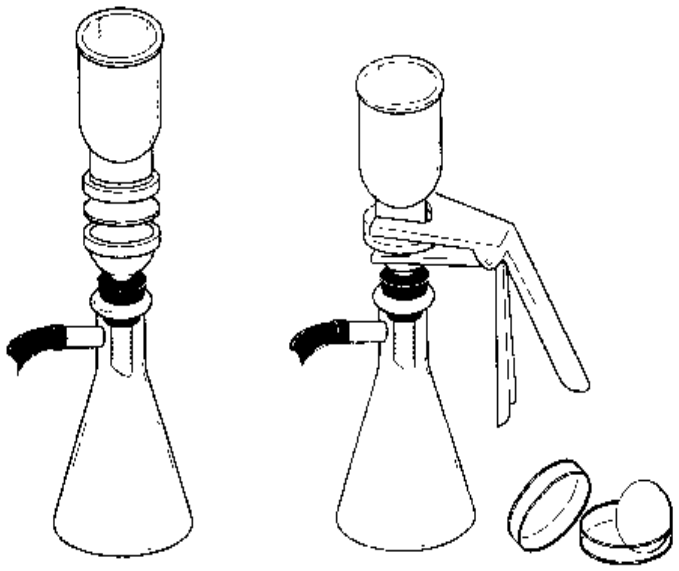


Figure 2–31

Schematic of plate culture methods used for the enumeration of bacteria: (*a*) pour plate and (*b*) spread plate. (*From Crites and Tchobanoglous, 1998.*)

Figure 2–32

Membrane filter apparatus used to test for bacteria in relatively clean waters. After centering the membrane filter on the filter support, the funnel top is attached and the water sample to be tested is poured into the funnel. To aid in the filtration process, a vacuum line is attached to the base of the filter apparatus. After the sample has been filtered, the membrane filter is placed in a petri dish containing a culture medium for bacterial analysis.

larger than the size of the pores of the membrane filter. The membrane filter containing the bacteria is then placed, right side up, in contact with an agar that contains the nutrients necessary for the growth of the specific target bacteria. After incubation, the colonies formed on the surface of the filter can be counted and the concentration in the original water sample determined. The membrane filter technique has the advantage of being faster than the MPN procedure and of giving a direct count of the number of organisms (e.g., coliform organisms). In the environmental field, the MF method is used for coliform and fecal streptococcus enumeration as opposed to direct and pour and spread plate methods. All of these methods are subject to limitations in interpretation (Standard Methods, 1998).

Multiple-Tube Fermentation. The multiple-tube fermentation technique is based on the principle of dilution to extinction as illustrated on Fig. 2-33. Concentrations of total coliform bacteria are most often reported as the *most probable number per 100 mL* (MPN/100 mL). The MPN is based on the application of the Poisson distribution for extreme values to the analysis of the number of positive and negative results obtained when testing multiple portions of equal volume and in portions constituting a geometric series. It is emphasized that the MPN is not the absolute concentration of organisms that are present, but only a statistical estimate of that concentration. The

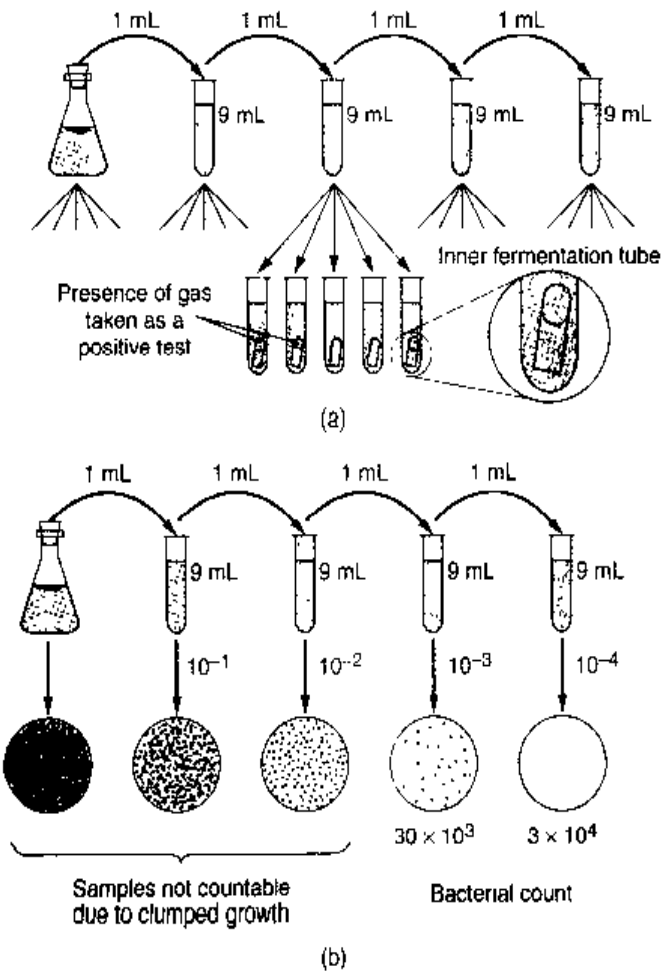

Figure 2-33

Schematic illustration of the methods used to obtain bacterial counts: (a) multiple tube fermentation technique using a liquid medium and (b) use of a solid medium.

complete multiple-tube fermentation procedure for total coliform involves three test phases identified as the presumptive, confirmed, and completed test. A similar procedure is available for the fecal coliform group as well as for other bacterial groups (Standard Methods, 1998).

The MPN can be determined using the Poisson distribution directly, MPN tables derived from the Poisson distribution, or the Thomas equation.

The joint probability (based on the Poisson distribution) of obtaining a given result from a series of three dilutions is given by Eq. (2–74). It should be noted that Eq. (2–74) can be expanded to account for any number of serial dilutions.

$$y = \frac{1}{a}\left[(1 - e^{-n_1\lambda})^{p_1}(e^{-n_1\lambda})^{q_1}\right]\left[(1 - e^{-n_2\lambda})^{p_2}(e^{-n_2\lambda})^{q_2}\right]\left[(1 - e^{-n_3\lambda})^{p_3}(e^{-n_3\lambda})^{q_3}\right] \quad (2\text{–}74)$$

where y = probability of occurrence of a given result
a = constant for a given set of conditions
n_1, n_2, n_3 = sample size in each dilution, mL
λ = coliform density, number/mL
p_1, p_2, p_3 = number of positive tubes in each sample dilution
q_1, q_2, q_3 = number of negative tubes in each sample dilution

When the Poisson equation or MPN tables are not available, the Thomas equation (Thomas, 1942) can be used to estimate the MPN.

$$\text{MPN/100 mL} = \frac{\text{number of positive tubes} \times 100}{\sqrt{\begin{pmatrix}\text{mL of sample in}\\ \text{negative tubes}\end{pmatrix} \times \begin{pmatrix}\text{mL of sample in}\\ \text{all tubes}\end{pmatrix}}} \quad (2\text{–}75)$$

In applying the Thomas equation to situations in which some of the dilutions have all five tubes positive, the count of positive tubes should begin with the highest dilution in which at least one negative result has occurred. The application of the Thomas equation is illustrated in Example 2–13.

EXAMPLE 2–13 Calculation of MPN Using Multiple-Tube Fermentation Test Results The results of a coliform analysis using the multiple-tube fermentation test for the effluent from an intermittent sand filter (see Chap. 11) are as given below. Using these data, determine the coliform density (MPN/100 mL) using the Poisson equation, the Thomas equation, and the MPN tables given in Appendix E.

Size of portion, mL	Number positive	Number negative
1.0	4	1
0.1	3	2
0.01	2	3
0.001	0	5

Solution

1. Determine the MPN using the Poisson equation [Eq. (2–74)]. Substitute the appropriate values for n, p, and q and solve the Poisson equation by successive trials.

$n_1 = 1.0 \qquad p_1 = 4 \qquad q_1 = 1$

$n_2 = 0.1 \qquad p_2 = 3 \qquad q_2 = 2$

$n_3 = 0.01 \qquad p_3 = 2 \qquad q_3 = 3$

$n_4 = 0.001 \qquad p_4 = 0 \qquad q_4 = 5$

   a. Substitute the coefficient values in Eq. (2–74) and determine *ya* values for selected values of λ.

$$y = \frac{1}{a}[(1 - e^{-1.0\lambda})^4(e^{-1.0\lambda})^1][(1 - e^{-0.1\lambda})^3(e^{-0.1\lambda})^2][(1 - e^{-0.01\lambda})^2(e^{-0.01\lambda})^3][(1 - e^{-0.001\lambda})^0(e^{-0.001\lambda})^5]$$

λ	*ya*
3.80	3.6754×10^{-7}
3.84	3.6773×10^{-7}
3.85	3.6774×10^{-7}
3.86	3.6773×10^{-7}
3.90	3.6755×10^{-7}

   b. The maximum value of *ya* occurs for a λ value of 3.85 organisms per milliliter. Thus the MPN/100 mL is

$$\text{MPN/100 mL} = 100 \times 3.85 = 385$$

2. Determine the MPN using the Thomas equation [Eq. (2–75)].
   a. Number of positive tubes $(4 + 3 + 2) = 9$
   b. mL of sample in negative tubes $= [(1 \times 1.0) + (2 \times 0.1) + (3 \times 0.01) + (5 \times 0.001)] = 1.235$
   c. mL of sample in all tubes $= [(5 \times 1.0) + (5 \times 0.1) + (5 \times 0.01) + (5 \times 0.001)] = 5.555$

$$\text{MPN/100 mL} = \frac{9 \times 100}{\sqrt{(1.235) \times (5.555)}} = 344/100 \text{ mL}$$

3. From Appendix G, eliminating the portion with no positive tubes, as outlined, the MPN/100 mL is 390.

Comment It should be noted that MPN tables were developed for use before the advent of the small hand-held scientific calculator as a means of computing the results from a multiple-tube fermentation test. With the use of the scientific calculator, the results from all of the serial dilutions can be considered.

Presence-Absence Test. The presence-absence (P-A) test for coliform organisms is a modification of the multiple-tube fermentation technique described above. The test is intended for use for samples collected from water distribution systems or water-treatment plants. Rather than using multiple dilutions, a single 100-mL sample is tested for the P-A of coliform organisms using lauryl sulfate tryptose lactose broth as used in the MPN test. Coliform organisms are present if a distinct yellow color forms, indicating that lactate fermentation has occurred in the sample. The test is based on the rationale that no organisms should be present in 100 mL. It has been used in wastewater for highly treated samples.

In addition to the modified MPN test, several commercial enzymatic assays have been developed that can be used to detect both total coliform bacteria as well as *E. coli*. In the enzymatic assays, wastewater samples are added to bottles or MPN tubes containing powdered ingredients comprised of salts and specific enzyme substrates that serve as the sole carbon source. Samples containing coliform organisms turn yellow, and samples containing *E. coli* will fluoresce when exposed to long-wave UV illumination. Other tests are also available for detecting *E. coli* (Standard Methods, 1998).

Heterotrophic Plate Count. The heterotrophic plate count (HPC) is a procedure for estimating the number of live heterotrophic bacteria in wastewater samples. The HPC is often used to evaluate the performance of treatment processes and regrowth in effluent distribution systems in reuse applications. The HPC can be determined using the (1) pour plate method, (2) spread plate method, or (3) membrane filter method as described above. In the HPC test, colonies of bacteria, which may be derived from pairs, chains, clusters, or single cells, are measured. The results are reported as colony-forming units per milliliter (CFU/mL). Test details may be found in Standard Methods, 1998.

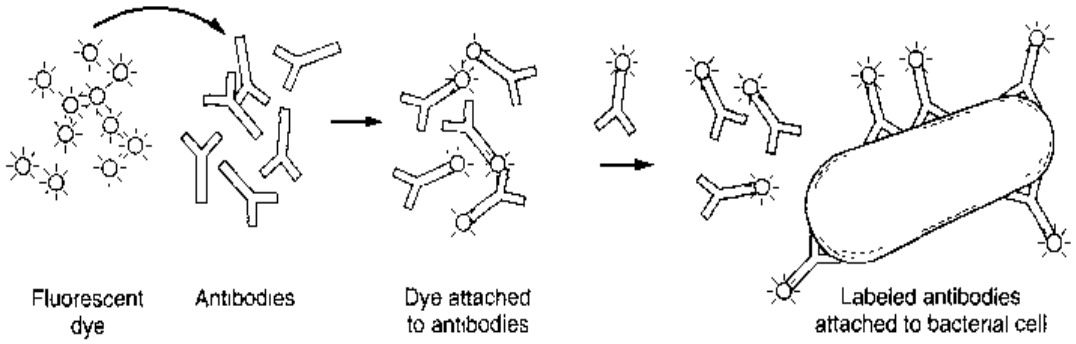
Identification of Specific Bacteria and Protozoa. Over the years, a variety of techniques have been developed for the identification of specific bacteria including growth-dependent methods, the use of fluorescent antibodies, and the use of nucleic acid probes (BioVir, 1997; Madigan et al., 2000). A brief description of the latter two methods is given because of their use in the study of biological treatment and disinfection processes. The availability of the techniques described below has made it possible to study specific reactions and organisms, and will ultimately help to further our understanding of the microbial interactions which occur in natural systems.

In the fluorescence method, an antibody (a soluble protein, also known as immunoglobulin, produced by a single B cell clone), is tagged with a fluorescent dye such as rhodamine B or fluorescein. The covalent attachment of the dye to the antibody does not affect the specificity of the antibody. Once the tagged antibody has found the organism in question and becomes attached to the surface (see Fig. 2–34), the sample can be examined using fluorescence microscopy. Organisms to which the antibodies attach will glow when exposed to the fluorescent light of the microscope. This method of analysis is commonly used for bacteria, and is also the method of choice for the identification of *Cryptosporidium parvum* and *Giardia lamblia*.

A nucleic acid probe, as used in microbial studies, is a molecule having a strong interaction only with a genomic sequence unique to the targeted organisms in question, and possessing a means for detection once a probe-target interaction has been achieved (Keller and Manak, 1989). The genetic importance of DNA and RNA is discussed in

Figure 2–34

Schematic of the fluorescence method used for the enumeration of bacteria. *(From Crites and Tchobanoglous, 1998.)*



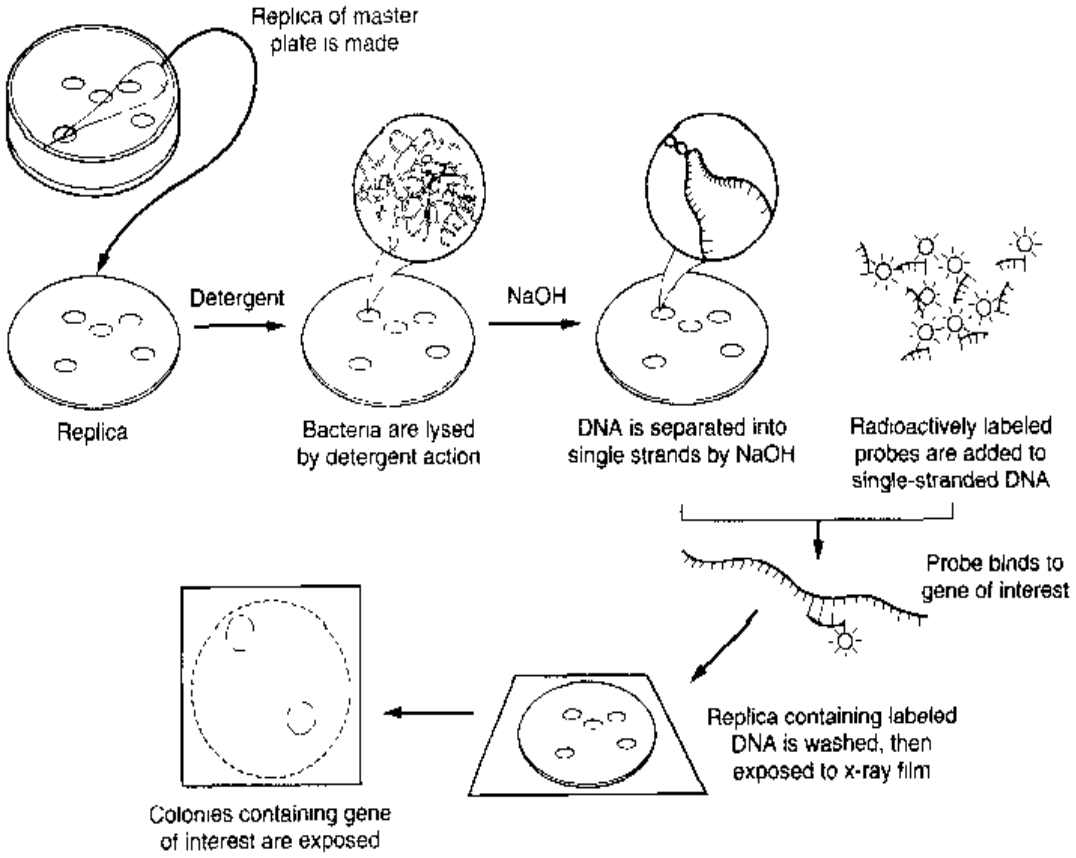


Figure 2–35

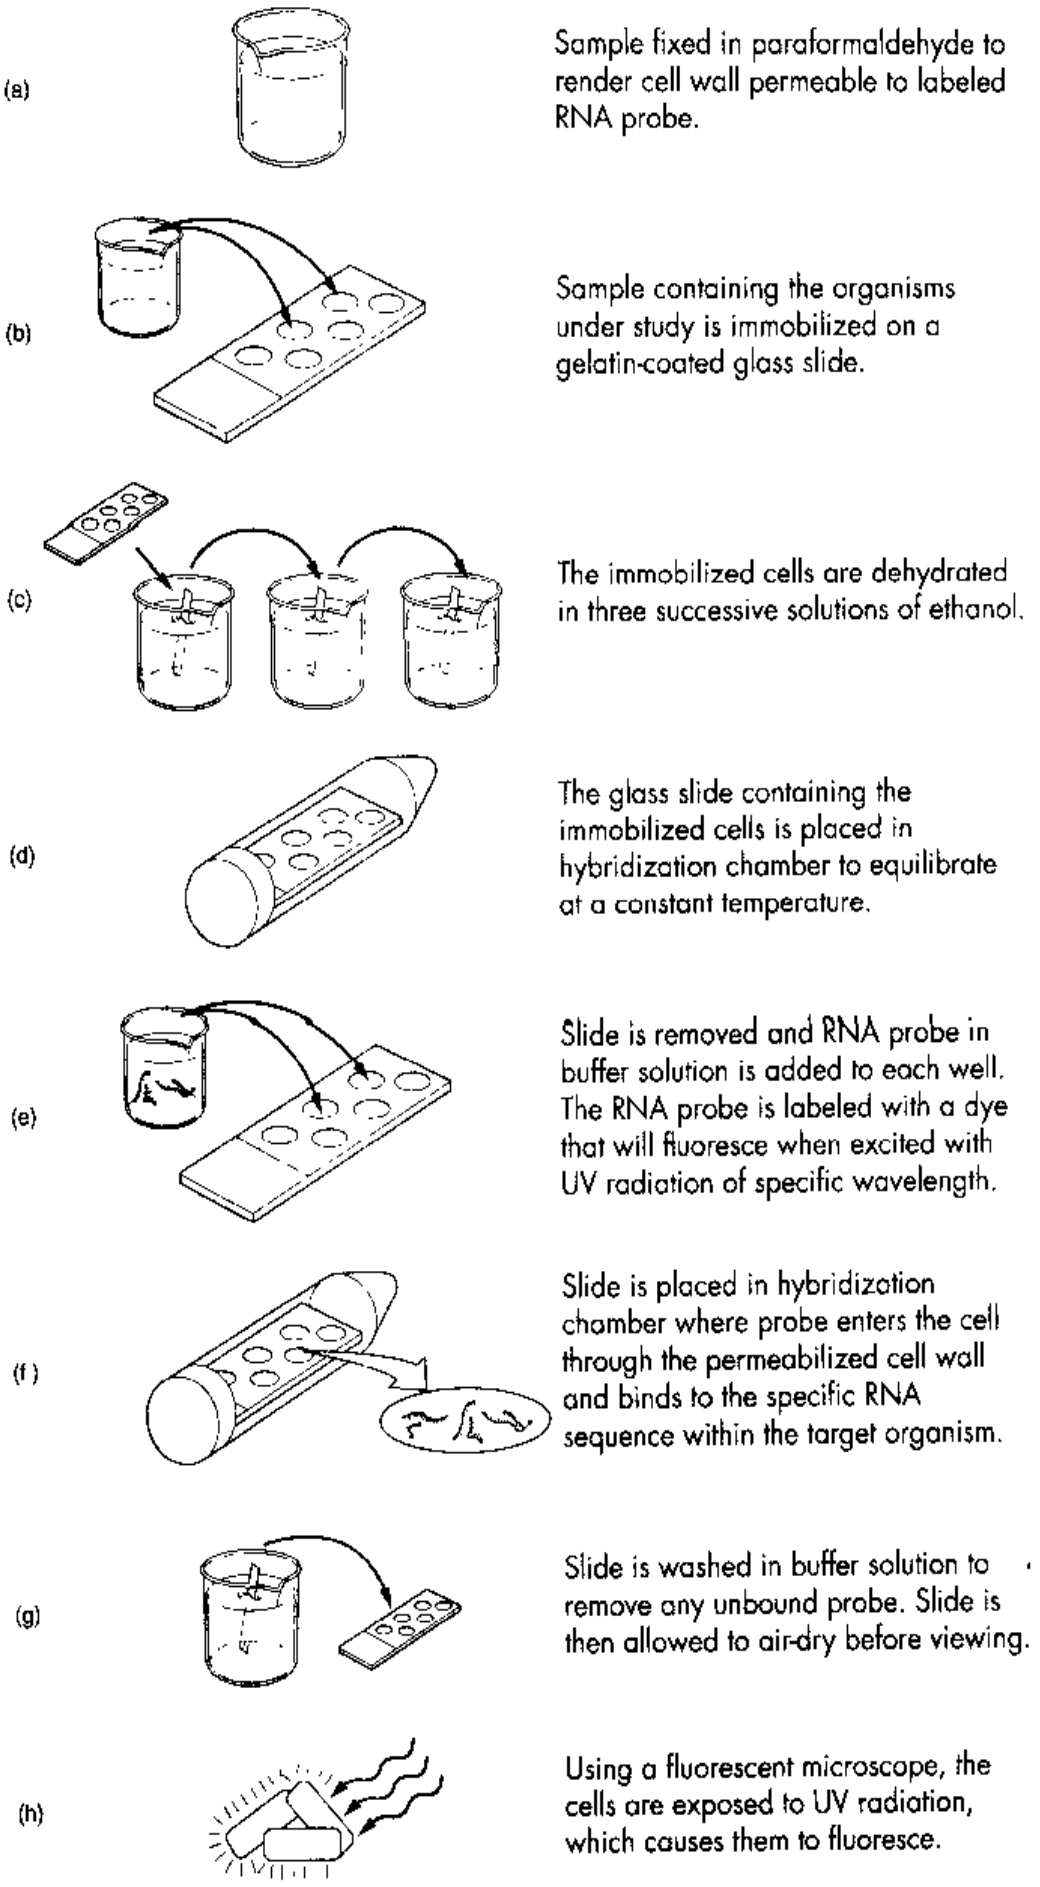
Schematic of the DNA probe method used for the enumeration of bacteria *(From Crites and Tchobanoglous, 1998.)*

greater detail in Sec. 7–2 in Chap. 7. In the nucleic acid probe method, a nucleic acid probe is synthesized that is complementary to either a DNA or RNA sequence unique to the targeted organism or organisms (see Fig. 2–35). The probe is then labeled with either a radioisotope, a fluorescent dye, or an enzyme. The use of fluorescent or enzyme labels has greatly enhanced the use of probes, and has reduced the use of radioactive probes and handling problems associated with the management of radioactive materials. The next step in the nucleic acid probe technique is to hybridize the probe to the nucleic acid in a bacterial cell. With a nucleic acid probe specific to DNA, the hybridization step generally involves filtering a solution of lysed organisms onto a polycarbonate filter and then soaking the filter in a liquid medium that contains the labeled nucleic acid probe. This process is commonly referred to as dot blot hybridization. With a nucleic acid probe specific to RNA, either dot blot hybridization or a method called in situ hybridization can be used.

In situ hybridization or fluorescent in situ hybridization (FISH) involves adding the nucleic acid probe to a solution of cells with permeablized cell walls (see Fig. 2–36). The final step in the nucleic acid probe approach is to detect the hybridized probe which is dependent on the method used to hybridize the probe. When dot blot hybridization is used, the hybridized probe is typically detected by placing the filter on a sheet of film sensitive to the type of label put on the nucleic acid probe. When FISH hybridization is used, cells containing the hybridized probe are generally detected using fluorescent microscopy. In situ hybridization has the advantage over dot blot hybridization of allowing the location of cells in the native habitat to be visualized (Loge, 1997).

Nucleic acid probes, with their ability to identify specific nucleic acid sequences, have become very important in the identification of pathogenic organisms. Nucleic acid probes have also been used to study biological treatment processes and the disinfection of wastewater following biological wastewater treatment. With the accelerated development of nucleic acid probes, it is certain that greater use will be made of this technique in developing a better understanding of the biological processes used to treat wastewater. Additional details may be found in Madigan et al. (2000).

Enumeration and Identification of Viruses



Virus particles, which vary in size from 0.02 to 0.08 μm (see Table 2–23), are too small to see with a light microscope. While an electron or transmission scanning microscope can be used, the process of preparing the sample for examination is costly and time-consuming, and most commercial laboratories do not have an electron scanning microscope. The methods used to determine enteric viruses and bacteriophage are as follows.

Enteric Viruses. There are more than 100 viral entities associated with human feces collectively known as enteric viruses. The health significance of these agents in humans ranges from poliomyelitis (polio), hepatitis, and gastroenteritis, to innocuous infections. These viruses are extremely small particles ranging from 20 to 80 nanometers (nm) in diameter. In comparison a human red blood cell averages 7600 nm in diameter. Each virus contains a single type of nucleic acid, either RNA or DNA, which is enclosed by a protein "shell" called a capsid. Replication of viruses can only take place in a living host cell. The virus is capable of using its genetic information to commandeer the host cell's machinery to produce more virus particles. In the case of enteric viruses, these particles (virons) are released into the host's feces and subsequently find their way into the wastewater environment. While these viruses can be visualized by transmission electron microscopy, the cost and small sample size makes this technology impractical for determining their presence in environmental samples.

In treated domestic wastewater, a secondary effluent will frequently have culturable virus concentration of less than 10 per liter. The numbers may be greater but, based upon the virus assay methods presently available, these are the order of magnitude commonly observed. Because of the low number of viruses expected in water and wastewater and restrictions in viral assay procedures, virus concentration methods are used. Large sample volumes, as large as 1000 gallons in the case of drinking water and one or more gallons in wastewater, are passed through filters in such a manner that viruses present are absorbed to the filter medium. Most often these are 10-inch spun-glass filters that are electropositive in charge and through which the sample water is

Figure 2–36

Schematic of the RNA probe method used for the in situ identification of bacteria. *(From Crites and Tchobanoglous, 1998.)*

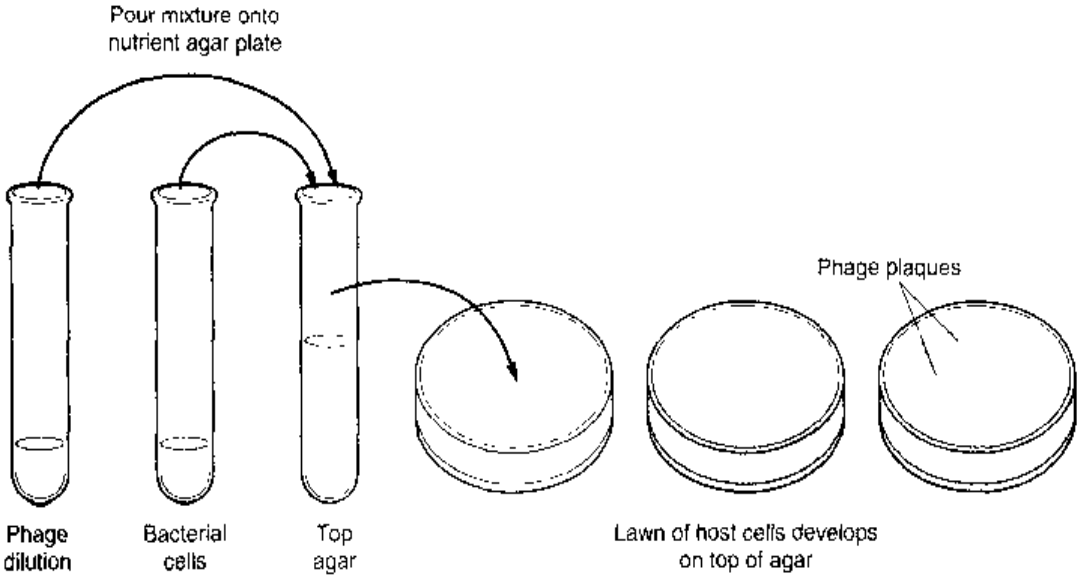


Figure 2–37
Schematic of the technique used for the enumeration of viruses.

passed at a rate of approximately 1 gal/min. The absorbed viruses are then eluted from the concentrating filter using as small a volume as possible, and this concentrate is assayed for the presence of culturable viruses. In some cases, such as in raw wastewater, the filtration step may be bypassed and virus from smaller sample volumes concentrated by a process combining flocculation, centrifugation, and elution from the consolidated flock. Laboratory studies have shown that the efficiency of virus recovery using these methods can be as low as 10 percent.

Virus assays are performed in the laboratory by inoculating the sample concentrate onto monolayers of cultured cells (a process commonly referred to as tissue culture), the most common of which is a buffalo green monkey kidney (GBMK) cell line. If viruses are present, they will grow and destroy the host cells in 10 to 14 days. One of the most common methods for the enumeration of viruses is the plaque assay (see Fig. 2–37). In this method the inoculated tissue culture cells are overlain with agar to localize the released viruses. After suitable incubation, any culturable virus present in the sample concentrate will begin to destroy the infected cells. The destroyed cells appear as a hole or plaque in the cell monolayer. Each plaque (plaque-forming unit, or PFU) is the result of the presence of a single or a clump of viruses. The plaques are counted and their numbers are equal to the PFU per volume of inoculum. Using the appropriate adjustments, the number of PFU per volume of water sampled can be calculated.

A most probable number (MPN) method may also be employed in which the destruction of the tissue culture cell sheet, called cytopathic effect (CPE), takes place without the agar overlay. Dilutions of the sample are inoculated into separate cell culture flasks, the flasks incubated and observed for the presence or absence of CPE. The most likely concentration of viruses in the original sample is calculated based upon the distribution of positive and negative CPE associated with the dilutions used.

Bacteriophage. Viruses that infect bacterial cells are called bacteriophage. There are a variety of these viruses called coliphage which infect many subspecies of *Escherichia coli*. These phages, as opposed to human enteric viruses, are consistently present in wastewater in relatively large numbers. Their source is the feces of humans and animals. A variety of coliphages are called "male-specific" because they infect the

bacterium via the pili (small appendages on the bacterium's surface) and bacteria with these appendages are called "male." Certain of these male-specific (also called F+) phages are the same shape and size as the smallest enteroviruses and, as with many enteroviruses, contain single-stranded RNA.

In the laboratory, these viruses are detected by the formation of plaques on "lawns" of susceptible *E. coli*. These lawns are formed by mixing the various dilution of phage sample with large numbers of host bacteria in a semisoft agar medium that will support bacterial growth. After incubation the bacteria will grow to large numbers, forming a "lawn." As the phages develop, they will lyse infected bacteria, forming plaques in the "lawn." The number of plaques is recorded as PFU per volume of sample. Phage can also be enumerated by an MPN method in which host bacteria and dilutions of phage sample are mixed in tubes containing liquid nutrient media and incubated. At the end of the incubation period the presence or absence of phage is verified by placing a small amount of liquid from each tube on a newly seeded agar "lawn" of host bacteria. After incubation the appearance of a clear spot in the lawn is evidence of a positive tube. The MPN is calculated as described previously.

These procedures are easier and less costly than the use of tissue culture as employed in the detection of animal viruses. Assay results are usually available within 24 to 48 hours. This group of viruses is gaining importance as surrogates for animal viruses when evaluating virus-removing capability of treatment processes. This is so because of their relative abundance in wastewater; their ease of detection; the low cost of the assay; and growing evidence that these viruses, in comparison with human enteric viruses, show an equal or greater resistance to environmental factors, including disinfection.

Polymerase Chain Reaction (PCR)

Polymerase chain reaction (PCR) is a technique, developed within the past 15 years, that has been used for the rapid detection of potential pathogenic microorganisms. The technique involves the amplification of the DNA of the genome of the microorganisms being tested by using a complementary cell fragment known as a *primer*. The primer triggers a reaction that results in the production of many millions of copies of the microorganism DNA. The basis for the technique is the repetitive enzymatic synthesis of DNA and the fact that amplification only takes place if the specific nucleic acid of the microorganism is present. To identify viruses that only contain RNA, the RNA must first be converted to DNA with a reverse transcriptase enzyme. The procedure for identifying RNA viruses in known as RT-PCR.

It should be noted, however, that there are some problems associated with the use of this technique, including (1) the small sample volumes that can be assayed, (2) inhibition by interfering constituents in environmental samples, (3) the fact that the test is, at present, not quantitative (i.e., the number of organisms is not enumerated), and (4) inability of the test to differentiate between viable, inactivated, or dead microorganisms. The inability to differentiate between viable and inactivated microorganisms (e.g., organisms inactivated as a result of exposure to UV radiation) limits the use of this technique for some environmental studies (e.g., disinfection). At present this is the only technique that can be used to detect certain viruses (such as the Norwalk virus) for which culture techniques are not now available. With the rapid improvements that have been made in the test procedure since it was first introduced, it appears that many of the

current limitations of the test will be overcome. Some of the limitations can be overcome now by combining the PCR technique with one or more of the other available techniques, but the time and effort involved is considerable.

Development of Microorganisms Typing Techniques

The development of techniques that can be used for the identification (typing) of specific microorganisms is another area of microbial research that is developing rapidly. For example, the ability to differentiate between fecal coliform organisms of animal, avian, and human origin would make it possible to trace the sources of the organisms and the transmission routes for specific pathogens. The principal techniques that are now used to identify specific microorganisms are discussed in Sec. 7–2 in Chap. 7.

New and Reemerging Microorganisms

Within the past 5 years there has been a disturbing increase in the number of disease outbreaks in the United States and in many other parts of the world, especially in light of the fact it was thought that a number of endemic contagious diseases had been controlled or eliminated (only smallpox to date) (Levins et al., 1994). The bacteria *Legionella pneumophila,* the causative agent in Legionnaires' disease, found in wastewater and reclaimed wastewater, is an example of a disease-causing organism that has only recently been identified (Levins et al., 1994). The recent high incidence of tuberculosis reported in Africa is an example of the reemergence of a disease that was thought to be under control or essentially eliminated. The significance of the identification of new disease organisms, disease outbreaks, and the reemergence of old diseases is that the concern for public health must remain the primary objective of wastewater management.

2–9 TOXICITY TESTS

Toxicity tests are used to:

1. Assess the suitability of environmental conditions for aquatic life
2. Establish acceptable receiving water concentrations for conventional parameters (such as DO, pH, temperature, salinity, or turbidity)
3. Study the effects of water quality parameters on wastewater toxicity
4. Assess the toxicity of wastewater to one or more freshwater, estuarine, or marine test organisms
5. Establish relative sensitivity of a group of standard aquatic organisms to effluent as well as standard toxicants
6. Assess the degree of wastewater treatment needed to meet water pollution control requirements
7. Determine the effectiveness of wastewater-treatment methods
8. Establish permissible effluent discharge rates
9. Determine compliance with federal and state water quality standards and water quality criteria associated with National Pollution Discharge Elimination System (NPDES) permits (Standard Methods, 1998)

Such tests provide results that are useful in protecting human health, aquatic biota, and the environment from impacts caused by the release of constituents found in wastewater

into surface waters. Toxicity identification, in which the constituents or compounds responsible for the observed toxicity are delineated, is another important aspect of toxicity assessment.

During the past several decades, pollution control measures were focused primarily on conventional pollutants (such as oxygen-demanding materials, suspended solids, etc.) which were identified as causing water quality degradation. In the past 10 years, increased attention has been focused on the control of toxic substances, expecially those contained in wastewater-treatment plant discharges. The early requirements for monitoring and regulating toxic discharges were on a "chemical-specific" basis. The chemical-specific approach has many shortcomings, including the inability to identify synergistic effects or the bioavailability of the toxin. The more contemporary whole-effluent, or toxicity-based, approach to toxicity control involves the use of toxicity tests to measure the toxicity of treated wastewater discharges. The whole-effluent test procedure is used to determine the aggregate toxicity of unaltered effluent discharged into receiving waters; toxicity is the only parameter measured.

The national policy prohibiting the discharge of toxic pollutants in toxic amounts is documented in Section 101(a) (3) of the federal Clean Water Act. Because it is not economically feasible to determine the specific toxicity of each of the thousands of potentially toxic substances in complex effluents, whole-effluent toxicity testing using aquatic organisms is a direct, cost-effective means of determining effluent toxicity. Whole-effluent toxicity testing involves the introduction of appropriate bioassay organisms into test aquariums (see Fig. 2–38) containing various concentrations of the effluent in question and observing their responses. Toxicity terminology, general test procedures, the evaluation of test results, the application of the test results, and the means of identifying classes of toxic compounds are described in the following discussion.

Toxicity Terminology

Terms commonly encountered when considering the conduct of toxicity tests and the analysis, interpretation, and application of test results are summarized in Table 2–29. Because the terms reported in Table 2–29 are subject to change as new and improved

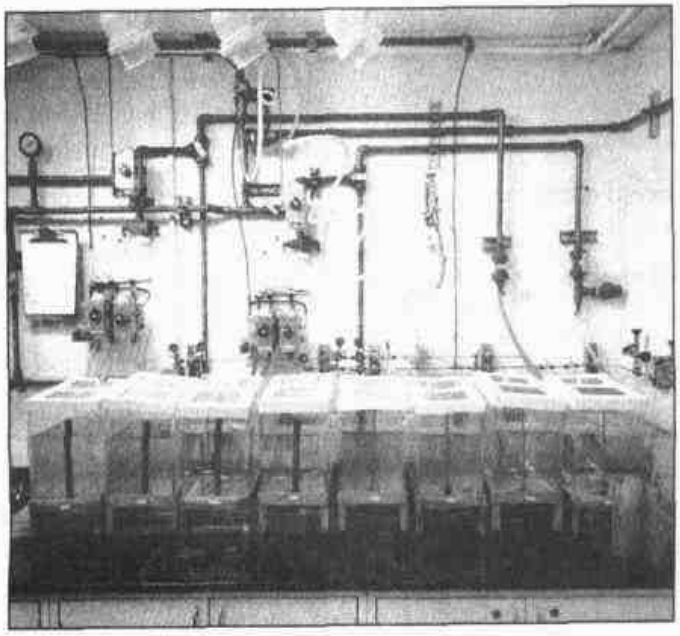

Figure 2–38

Typical setup used to conduct whole-effluent toxicity tests using fish where mortality is the test endpoint.

Table 2–29
Terms used in evaluating the effects of contaminants on aquatic test organisms[a,b]

Term	Description
Acute toxicity	Exposure that will result in significant response shortly after exposure (typically a response is observed within 48 or 96 h)
Chronic toxicity	Exposure that will result in sublethal response over a long term, often 1/10 of the life span or more
Chronic value (ChV)	Geometric mean of the NOEC and LOEC from partial and full cycle tests and early-life-stages tests
Cumulative toxicity	Effects on an organism caused by successive exposures
Dose	Amount of a constituent that enters the test organism
Effective concentration (EC)	Constituent concentration estimated to cause a specified effect in a specified time period (e.g., 96-h EC_{50})
Exposure time	Time period during which a test organism is expased to a test constituent
Inhibiting concentration (IC)	Constituent concentration estimated to cause a specified percentage inhibition or impairment in a qualitative function
In vitro (in glass or test tube)	Tests conducted in glass petri dishes or test tubes
In vivo (in living organism)	Toxicity tests conducted using the whole organism
Lethal concentration (LC)	Constituent concentration estimated to produce death in a specified number of test organisms in a specified time period (e.g., 96-h LC_{50})
Lowest-observed-effect concentration (LOEC)	Lowest constituent concentration in which the measured values are statistically different from the control
Maximum allowable-toxicant concentration (MATC)	Constituent concentration that may be present in receiving water without causing significant harm to productivity or other uses
Median tolerance limit (TL_m)	An older term used to denote the constituent concentration at which at least 50 percent of the test organisms survive for a specified period of time. Use of the term "median tolerance limit" has been superseded by the terms median lethal concentration (LC_{50}) and median effective concentration (EC_{50})
No-observed-effect concentration (NOEC)	Highest constituent concentration at which the measured effects are no different from the control
Sublethal toxicity	Exposure that will damage organism, but not cause death
Toxicity	Potential for a test constituent to cause adverse effects on living organisms

[a]Adapted from Hughes (1996) and Standard Methods (1998).

[b]It should be noted that the terms given in this table apply only to aquatic organisms and are, for the most part, distinct from the terms used for animals and humans.

methods of toxicity testing are developed, it is imperative that the latest version of Standard Methods and related U.S. EPA protocols be reviewed before undertaking any toxicity testing.

Toxicity Testing

Toxicity tests are classified according to (1) duration: short-term, intermediate, and/or long-term; (2) method of adding test solutions: static, recirculation, renewal, or flow-through; (3) type of test: in vitro (i.e., tests in petri dishes or test tubes) or in vivo (i.e., toxicity tests using the whole organism); and (4) purpose: NPDES permit requirements, mixing zone determinations, etc. In vitro toxicity testing has been validated widely in recent years. Even though organisms vary in sensitivity to effluent toxicity, the U.S. EPA has documented that (1) toxicity of effluents correlated well with toxicity measurements in the receiving waters when effluent dilution was measured; and (2) predictions of impacts from both effluent and receiving water toxicity tests compare favorably with ecological community responses in the receiving waters. The U.S. EPA has conducted nationwide tests with freshwater, estuarine, and marine ecosystems. Methods include both acute and chronic exposures. Typical short-term chronic toxicity test methods are reported in Table 2–30. Detailed contemporary testing and analysis protocols are sum-

Table 2–30
Typical examples of short-term chronic toxicity test methods using various freshwater and marine/estuarine aquatic species[a]

Species/common name	Test duration	Test endpoints
Freshwater species		
Cladoceran (*Ceriodaphnia dubia*)	Approximately 7 d (until 60 percent of control have 3 broods)	Survival, reproduction
Fathead minnow (*Pimephales promelas*)	7 d 9 d	Larval growth, survival Embryo-larval survival, percent hatch, percent abnormality
Freshwater algae (*Selenastrum capricomutum*)	4 d	Growth
Marine/estuarine species		
Sea urchin (*Arbacia punctulata*)	1.5 h	Fertilization
Red macroalgae (*Champia parvula*)	7–9 d	Cystocarp production (fertilization)
Mysid (*Mysidopsis bahia*)	7 d	Growth, survival, fecundity
Sheepshead minnow (*Caprinodon variegatus*)	7 d 7–9 d	Larval growth, survival Embryo-larval survival, percent hatch, percent abnormality
Inland silverside (*Menidia beryijina*)	7 d	Larval growth, survival

[a]From U.S. EPA (1988, 1989).

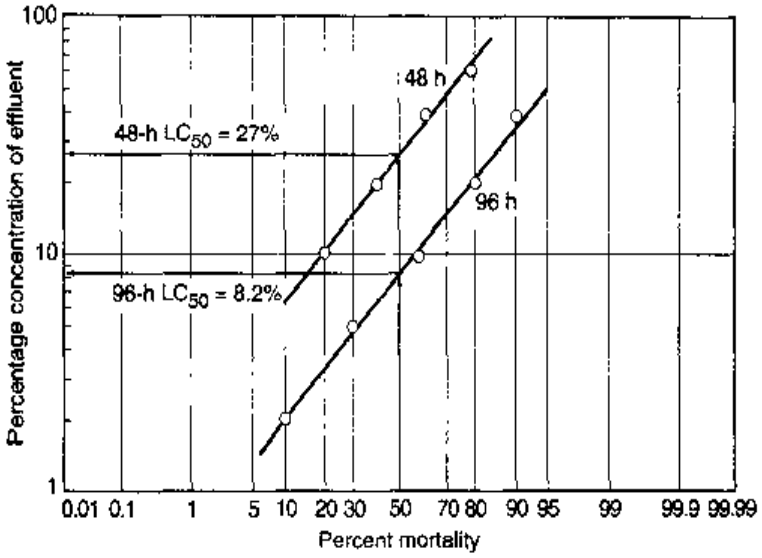
marized in Standard Methods (1998) and in U.S. EPA publications (U.S. EPA, 1985*a*, *b*, *c*, *d*).

Analysis of Toxicity Test Results

Methods used to analyze both short-term (acute) and long-term (chronic) toxicity data are considered in the following discussion.

Acute Toxicity Data. The median lethal concentration (LC_{50}) when mortality is the test endpoint, or median effective concentration (EC_{50}) when a sublethal effect (e.g., immobilization, fatigue in swimming, "avoidance") is the endpoint, are typically used to define acute toxicity (Stephen, 1982). A typical bioassay setup using fish where mortality is the test endpoint is shown on Fig. 2–38. A fish swimming chamber is used to assess sublethal effects. A fish is placed in a chamber where the flow-through velocity can be increased until the fish is swept out of the chamber. The washout velocity for fish exposed to a specific compound can be compared to the washout velocity for the control fish.

Because the LC_{50} value is the median value, it is important to provide some information on the variability of the test population. The LC_{50} values can be determined graphically or analytically using the Spearman Karber, moving average, binomial, and probit methods. The 95 percent confidence limits are usually specified. Most standard statistical packages available for desktop computers include a probit analysis program. Determination of LC_{50} values, both graphically and by means of probit analysis, is illustrated in Example 2–14. Typically, LC_{50} values are computed based on survival at both 48- and 96-h exposures.



EXAMPLE 2–14 Analysis of Acute Toxicity Data Determine graphically and by probit analysis the 48- and 96-h LC_{50} values in percent by volume for the following toxicity test data obtained using flathead minnows:

Concentration of waste, % by volume	No. of test animals	No. of test animals dead after[a]	
		48 h	96 h
60	20	16 (80)	20 (100)
40	20	12 (60)	18 (90)
20	20	8 (40)	16 (80)
10	20	4 (20)	12 (60)
5	20	0 (0)	6 (30)
2	20	0 (0)	2 (10)

[a]Percentage values are given in parentheses.

Solution

1. Plot the concentration of wastewater in percent by volume (log scale) against test animals surviving in percent (probability scale).

2. Fit a line to the data points by eye, giving most consideration to the points lying between 16 and 84% mortality, which corresponds to approximately one standard deviation.
3. Find the wastewater concentration causing 50% mortality. The estimated LC_{50} values are:
   a. 48-h LC_{50} = 27.0%
   b. 96-h LC_{50} = 8.2%
4. Compare the results obtained with a probit analysis to the values determined in Step 3. The probit analysis results are as follows.
   a. 48-h LC_{50} = 27.6%, 95% confidence limits 21.0 and 37.8%
   b. 96-h LC_{50} = 8.1%, 95% confidence limits 5.8 and 10.9%

Comment Although the LC_{50} values obtained using the graphical analysis approach are approximate, they are quite close to the values obtained using the probit analysis approach and serve as a good check. To obtain confidence limits, a probit or similar analysis must be performed.

Chronic Toxicity Data. Results of chronic toxicity tests often are analyzed statistically to determine the lowest-observed-effect concentration (LOEC), the no-observed-effect concentration (NOEC), and the chronic value (ChV). Generally, statistical significance is assumed to be at the $p = 0.05$ level. The chronic value (ChV) is calculated as the geometric mean of the LOEC and the NOEC.

Chronic toxicity limits may be specified with either NOEC or ChV as the endpoint. The term maximum acceptable toxicant concentration (MATC) often is used interchangeably with the chronic value. Similar to acute toxicity data, lethal concentration (LC) or effective concentration (EC) values can be used with chronic toxicity data to describe chronic toxicity tolerance levels. Recently, the concept of the inhibiting concentration (IC) has been introduced to characterize effects in chronic tests. A variety of

nonparametric and parametric statistical methods are available to determine NOECs and LOECs and LCs, ECs, and ICs (Standard Methods, 1998).

Application of Toxicity Test Results

In applying acute and chronic toxicity test results, the toxic units (TU) approach has been adopted by a number of federal and state agencies. In the toxic units approach (U.S. EPA, 1985), a TU concentration is established for the protection of aquatic life.

Toxic Unit Acute (TU_a). The TU_a is defined as the reciprocal of the wastewater concentration that caused the acute effect by the end of the exposure period.

$$TU_a = 100/LC_{50} \tag{2–76}$$

Toxic Unit Chronic (TU_c). The TU_c is defined as the reciprocal of the effluent concentration at which the measured effects, by the end of the chronic exposure period, are no different from the control.

$$TU_c = 100/NOEC \tag{2–77}$$

where NOEC = no-observed-effect concentration

Depending on the use to be made of the toxicity test results, a variety of different numerical values have been used for TU_a and TU_c, as a basis for assessing the suitability of a given effluent for discharge to the environment. For example, to protect against acute toxicity it has been suggested that the MATC should be less than $0.3 \times TU_c$. Because the limiting values vary from location to location, current regulatory standards must be reviewed in applying toxicity results. The application of toxicity test results is illustrated in Example 2–15. Some typical effluent toxicity requirements are summarized in Table 2–31.

EXAMPLE 2–15 Application of Toxicity Test Results A critical initial dilution of 100:1 is achieved for a treated effluent discharged to marine receiving waters. Toxicity tests were conducted with the wastewater-treatment plant effluent using three marine species. Based on the toxicity test results, it was found that *Champia parvula* was the most sensitive species acute endpoint (2.59 percent effluent) as measured by the EC_{50}, and also the most sensitive species chronic endpoint (1.0 percent) as measured by the NOEC. For protection of the aquatic environment, the acute and chronic toxicity requirements have been set at 10 TU_a and 1.0 Tu_c, respectively.

Results of acute toxicity tests

Species	Control exposure, h	Survival, %	Percent effluent	
			LC_{50} or EC_{50}[a]	NOEC
Mysidopis bahia	96	100	18.66	10.0
Cyprinodon variegatus	96	100	>100	50.0
Champia parvula	48/168	100	2.59	12.25

[a]EC50 results based on reduction of cystocarp production.

Results of chronic toxicity tests

Species	Control exposure, days	Survival, %	Percent effluent	
			NOEC	LOEC
Mysidopis bahia	7	82	6.0	10.0
Cyprinodon variegatus	7	98.8	15.0	>15.0
Champia parvula	7	100	1.0	2.25

Solution

1. Check compliance with acute toxicity requirements.
   a. Based on data for the most sensitive species tested, the number of acute toxic units (TU_a), based on Eq. (2–76), is

      $$TU_a = 100/LC_{50} = 100/2.59 = 38.6$$

   b. Following an initial dilution of 100, the TU_a value is

      $TU_a/100 = 38.6/100 = 3.86\ TU_{ad}$ (after dilution)

      Because the TU_a value after dilution (3.86 TU_{ad}) is less than 10 TU_a, the acute toxicity requirement has been met.
2. Check compliance chronic toxicity requirements.
   a. Based on data for the most sensitive species tested, the number of chronic toxic units (TU_c), based on Eq. (2–77), is

      $$TU_c = 100/NOEC = 100/1.0 = 100$$

   b. Following an initial dilution of 100, the TU_c value is

      $TU_c = 100/100 = 1.0\ TU_{cd}$ (after dilution)

      Because the TU_c value after dilution (1.0 TU_{cd}) is equal to 1.0 TU_c, the chronic toxicity requirement has been met.

In summary, there are a number of advantages to the use of whole-effluent toxicity testing. In this approach, the bioavailability of the toxics is measured and the effects of any synergistic interactions are also considered. Because the aggregate toxicity of all components of the wastewater effluent is determined, the toxic effect can be limited by limiting only one parameter, the effluent toxicity. Because contemporary receiving water management strategies are based on site-specific water quality criteria, toxicity testing facilitates comparison of effluent toxicity with site-specific water quality criteria designed to protect representative, sensitive species and yet allow for establishment of discharge limitations that will protect aquatic environments.

Identification of Toxicity Components

Toxicity testing can also be used to determine the source of toxicity, an especially important test for industrial discharges. For example, is the toxicity caused by the suspended

Table 2–31 Description of separation techniques that can be used to *fractionate* a wastewater sample[a]

Separation technique	Description
Filtration for suspended solids	Filtration is generally performed first to determine whether the toxicity is related to the soluble or insoluble phase of the sample. Typically, 1-μm glass fiber filters that have been prewashed with ultrapure water are used. The insoluble phase should be resuspended in control water to ensure that filtration, not adsorption on the filter medium, removed the toxicity
Filtration for colloidal solids	A 0.1-μm filter should be used to determine if the colloidal fraction is responsible for the toxicity
Ion exchange	Inorganic toxicity can be studied by using cationic and anionic exchange resins to remove potentially toxic inorganic compounds or ions
Molecular weight classification	Evaluating the molecular weight distribution of the influent, and the toxicity of each molecular weight range, can often narrow the list of suspected contaminants
Biodegradability test	Controlled biological treatment of effluent samples in the lab can result in almost compete oxidation of the biodegradable portion of organics. Bioassay analysis can then quantify the toxicity associated with the nonbiodegradable components, as well as the reduction in toxicity attainable by biological treatment
Oxidant reduction	Residual chemical oxidants carried over from a process (e.g., chlorine and chloramines used for disinfection, or ozone and hydrogen peroxide used in sludge conditioning) can be toxic to most organisms. A simple batch reduction of these oxidants at various concentrations, using an agent such as sodium thiosulfate, can be used to assess the toxicity of any remaining oxidants
Metal chelation	The toxicity of the sum of all cationic metals (with the exception of mercury) can be determined by chelation of samples, using varying concentrations of ethylenediaminetetraacetic acid (EDTA) and evaluating the change in toxicity
Air stripping	Batch air stripping at acid, neutral, and basic pH can remove essentially all volatile organics. At a basic pH, ammonia is removed as well. Thus, if both volatile organics and ammonia are suspected toxicants, an alternative ammonia removal technique, such as a zeolite exchange, should be used. (Note that ammonia is toxic in the nonionized form, so ammonia toxicity is very pH-dependent.)
Resin adsorption and solvent extraction	Specific nonpolar organics can sometimes be identified as toxics, using a resin-adsorption/solvent-extraction process. A sample is adsorbed on a long-chain organic resin, the organics are reextracted from the resin with a solvent (e.g., methanol), and the toxicity of the sample is determined using a bioassay test procedure

[a] Adapted from Eckenfelder (2000).

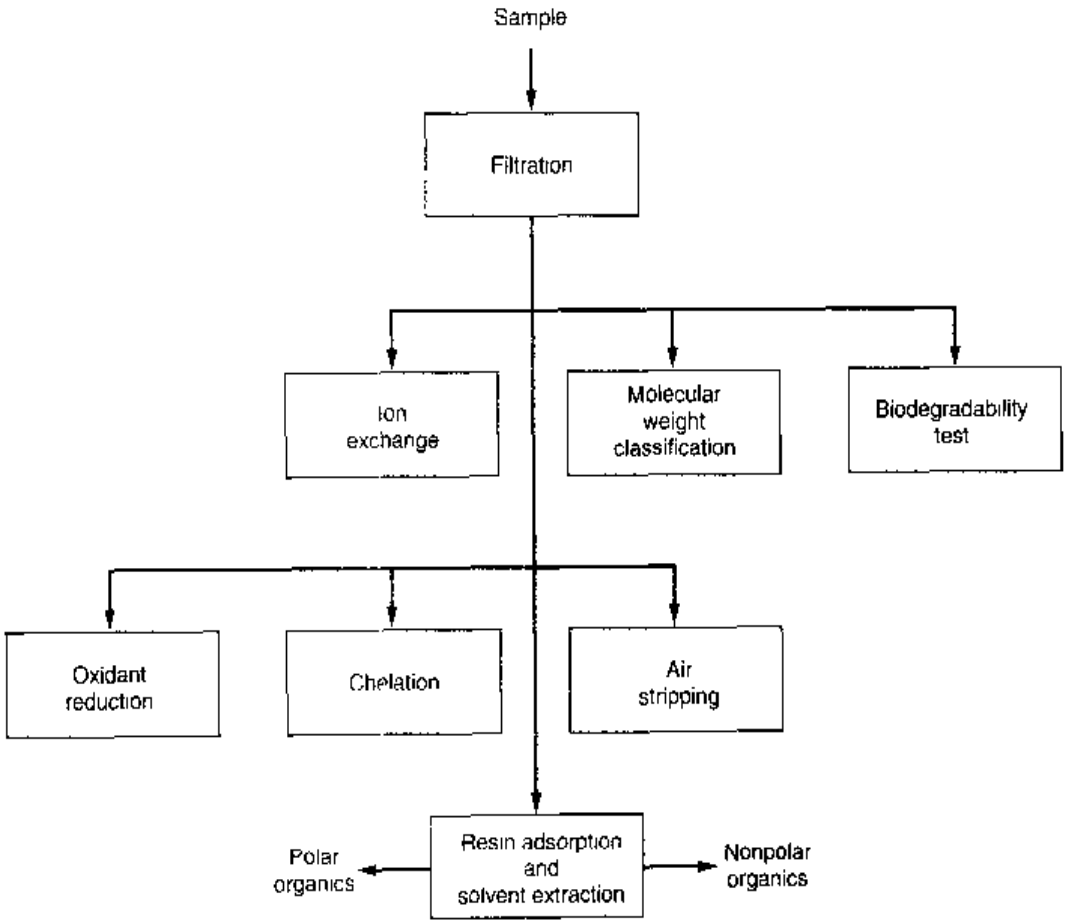


Figure 2–39
Separation techniques that can be used to fractionate a wastewater sample (see also Fig. 2–25). *(Adapted from Eckenfelder, 2000.)*

solids, the colloidal solids, the long- or short-chain dissolved organic constituents, or the dissolved inorganic constituents? To determine the source(s) of the toxicity, each of the potential sources must be isolated from the other constituents in the sample and tested for toxicity. The various methods that can be used to fractionate a wastewater sample are illustrated graphically on Fig. 2–39 and described in Table 2–31.

PROBLEMS AND DISCUSSION TOPICS

2–1 The following test results were obtained for four water samples. Check the accuracy of the analytical measurements for one of the waters (to be selected by the instructor). Do you suspect that a constituent of significance has been neglected? If so, is it a cation or anion?

	Concentration, mg/L					Concentration, mg/L			
Cation	**A**	**B**	**C**	**D**	**Anion**	**A**	**B**	**C**	**D**
Ca^{2+}	121.3	76.0	190 2	93.8	HCO_3^-	280	128.2	260.0	167.4
Mg^{2+}	36.2	27.2	84 1	28.0	SO_4^{2-}	116	240.0	64.0	134.0
Na^+	8.1	22.9	75 2	13.7	Cl^-	61	37.2	440.4	92.5
K^+	12	18.7	5 1	30.2	NO_3^-	15.6	2.0	35.1	—
Fe^{2+}	—	2.1	. 0 2	—	CO_3^{2-}	—	—	30	—

2–2 Determine the activity coefficients and activity for the constituents for one of the waters in Problem 2–1 (to be selected by instructor).

2–3 Compare the values obtained for the activity coefficients obtained using Eq. (2–10) and the equation proposed by Davies (1962) as given below for one of the waters given in Problem 2–1 (to be selected by instructor).

$$\log \gamma = -0.51(z_i)^2 \left(\frac{\sqrt{I}}{1 + \sqrt{I}} - 0.3\,I \right) \text{ at } 25^\circ\text{C}$$

2–4 Estimate the TDS for one of the water samples in Problem 2–1 (to be selected by instructor) using Eq. [2–12] and by summing the mass of the individual ionic species. How do the computed values compare?

2–5 Obtain the most recent edition of Standard Methods and develop a sampling plan including sample size, type of container, type of preservatives, if used, the time before analysis, and any other requirements to determine the concentration of the following constituents (to be selected by instructor). Wastewater samples are to be collected at the headworks and at the effluent discharge point from a wastewater-treatment plant.

a. Organic carbon (BOD, TOC, and COD)
b. Particulate material (TS, TSS, TDS, TVS, VSS, VDS, and turbidity)
c. Nutrients (TN, TKN, NO_3^-, NO_2, NH_4^+, TP, Org P, and Inorg P)
d. Indicator organisms (coliform and coliphages)
e. Metals (Cd, Cu, Hg, and Zn)

2–6 A sample of primary effluent has an expected BOD_5 of 280 mg/L ± 150 mg/L. Determine the number of tests and the volume of sample, seeded dilution water, and unseeded dilution water that would be required for each test to measure the BOD_5 of the sample.

2–7 The following test results were obtained for four different wastewater samples. The size of the sample was 100 mL. Determine the concentration of total and volatile solids, expressed as mg/L, for one of the samples (to be selected by instructor).

		Weight, g			
Item	**Unit**	**A**	**B**	**C**	**D**
Sample size	mL	90	100	120	200
Tare mass of evaporating dish	g	22.6435	22.6445	22.6550	22.6445
Mass of evaporating dish plus residue after evaporation at 105°C	g	22.6783	22.6832	22.6995	22.6667
Mass of evaporating dish plus residue after ignition at 550°C	g	22.6768	22.6795	22.6832	22.6433

2–8 The total suspended solids for a series of wastewater samples was found to be 175, 197, 113, and 247 mg/L, respectively. If the following test results were obtained, determine the size of sample (to be selected by instructor) used in the analysis.

Item	Weight, g			
	A	B	C	D
Tare mass of glass fiber filter	1.5244	1.5243	1.5241	1.5246
Mass of glass fiber filter plus residue after drying at 105°C	1.5953	1.5379	1.5449	1.5667

2-9 The following test results were obtained for a wastewater sample taken at an industrial facility. All of the tests were performed using a sample size of 100 mL. Determine the concentration of total solids, total volatile solids, total suspended solids, and dissolved solids for one of the samples (to be selected by instructor).

Item	Weight, g			
	A	B	C	D
Tare mass of evaporating dish	54.6422	54.6423	54.6424	54.6423
Mass of evaporating dish plus residue after evaporation at 105°C	54.7022	54.7173	54.7224	54.7148
Mass of evaporating dish plus residue after ignition at 550°C	54.6722	54.6893	54.6801	54.6818
Tare mass of Whatman GF/C filter	1.5348	1.5347	1.5347	1.5346
Mass of Whatman GF/C filter plus residue after drying at 105°C	1.5553	1.5586	1.5622	1.5571
Mass of Whatman GF/C filter plus residue after ignition at 550°C	1.5453	1.5454	1.5471	1.5418

2-10 The following test results were obtained for a wastewater sample taken at the headworks to a wastewater-treatment plant. All of the tests were performed using a sample size of 50 mL. Determine the concentration of total solids, total volatile solids, total suspended solids, volatile suspended solids, and dissolved solids for one of the samples (to be selected by instructor).

Item	Weight, g			
	A	B	C	D
Tare mass of evaporating dish	53.5435	53.5434	53.5436	53.5433
Mass of evaporating dish plus residue after evaporation at 105°C	53.5765	53.5693	53.5725	53.5793
Mass of evaporating dish plus residue after ignition at 550°C	53.5750	53.5652	53.5695	53.5772
Tare mass of Whatman GF/C filter	1.5433	1.5435	1.5436	1.5434
Mass of Whatman GF/C filter plus residue after drying at 105°C	1.5653	1.5705	1.5735	1.5625
Mass of Whatman GF/C filter plus residue after ignition at 550°C	1.5502	1.5575	1.5631	1.5531

2–11 The following data were obtained from a serial filtration test of a settled effluent after biological treatment. Prepare a plot of one of the samples (to be selected by instructor). How great an error in the measurement of the total suspended and colloidal solids would occur if a filter paper with a nominal pore size of 1.2 μm was used to determine the total suspended solids, as compared to using a filter with a nominal pore size of 0.1 μm filter.

Nominal pore size, μm	Weight, mg/L			
	A	B	C	D
12	20.2	29.4	22.5	25.1
8	8.8	11.5	8.0	15.1
5	4.1	3.5	4.9	2.2
3	7.5	5.1	11.6	8.9
1	15.1	13.5	21.2	25.0
0.1	9.9	15.1	24.9	17.5

2–12 Estimate the alkalinity, expressed as mg/L as $CaCO_3$, for one of the water samples in Problem 2–1 (to be selected by instructor)

2–13 What is the molar mass of a gas at 20°C assuming the gas has a density of 0.68 g/L at standard temperature and pressure (STP).

2–14 Compare the saturation concentrations of O_2, N_2, and CO_2 between San Francisco (sea level) and Taos, NM (elevation 2150 m), Denver, CO (elevation 1600 m), or La Paz, Bolivia (elevation 4270 m) (city to be selected by instructor).

2–15 Determine the equilibrium concentration of oxygen in the liquid phase in a covered pure oxygen treatment process subject to 1, 1.5, 2.0, 2.5, and 3.0 atms of pressure (pressure to be selected by instructor). Assume the composition of the gas above the liquid is 84 percent O_2, 12 percent N_2, and 4 percent CO_2.

2–16 Using Henry's law, determine the saturation concentration of O_2, N_2, or CO_2 (gas to be selected by instructor) in water at 0, 10, 20, 30, 40, and 50°C. Construct a plot of O_2, N_2, or CO_2 saturation concentration as a function of temperature.

2–17 The local Air Pollution Control District has threatened to fine and penalize the local wastewater-management agency, your client, because of frequently recurring odor complaints from residents who live downwind of the plant. The plant manager, a full-time employee at the treatment plant, claims that no problem exists. He proves his point by consistently finding less than 5 dilutions to MDTOC at the plant boundary using a hand-held sniff dilution olfactometer as employed by the local Air Pollution Control District. You, however, live downwind of the plant and have frequently detected odors from it. Why do these differences exist? How would you resolve them objectively?

2–18 You have been asked to review an odor-control system that has apparently failed to control odors from a sludge-dewatering building adequately. The wastewater-management agency, your client, claims the system has failed to perform according to specifications. The engineering contractor who installed the system claims that the specifications were not adequate.

In your investigation you find that the agency employed a reputable odor consultant to develop the odor-control-system specifications. The consultant used the ASTM Panel Method for

odor measurement, using evacuated glass cylinders for sample collection. Several measurements were made, and the maximum observed value was doubled to develop the control-system specifications. In this way a 90 percent odor-removal requirement was established to meet the desired final odor-emission limit of 2.8×10^4 odor units per minute (the product of airflow in m^3/min and number of dilutions to MDTOC).

Using a direct-reading olfactometer, you find that the control system removes 99 percent of the odor, and that at a rate of 10^6 odor units per minute the final odor emission is 10^6 odor units per minute. What reasons might explain your findings? How would you resolve the problem?

2–19 You have been asked by a wastewater-management agency to review the adequacy of their odor-control program. What would be your major considerations in making such a review?

2–20 In a BOD determination, 6 mL of wastewater are mixed with 294 mL of diluting water containing 9.1 mg/L of dissolved oxygen. After a 5-d incubation at 20°C, the dissolved oxygen content of the mixture is 2.8 mg/L. Calculate the BOD of the wastewater. Assume that the initial dissolved oxygen of wastewater is zero.

2–21 Solve Problem 2–19 for one of the following conditions (to be selected by instructor):

a. sample size, 8 mL, oxygen in dilution water, 9.0 mg/L, oxygen in mixture after 7-d incubation at 20°C, 1.8 mg/L
b. sample size, 6 mL, oxygen in dilution water, 9.2 mg/L, oxygen in mixture after 6-d incubation at 20°C, 1.65 mg/L
c. sample size, 6 mL, oxygen in dilution water, 8.9 mg/L, oxygen in mixture after 4-d incubation at 20°C, 1.5 mg/L
d. sample size, 10 mL, oxygen in dilution water, 9.15 mg/L, oxygen in mixture after 5-d incubation at 20°C, 1.42 mg/L

2–22 Determine the UBOD and BOD_5 (in mg/L) of a mixture of 150 mg/L glutamic acid ($C_5H_{10}N_2O_4$) and 150 mg/L glucose ($C_6H_{12}O_6$). Assume the value of the BOD_5 first-order reaction rate constant is 0.23/d (base e).

2–23 The BOD_5 of a waste sample was found to be 40.0 mg/L. The initial oxygen concentration of the BOD dilution water was equal to 9 mg/L, the DO concentration measured after incubation was equal to 2.74 mg/L, and the size of sample used was equal to 40 mL. If the volume of the BOD bottle used was equal to 300 mL, estimate the initial DO concentration in the waste sample.

2–24 Solve Problem 2–23 for one of the following conditions (to be selected by instructor):

a. sample size, 20 mL, BOD_5 of sample 78 mg/L, oxygen in dilution water, 9.15 mg/L, oxygen in mixture after 5-d incubation at 20°C, 1.83 mg/L
b. sample size, 30 mL, BOD_5 of sample 115 mg/L, oxygen in dilution water, 8.9 mg/L, oxygen in mixture after 5-d incubation at 20°C, 1.27 mg/L
c. sample size, 40 mL, BOD_5 of sample 100 mg/L, oxygen in dilution water, 9.0 mg/L, oxygen in mixture after 5-d incubation at 20°C, 1.63 mg/L
d. sample size, 10 mL, BOD_5 of sample 200 mg/L, oxygen in dilution water, 9.1 mg/L, oxygen in mixture after 5-d incubation at 20°C, 1.53 mg/L;

2–25 What size of sample expressed as a percent is required if the 5-d BOD is 120, 230, 333, or 400 mg/L (to be selected by instructor) and the total oxygen consumed in the BOD bottle is limited to 2 mg/L.

2-26 A wastewater sample is diluted by a factor of 10 using seeded dilution water. If the following results are obtained, determine the 5-d BOD.

	Dissolved oxygen, mg/L	
Time	Diluted sample	Seeded sample
0	8.65	8.75
1	5.35	8.60
2	5.12	8.56
3	4.45	8.50
4	3.75	8.48
5	2.80	8.44
6	2.20	8.37

2-27 Using the data from Problem 2-26, determine the 2-, 4-, and 6-d BOD.

2-28 The 5-d 20°C BOD of a wastewater is 185 mg/L. What will be the ultimate BOD (UBOD)? What will be the 10-d demand? If the bottle had been incubated at 33°C, what would the 5-d BOD have been? $k = 0.23\ d^{-1}$.

2-29 The 5-d BOD at 20°C is equal to 350 mg/L for three different samples, but the 20°C k values are equal to $0.25\ d^{-1}$, $0.35\ d^{-1}$, and $0.46\ d^{-1}$. Determine the ultimate BOD (UBOD) of each sample.

2-30 The BOD value of a wastewater was measured at 2 and 8 d, 1 and 9 d, 2 and 7 d, and 3 and 10 d (days to be selected by instructor) and found to be 125 and 225 mg/L, respectively. Determine the 5-d value using the first-order rate model.

2-31 The following BOD results were obtained on a series of untreated wastewater samples at 20°C. Determine for one of the samples (to be selected by instructor) the reaction rate constant k and the ultimate BOD (UBOD) using both the least-squares and the Fujimoto methods.

Time, t	BOD, mg/L				
d	A	B	C	D	E
0	0	0	0	0	0
1	65	52	170	20	110
2	109	82	235	32	160
3	138	108	275	40	193
4	158	123	300	42	220
5	178	137	322	46	241
6	190	149	335	48	258
7	200	158	342	49	270
8	205	165	349	50	280
9	210	170	351	50	288
10	212	175	354		292
11		178	358		293
12		180	359		294

2–32 Given the following results, determined for a wastewater sample at 20°C the ultimate carbonaceous oxygen demand, the ultimate nitrogenous oxygen demand (NOD), the carbonaceous BOD reaction-rate constant (k), and the nitrogenous NOD reaction-rate constant (k_n). Determine $k(\theta = 1.05)$ and $k_n(\theta = 1.08)$ at 25°C.

	BOD, mg/L			
Time, d	A	B	C	D
0	0	0	0	0
2	18	30	45	36
4	26	43	75	58
6	30	52	95	70
8	33	58	114	80
10	56	60	135	90
12	69	90	144	98
14	77	104	149	102
16	82	114	151	145
18	84	120	152	170
20	87	125	152	182
25	90	135	170	210
30	91 5	142	239	222
35	92.5	147	260	233
40	93	148	268	239
45	94	149	271	240
50	94.5	150	272	241

2–33 Compute the carbonaceous and nitrogenous oxygen demand of a waste represented by the formula $C_9N_2H_6O_2$, $C_6N_2H_4O$, $C_{12}N_4H_6O_2$, or $C_{19}N_2H_8O_2$ (formula to be selected by instructor). Assume N is converted to NH_3 in the first step.

2–34 Determine the carbonaceous and nitrogenous oxygen demand in mg/L for a 1-L solution containing 300, 350, 333, or 450 mg (value to be selected by instructor) of acetic acid [$CH_3(NH_2)COOH$].

2–35 The following data have been obtained for five different wastewater samples. Estimate the total quantity of oxygen in mg/L that must be furnished to stabilize completely one of the wastewaters (to be selected by instructor). What is the corresponding COD and the ThOD for the wastewater?

		Wastewater				
Item	Unit	A	B	C	D	E
BOD	mg/L	400	375	225	185	325
k (base e)	d^{-1}	0.29	0.23	0.027	0.025	0.023
NH_3	mg/L	80	65	75	67	83

2-36 An industrial wastewater is known to contain only stearic acid ($C_{18}H_{36}O_2$), glycine ($C_2H_5O_2N$), and glucose ($C_6H_{12}O_6$). The results of a laboratory analysis for four different samples are as follows. For one these samples (to be selected by instructor), determine the concentration of each of the three constituents in mg/L.

a. organic nitrogen = 11 mg/L, organic carbon = 130 mg/L, and COD = 425 mg/L. Determine the concentration of each of the three constituents in mg/L.
b. organic nitrogen = 13 mg/L, organic carbon = 109 mg/L, and COD = 440 mg/L. Determine the concentration of each of the three constituents in mg/L.
c. organic nitrogen = 9 mg/L, organic carbon = 123 mg/L, and COD = 625 mg/L. Determine the concentration of each of the three constituents in mg/L.
d. organic nitrogen = 12 mg/L, organic carbon = 143 mg/L, and COD = 425 mg/L. Determine the concentration of each of the three constituents in mg/L.

2-37 How many mg/L of $Cr_2O_7^{2-}$ are consumed if the COD of a wastewater sample is found to 450, 325, 533, or 622 mg/L (value to be selected by instructor)?

2-38 Given the absorption calibration data for methylene blue dye as measured with a spectrophotometer, determine the concentration of methylene blue at absorbance measurements of 0.366, 0.812, 2.010, and 2.310.

Concentration, mL/L	Absorbance at 280 nm
0.1	0.065
0.25	0.147
0.5	0.288
1	0.578
2	1.182
3	1.994
4	2.503
5	2.507
6	2.519
7	2.519

2-39 Bacteria have equivalent diameters of 2×10^{-6} μm and densities of approximately 1 kg/L. Under optimal conditions, bacteria can divide every 30 min. Determine the mass of bacteria that would accumulate in 72 h under continuing optimal growth conditions. Can this occur? Explain.

2-40 If the bacteria found in feces have an average volume of 2.0 μm^3, determine the concentration of suspended solids that would be represented by a bacterial density equal to 108 organisms/mL. Assume the density of the bacteria is 1.005 kg/L.

2-41 Derive, from fundamental considerations, an expression that can be used to compute the MPN based on a single sample comprised of 5 fermentation tubes.

2-42 Use the Poisson formula to compute the most probable number (MPN) of coliform organisms per 100 mL based on the following test results (sample one column only). Positive test results are indicated by (+), and negative results by (−).

Sample volume, mL	A		B		C		D	
	(+)	(−)	(+)	(−)	(+)	(−)	(+)	(−)
100	5	0	5	0	—	—	5	0
10	5	0	5	0	—	—	5	0
1	4	1	4	1	5	0	4	1
0.1	3	2	2	3	2	3	4	1
0.01	1	4	—	—	0	5	0	5

2–43 The results of a presumptive coliform test were 2 of 5 tubes of 10-mL portions positive. What is the MPN per 100 mL?

2–44 The results of a presumptive coliform test were 4 of 5 tubes of 10-mL portions positive. What is the MPN per 100 mL?

2–45 Six weekly effluent samples have been analyzed for bacterial content using the standard confirmed test. Determine the coliform density, expressed as MPN, for three of the weekly samples (to be selected by instructor) using the Poisson equation (Eq. 2–74). Check the answers obtained using the standard MPN tables and with the Thomas equation (Eq. 2–75).

Size of portion, mL	Sample number					
	1	2	3	4	5	6
100.0			5/5	5/5	5/5	5/5
10.0		4/5	4/5	5/5	5/5	5/5
1.0	4/5	5/5	5/5	5/5	5/5	5/5
0.1	3/5	3/5	3/5	2/5	1/5	5/5
0.01	1/5	2/5	2/5	3/5	2/5	5/5
0.001					0/5	1/5

2–46 Using the data given in Problem 2–45 determine the coliform density, expressed as MPN, for the fourth, fifth, and sixth weekly samples using the Poisson equation (Eq. 2–74). Check the answers obtained using the standard MPN tables and with the Thomas equation (Eq. 2–75).

2–47 Discuss the advantages and disadvantages of using the fecal coliform and fecal streptococci tests to indicate bacteriological contamination. Cite a minimum of three references from the literature.

2–48 Determine graphically the 48- and 96-hr LC_{50} values in percent by volume for the following toxicity test data below.

Concentration of waste, % by volume	Number of test animals	Number of test animals dead after	
		48 hr	96 hr
80	20	17	20
60	20	13	20

(continued)

(*Continued*)

Concentration of waste, % by volume	Number of test animals	Number of test animals dead after	
		48 hr	96 hr
40	20	10	15
20	20	6	13
10	20	3	9
5	20	1	4
2	20	0	2

2–49 Determine graphically the 48- and 96-hr LC_{50} values in percent by volume for the following toxicity test data below.

Concentration of waste, % by volume	Number of test animals	Number of test animals dead after		
		24 h	48 h	96 h
12	20	8	2	0
10	20	10	5	0
8	20	13	8	1
6	20	16	11	3
4	20	20	16	6
2	20	20	20	14

PROBLEMS AND DISCUSSION TOPICS 205

REFERENCES 212

Determining wastewater flowrates and constituent mass loadings is a fundamental step in initiating the conceptual process design of wastewater treatment facilities. Reliable data for existing and projected flowrates affect the hydraulic characteristics, sizing, and operational considerations of the treatment system components. Constituent mass loading, the product of constituent concentration and flowrate, is necessary to determine the capacity and operational characteristics of the treatment facilities and ancillary equipment to ensure that treatment objectives are met.

Important factors and issues, typical to most planning and design projects, addressed in this chapter include: (1) components of wastewater flows; (2) wastewater sources and flowrates; (3) analysis of flowrate data; (4) analysis of constituent mass loading data; (5) statistical analysis of flowrates, constituent concentrations, and mass loadings; and (6) selection of design flowrates and mass loadings.

3–1 COMPONENTS OF WASTEWATER FLOWS

The components that make up the wastewater flow from a community depend on the type of collection system used and may include:

1. *Domestic (also called sanitary) wastewater.* Wastewater discharged from residences and from commercial, institutional, and similar facilities.
2. *Industrial wastewater.* Wastewater in which industrial wastes predominate.
3. *Infiltration/inflow (I/I).* Water that enters the collection system through indirect and direct means. Infiltration is extraneous water that enters the collection system through leaking joints, cracks and breaks, or porous walls. Inflow is stormwater that enters the collection system from storm drain connections (catch basins), roof leaders, foundation and basement drains, or through access port (manhole) covers.
4. *Stormwater.* Runoff resulting from rainfall and snowmelt.

Three types of collection systems are used for the removal of wastewater and stormwater: sanitary collection systems, storm collection systems, and combined collection systems. Where separate collection systems are used for the collection of wastewater (sanitary collection systems) and stormwater (storm collection systems), wastewater flows in sanitary collection systems consist of three major components: (1) domestic wastewater, (2) industrial wastewater, and (3) infiltration/inflow. Where only one collection system (combined) is used, wastewater flows consist of these three components plus stormwater. In both cases, the percentage of the wastewater components will vary with local conditions and the time of the year.

3–2 WASTEWATER SOURCES AND FLOWRATES

Data that can be used to estimate average wastewater flowrates from various domestic, commercial, institutional, and industrial sources and the infiltration/inflow contribution are presented in this section. Variations in the flowrates that must be established before collection systems and treatment facilities are designed are also discussed.

Domestic Wastewater Sources and Flowrates

The principal sources of domestic wastewater in a community are the residential areas and commercial districts. Other important sources include institutional and recreational facilities. For areas now served with collection systems, wastewater flowrates are commonly determined from existing records or by direct field measurements (see Fig. 3–1). For new developments, wastewater flowrates are derived from an analysis of population data and estimates of per capita wastewater flowrates from similar communities.

Water consumption records may also be used for estimating flowrates. These records are especially useful in other parts of the world where water use for landscape irrigation is limited and 90 percent or more of the water used becomes wastewater. In the United States, on the average about 60 to 90 percent of the per capita water consumption becomes wastewater. The higher percentages apply to the northern states during cold weather; the lower percentages are applicable to the semiarid region of the southwestern United States where landscape irrigation is used extensively. When water consumption records are used for estimating wastewater flowrates, the amount of water consumed for purposes such as landscape irrigation (that is not discharged to the collection system), leakage from water mains and service pipes, or product water that is used by manufacturing establishments must be evaluated carefully.

Residential Areas. For many residential areas, wastewater flowrates are commonly determined on population and the average per capita contribution of wastewater.

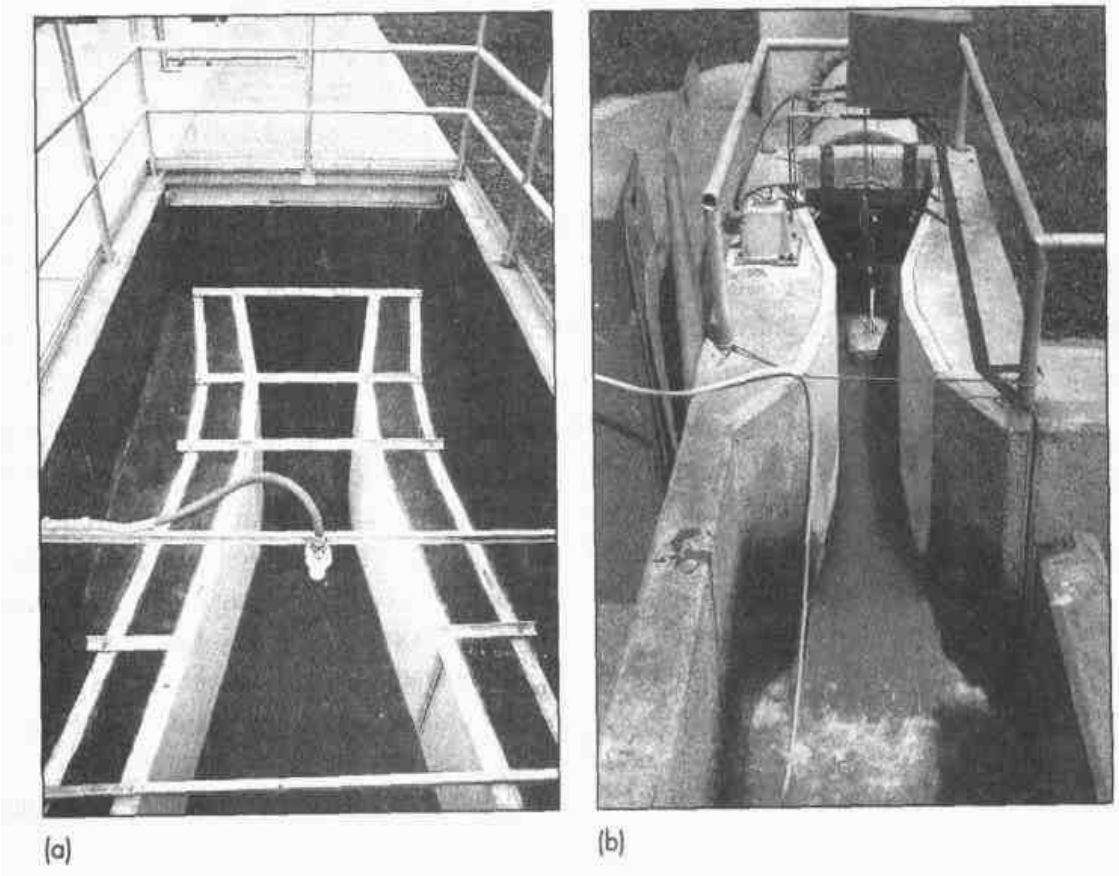

Figure 3–1

Flowrate measurement using a Parshall flume: (a) Parshall flume equipped with a sonic indicator to determine the depth of flow that is correlated to the flowrate and (b) Parshall flume equipped with a float indicator to determine the depth of flow.

Table 3–1
Typical wastewater flowrates from urban residential sources in the United States[a]

Household size, no. of persons	Flowrate, gal/capita·d		Flowrate, L/capita·d	
	Range	Typical	Range	Typical
1	75–130	97	285–490	365
2	63–81	76	225–385	288
3	54–70	66	194–335	250
4	41–71	53	155–268	200
5	40–68	51	150–260	193
6	39–67	50	147–253	189
7	37–64	48	140–244	182
8	36–62	46	135–233	174

[a] Adapted in part from AWWARF (1999).

For residential areas where large residential development is planned, it is often advisable to develop flowrates on the basis of land-use areas and anticipated population densities. Where possible, these rates should be based on actual flow data from selected similar communities, preferably in the same locale. In the past, the preparation of population projections for use in estimating wastewater flowrates was often the responsibility of the engineer, but today population projection data are usually available from local, regional, and state planning agencies.

Wastewater flowrates can vary depending on the quantity and quality of the water supply; rate structure; and economic, social, and other characteristics of the community. Data on ranges and typical flowrate values are given in Table 3–1 for residential sources in the United States. Beginning in recent years, greater attention is now being given to water conservation and the installation of water-conserving devices and appliances. Reduced household water use changes not only the quantity of wastewater generated but, as discussed later in this chapter, the characteristics of wastewater as well.

Commercial Districts. Depending on the function and activity, unit flowrates for commercial facilities can vary widely. Because of the wide variations that have been observed, every effort should be made to obtain records from actual or similar facilities. If no other records are available, estimates for selected commercial sources, based on function or persons served, may be made using the data presented in Table 3–2. In the past, commercial wastewater flowrates were often based on existing or anticipated future development or comparative data. Flowrates were generally expressed in terms of quantity of flow per unit area [i.e., m^3/ha·d (gal/ac·d)]. Typical unit-flowrate allowances for commercial developments normally range from 7.5 to 14 m^3/ha·d (800 to 1500 gal/ac·d). The latter approach can be used to check the values obtained from existing records or estimates made using Table 3–2.

Table 3–2
Typical wastewater flowrates from commercial sources in the United States[a]

Source	Unit	Flowrate, gal/unit·d		Flowrate, L/unit·d	
		Range	Typical	Range	Typical

Institutional Facilities. Typical flowrates from some institutional facilities are shown in Table 3–3. Again, it is stressed that flowrates vary with the region, climate, and type of facility. The actual records of institutions are the best sources of flow data for design purposes.

Recreational Facilities. Wastewater flowrates from many recreational facilities are subject to seasonal variations. Typical data on wastewater flowrates from recreational facilities are presented in Table 3–4.

Strategies for Reducing Interior Water Use and Wastewater Flowrates

Because of the importance of conserving both resources and energy, various means for reducing wastewater flowrates and pollutant loadings from domestic sources are available. The reduction of wastewater flowrates from domestic sources results directly from the reduction in interior water use. Therefore, the terms *interior water use* and *domestic wastewater flowrates* are used interchangeably. Representative water use rates for various devices and appliances are reported in Table 3–5. Information on the relative distribution of water use within a residence is reported in Table 3–6. Devices and appliances that can be used to reduce interior domestic water use and wastewater flows are described in Table 3–7.

Table 3–4
Typical wastewater flowrates from recreational facilities in the United States[a]

Facility	Unit	Flowrate, gal/unit·d		Flowrate, L/unit·d	
		Range	Typical	Range	Typical

[a] Adapted from Metcalf & Eddy (1991), Salvato (1992), and Crites and Tchobanoglous (1998).

Another method of achieving flow reduction that has been adopted by a number of communities is to restrict the use of appliances, such as automatic dishwashers and kitchen food-waste grinders (i.e., garbage disposal units), that tend to increase water consumption. The use of one or more of the flow-reduction devices is specified for all new residential dwellings in many communities; in others, the use of waste-food grinders has been limited in new housing developments. Further, many individuals concerned about conservation have installed such devices on their own, as a means of

Table 3–5
Typical rates of water use for various devices and appliances in the United States[a]

[b] Mean indoor water use = 260 L/capita·d (69 gal/capita·d).

reducing water consumption. New designs in front-loading clothes washers also offer significant reductions in water use, on the order of 50 to 75 percent of older models. A comparison of residential interior water use (and resulting per capita wastewater flows), from a recent survey, is given in Table 3–8 for homes without and with water-conserving fixtures (AWWA, 1998). The potential saving of employing selected water-efficient devices is illustrated in Example 3–1.

Table 3–7
Flow-reduction devices and appliances

Device/appliance	Description and/or application
Faucet aerators	Increases the rinsing power of water by adding air and concentrating flow, thus reducing the amount of wash water used
Flow-limiting showerheads	Restricts and concentrates water passage by means of orifices that limit and divert shower flow for optimum use by the bather
Low-flush toilets	Reduces the amount of water per flush
Pressure-reducing valve	Maintains home water pressure at a lower level than that of the water distribution system. Decreases the probability of leaks and dripping faucets
Pressurized shower	Water and compressed air are mixed together. Impact provides the sensation of conventional shower
Retrofit kits for bathroom	Kits may consist of shower flow restrictors, toilet dams or fixture displacement bags, and toilet leak-detector tablets
Toilet dam	A partition in the toilet tank that reduces the amount of water per flush
Toilet leak detectors	Tablets that dissolve in the toilet tank and release dye to indicate leakage of the flush valve
Vacuum toilet	A vacuum along with a small amount of water is used to remove solids from toilet
Water-efficient dishwasher	Reduces the amount of water used to wash dishes
Water-efficient clothes washer	Reduces the amount of water used to wash clothes. New front-loading machines have been developed that not only use less water but are more energy-efficient

Table 3–8
Typical comparisons of interior water use without and with water-conservation practices and devices in the United States[a]

	Flow, gal/capita·d		Flow, L/capita·d	
Use	Without water conservation	With water conservation	Without water conservation	With water conservation

EXAMPLE 3–1 Determine Water Savings by Employing Water-Efficient Appliances A new subdivision of 2000 homes is planned, and a condition of the building permit is to determine the savings in water consumption (and wastewater flows) if the following water-efficient appliances are used: front-loading washing machines, ultra-low flush toilets, and ultra-low-flow showerheads. Use 3.5 residents per home and values for devices and appliances from Table 3–8.

The estimated water use and percentage savings are illustrated in the following table.

		Unit water use, L/capita·d		Water use, L/day	
Appliance/device	No. of Residents	No conservation	With conservation	No conservation	With conservation
Clothes washing	7000	64	45	448,000	315,000
Toilets	7000	73	35	511,000	245,000
Showers	7000	50	42	350,000	294,000
Total				1,309,000	854,000
Percent savings					34.8

Comment Three of the largest water-using appliances and devices utilized in the home are those described in this example. Interior water use and the generation of wastewater can be reduced significantly with the community-wide installation of water-efficient appliances and devices, thus reducing the flows that will have to be handled by the collection system and treatment plant. Where high infiltration rates occur within the collection system, it is difficult or impossible to assess the beneficial effects of using water conservation devices.

Water Use in Developing Countries

The typical flowrates and use patterns presented in Tables 3–1 through 3–6 and Table 3–8 are based on water use and wastewater flowrate data from communities and facilities in the United States. Many developed countries have flowrates in similar ranges. Water use and, consequently, wastewater-generation rates in developing countries, however, are significantly lower. In some cases, the water supply is only available for limited periods of the day. Water-use data from some developing countries are given in Table 3–9.

Sources and Rates of Industrial (Nondomestic) Wastewater Flows

Nondomestic wastewater flowrates from industrial sources vary with the type and size of the facility, the degree of water reuse, and the onsite wastewater-treatment methods, if any. Extremely high peak flowrates may be reduced by the use of onsite detention tanks and equalization basins. Typical design values for estimating the flows from industrial areas that have no or little wet-process-type industries are 7.5 to 14 m^3/ha·d (1000 to 1500 gal/ac·d) for light industrial developments and 14 to 28 m^3/ha·d (1500 to

Table 3-9
Water consumption in developing countries and areas[a]

Country/Area	Per capita water consumption	
	Gal/d	L/d
China	21	80
Africa	4–9	15–35
Southeast Asia	8–19	30–70
Western Pacific	8–24	30–90
Eastern Mediterranean	11–23	40–85
Algeria, Morocco, Turkey	5–17	20–65
Latin America and Caribbean	19–51	70–190
World average	9–24	35–90

[a]Adapted, in part, from Salvato (1992).

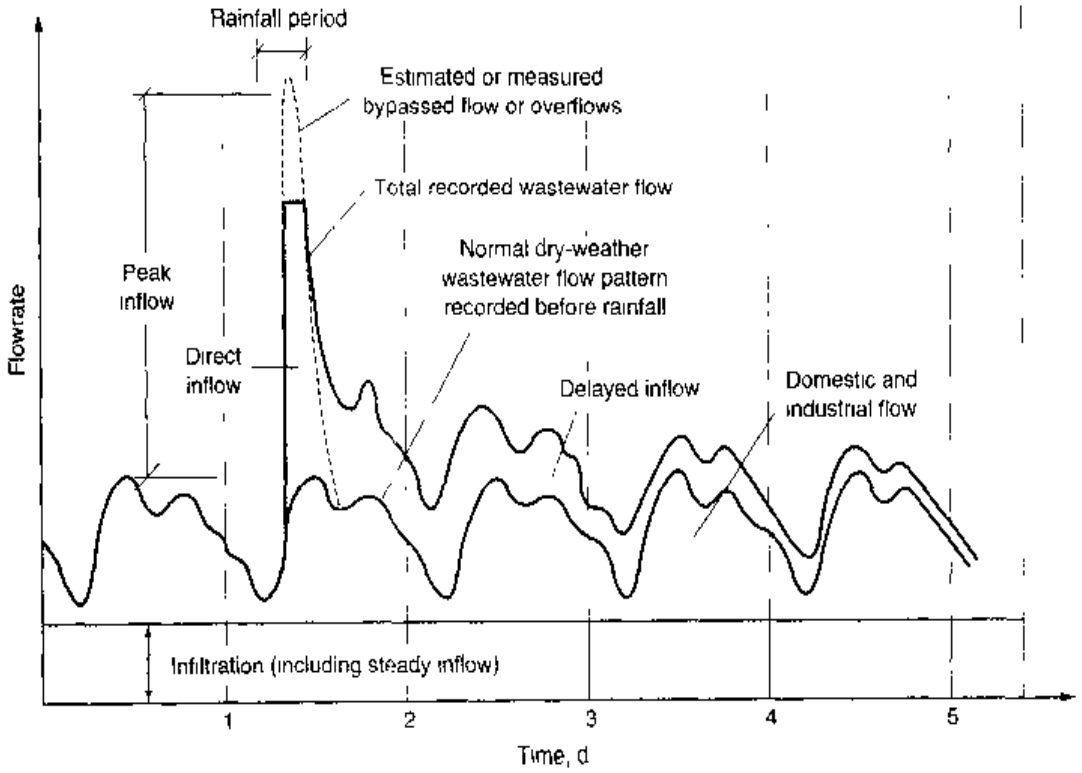
3000 gal/ac·d) for medium industrial developments. For industries without internal water recycling or reuse programs, it can be assumed that about 85 to 95 percent of the water used in the various operations and processes will become wastewater. For large industries with internal water-reuse programs, separate estimates based on actual water consumption records must be made. Average domestic (sanitary) wastewater contributed from industrial facilities may vary from 30 to 95 L/capita·d (8 to 25 gal/capita·d).

Infiltration/Inflow

Extraneous flows in collection systems, described as infiltration and inflow, are illustrated on Fig. 3–2 and are defined as follows:

Infiltration. Water entering a collection system from a variety of entry points including service connections and from the ground through such means as defective pipes, pipe joints, connections, or access port (manhole) walls.

Steady inflow. Water discharged from cellar and foundation drains, cooling-water discharges, and drains from springs and swampy areas. This type of inflow is steady and is identified and measured along with infiltration.



Direct inflow. Those types of inflow that have a direct stormwater runoff connection to the sanitary collection system and cause an almost immediate increase in wastewater flowrates. Possible sources are roof leaders, yard and areaway drains, access port covers, cross connections from storm drains and catch basins, and combined systems.

Total inflow. The sum of the direct inflow at any point in the system plus any flow discharged from the system upstream through overflows, pumping station bypasses, and the like.

Delayed inflow. Stormwater that may require several days or more to drain through the collection system. Delayed inflow can include the discharge of sump pumps from cellar drainage as well as the slowed entry of surface water through access ports (manholes) in ponded areas.

Figure 3–2

Graphic identification of infiltration/inflow.

The initial impetus in the United States for defining and identifying infiltration/inflow was the Federal Water Pollution Control Act Amendments of 1972. As a condition of receiving a federal grant for the design and construction of wastewater-treatment facilities, grant applicants had to demonstrate that their wastewater-collection systems were not subject to excessive infiltration/inflow. By correcting infiltration/inflow problems and "tightening" the collection system, benefits to the community include (1) reducing wastewater backups and overflows in the collection system, (2) increasing the efficiency of operation of wastewater-treatment facilities, and (3) improving the utilization of collection system hydraulic capacity for wastewater requiring treatment instead of for infiltration/inflow. Because an understanding of the effects of infiltration/inflow is important in determining treatment-plant flowrates, a discussion of excessive infiltration/inflow is included in this section.

Infiltration into Collection Systems. One portion of the rainfall in a given area runs quickly into the stormwater systems or other drainage channels; another portion evaporates or is absorbed by vegetation; and the remainder percolates into the ground, becoming groundwater. The proportion of the rainfall that percolates into the ground depends on the character of the surface and soil formation and on the rate and distribution of the precipitation. Any reduction in permeability, such as that due to buildings, pavements, or frost, decreases the opportunity for precipitation to become groundwater and increases the surface runoff correspondingly. The amount of groundwater flowing from a given area may vary from a negligible amount for a highly impervious district or a district with a dense subsoil to 25 or 30 percent of the rainfall for a semipervious district with a sandy subsoil permitting rapid passage of water. The percolation of water through the ground from rivers or other bodies of water sometimes has considerable effect on the groundwater table, which rises and falls continually.

The presence of high groundwater results in leakage into the collection systems and in an increase in the quantity of wastewater and the expense of disposing of it. The amount of flow that can enter a collection system from groundwater, or infiltration, may range from 0.01 to 1.0 $m^3/d \cdot mm\text{-}km$ (100 to 10,000 gal/d·in-mi) or more. The number of millimeter-kilometers (inch-miles) in a wastewater-collection system is the sum of the products of sewer diameters, in millimeters (inches), times the lengths, in kilometers (miles), of sewers of corresponding diameters.

Infiltration may also be estimated based on the area served by the collection system and may range from 0.2 to 28 $m^3/ha \cdot d$ (20 to 3000 gal/ac·d) (Metcalf & Eddy, 1981). The variation in the amount of infiltration encompasses a wide range because the lot sizes may vary in area, which in turn affects the length and extent of the collection system network. During heavy rains, when there may be leakage through access port covers, or inflow as well as infiltration, the rate may exceed 500 $m^3/ha \cdot d$ (50,000 gal/ac·d).

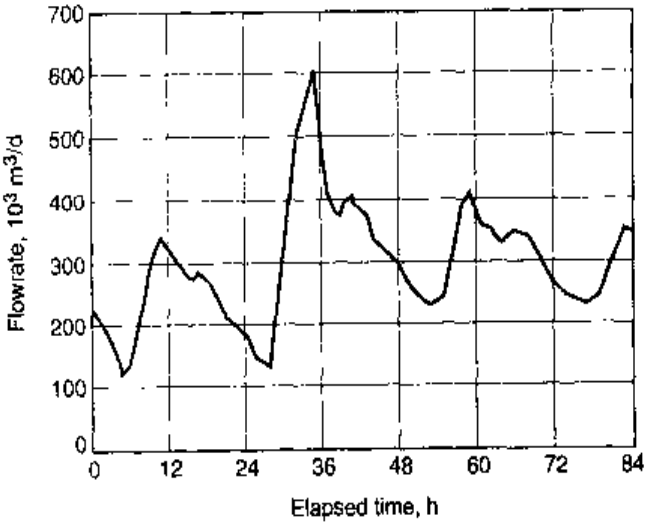
Infiltration/inflow is a variable part of the wastewater, depending on the quality of the material and workmanship in constructing the collection systems and building connections, the character of the maintenance, and the elevation of the groundwater compared with that of the collection system. The rate and quantity of infiltration depend on the length of the collection system, the area served, the soil and topographic conditions, and, to a certain extent, the population density (which affects the number and total length of house connections). Although the elevation of the water table varies with the quantity of rain and melting snow percolating into the ground, the leakage through defective joints, porous concrete, and cracks has been large enough, in some cases, to lower the groundwater table to the level of the collection system.

Most of the piping systems built during the first half of the 20th century were laid with cement mortar joints or hot-poured bituminous compound joints. Access ports were almost always constructed of brick masonry. Deterioration of pipe joints, pipe-to-access port joints, and the waterproofing of brickwork has resulted in a high potential for infiltration into these old sewers. The use of high-quality pipe with dense walls, precast access port sections, and joints sealed with rubber or synthetic gaskets is standard practice in modern collection-system design. The use of these improved materials has greatly reduced infiltration into and exfiltration from newly constructed collection systems, and infiltration rates with time are expected to be much slower than with older sewers.

Inflow into Collection Systems. As described previously, the type of inflow that causes a "steady flow" cannot be identified separately and so is included in the measured infiltration. The direct inflow can cause an almost immediate increase in flowrates in sanitary systems. The effects of inflow on peak flowrates that must be handled by a wastewater treatment plant are shown in Example 3–2.

EXAMPLE 3–2 Determine Infiltration/Inflow from Wastewater Flow Records A large city has measured high flowrates during the wet season of the year. The flow during the dry period of the year, when rainfall is rare and groundwater infiltration is negligible, averages 120,000 m^3/d (31.7 Mgal/d). During the wet period when groundwater levels are elevated, the flowrate averaged 230,000 m^3/d (60.8 Mgal/d) excluding those days during and following any significant rainfall events. During a recent storm, hourly

flowrates were recorded during the peak flow period, as well as several days following the storm. The flow plots are shown on the accompanying figure. Compute the infiltration and inflow and determine if the infiltration is excessive. Excessive infiltration is defined by the local regulatory agency as rates over 0.75 $m^3/d \cdot mm\text{-}km$ (8000 gal/d·in-mi) of collection system. The composite diameter-length of the collection system is 270,000 mm-km (6600 in-mi).



Solution

1. Determine the infiltration and inflow components during the wet season.
   a. Because infiltration is low during dry periods, high groundwater infiltration is computed as wet weather average flow minus base (dry weather) flow:

   $$\text{Infiltration} = (230{,}000 - 120{,}000)\ m^3/d$$
   $$= 110{,}000\ m^3/d$$

   b. The maximum hourly inflow is determined graphically from the accompanying figure as the difference between the peak hourly wet weather flow during the storm and the comparable flowrate on the preceding day. The maximum flowrate at hour 35 is 606,000 m^3/d, and the flow at hour 11 is 340,000 m^3/d. In this case, the maximum inflow is

   $$\text{Inflow} = (606{,}000 - 340{,}000)\ m^3/d$$
   $$= 266{,}000\ m^3/d$$

2. Determine if the infiltration is excessive.
   a. Calculate the infiltration by dividing the calculated flowrate by the composite diameter-length of the collection system.

   $$\text{Infiltation} = \frac{(110{,}000\ m^3 \cdot d)}{(270{,}000\ mm\text{-}km)} = 0.407\ m^3/d \cdot mm\text{-}km$$

   b. Using the regulatory agency criterion of 0.75 $m^3/d \cdot mm\text{-}km$, the infiltration is not excessive.

Comment In this example, the peak flow during the storm period was 4.7 times the average dry weather flow. As discussed later in this chapter, the peak flow factor is high for a system of this size. Because inflow represents over 50 percent of the peak flow and requires oversizing of the hydraulic capacity of the treatment plant, methods of inflow reduction should be investigated to decrease the hydraulic load on the collection system and treatment facilities.

Exfiltration from Collection Systems

Collection systems that have high infiltration rates and are in need of rehabilitation also may exhibit high exfiltration. When exfiltration occurs, untreated wastewater leaks out of pipe joints and service connections. If the piping and joints are in poor condition, significant quantities of wastewater may seep into the ground, travel through the gravel bedding of the piping system, or even surface in extreme cases. Seepage of untreated wastewater into the ground near shallow wells can result in pollution of the water supply. Well contamination has occurred in urban areas such as Los Angeles, California, where collection systems are within 300 m (1000 ft) of water wells. Exfiltration in collection systems near surface water bodies can also contribute to ongoing high coliform counts in those water bodies that may be difficult to correct. Reduction of inflow/filtration in collection systems may serve to limit exfiltration and remove potential threats to water supplies and public health. The potential effects of exfiltration on surface water quality are illustrated in Example 3–3.

EXAMPLE 3–3 Determine the Pollution Contributing Effects of Exfiltration on Nearby Water Body Untreated wastewater from a damaged collection system pipeline leaks into a nearby lake. The leakage is estimated to be 10,000 L/d. What increase in concentration of organisms can be expected in the lake if the initial coliform count is 10^7 organisms/100 mL and the wastewater is diluted by 1000 to 1? Assume the number of coliform organisms in the dilution water is zero.

Solution

1. To solve this problem, a concentration balance (see Chap. 4 for additional details for mass and concentration balances) must be made as follows:

Total number of organisms in mixture	=	Total number of organisms in leakage	+	Total number of organisms in leakage
$Q_M C_M$	=	$Q_L C_L$	+	$Q_{DW} C_{DW}$

Where Q_M = volume of the mixture
C_M = concentration of organisms/100 mL in the mixture
Q_L = volume of leakage

C_L = concentration of organisms/100 mL in the leakage
Q_{DW} = volume of the dilution water
C_{DW} = concentration of organisms/100 mL in the dilution water

2. Substitute for the various quantities and solve for the number of organisms in the mixture.

$$[10^4\ \text{L} + 10^3\ (10^4\ \text{L})]\left(\frac{C_M}{100\ \text{mL}}\right) = 10^4\ \text{L}\left(\frac{10^7}{100\ \text{mL}}\right) + 10^3(10^4\ \text{L})\left(\frac{0}{100\ \text{mL}}\right)$$

$$(10^4\ \text{L} + 10^7\ \text{L})\left(\frac{C_M}{100\ \text{mL}}\right) = 10^4\ \text{L}\left(\frac{10^7}{100\ \text{mL}}\right)$$

$$C_M \approx \frac{10^4}{100\ \text{mL}}$$

Comment Because untreated wastewater contains a high concentration of coliform organisms, the receiving water, even under the assumed condition that the exfiltration is well mixed, can contain high concentration levels. Such high coliform counts would be taken as indicators that a potential health hazard may exist. Therefore, in this example, because the exfiltration from the collection system into the lake is significant, receiving water-quality objectives will be difficult to maintain.

Combined System Flowrates

Flow in the combined system is composed mainly of rainfall runoff and wastewater. Flow enters the combined system continuously during both dry and wet weather from the contributing wastewater sources (see Fig. 1–1 in Chap. 1). This flow may include domestic, commercial, and industrial wastewater and infiltration. During a rainfall event, the amount of storm flow is normally much larger than the dry-weather wastewater flow, and the observed flows during wet weather can mask completely the dry weather flow patterns.

As flow proceeds through the combined system to the interceptor, it is modified by hydraulic routing effects as well as any surcharged conditions within the system (surcharging results when the pipeline capacity is exceeded). When the collection system capacity is exceeded, a portion of the flow may be discharged directly into a receiving body through overflows, either intentionally or accidentally, or routed to a special combined sewer overflow (CSO) treatment facility. In some cases where the combined system is undersized, flooding or surcharging may occur at various upstream locations within the system. Either condition (untreated overflow to receiving waters or flooding) is undesirable and most likely will result in a violation of the discharge permit and/or public health regulations.

The effects of combined system flowrates are illustrated on Fig. 3–3. The catchment hydrograph (flow versus time), as illustrated on Fig. 3–3*b*, closely resembles that

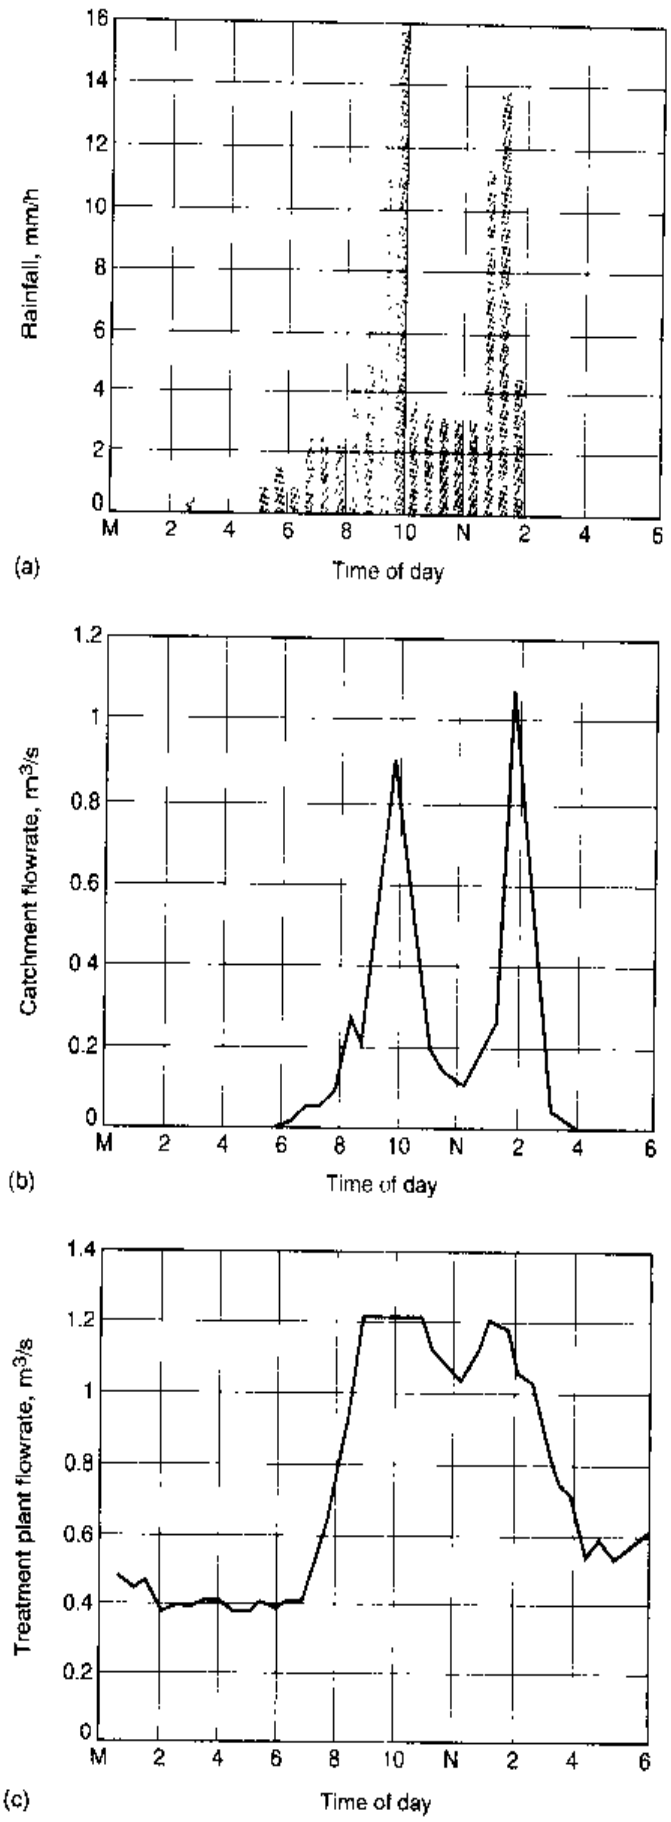


Figure 3–3

Flow variations in a combined collection system during wet weather; (*a*) rainfall hyetograph, (*b*) typical catchment flowrate, and (*c*) observed treatment plant flowrate.

of the variations in rainfall intensity. The short response time between the rainfall event and the increase in the flowrate can be taken as an indication of a short travel time for flow from all points in the upstream combined system. In contrast, the hydrograph at the treatment plant (see Fig. 3-3*c*) shows less distinct flow peaks and a lag time of several hours for flows to return to normal dry-weather levels following rainfall cessation. The higher flows at this location are due to the larger contributing combined system, and the smoothed peaks result from loss of flow through overflows and hydraulic routing effects. The peak flowrates and accompanying mass loadings, however, must be accounted for in the hydraulic design of the treatment plant and in the selection of appropriate unit operations and processes.

Calculation of flowrates in a combined system is a complicated and challenging task. The first step in the process involves quantifying wastewater, rainfall runoff, and other sources of flow such as groundwater infiltration. These sources of flow are then combined and routed through the various components of the system. Finally, the volumes of flow exiting the system through CSO outlets, entering the downstream treatment facility, or being transported to other points in the system are determined.

Owing to the complexity of combined systems, it is normally necessary to use computer models to simulate the complete combined system including dry-weather wastewater flows, hydraulic routing through the piping system, discharges through the outlets, and the flow through the interceptor and to the treatment plant. Computer models that are in the public domain and are suitable for the assessment of combined systems include the Storm Water Management Model (SWMM) and the Corps of Engineers STORM and Hydrologic Simulation Model—Fortran (HSPF). Summaries of these programs are found in Nayyer (1992).

3–3 STATISTICAL ANALYSIS OF FLOWRATES, CONSTITUENT CONCENTRATIONS, AND MASS LOADINGS

The statistical analysis of wastewater flowrate and constituent concentration data involves the determination of statistical parameters used to quantify a series of measurements. Commonly used statistical parameters and graphical techniques for the analysis of wastewater management data are reviewed below.

Common Statistical Parameters

Commonly used statistical measures include the mean, median, mode, standard deviation, and coefficient of variation, based on the assumption that the data are distributed normally. Although the terms just cited are the most commonly used statistical measures, two additional statistical measures are needed to quantify the nature of a given distribution. The two additional measures are the coefficient of skewness and the coefficient of kurtosis. If a distribution is highly skewed, as determined by the coefficient of skewness, normal statistics cannot be used. For most wastewater data that are skewed, it has been found that the log of the value is normally distributed. Where the log of the values is normally distributed, the distribution is said to be log-normal. The common statistical measures used for the analysis of wastewater management data [Eqs. (3–1) through (3–9)] are summarized in Table 3–10.

Table 3–10
Statistical parameters used for the analysis of wastewater management data[a]

Parameter	Definition
Mean value $\bar{x} = \frac{\sum f_i x_i}{n}$ (3–1)	$\bar{x}$ = mean value
Standard deviation $s = \sqrt{\frac{\sum f_i (x_i - \bar{x})^2}{n-1}}$ (3–2)	f_i = frequency (for ungrouped data $f_i = 1$)
Coefficient of variation $C_v = \frac{100s}{\bar{x}}$ (3–3)	x_i = midpoint of the ith data range (for ungrouped data x_i = the ith observation)
Coefficient of skewness $\alpha_3 = \frac{\sum f_i (x_i - \bar{x})^3/(n-1)}{s^3}$ (3–4)	n = number of observations (Note $\sum f_i = n$)
Coefficient of kurtosis $\alpha_4 = \frac{\sum f_i (x_i - \bar{x})^4/(n-1)}{s^4}$ (3–5)	s = standard deviation
Geometric mean $\log M_g = \frac{\sum f_i (\log x_i)}{n}$ (3–6)	C_v = coefficient of variation, percent
Geometric standard deviation $\log s_g = \sqrt{\frac{\sum f_i (\log^2 x_g)}{n-1}}$ (3–7)	α_3 = coefficient of skewness
Using probability paper $s = P_{84.1} - \bar{x}$ or $P_{15.9} + \bar{x}$ (3–8)	α_4 = coefficient of kurtosis
$s_g = \frac{P_{84.1}}{M_g} = \frac{M_g}{P_{15.9}}$ (3–9)	M_g = geometric mean
	s_g = geometric standard deviation
	$\log x_g = \log x_i - \log M_g$
	Median value
	If a series of observations are arranged in order of increasing value, the middlemost observation, or the arithmetic mean of the two middlemost observations, in a series is known as the median
	Mode
	The value occurring with the greatest frequency in a set of observations is known as the mode. If a continuous graph of the frequency distribution is drawn, the mode is the value of the high point, or hump, of the curve. In a symmetrical set of observations, the mean, median, and mode will be the same value
	Coefficient of skewness
	When a frequency distribution is asymmetrical, it is usually defined as being a skewed distribution
	Coefficient of kurtosis
	Used to define the peakedness of the distribution. The value of the kurtosis for a normal distribution is 3. A peaked curve will have a value greater than 3, whereas a flatter curve will have a value less than 3

[a]Adapted from Metcalf & Eddy (1991) and Crites and Tchobanoglous (1998).

Graphical Analysis of Data

Graphical analysis of wastewater management data is used to determine the nature of the distribution. For most practical purposes, the type of the distribution can be determined by plotting the data on both arithmetic- and logarithmic-probability (log-probability) paper and noting whether the data can be fitted with a straight line. The three steps involved in the use of arithmetic and log-probability paper are as follows.

1. Arrange the measurements in a data set in order of increasing magnitude and assign a rank serial number.
2. Compute a corresponding plotting position for each data point using Eq. (3–10).

$$\text{Plotting position } (\%) = \left(\frac{m}{n+1}\right) \times 100 \tag{3–10a}$$

where m = rank serial number
n = number of observations

The term $(n + 1)$ is used to correct for a small sample bias. The plotting position represents the percent or frequency of observations that are equal to or less than the indicated value. Another expression often used to define the plotting position is known as Blom's transformation:

$$\text{Plotting position, } \% = \frac{m - 3/8}{n + 1/4} \times 100 \tag{3–10b}$$

3. Plot the data on arithmetic- and log-probability paper. The probability scale is labeled "Percent of values equal to or less than the indicated value."

If the data, plotted on arithmetic-probability paper, can be fit with a straight line, then the data are assumed to be normally distributed. Significant departure from a straight line can be taken as an indication of skewness. If the data are skewed, log-probability paper can be used. The implication here is that the logarithm of the observed values is normally distributed. On log-probability paper, the straight line of best fit passes through the geometric mean M_g and through the intersection of $M_g \times s_g$ at a value of 84.1 percent and M_g/s_g at a value of 15.9 percent. The geometric standard deviation s_g can be determined using Eq. (3–9) given in Table 3–10. The use of arithmetic- and logarithmic-probability paper is illustrated in Example 3–4.

EXAMPLE 3–4 Statistical Analysis of Wastewater Constituent Concentration Data Determine the appropriate statistical parameters for the following set of effluent data from a wastewater-treatment plant, collected over a 24-month period.

	Value, g/m³	
Month	**TSS**	**COD**
1	13.50	15.00
2	25.90	11.25
3	28.75	35.35
4	10.75	13.60
5	12.50	15.30
6	9.85	15.75
7	13.90	16.80

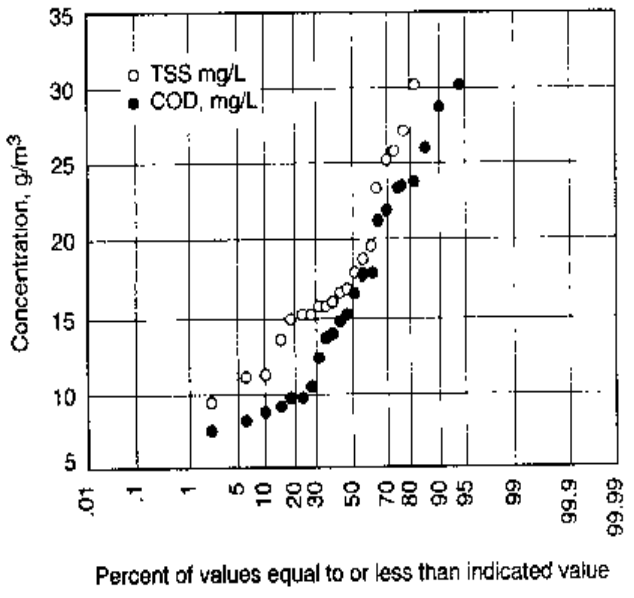
(continued)

(*Continued*)

Month	Value, g/m³ TSS	COD
8	15.10	15.20
9	23.40	18.75
10	21.90	37.50
11	23.70	27.00
12	18.00	23.30
13	37.00	46.60
14	30.10	36.25
15	21.25	30.00
16	23.50	25.75
17	16.75	17.90
18	8.35	11.35
19	18.10	25.20
20	9.25	16.10
21	9.90	16.75
22	8.75	15.80
23	15.50	19.50
24	7.60	9.40

Solution

1. Determine the nature of the distribution by plotting the data on arithmetic- and log-probability paper.
   a. Determine the plotting position using Eq. (3–10*a*) where *n* equals 24.



Number	Plotting position, %[a]	Value, g/m³ TSS	COD
1	4	7.60	9.40
2	8	8.35	11.25
3	12	8.75	11.35
4	16	9.25	13.60

24	96	37.00	46.60

[a]Plotting position (%) $= \left(\frac{m}{n+1}\right) \times 100$.

b. Plot the above data on both arithmetic- and log-probability paper. As shown in the accompanying plot, both the TSS and COD data are log-normal.

2. Determine the geometric mean for TSS and COD and the corresponding geometric standard deviation using Eq. (3–9).

$$s_g = \frac{P_{84.1}}{M_g} = \frac{M_g}{P_{15.9}}$$

Constituent	M_g	s_g
TSS	23	2.19
COD	30	2.14

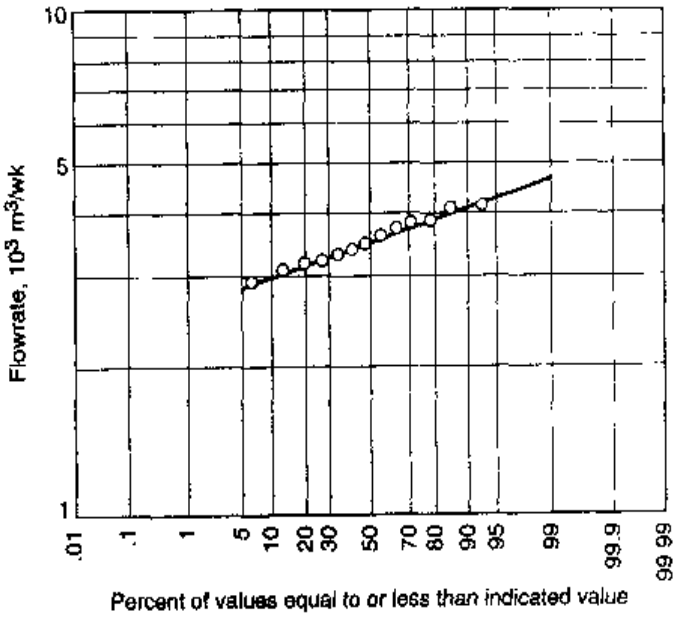
EXAMPLE 3–5 Statistical Analysis of Wastewater Flowrate Data Using the following weekly flowrate data obtained from an industrial discharger for a calendar quarter of operation, determine the statistical characteristics and predict the maximum weekly flowrate that will occur during a full year's operation.

Week no.	Flowrate, m^3/wk	Week no.	Flowrate, m^3/wk
1	2900	8	3675
2	3040	9	3810
3	3540	10	3450
4	3360	11	3265
5	3770	12	3180
6	4080	13	3135
7	4015		

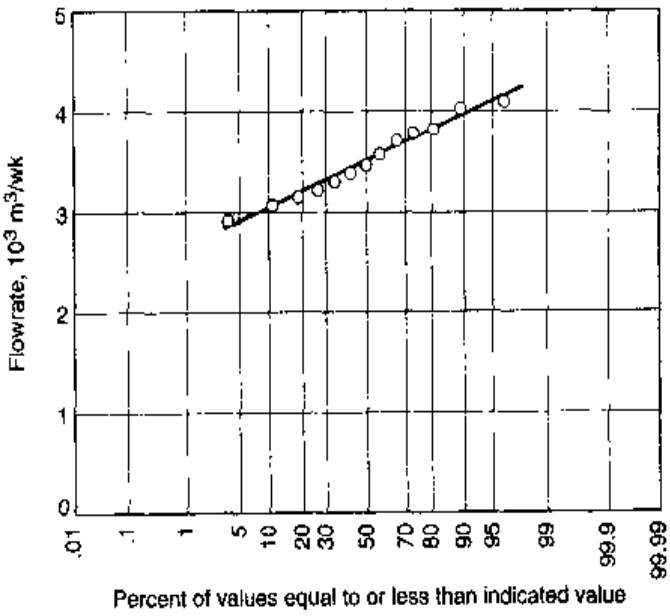
Solution

1. Plot the flowrate data using the log-probability method.
   a. Set up a data analysis table with three columns as described below.
      i. In column 1, enter the rank serial number starting with number 1.
      ii. In column 2, arrange the flowrate data in ascending order.
      iii. In column 3, enter the probability plotting position.

Rank serial no., m	Flowrate, m^3/wk	Plotting position,[a] %
1	2900	7.1
2	3040	14.3
3	3135	21.4
4	3180	28.6
5	3265	35.7
6	3360	42.9
7	3450	50.0
8	3540	57.1
9	3675	64.3
10	3770	71.4



(continued)



(*Continued*)

Rank serial no., m	Flowrate, m^3/wk	Plotting position,[a] %
11	3810	78.6
12	4015	85.7
13	4080	92.9

[a]Plotting position = $[m/(n + 1)]100$.

b. Plot the weekly flowrates expressed in m^3/wk versus the plotting position. The resulting plots are presented below. Because the data fall on a straight line on both plots, the flowrate data can be described adequately by either distribution. This fact can be taken as indication that the distribution is not skewed significantly and that normal statistics can be applied.

2. Determine the statistical characteristics of the flowrate data.
   a. Set up a data analysis table to obtain the quantities needed to determine the statistical characteristics.

Flowrate, m^3/wk	$(x - \bar{x})$	$(x - \bar{x})^2$	$(x - \bar{x})^3$ 10^{-6}	$(x - \bar{x})^4$ 10^{-9}
2,900	−578	334,084	−193	11,161
3,040	−438	191,844	−84	3,680
3,135	−343	117,649	−40	1,384
3,180	−298	88,804	−26	789

(*continued*)

(*Continued*)

Flowrate, m^3/wk	$(x - \bar{x})$	$(x - \bar{x})^2$	$(x - \bar{x})^3$ 10^{-6}	$(x - \bar{x})^4$ 10^{-9}
3,265	−213	45,369	−9.6	206
3,360	−118	13,924	−1.6	19.4
3,450	−28	784	−0.02	0.06
3,540	62	3,844	0.24	1.48
3,675	197	38,809	7.6	151
3,770	292	85,264	25	727
3,810	332	110,224	37	1,215
4,015	537	288,369	155	8,316
4,080	602	362,404	218	13,134
45,220		1,681,372	88.62	40,784

b. Determine the statistical characteristics using the parameters given in Table 3–10.

i. Mean

$$\bar{x} = \frac{\Sigma x}{n}$$

$$\bar{x} = \frac{45{,}220}{13} = 3478 \text{ m}^3/\text{wk}$$

ii. Median (the middlemost value)

Median = 3450 m^3/wk (see data table above)

iii. Mode

Mode = 3(Med) − 2($\bar{x}$) = 3(3450) − 2(3478) = 3394 m^3/wk

iv. Standard deviation

$$s = \sqrt{\frac{\Sigma(x - \bar{x})^2}{n - 1}}$$

$$s = \sqrt{\frac{1{,}681{,}372}{12}} = 374.3 \text{ m}^3/\text{wk}$$

v. Coefficient of variation

$$C_V = \frac{100\, s}{\bar{x}}$$

$$C_V = \frac{100(374.3)}{3478} = 10.8\%$$

vi. Coefficient of skewness

$$\alpha_3 = \frac{\Sigma(x - \bar{x})^3/n - 1}{s^3}$$

$$\alpha_3 = \frac{88.62 \times 10^6/12}{(374.3)^3} = 0.141$$

vii. Coefficient of kurtosis

$$\alpha_4 = \frac{\Sigma(x - \bar{x})^4/n - 1}{s^4}$$

$$\alpha_4 = \frac{40{,}784 \times 10^9/12}{(374.3)^4} = 1.73$$

Reviewing the statistical characteristics, it can be seen that the distribution is somewhat skewed ($\alpha_3 = 0.141$ versus 0 for a normal distribution) and is considerably flatter than a normal distribution would be ($\alpha_4 = 1.73$ versus 3.0 for a normal distribution).

3. Determine the probable annual maximum weekly flowrate.
   a. Determine the probability factor

$$\text{Peak week} = \frac{m}{n + 1} = \frac{52}{52 + 1} = 0.981$$

   b. Determine the flowrate from the figure given in Step 1b at the 98.1 percentile.

Peak weekly flowrate = 4500 m^3/wk

Comment The statistical analysis of data is important in establishing the design conditions for wastewater-treatment plants. The application of statistical analysis to the selection of design flowrates and mass loadings is considered in the following section.

3–4 ANALYSIS OF WASTEWATER FLOWRATE DATA

Because the hydraulic design of both collection and treatment facilities is affected by variations in wastewater flowrates, the flowrate characteristics have to be analyzed carefully from existing records. In cases where only flowrate data in the collection system is available, it must be recognized that the flowrates may differ somewhat from the flowrate entering the treatment plant because of the flow-dampening effect of the sewer system. Peak hourly flowrates may also be attenuated by the available storage capacity in the sewer system.

Definition of Terms

Before considering the variations in flowrates and constituent concentrations, it will be helpful to define some terminology that is used commonly to quantify the variations that are observed. The principal terms used to describe these observed variations are

defined in Table 3–11. As will be discussed in Sec. 3–6, these terms are also of importance in the selection and sizing of individual unit treatment processes and operations.

Variations in Wastewater Flowrates

Wastewater flowrates vary during the time of day, day of the week, season of the year, or depending upon the nature of the dischargers to the collection system. Short-term, seasonal, and industrial variations in wastewater flowrates are briefly discussed here.

Short-Term Variations. The variations in wastewater flows observed at treatment plants tend to follow a diurnal pattern, as shown on Fig. 3–4. Minimum flows occur during the early morning hours when water consumption is lowest and when the base flow consists of infiltration and small quantities of sanitary wastewater. The first peak flow generally occurs in the late morning when wastewater from the peak morning water use reaches the treatment plant. A second peak flow generally occurs in the

Table 3–11
Terminology used to quantify observed variations in flowrate and constituent concentrations[a]

Item	Description
Average dry-weather flow (ADWF)	The average of the daily flows sustained during dry-weather periods with limited infiltration
Average wet-weather flow (AWWF)	The average of the daily flows sustained during wet-weather periods when infiltration is a factor
Average annual daily flow	The average flowrate occurring over a 24–h period based on annual flowrate data
Instantaneous peak	Highest record flowrate occurring for a period consistent with the recording equipment. In many situations the recorded peak flow may be considerably below the actual peak flow because of metering and recording equipment limitations
Peak hour	The average of the peak flows sustained for a period of 1 hour in the record examined (usually based on 10-min increments)
Maximum day	The average of the peak flows sustained for a period of 1 day in the record examined (the duration of the peak flows may vary)
Maximum month	The average of the maximum daily flows sustained for a period of 1 month in the record examined
Minimum hour	The average of the minimum flows sustained for the period of 1 hour in the record examined (usually based on 10-min increments)
Minimum day	The average of the minimum flows sustained for the period of a day in the record examined (usually for the period from 2 A.M. to 6 A.M.)
Minimum month	The average of the minimum daily flows sustained for the period of 1 month in the record examined
Sustained flow (and load)	The value (flowrate or mass loading) sustained or exceeded for a given period of time (e.g., 1 hour, 1 day, or 1 month)

[a]Adapted in part from Crites and Tchobanoglous (1998).

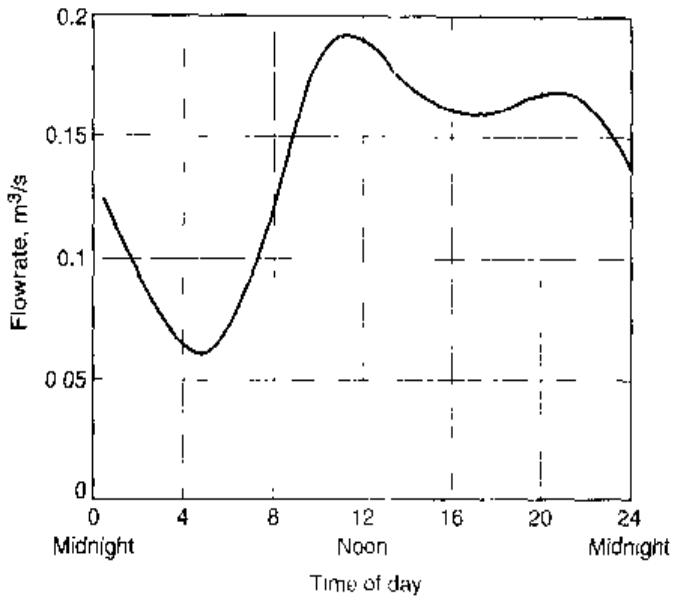


Figure 3–4
Typical hourly variations in domestic wastewater flowrates.

early evening between 7 and 9 P.M. The time of occurrence and the amplitude of the peak flowrates vary with the size of the community and the length of the collection system. As the community size increases, the variations between the high and low flows decrease due to (1) the increased storage in the collection system of large communities that tends to equalize flowrates and (2) changes in the economic and social makeup of the community. When extraneous flows are minimal, wastewater discharge curves resemble water consumption curves, but with a lag of several hours.

Seasonal Variations. Seasonal variations in domestic wastewater flows are commonly observed at resort areas, in small communities with college campuses, and in communities that have seasonal commercial and industrial activities. The magnitude of the variations to be expected depends on both the size of the community and the seasonal activity.

Industrial Variations. Industrial wastewater discharges are difficult to predict. Many manufacturing facilities generate relatively constant flowrates during production, but the flowrates change markedly during cleanup and shutdown. While internal process changes may lead to reduced discharge rates, plant expansion and increased production may lead to increased wastewater generation. Where joint municipal and industrial treatment facilities are to be constructed, special attention should be given to industrial flowrate projections, whether they are prepared by the industry or jointly with the city's staff or engineering consultant. Industrial discharges are most troublesome in smaller wastewater-treatment plants where there is limited capacity to absorb shock loadings.

Wastewater Flowrate Factors

Quantifying the variations in flowrates is important in the design and operation of wastewater-treatment plants. One of the measures used in determining the "peak" or maximum flows is the peaking factor. Peaking factors can be developed based on maximum

hour, maximum day, maximum month, or other time periods. The peaking factor is particularly useful in estimating the maximum hydraulic conditions that might occur and have to be accommodated. Peaking factors can also be applied to mass loadings. Peaking factors are applied most frequently to determine the peak hourly flowrate. Because it is difficult to compare numerical peak flow values from different wastewater-treatment plants, peak hourly flowrate values are normalized by dividing by the long-term average flowrate. The resultant ratio, known as a peaking factor, is defined as follows:

$$\text{Sustained peaking factor, PF} = \frac{\text{peak flowrate (e.g., hourly, daily)}}{\text{average long-term flowrate}} \tag{3–11}$$

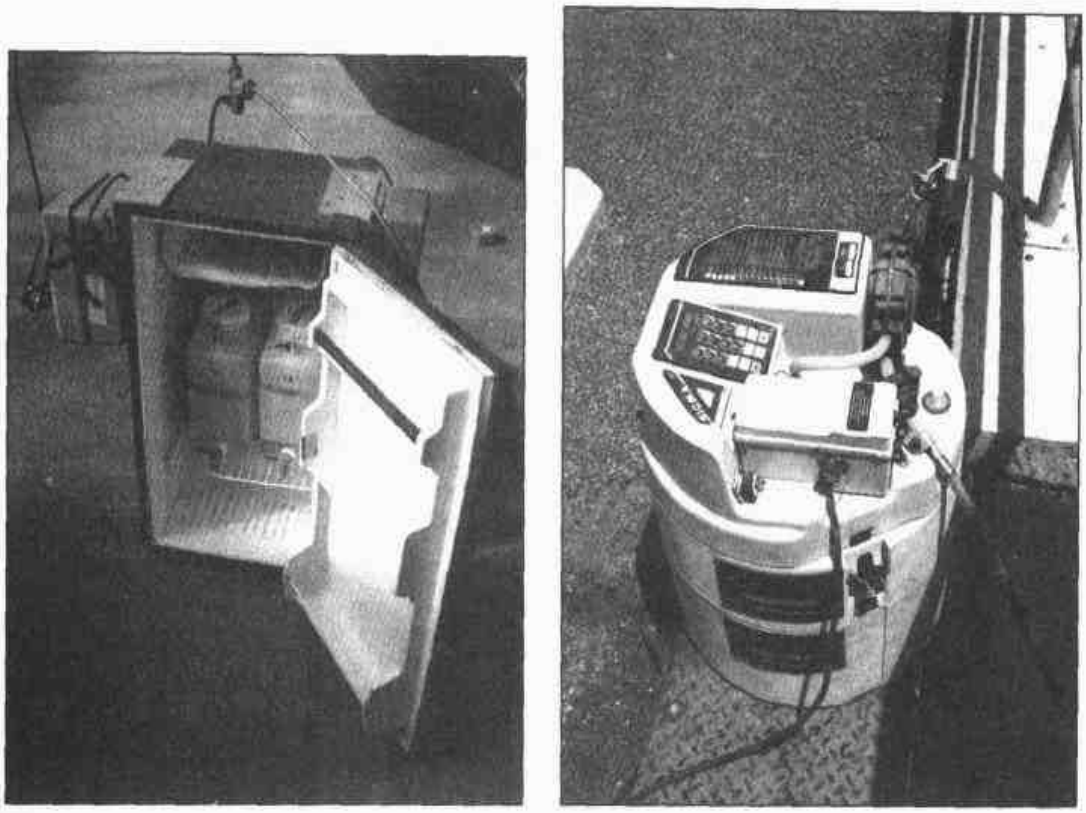
The most common method of determining the peaking factor is from the analysis of flowrate data. Where flowrate records are available, at least 3 years of data should be analyzed to define the peak to average day peaking factor.

3–5 ANALYSIS OF CONSTITUENT MASS LOADING DATA

The analysis of wastewater data involves the determination of the flowrate and mass loading variations. The analysis may involve determining the concentrations of specific constituents, mass loadings (flowrate times concentration), or sustained mass loadings, loadings that occur over a defined period of time.

From the standpoint of treatment processes, one of the most serious deficiencies results when the design of a treatment plant is based on average flowrates and average BOD and TSS loadings, with little or no recognition of peak conditions. In many communities, peak influent flowrates and BOD and TSS loadings can reach two or more times average values. It must also be emphasized that, in nearly all cases, peak flowrates and BOD and TSS mass-loading rates do not occur at the same time. Analysis of current records is the best method of arriving at appropriate peak and sustained mass loadings.

The principal factors responsible for loading variations are (1) the established habits of community residents, which cause short-term (hourly, daily, and weekly) variations; (2) seasonal conditions, which usually cause longer-term variations; and (3) industrial activities, which cause both long- and short-term variations.



Wastewater Constituent Concentrations

The physical, chemical, and biological characteristics of wastewater vary throughout the day. An adequate determination of the waste characteristics will result only if the sample tested is representative. Typically, composite samples made up of portions of samples collected at regular intervals during a day are used (see Fig. 3–5). The amount of liquid used from each sample is proportional to the rate of flow at the time the sample was collected. Adequate characterization of wastewater is of fundamental importance in the design of treatment and disposal processes.

Quantity of Waste Discharged by Individuals in the United States. Typical data on the total quantities of waste discharged per person per day (dry weight basis) from individual residences are reported in Table 3–12. The data presented in Table 3–12 have been gathered from numerous sources (primarily the United States) by

Figure 3–5

Samplers used to collect wastewater samples for analysis: (*a*) refrigerated unit used to collect daily composite samples and (*b*) portable sampler used to collect individual hourly samples throughout a day at different locations. The individual samples are composited to obtain flow-weighted mass loadings.

(*a*) (*b*)

[a] Adapted from Crites and Tchobanoglous (1998).
[b] TKN is total Kjeldahl nitrogen.

Crites and Tchobanoglous, 1998. The total number of pathogenic organisms discharged will depend on whether an individual is ill and is shedding pathogens. If one or more members of a family are ill and shedding pathogens, the number of measured organisms can increase by several orders of magnitude. The corresponding constituent concentrations, assuming the quantities of waste given in Table 3–12 were diluted in 190 and 460 L (50 and 120 gal) of water, are reported in Table 3–13. As noted in Table 3–13, the typical mass amounts of waste discharged (column 3) are based on the assumption that 25 percent of the homes are equipped with kitchen food-waste grinders. The concentrations are based on flowrates ranging from 190 L/capita·d (50 gal/capita·d) to 460 L/capita·d (120 gal/capita·d). The lower flowrate is typical for rural areas; the higher flowrate is typical for urban areas and is recognized by the U.S. EPA as not containing excessive inflow/infiltration (*Federal Register*, 1989).

Quantity of Waste Discharged by Individuals in Countries Outside of the United States. The amounts of waste discharged by individuals in other countries can vary significantly due to cultural and socioeconomic differences. Constituent data for nine other countries as compared to the United States are reported in Table 3–14. Water use by individuals also differs significantly in other countries; in most cases the quantities used are significantly less. Consequently, the strength of the wastewater may be much higher than found in U.S. practice and can significantly affect wastewater treatability. In some cases, the wastewater composition may be high in organic content but low in alkalinity and thus cannot be nitrified fully. Concentrations of TSS and BOD for another culture compared to the United States are illustrated in Example 3–6.

Table 3–13
Typical unit loading factors and expected wastewater constituent concentrations from individual residences in the United States[a]

Constituent	Unit	Typical value[b]	Concentration, mg/L: Volume, L/capita·d (gal/capita·d) 190 (50)	460 (120)

[b] West Bank and Gaza Strip.
[c] From Table 3–11.

EXAMPLE 3–6 Estimate Waste Constituent Concentration Using data from Table 3–14, determine the BOD, TSS, and ammonia nitrogen concentrations for the West Bank and the Gaza Strip assuming the water supply is intermittent and the wastewater flowrate is 60 L/capita·d.

Solution

1. From Table 3–14, use the following average constituent contributions:
   a. BOD = 50 g/capita·d
   b. TSS = 60 g/capita·d
   c. NH_3-N = 3 g/capita·d
2. Compute BOD concentration

$$\text{BOD} = \left(\frac{50\ \text{g/capita·d}}{60\ \text{L/capita·d}}\right)\left(\frac{10^3\ \text{L}}{\text{m}^3}\right) = 833\ \text{g/m}^3$$

3. Compute TSS concentration

$$\text{TSS} = \left(\frac{60\ \text{g/capita·d}}{60\ \text{L/capita·d}}\right)\left(\frac{10^3\ \text{L}}{\text{m}^3}\right) = 1000\ \text{g/m}^3$$

4. Compute the NH_3-N concentration

$$NH_3\text{-}N = \left[\frac{(3\ g/capita{\cdot}d)}{(60\ L/capita{\cdot}d)}\right]\left(\frac{10^3\ L}{m^3}\right) = 50\ g/m^3$$

Comment In many parts of the world where water usage is low, constituent concentrations for BOD and TSS may range up to 1000 g/m^3 (mg/L). In the above example, the concentrations of BOD and TSS are nearly 2 to 4 times the BOD and TSS concentrations typically found in the United States (see Table 3–13). Ammonia nitrogen (NH_3-N) concentrations may also be higher, perhaps on the order of two times or more of those in the United States.

Composition of Wastewater in Collection Systems. Typical data on the composition of untreated domestic wastewater as found in wastewater-collection systems (in the United States) are reported in Table 3–15. The data presented in Table 3–15 for medium-strength wastewater are based on an average flow of 460 L/capita·d (120 gal/capita·d) and include constituents added by commercial, institutional, and industrial sources. Typical concentrations for low-strength and high-strength wastewater, which reflect different amounts of infiltration, are also given. Because there is no "typical" wastewater, it must be emphasized that the typical data presented in Table 3–15 *should only be used as a guide.* The constituent concentrations presented in Table 3–13, developed from the waste amounts given in Table 3–12, can also be compared to the values given in Table 3–15. It is interesting to note that the values given in Table 3–13 correspond closely to the values given in Table 3–15 for typical wastewater.

Mineral Increase Resulting from Water Use. Data on the increase in the mineral content of wastewater resulting from water use, and the variation of the increase within a collection system, are especially important in evaluating the reuse potential of wastewater. Typical data on the incremental increase in mineral content that can be expected in municipal wastewater resulting from domestic use are reported in Table 3–16. Increases in the mineral content of wastewater may be due in part to addition of highly mineralized water from private wells and groundwater and from industrial use. Domestic and industrial water softeners also contribute significantly to the increase in mineral content and, in some areas, may represent the major source. Occasionally, water added from private wells and groundwater infiltration will (because of its high quality) serve to dilute the mineral concentration in wastewater.

Variations in Constituent Concentrations

Several types of constituent concentration variations can occur depending upon the characteristics of the contributors to the wastewater-collection system. Types of variations are discussed below.

Short-Term Variation in Constituent Values. Constituent concentration variations may change significantly during the course of a day. An example of typical

Table 3-15

Silica (SiO_2)	2–10
Total alkalinity (as $CaCO_3$)	60–120
Total dissolved solids (TDS)	150–380

[a] Based on 460 L/capita·d (120 gal/capita·d).
[b] Values do not include commercial and industrial additions.
[c] Excluding the addition from domestic water softeners.
Note: mg/L = g/m^3.

variations in domestic wastewater strength is shown on Fig. 3-6. The BOD variation generally follows the flow. The peak BOD (organic matter) concentration often occurs in the evening.

Seasonal Variation in Constituent Values. For domestic flow only, and neglecting the effects of infiltration, the unit (per capita) loadings and the strength of the wastewater from most seasonal sources, such as resorts, will remain about the same on a daily basis throughout the year even though the total flowrate varies. The total mass of BOD and TSS of the wastewater, however, will increase directly with the population served.

Infiltration/inflow, as discussed earlier in this chapter, is another source of water flow into the collection system. In most cases, the presence of this extraneous water tends to decrease the concentrations of BOD and TSS, depending on the characteristics of the water entering the sewer. In some cases, concentrations of some inorganic constituents may actually increase where the groundwater contains high levels of dissolved constituents.

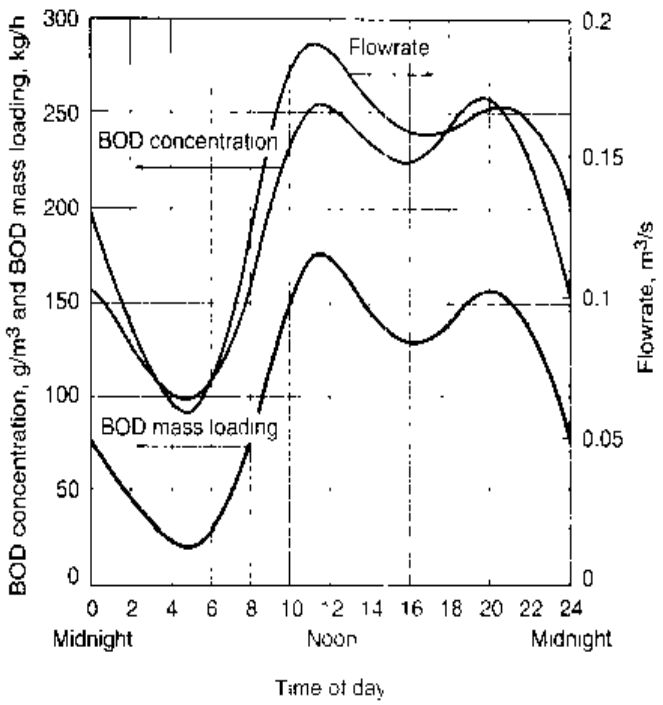

Figure 3–6

Typical hourly variations in flow and strength of domestic wastewater.

Variations in Industrial Wastewater. The composition of wastewater from industrial operations varies widely depending on the function and activity of the particular industry. Examples of the constituent concentration variability are illustrated in Table 3–17. From these examples, it can be observed that flow values and water quality measurements may vary by several orders of magnitude over a period of a year. Because of this variation, it is often difficult to define "typical operating conditions" for industrial activities.

The concentrations of both BOD and TSS in industrial wastewater can vary significantly throughout the day. For example, the BOD and TSS concentrations contributed from vegetable-processing facilities during the noon wash-up period may far exceed those contributed during working hours. Problems with high short-term loadings most commonly occur in small treatment plants that have limited reserve capacity to handle "shock loadings." The seasonal impact of industrial wastes such as canneries can cause both the flow and BOD loadings to increase from two to five times average conditions.

If industrial wastes are to be discharged to the collection system for treatment in a municipal wastewater facility, it will be necessary to characterize the wastes adequately to identify the ranges in constituent concentrations and mass loadings. Such characterization is also needed to determine if pretreatment is required before the waste is permitted to be discharged into the collection system. If pretreatment is needed, the effluent from the pretreatment facilities must also be characterized. Further, any proposed future process changes should also be assessed to determine what effects they might have on the wastes to be discharged. Where data are not available, every effort should be made to obtain information from similar facilities. With sufficient characterization of the wastewater from industrial discharges, suitable pretreatment facilities can be provided and plant upsets can be avoided.

Table 3–17
Range of effluent constituent concentrations for two industrial activities

Constituent	Unit	Wool textile mill[a]		Tomato cannery[b]	
		Annual average	Daily maximum	Peak season[c]	Off season[d]
Flowrate	m^3/d	–	–	4164–22,300	1140–6400

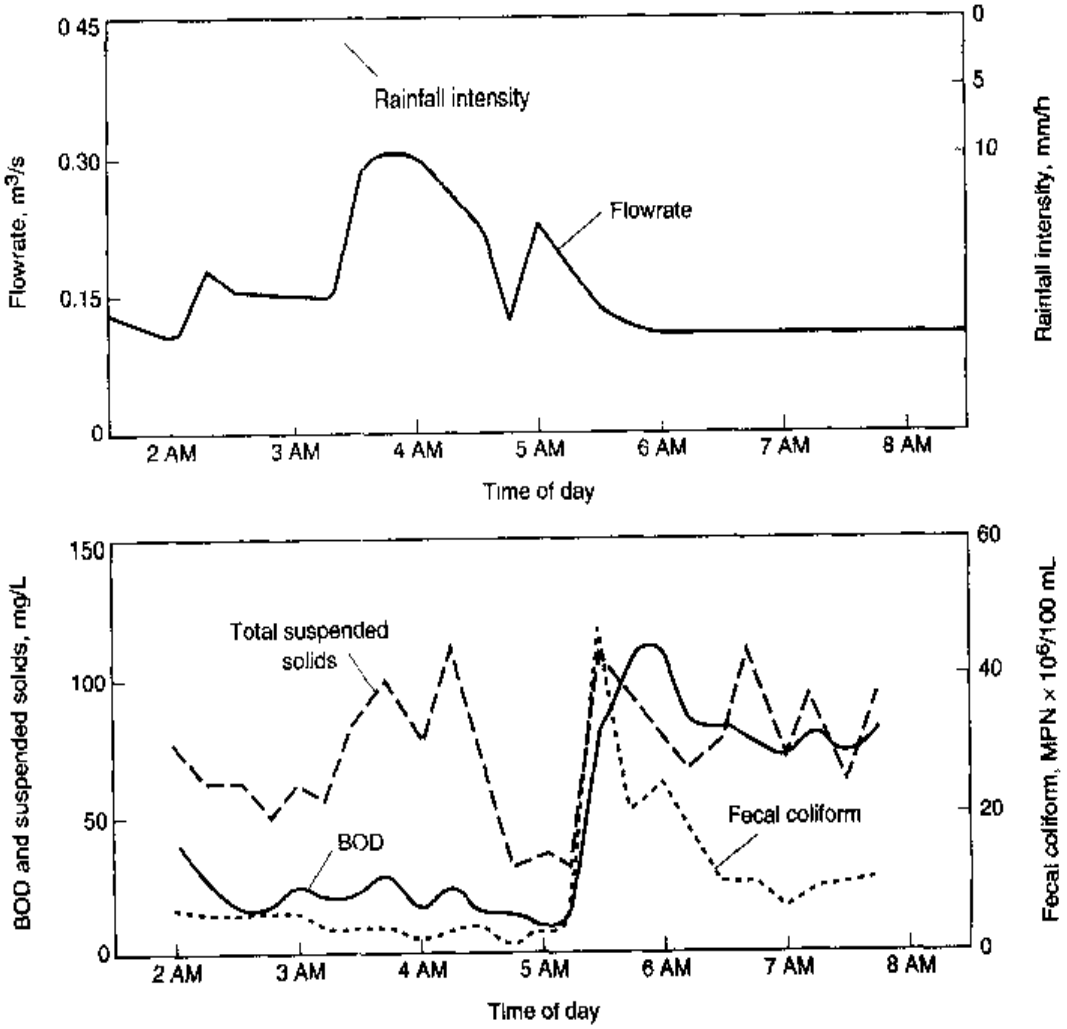
[c] Peak season is from early July to late September, when fresh-harvest tomatoes are canned. Treatment consists of screening and brief sedimentation.

[d] Off season is from November to June, when canned tomatoes are remanufactured into tomato paste, tomato sauce, and other tomato products (e.g., salsa, ketchup, spaghetti sauce). Treatment typically consists of screening, aeration, and sedimentation



Note: $m^3/d \times 0.264 \times 10^{-3} = Mgal/d$.

Variations in Constituent Values in Combined Collection Systems. Flowrates, constituent concentrations, and mass loads emanating from combined collection systems can vary widely. Typical factors influencing the characteristics of wastewater from combined collection systems are shown in Table 3–18. Example variations of BOD, TSS, and fecal coliform measured in a combined system are shown on Fig. 3–7, during and after a storm event. As shown, the BOD and fecal coliform bacteria concentrations are low during the storm when runoff flows are high. After the storm, when runoff subsides and the flow consists primarily of wastewater, concentrations rise significantly. When this rise occurs, it can be concluded that the BOD and fecal coliform concentrations in the stormwater are significantly lower than in the wastewater component. Unlike BOD and fecal coliform bacteria, TSS concentrations rise slightly during the storm, and remain unchanged after the storm, indicating that TSS concentrations from stormwater runoff and wastewater are similar. The slight rise in the TSS

Table 3–18
Typical factors influencing the characteristics of combined wastewater

Parameter	Quantity-related factors	Quality-related factors
Precipitation	Rainfall depth and volume Storm intensity Storm duration	Regional atmospheric quality
Wastewater sources	Flowrate and variability Type of contributing sources (residential, commercial, etc.)	Type of contributing sources
Drainage basin characteristics	Size, time of concentration Land-use type Impervious area Soil characteristics Runoff control practices	Pollutant buildup and wash-off Watershed management practices
Sewer system, interceptor design and condition	Pipe size, slope, and shape Quantity of infiltration Surcharging or backwater conditions Type of flow regulation or diversion Capacity reduction from sediment buildup	Chemical and biological transformations Quality of infiltration Sediment load resuspended from collection system

Figure 3–7
Typical variations of flowrate, BOD, TSS, and fecal coliform in a combined collection system during a storm event.

concentration during the peak flow may be due to a phenomenon common to many combined sewer systems known as the "first flush." The first flush has often been observed following the initial phase of a rainfall event in which much of the accumulated surface contaminants are washed into the combined system. In combined collection systems, the increased flows may be capable of resuspending material deposited previously during low-flow periods. Together, the resuspended material and contaminants washed off surfaces result in high contaminant concentrations. Factors known to contribute to the magnitude and frequency of the first-flush effect include combined sewer slopes; street and catch basin cleaning frequency and design; rainfall intensity and duration; and surface buildup of debris and contaminants.

Wastewater from combined collection systems usually contains more inorganic matter than wastewater from sanitary collection systems because of the larger quantities of storm drainage that enter the combined sewer system. Characteristics of combined wastewater and stormwater as compared to municipal wastewater are shown in Table 3–19.

Table 3–19
Comparison of characteristics of combined wastewater with other sources

Parameter	Unit	Range of parameter concentrations			
		Rainfall[a]	Stormwater runoff[b]	Combined wastewater[c]	Municipal wastewater[d]
Total suspended solids, TSS	mg/L	<1	67–101	270–550	120–370

Flow-Weighted Constituent Concentrations

Flow-weighted constituent concentrations are obtained by multiplying the flow (typically hourly values over a 24-h period) times the corresponding constituent concentration, summing the results, and dividing by the summation of the flows as given by Eq. (3–12).

$$C_w = \frac{\sum_{i=1}^{n} C_i Q_i}{\sum_{i=1}^{n} Q_i} \tag{3–12}$$

where C_w = flow-weighted average concentration of the constituent
n = number of observations
C_i = average concentration of the constituent during ith time period
Q_i = average flowrate during ith time period

Whenever possible, flow-weighted constituent concentrations should be used because they are a more accurate representation of the actual wastewater strength that must be treated. Determination of the simple arithmetic average and flow-weighted constituent concentrations is illustrated in Example 3–7.

EXAMPLE 3–7 Calculation of Flow-Weighted BOD and TSS Concentrations Compute the flow-weighted BOD and TSS values using the data provided on Fig. 3–6 for a community of about 5000 persons. Compare the flow-weighted values to the simple arithmetic averages. What is the significance of the difference?

Solution

1. Create a spreadsheet for calculating the flow-weighted values. Divide the BOD, TSS, and flow curves into 24 one-hour periods. Enter the time intervals (e.g., 12 to 1 A.M.) in column 1.
2. For each time period, calculate the average BOD value during the interval. For example, the average BOD value during the first interval (12 to 1 A.M.) is

   Value at beginning of interval = 155 g/m^3

   Value at end of interval = 150 g/m^3

   $$\text{Average BOD} = \frac{155 + 150}{2} = 152.5 \text{ g/m}^3$$

   The average BOD values for each successive time interval are entered in column 2.
3. Enter the average values for TSS and flow in columns 3 and 4, respectively.
4. For each time period, multiply the average BOD value (column 2) times the average flowrate (column 4), and enter the results in column 5.
5. For each time period, multiply the average TSS (column 3) value by the average flowrate (column 4), and enter the results in column 6.

6. Calculate the sum and simple arithmetic average for columns 2 through 6.
7. Divide the sum of the values in columns 5 and 6 (BOD × flow and TSS × flow, respectively) by the sum of the values in column 4 (flow) to obtain the flow-weighted average for BOD and TSS. The resulting values are given in the last two lines of the spreadsheet.

Time interval (1)	BOD, g/m^3 (2)	TSS, g/m^3 (3)	Flowrate Q, m^3/s (4)	BOD × Q, kg/d (5) = (2) × (4) × 86.4[a]	TSS × Q, kg/d (6) = (3) × (4) × 86.4[a]
12–1 A.M.	152.5	157.5	0.12	1,581	1,633
1–2	135.0	140.0	0.10	1,166	1,210
2–3	115.0	122.5	0.08	795	847
3–4	102.5	112.5	0.0625	554	608
4–5	92.5	102.5	0.056	448	496

8–9	182.5	195.0	0.1475	2,326	2,485
9–10	226.5	244.0	0.1835	3,591	3,868
10–11	251.5	269.0	0.1895	4,118	4,404
11–12	256.5	279.0	0.1965	4,355	4,737
12–1 P.M.	246.5	270.0	0.185	3,940	4,316
1–2	232.0	250.0	0.1725	3,458	3,726
2–3	222.0	237.5	0.165	3,165	3,386
3–4	214.5	226.0	0.161	2,984	3,144
4–5	214.0	212.5	0.157	2,903	2,883
5–6	219.5	202.5	0.158	2,996	2,764
6–7	232.0	199.0	0.162	3,247	2,785
7–8	262.5	209.0	0.1675	3,799	3,025
8–9	290.0	218.0	0.173	4,335	3,258
9–10	265.0	206.5	0.1675	3,855	2,988
10–11	209.5	192.5	0.1575	2,851	2,620
11–12	174.0	174.0	0.1425	2,142	2,142
Totals	4651.0	4554.5	3.3455	61,148	59,753
Average values	193.8	189.8	0.1393		
Flow-weighted concentration values				211.5	206.7

[a]Conversion factor: $g/m^3 \times m^3/s \times 86{,}400\ s/d \times 1\ kg/10^3\ g = 86.4 \times C \times Q = kg/d$.

Comment When comparing the computation of a simple average to a flow-weighted value, the differences can be significant. In this example, if simple averages were used, the BOD loading would have been understated by 17.7 mg/L (9.1 percent), and the TSS loading by 16.9 mg/L (8.9 percent). If simple averages had been used in establishing process loading values in this case, the treatment facilities would be underdesigned by 9 percent.

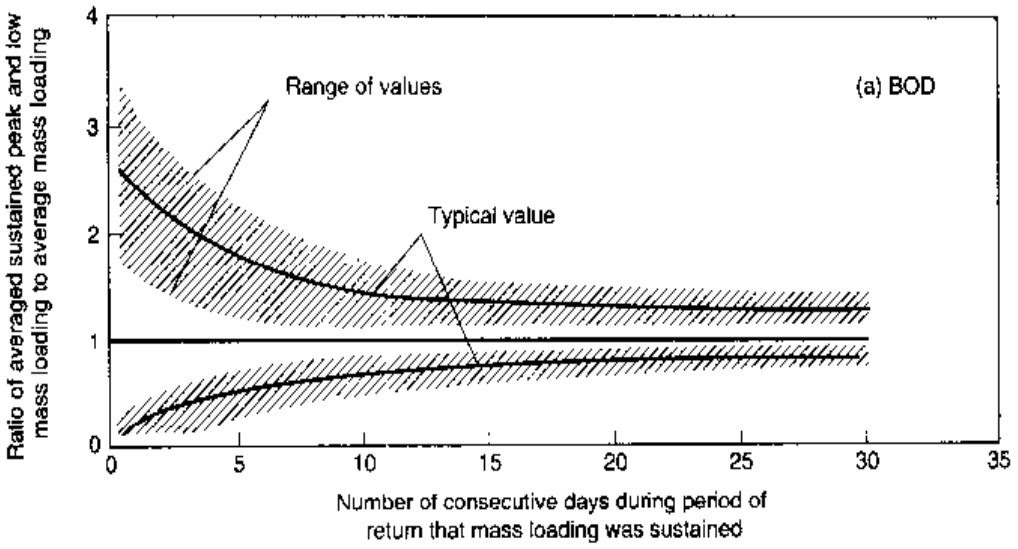
Calculation of Mass Loadings

Constituent mass loadings are usually expressed in kilograms per day and may be computed using Eq. (3–13*a*) when the flowrate is expressed in cubic meters per day, or Eq. (3–13*b*) when the flowrate is expressed in million gallons per day. Note that in the SI system of units, the concentration expressed in milligrams per liter is equivalent to grams per cubic meter.

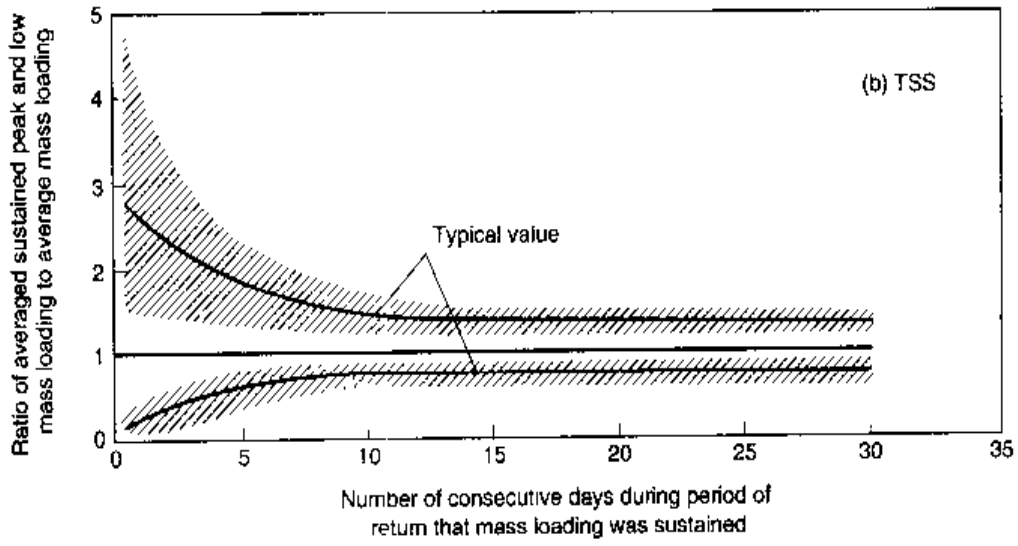
$$\text{Mass loading, kg/d} = \frac{(\text{concentration, g/m}^3)(\text{flowrate, m}^3\text{/d})}{(10^3\text{g/kg})} \qquad (3\text{–}13a)$$

$$\text{Mass loading, lb/d} = (\text{concentration, mg/L})(\text{flowrate, Mgal/d})\left[\frac{8.34\text{ lb}}{\text{Mgal}\cdot(\text{mg/L})}\right] \qquad (3\text{–}13b)$$

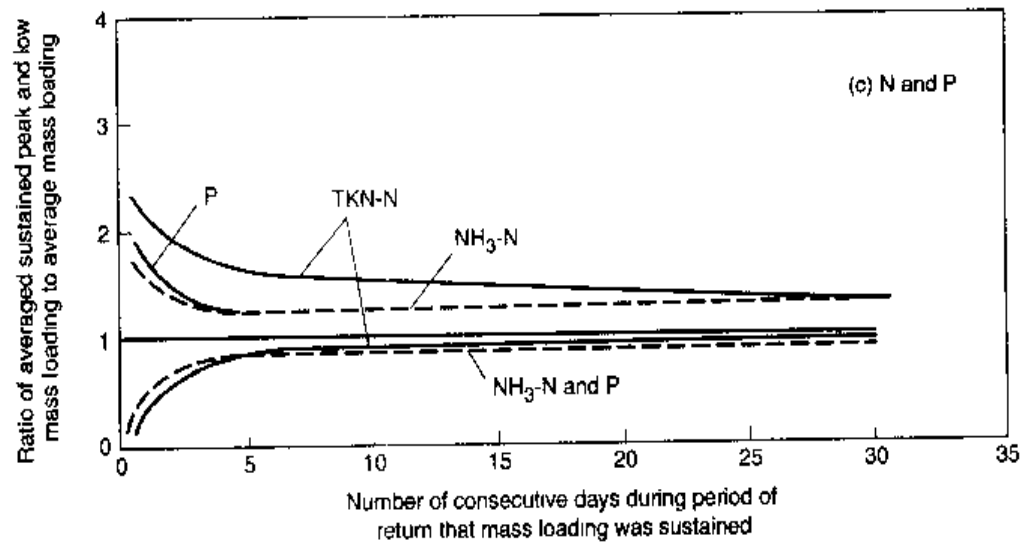
To design treatment processes to function properly under varying loading conditions, data must be available for the sustained peak mass loadings of constituents that are to be expected. In the past, such information has seldom been available. When the data are not available, curves similar to those shown on Fig. 3–8 can be used. The curves for BOD, TSS, TKN (total Kjeldahl nitrogen), NH_3 (ammonia), and phosphorus were derived from an analysis of the records of over 50 treatment plants throughout the country. It should be noted that significant variations will be observed from plant to plant, depending on the size of the system, the percentage of combined wastewater, the size and slope of the interceptors, and the types of wastewater contributors.



The procedure used to develop the mass loading curves shown on Fig. 3–10 is as follows. First, the average mass loading is determined for the period of record. Second, the records are reviewed for the highest and lowest sustained one-day mass loading. These values are divided by the average mass loading and the numbers are plotted. Third, the same procedures are followed for two consecutive days, three consecutive days, etc., sustained loadings until ratio values are found for the period of interest (usually 10 to 30 days).



The daily mass loading rates for the various plants were developed using hourly data and the following expression:



$$\text{Daily mass loading, kg/d} = \sum_{i=1}^{24} \frac{(\text{concentration, g/m}^3)(\text{flowrate, m}^3\text{/d})}{(10^3\text{ g/kg})} \qquad (3\text{–}14a)$$

Figure 3–8

Typical information on the ratio of averaged peak and low-constituent mass loadings to average mass loadings for: (a) BOD, (b) TSS, and (c) nitrogen and phosphorus.

Daily mass loading, lb/d

$$= \sum_{i=1}^{24} (\text{concentration, mg/L})(\text{flowrate, Mgal/d})\left[\frac{8.34 \text{ lb}}{\text{Mgal}\cdot(\text{mg/L})}\right] \quad (3\text{–}14b)$$

The development of a sustained peak mass loading curve is illustrated in Example 3–8.

EXAMPLE 3–8 Development of BOD Sustained Mass Loading Values Develop a sustained BOD peak mass loading curve for a treatment plant with a design flowrate of 1 m^3/s (22.8 Mgal/d). Assume that the long term daily average BOD concentration is 200 g/m^3.

Solution

1. Compute the daily mass loading value for BOD.

   Daily BOD mass loading, kg/d

   $$= \frac{(200 \text{ g/m}^3)(1 \text{ m}^3/\text{s})(86{,}400 \text{ s/d})}{(10^3 \text{ g/kg})} = 17{,}280 \text{ kg/d}$$

2. Set up a computation table for the development of the necessary information for the peak sustained BOD mass loading curve (see following table).
3. Obtain peaking factors for the sustained peak BOD loading rate from Fig. 3–8*a*, and determine the sustained mass loading rates for various time periods [see table, cols. (1), (2), and (3)].
4. Develop data for the sustained mass loading curve and prepare a plot of the resulting data (see following figure).

Length of sustained peak, d (1)	Peaking factor[a] (2)	Peak BOD mass loading, kg/d (3)	Total mass loading, kg[b] (4)
1	2.4	41,472	41,472
2	2.1	36,288	72,576
3	1.9	32,832	98,496
4	1.8	31,104	124,416
5	1.7	29,376	146,880
10	1.4	24,192	241,920
15	1.3	22,464	336,960
20	1.25	21,600	432,000
30	1.21	19,872	596,160
365	1.0	17,280	

[a] From Fig. 3–8*a*.

[b] Col. 1 × col. 3 = col. 4.

Comment The interpretation of the curve plotted for this example is as follows. If the sustained peak loading period were to last for 10 days, the total amount of BOD that would be received at a treatment facility during the 10-day period would be 241,695 kg. The corresponding amounts for sustained peak periods of 1 and 2 days would be 41,401 and 72,451 kg, respectively. Computations for an example of this type can be facilitated by using a personal computer spreadsheet program.

Effect of Mass Loading Variability on Treatment Plant Performance

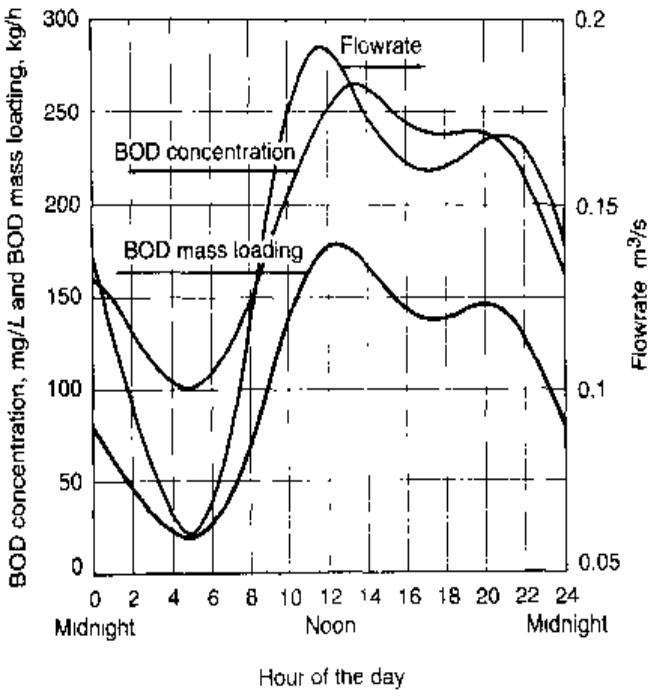
During the course of a day, the mass loading that is received by the treatment plant can vary widely. An example of a diurnal mass loading curve is illustrated on Fig. 3–9. The variation in loading rates and the compounding effects during the high-flow and concentration periods is illustrated clearly on Fig. 3–9. The variations are more pronounced in small collection systems where the collection system storage capacity does not provide a significant dampening effect. The impact of these load variations is seen most dramatically in the effects on biological treatment operating conditions. The maximum hourly BOD loading may vary as much as 3 to 4 times the minimum hourly BOD load in a 24-h period. Over longer periods of time, the mass loadings can also vary widely (see Fig. 3–10). These types of variations have to be accounted for in the design of the biological treatment system. In extreme cases, flow equalization may be required.

3–6 SELECTION OF DESIGN FLOWRATES AND MASS LOADINGS

The rated capacity of wastewater-treatment plants is normally based on the average annual daily flowrate at the design year plus an allowance for future growth. As a practical matter, however, wastewater-treatment plants have to be designed to meet a number of conditions that are influenced by flowrates, wastewater characteristics, and constituent

Figure 3–9

Illustration of diurnal wastewater flow, BOD, and mass loading variability.



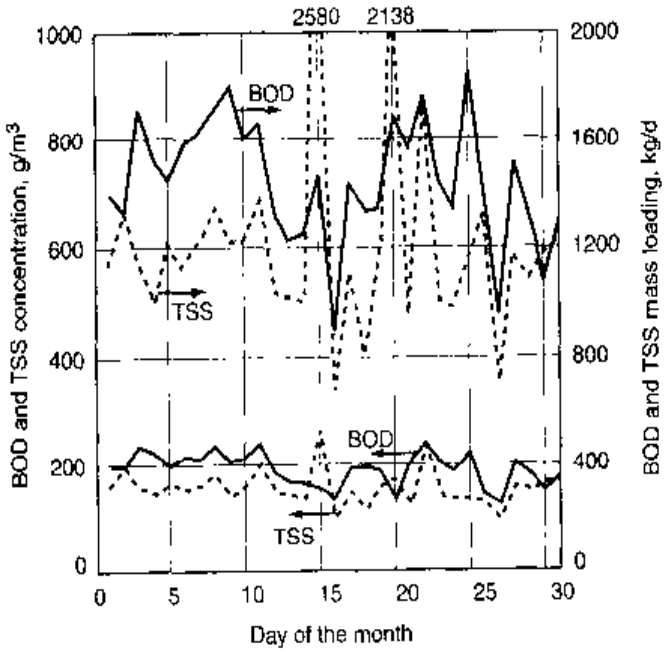


Figure 3–10

Example variations of TSS and BOD concentrations and mass loadings over a monthly period.

concentrations, and a combination of both (mass loading). Conditions that must be considered include peak and minimum hydraulic flowrates and the maximum, minimum, and sustained process constituent mass loading rates. Additionally, periods of initial operation and low flows and loads must be taken into consideration in design. The importance of wastewater flowrates and mass loadings in process design and operation is considered in this section.

Typical flowrate and mass loading factors that are important in the design and operation of wastewater-treatment facilities are described in Table 3–20. The overall

Table 3–20
Typical flowrate and mass loading factors used for the design and operation of wastewater-treatment facilities[a]

Factor	Purpose for design and operation
Flowrate	
Average daily flow	Development of flowrate ratios and for estimating pumping and chemical costs
Minimum hour	Sizing turndown of pumping facilities and determining low range of plant flowmeter
Minimum day	Sizing of influent channels to control solids deposition; sizing effluent recycle requirements for trickling filters
Minimum month	Selection of minimum number of operating units required during low-flow periods; scheduling shutdown for maintenance
Peak hour	Sizing of pumping facilities and conduits; sizing of physical unit operations: grit chambers, sedimentation tanks, and filters; sizing chlorine contact tanks. Also important in developing process control strategies for managing high flows
Maximum day	Sizing of equalization basins, chlorine contact tanks, sludge pumping system
Maximum month	Record keeping and reporting; sizing of chemical storage facilities
Mass loading	
Minimum month	Process turndown requirements
Minimum day	Sizing of trickling filter recycle rates
Maximum day	Sizing of selected process units
Maximum month	Sizing of sludge storage facilities; sizing of composting requirements
15-day maximum	Sizing anaerobic and aerobic digesters
Sustained loading	Sizing of selected process units and ancillary process equipment

[a] Adapted in part from Metcalf & Eddy (1991) and Crites and Tchobanoglous (1998).

objective of wastewater treatment is to provide a wastewater-treatment system that is capable of coping with a wide range of probable wastewater conditions while complying with the overall performance requirements.

Design Flowrates

The development and forecasting of flowrates is necessary to determine the design capacity as well as the hydraulic requirements of the treatment system. Flowrates need to be developed both for the initial period of operation and for the future (design) period. Consideration of the flowrates during the early years of operation is often overlooked, and oversizing of equipment and inefficient operation can result. The focus of the following discussion is on the development of various design flowrates.

Rationale for the Selection of Flowrates. The rationale for selecting flowrates is based on hydraulic and process considerations. As stated, the process units and hydraulic conduits must be sized to accommodate the anticipated peak flowrates that will pass through the treatment plant. Provisions have to be made to ensure bypassing of wastewater does not occur either in the collection system or at the treatment plant. Many of the process units are designed based on detention time or overflow rate (flowrate per unit of surface area) to achieve the desired removal rates of BOD and TSS. Because the performance of these units can be affected significantly by varying flowrate conditions and mass loadings, minimum and peak flowrates must be considered in design.

Forecasting Flowrates. In determining the design flowrate, elements to be considered are (1) the existing base flows; (2) estimated future flows for residential, commercial, institutional, and industrial sources; and (3) nonexcessive infiltration/inflow. Existing base flows equal actual metered flowrates minus excessive infiltration/inflow (defined as infiltration/inflow that can be controlled by cost-effective improvements to the collection system).

A yardstick by which total dry-weather base flow can be measured is 460 L/capita·d (120 gal/capita·d), established by the U.S. EPA as a historical average where infiltration is not excessive. The base flow includes 270 L/capita·d (70 gal/capita·d) for domestic flows, 40 L/capita·d (10 gal/capita·d) for commercial and small industrial flows, and 150 L/capita·d (40 gal/capita·d) for infiltration (*Federal Register,* 1989).

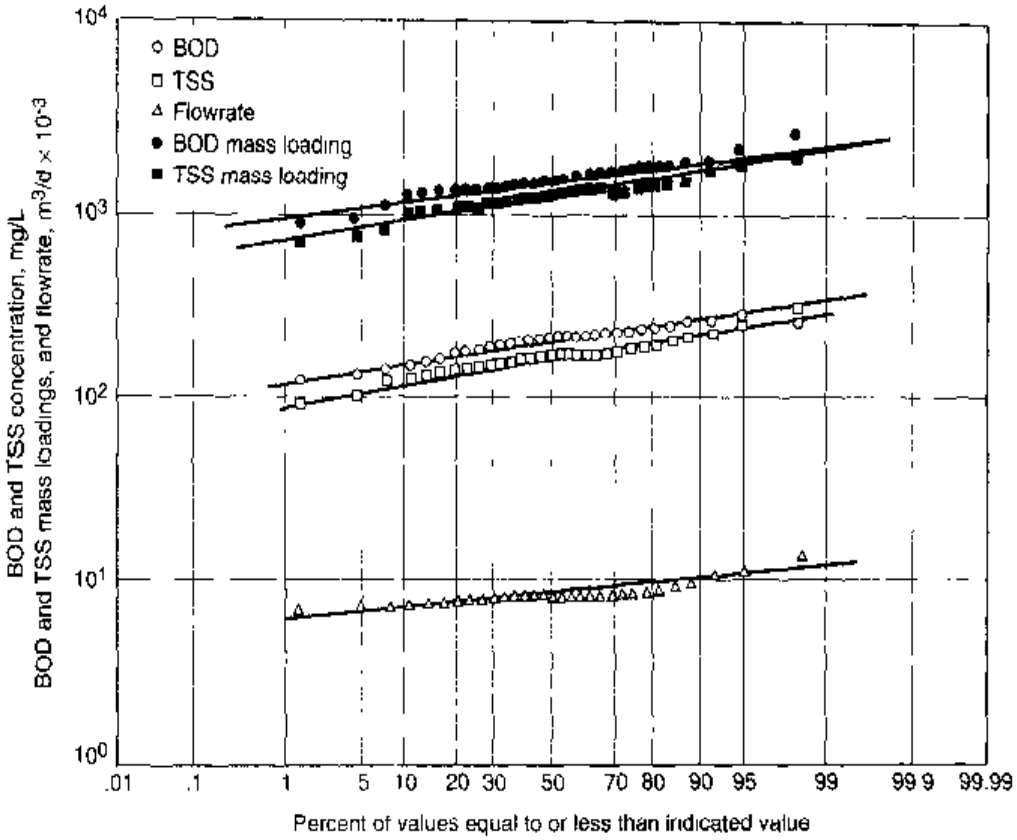
A useful technique in forecasting flowrates is probability analysis, discussed earlier in this chapter. Where flowrate data are available, preferably for at least 2 years, future flowrates for design can be predicted with a reasonable certainty. An example of a probability analysis of flowrates, as well as BOD and TSS concentrations and mass loadings, is shown on Fig. 3–11. The probability analysis can be used to estimate occurrences of peak flows and loads, and to establish a basis for selecting design flows and loads. For example, a maximum 1-day occurrence can be determined based on a 99.7 percent probability; the value will not be equaled or exceeded in the time period analyzed. A probability value, such as the 95 percentile, can also be established for forecasting the design loadings to meet permit requirements.

Minimum Flowrates. As noted in Table 3–20, low flowrates are also of concern in treatment-plant design, particularly during the initial years of operation when the plant is operating well below the design capacity, and in designing pumping stations. In cases where very low nighttime flow is expected, provisions for recycling treated effluent may have to be included to sustain the process (e.g., biological treatment processes such as trickling filters and to maintain optimal flowrates through ultraviolet disinfection systems). In the absence of measured flowrate data, minimum daily flowrates may be assumed to range from 30 to 70 percent of average flowrates for medium- to large-size communities, respectively (WEF, 1998).

Sustained Flowrates. Sustained flowrates are those that are equaled or exceeded for a specified number of consecutive days based on annual operating data. Data for sustained flowrates may be used in sizing equalization basins and other plant

Figure 3–11

Typical probability plots for flowrate, BOD, and TSS.



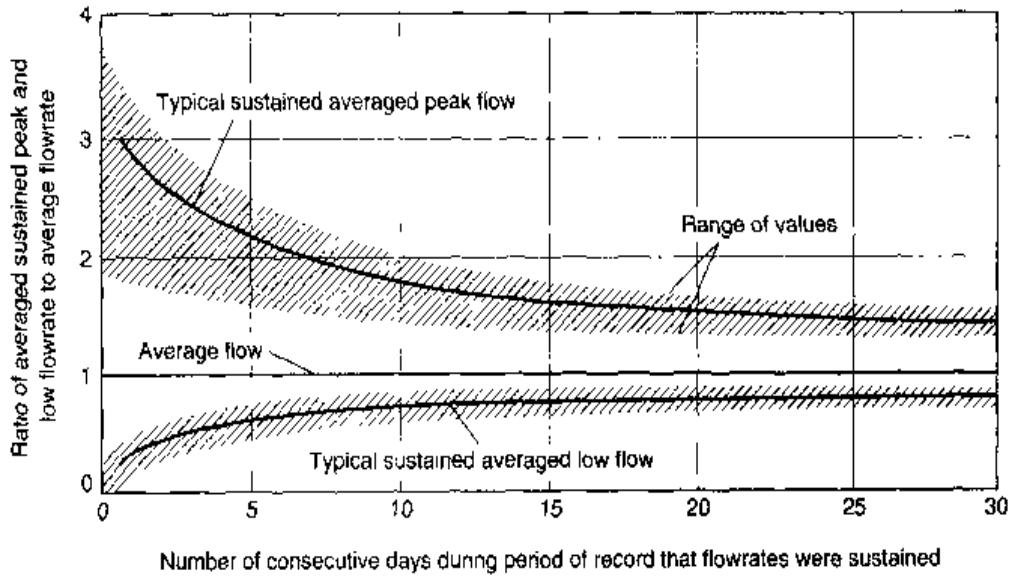


Figure 3–12

Typical ratios of averaged sustained peak and low daily flowrates to average annual daily flowrates for time periods up to 30 days.

hydraulic components. An example plot of sustained and low flowrates is shown on Fig. 3–12. When developing plots similar to Fig. 3–12, the longest available period should be used.

Peak Flowrate Factors. The flowrate peaking factors (the ratio of peak flowrate to average flowrate) most frequently used in design are those for peak hour and maximum day (see Table 3–20). Peak hourly flowrates are used to size the hydraulic conveyance

system and other facilities such as sedimentation tanks and chlorine contact tanks where little volume is available for flow dampening. Other peaking factors such as maximum week or maximum month may be used for treatment facilities such as pond systems that have long detention times or for sizing solids and biosolids processing facilities that also have long detention times or ample storage. Peaking factors may be developed from flowrate records or based on published curves or data from similar communities.

The most common method of determining peaking factors is from the analysis of flowrate data (see Fig. 3–1). Where flowrate records are available, at least 2 years of data should be analyzed to develop the peak to average flowrate factors. These factors may then be applied to estimated future average flowrates, adjusted for any anticipated future special conditions. Where commercial, institutional, or industrial wastewaters are expected to make up a significant portion of the average flowrates (say 25 percent or more of all flows, exclusive of infiltration), peaking factors for the various categories of flow should be estimated separately. Peak flows from each category most probably will not occur simultaneously; therefore, some adjustment may have to be made to the total peak flow to prevent overestimating the peaking conditions. If possible, peaking factors for industrial wastewater should be estimated on the basis of average water use, number of shifts worked, and pertinent details of plant operations.

If flow measurement records are inadequate to establish peaking factors, published information may be used. Many sources for peaking factor data are available including state agencies, cities and special districts that provide wastewater collection and treatment services, and professional publications from organizations such as the Water Environment Federation and the American Society of Civil Engineers (see WEF, 1998). An example peaking factor curve is given on Fig. 3–13, and it may be used for estimating peak hourly flowrates from domestic sources. The curve given on Fig. 3–13 was developed from analyses of the records of numerous communities throughout the United States. The curve is based on average residential flowrates, exclusive of infiltration/inflow, and includes small amounts of commercial flows and industrial wastes.

In developing factors for peak hourly flowrates, the characteristics of the collection system serving the wastewater-treatment plant must be considered carefully. Improve-

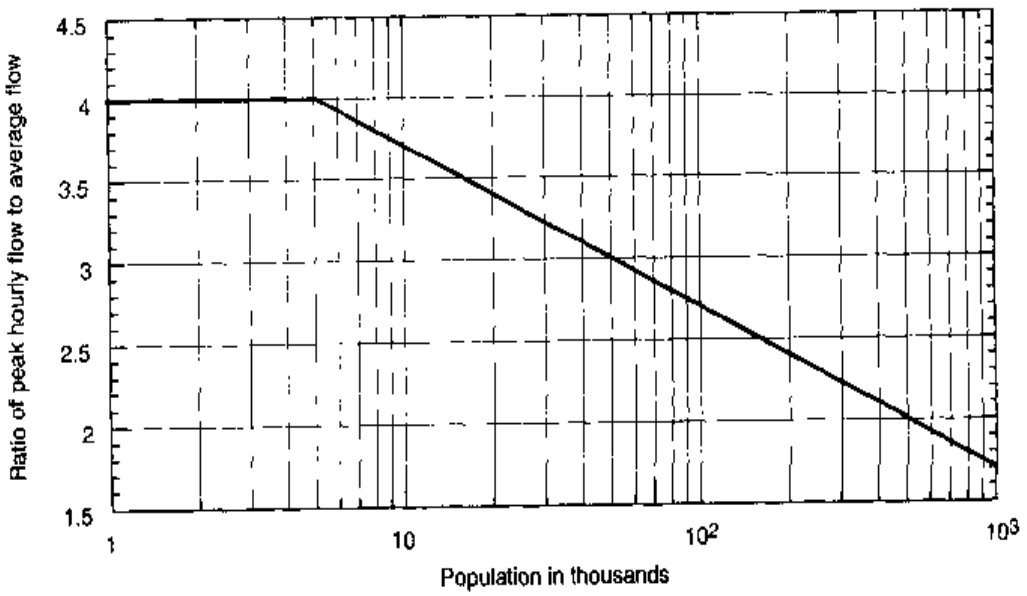

Figure 3–13

Peaking factor curve (ratio of peak hourly to average daily flow).

ments to or rehabilitation of the collection system may also increase or decrease the peaking factors. For pumped flows where reliable metering data are not available, factors to be considered include:

- Interviews with operators regarding observations of operating conditions
- Review of pumping records (historical data on number of pumps in service and running time, if available)
- Operating speed of pumps
- Condition of pumps from maintenance records (unit output will be lower if impellers are worn)

Field testing at pumping stations can also be performed to measure the combined output of a simulated historical high-flow event. Assistance in performing pump tests is often available from the local energy service provider.

Where flow to the treatment plant is by gravity, the peak flowrate can be estimated based on the following:

- Capacity of the influent sewers
- Investigation of upstream access ports (i.e., manholes) to determine if a high watermark is visible
- Interviews with operating staff and review of any documented field records

Forecasting design flowrates, including the use of peaking factors, is illustrated in Example 3–9.

EXAMPLE 3–9 Forecasting Design Flowrates A residential community with a current population of 15,000 is planning to expand its wastewater-treatment plant. In 20 years, the population is estimated to increase to 25,000 residents and 2000 day students are expected to attend a proposed junior college. A new industry will also move in and contribute an average flowrate of 840 m^3/d and a peak flowrate of 1260 m^3/d. The plant will operate 8 h/d and will shut down one day per week. The present average daily wastewater flowrate is 6500 m^3/d and the infiltration/inflow has been determined to be nonexcessive. Infiltration is estimated to be 100 L/capita·d at average flow and 150 L/capita·d at peak flow. Residential water use in the new homes is expected to be 10 percent less than the existing residences because of the installation of water-saving appliances and fixtures. Compute the future average, peak, and minimum design flowrates. For peak residential flowrates, use a peaking factor of 2.75 and assume the ratio of minimum to average flowrate is 0.35.

Solution

1. Compute the present and future per capita wastewater flowrates
   a. For present conditions, compute the average domestic flowrate excluding infiltration
      i. Compute infiltration

$$\text{Infiltration} = 15{,}000 \text{ persons} \times 100 \text{ L/capita·d} \times \frac{1 \text{ m}^3}{1000 \text{ L}} = 1500 \text{ m}^3/\text{d}$$

ii. Compute average domestic flowrate

$$\text{Domestic flow, m}^3\text{/d} = \text{total average flow} - \text{infiltration}$$
$$= 6500 - 1500 = 5000\ \text{m}^3\text{/d}$$

b. Compute present per capita flowrate by dividing the existing domestic flowrate by the present population

$$\text{Per capita flowrate} = \frac{(5000\ \text{m}^3\text{/d})}{15{,}000\ \text{persons}} = 0.33\ \text{m}^3\text{/capita·d}$$

c. For future conditions, reduce existing per capita flowrate by 10%

Future per capita flowrate = $0.33 \times 0.9 = 0.297\ \text{m}^3\text{/capita·d}$

		Flowrate, m^3/d
2.	Compute future average flowrate	
a.	Existing residents –	5,000
b.	Future residents = $10{,}000 \times 0.297\ m^3$/capita·d =	2,970
c.	Day students (assume 95 L/capita·d from Table 3–3) = $2000 \times 0.095\ m^3$/capita·d	190
	Subtotal residential	8,160
d.	Industrial flowrate =	840
e.	Infiltration = (25,000)(100 L/capita·d)(1 $m^3/10^3$ L) =	2,500
f.	Total future average flowrate =	11,500
3.	Compute future peak flowrate	
a.	Residential peak flowrate = 8160×2.75 =	22,440
b.	Industrial peak flowrate =	1,260
c.	Infiltration = (25,000)(150 L/capita·d)(1 $m^3/10^3$ L) =	3,750
d.	Total future peak flowrate =	27,450
4.	Compute the minimum flowrate	
a.	Residential: As indicated on Fig. 3–4, the low flowrate usually occurs in the early morning hours. The future minimum flowrate, excluding college day students = $0.35 \times (5000 + 2970)$ =	2,780
b.	Industrial (facilities are shut down at night)=	0
c.	Infiltration = (25,000)(100 L/capita·d)(1 $m^3/10^3$ L) =	2,500
d.	Total minimum flowrate =	5,280

Comment In this example, infiltration/inflow contributes nearly 50 percent of the minimum flowrate and over 20 percent of the average flowrate; an illustration of the influence of extraneous flows on treatment plant design. If wastewater-flow records are not adequate or are unavailable, future average daily flow may be calculated based on the future population and unit wastewater flowrates, similar to those given in Tables 3–1 to 3–5. Appropriate adjustments should be made in the calculations to account for any special conditions such as flow reduction, infiltration/inflow allowances, and industrial flows. When peak flowrates for more than one flow component are calculated, some adjustment in the total peak flowrate should be made if the peaks from the components do not occur simultaneously.

Upstream Control of Peak Flowrates. Planning wastewater facilities to handle peak flowrates may involve other considerations including (1) improvements to the collection system to reduce peak flow related to infiltration/inflow (I/I), (2) installation of flow-equalization facilities to provide storage either in the collection system or at the treatment plant. Other alternatives for peak flowrate control, namely, provision for flow splitting and sidestream treatment facilities, are discussed in Chaps. 5 and 15.

Improvement to the collection system may involve a lengthy and costly process and may not have an immediate effect on significantly reducing peak flowrates. In some cases, the amount of flow reduction resulting from collection system rehabilitation has been less than anticipated, particularly if infiltration is a significant component of I/I. In unusual circumstances, the flowrates have actually increased after completion of the collection system improvement program. Therefore, safety factors should be considered when estimating possible peak flowrate reduction resulting from collection system improvements.

Flow equalization can be an effective measure in reducing peak flows. Benefits derived by upstream flow equalization include (1) reduced hydraulic loading on already overtaxed collection facilities, (2) reduced collection system overflows (and reduced public health threats), and (3) reduced peak hydraulic loading of the treatment plant. Equalization depends on available volume and may be of limited value in extreme peak flow conditions. Siting of equalization facilities in the collection system is often difficult because of limited available space at locations that are compatible with the system hydraulics. Operation and maintenance may also be difficult to manage, particularly in remote areas. Ease of operation, maintenance, and control and environmental factors are major reasons that many equalization facilities are located at treatment plants. The analysis for sizing flow equalization facilities is presented in Chap. 5.

Design Mass Loadings

The importance of mass loading in the design of wastewater-treatment facilities is identified in Table 3–20. For example, the sizing of aeration facilities and the amounts of solids and biosolids produced are directly related to the mass of BOD that must be processed. Further, the performance of the preliminary and primary treatment facilities has to be taken into account as ineffective operation of these facilities can result in the transfer of greater organic loads to the biological treatment system. Peak process loading rates are also important in sizing the process units and their support systems so that treatment plant performance objectives can be achieved consistently and reliably. The performance of primary sedimentation tanks is discussed in Chap. 5.

PROBLEMS AND DISCUSSION TOPICS

3–1 A community is rapidly approaching the design capacity of its wastewater-treatment plant. As an alternative to expanding the plant, a water conservation program has been proposed. If the current average residential unit flowrate is 320 L/capita·d and the proposed water conservation rate reduction is 25, 35, 40 percent (to be selected by instructor), is the proposal reasonable? State your justification.

3–2 The new commercial development is being considered, and four developers have submitted competing proposals. An Environmental Assessment Report is being prepared to evaluate the wastewater flows from each of the competing proposals. Estimate the average daily and peak wastewater flowrates from one of the proposed developments (to be selected by instructor). The proposals consist of the following elements:

		Developer			
Type of facility	**Units**	**A**	**B**	**C**	**D**
Hotel	Number of guest rooms	120	80	60	250
	Number of employees	25	16	14	40
Department stores	Number of toilet rooms	8	12	16	
	Number of employees	40	60	80	
Self-service laundry	Number of machines		20	16	18
Restaurant, no bar	Number of seats	125	100	100	50
Restaurant, with bar	Number of seats	100	125	75	80
Theater (indoor)	Number of seats	500	400		350

3–3 Estimate the average and maximum flowrates from one of the following recreational areas (to be selected by instructor) that consists of the following facilities:

		Area			
Type of facility	**Units**	**A**	**B**	**C**	**D**
Visitor center	No. of visitors	250	300	400	500
Motel with kitchen	No. of guests		60	100	60
Resort cabins	No. of guests		100	40	
Cottages	No. of guests	60		60	120
Campground (toilets only)	No. of persons	140	120		200
Recreational vehicle park	Number of individual connection	40	50	20	50
Self-service laundry	Number of machines	8	10	6	10
Shopping center	Number of employees	10	15	15	20
	Number of parking spaces	30	40	40	60
Automobile service station	Number of vehicles	80	120	160	200
Restaurant with bar	Number of customers	200	300	400	500

State all of your assumptions clearly.

3–4 A college dormitory complex is planning to institute a water conservation program to reduce its wastewater flows. The complex consists of four dormitories each with the following characteristics:

Characteristics	Unit	Dormitory A	B	C	D
Wastewater flowrate	L/d	125,000	105,000	140,000	160,000
Number of beds	No	300	250	300	350
Existing fixture flowrates					
Toilets,	L/use	9	10	11	11
Showerheads,	L/min·use	18	20	23	23
Faucets,	L/capita·d	10	8	9	11
Flowrate reduction required	%	15	20	25	25

Using the data given above, develop a water conservation program that will accomplish the flowrate reduction goal for one of the facilities (to be selected by instructor).

3–5 Compute the flow-weighted BOD and TSS concentrations from one of the following flowrate regimes (to be selected by instructor).

Time	BOD, mg/L	TSS, Mg/L	Flowrate A, m^3/d	Flowrate B, m^3/d	Flowrate C, m^3/d
0200	130	150	8,000	7,200	10,000
0400	110	135	6,000	6,400	8,400
0600	160	150	9,400	9,800	13,600
0800	220	205	12,800	13,500	19,200
1000	230	210	13,000	13,800	19,500
1200	245	220	14,400	14,500	21,800
1400	225	210	12,000	12,500	18,500
1600	220	200	9,600	10,000	14,800
1800	210	205	11,000	10,500	15,000
2000	200	210	8,000	8,500	11,500
2200	180	185	9,000	8,200	12,600
2400	160	175	8,400	7,700	11,600

3–6 The data in the table below consist of population values for a city, and average monthly influent flow values at the city wastewater-treatment plant, from 1996 through 1999. The city is located in an area of high groundwater. Using these data answer the following questions.

a. What is the nature of the distribution of the monthly flowrate values? Use the plotting position method described in Sec. 3–3 (see Eq. 3–10) to plot the monthly influent values versus the corresponding probabilities for each year on arithmetic- and log-probability paper, and check for linearity.

b. What is the average annual flow, average dry-weather flow (ADWF), and average wet-weather flow (AWWF) for each year? If the data are arithmetically distributed, use the arithmetic mean; if the data are log-normally distributed, use the geometric mean (see Table 3–10).

Assume the dry season occurs from May to October, and the wet season occurs from November to April.

c. What is the per capita flow contribution from commercial and light industrial activities? Assume that the residential contribution to the dry-weather flow is 300 L/capita·d, and that commercial and light industrial activities make up the remaining flow.

d. What is the per capita flow contribution from infiltration and inflow for each year? Assume that the difference between the wet- and dry-weather flows is due to infiltration and inflow.

Community population and average monthly influent flowrate data for the period from 1996 through 1999

Year	1996	1997	1998	1999
Population	**8,690**	**9,400**	**11,030**	**12,280**
Month	**Influent flowrate, m^3/d**			
January	8,800	13,900	8,300	10,000
February	6,200	9,900	11,800	18,400
March	6,800	8,100	9,400	13,000
April	4,000	4,200	6,500	5,000
May	4,000	5,700	5,300	7,600
June	3,600	3,600	4,800	4,600
July	2,400	2,600	3,300	3,800
August	2,000	1,500	3,800	3,100
September	2,800	2,000	2,800	2,200
October	3,200	4,800	4,400	4,400
November	4,800	3,200	6,000	6,500
December	5,200	6,700	7,300	8,600

3–7 Consider the city described in Problem 3-6. Assume that the build-out population for the community is 16,000, and that the residential wastewater flowrate will be 300 L/capita·d. The commercial flowrate in 1999 (1000 m^3/d) is 80 percent of what it will be at build-out. Due to high infiltration and inflow (I/I) rates, a sewer repair program will be implemented. The I/I contribution will be either 500, 400, 300, or 200 L/cap·d (to be selected by instructor), depending on the degree of repair achieved. Estimate the ADWF, AWWF, and the average annual flow that will be received at the community treatment plant at build out. Justify the use of the AWWF as the nominal design capacity for the treatment plant.

3–8 Consider the treatment plant for the city described in Problem 3–6. Use the plotting position method described in Sec. 3-3 (see Eq. 3-10) to plot the monthly influent values versus the corresponding probabilities for each year. Determine the nature of the distribution by plotting the values on arithmetic- and log-probability paper and checking for linearity. If the average annual flow to the treatment facility at build-out is estimated to be 8000 m^3/d, what will the peak monthly flow be? (Hint: the average annual flow occurs at the 50 percent line on the probability graph. Use the slope of the wettest year to pass a line through the 50 percent line at 8000 m^3/d, and read the flow value for the highest month from the graph.)

3–9 Use the following influent data for a wastewater-treatment plant to conduct the statistical analyses described in Problem 3–6, steps a, b, c, and d. If the data in the table below are not distributed either arithmetic-normally or log-normally, suggest a method for determining the required parameters.

Community population and average monthly influent flowrate data for the period from 1996 through 1999

Year	1996	1997	1998	1999
Population	17,040	17,210	17,380	17,630
Month	Influent flowrate, m^3/d			
January	8,800	7,760	9,360	7,600
February	9,440	7,280	7,920	7,840
March	8,640	7,200	8,800	7,680
April	7,840	6,960	8,080	7,440
May	7,440	6,800	7,680	7,280
June	7,200	6,880	7,520	7,360
July	7,120	6,960	7,280	7,200
August	7,040	6,720	7,200	7,280
September	6,880	6,880	7,040	7,200
October	6,960	6,800	7,280	7,440
November	7,120	7,120	7,360	7,680
December	7,360	7,600	7,680	8,000

3–10 A treatment plant is planned to be installed in a recreational resort that contains a developed campground for 200 persons, lodges and cabins for 100 persons, and resort apartments for 150 persons. Assume that persons staying in lodges use the dining hall for 3 meals per day and that a 50-seat cafeteria with 4 employees and an estimated 200 customers per day has been constructed. Daily attendance at the visitor center is 500 persons. Other facilities include a 10-machine laundromat, a 20-seat cocktail lounge, and three gas stations at 1100 L/d per station. Determine the average wastewater flowrate in L/d using the unit flows assuming the housing facilities are at maximum capacity.

3–11 Obtain an annual report or one year of flow and BOD data from your local wastewater-treatment facility. From these records, prepare probability plots for the flowrate and mass loadings. Determine the values at 50 and 95 percent probability.

3–12 From the flowrate data obtained for Problem 3–11, determine the mean and standard deviation.

3–13 The wastewater-treatment plant has been experiencing high wastewater flowrates during the wet weather months. The average monthly flows for four flow regimes are reported below (one regime to be selected by instructor). The rapid increase in flows during the winter months is due mainly to increased infiltration/inflow. Infiltration is estimated to be 67 percent of the excess flow. The lengths of the collection system pipelines that need to be repaired are also listed below. The average repair cost is $200,000/km and the repair will be effective in reducing the infiltration by 30 percent. How many years from now will it take to pay back the cost

of the sewer repair program based on the annual savings in treatment cost, assuming the future annual flowrates are equal to those in the table below? The current cost of treatment is \$10.00/m^3 and the future cost of treatment is estimated to escalate at 6 percent per year. Assume the sewer repair will be complete in three years for Areas A and B, and four years for Areas C and D.

	Average monthly flowrate, m^3/d			
	Flowrate regime			
Month	**A**	**B**	**C**	**D**
January	293,000	410,000	460,000	470,000
February	328,000	459,000	440,000	485,000
March	279,000	391,000	515,000	560,000
April	212,000	296,000	333,000	400,000
May	146,000	204,000	230,000	300,000
June	108,000	151,000	170,000	225,000
July	95,000	133,000	150,000	200,000
August	89,000	125,000	141,000	188,000
September	93,000	130,000	140,000	165,000
October	111,000	155,000	167,000	192,000
November	132,000	185,000	200,000	240,000
December	154,000	215,000	225,000	215,000
Length of collection system, km	300	400	450	600

3-14 Nine months of flow records have been collected for a new wastewater-treatment plant. Inspection of the records indicates that weekend flowrates tend to be higher than weekday flowrates. The weekday and weekend flowrates have been averaged and arranged in ascending order as given below. Develop arithmetic- and log-probability plots for both the weekday and weekend data for either Flowrate regime A or Flowrate regime B (to be selected by instructor) and comment on the skewness of the data. Determine the mean and 95 percentile values for each set of flow data, and determine the probable one-day maximum flowrate. Discuss the significance of the data analysis.

	Flowrate regime A		Flowrate regime B	
Number	**Weekday average flowrate, $m^3/d \times 10^3$**	**Weekend average flowrate, $m^3/d \times 10^3$**	**Weekday average flowrate, $m^3/d \times 10^3$**	**Weekend average flowrate, $m^3/d \times 10^3$**
1	39.7	42.8	55.7	56.4
2	40.5	43.1	56.1	57.5
3	40.9	43.5	56.6	58.1

(continued)

(*Continued*)

Number	Flowrate regime A		Flowrate regime B	
	Weekday average flowrate, $m^3/d \times 10^3$	Weekend average flowrate, $m^3/d \times 10^3$	Weekday average flowrate, $m^3/d \times 10^3$	Weekend average flowrate, $m^3/d \times 10^3$
4	41.3	43.9	57.2	58.6
5	42.0	44.3	57.7	59.5
6	42.1	44.7	58.2	60.6

30	53.0	58.3	75.9	77.5
31	53.2	59.1	76.9	78.6
32	54.3	60.6	78.9	80.7
33	55.3	60.9	79.2	82.8
34	56.0	61.7	80.3	85.0
35	60.6	62.1	80.8	88.4
36	62.5	63.6	82.8	91.1

3–15 Land use in a new development is given in the following first table. A new school being built will have 1500 students. The average flowrate is 75 L/student, and the peaking factor (ratio of peak flow to average flow) is 4.0. Average flowrate allowances and the peaking factors for the other developments are shown in the second table. Determine the peak wastewater flowrate from one of the areas (to be selected by instructor).

Type of development	Area A, ha	Area B, ha	Area C, ha	Area D, ha
Residential	125	150	150	160
Commercial	11	10	15	16
School	4	4	4	4
Industrial	6	8	20	10

Type of development	Average flowrate, $m^3/ha \cdot d$	Peaking factor
Residential	40	3.0
Commercial	20	2.0
Industrial	30	2.5

REFERENCES 308

The constituents of concern found in wastewater are removed by physical, chemical, and biological methods. The individual methods usually are classified as physical unit operations, chemical unit processes, and biological unit processes. Treatment methods in which the application of physical forces predominate are known as *physical unit operations*. Examples of physical unit operations include screening, mixing, sedimentation, gas transfer, filtration, and adsorption. Treatment methods in which the removal or conversion of constituents is brought about by the addition of chemicals or by other chemical reactions are known as *chemical unit processes*. Examples of chemical unit processes include disinfection, oxidation, and precipitation. Treatment methods in which the removal of constituents is brought about by biological activity are known as *biological unit processes*. Biological treatment is used primarily to remove the biodegradable organic constituents and nutrients in wastewater. Examples of biological treatment processes include the activated-sludge and trickling-filter processes. Unit operations and processes occur in a variety of combinations in treatment flow diagrams.

From practical observations, the rates at which physical, chemical, and biological reactions and conversions occur are important, as they will affect the size of the treatment facilities that must be provided (see Fig. 4–1). The rate at which reactions and conversions occur, and the degree of their completion, is generally a function of the constituents involved, the temperature, and the type of reactor (i.e., container or tank in which the reactions take place). Hence, both the effects of temperature and the type of

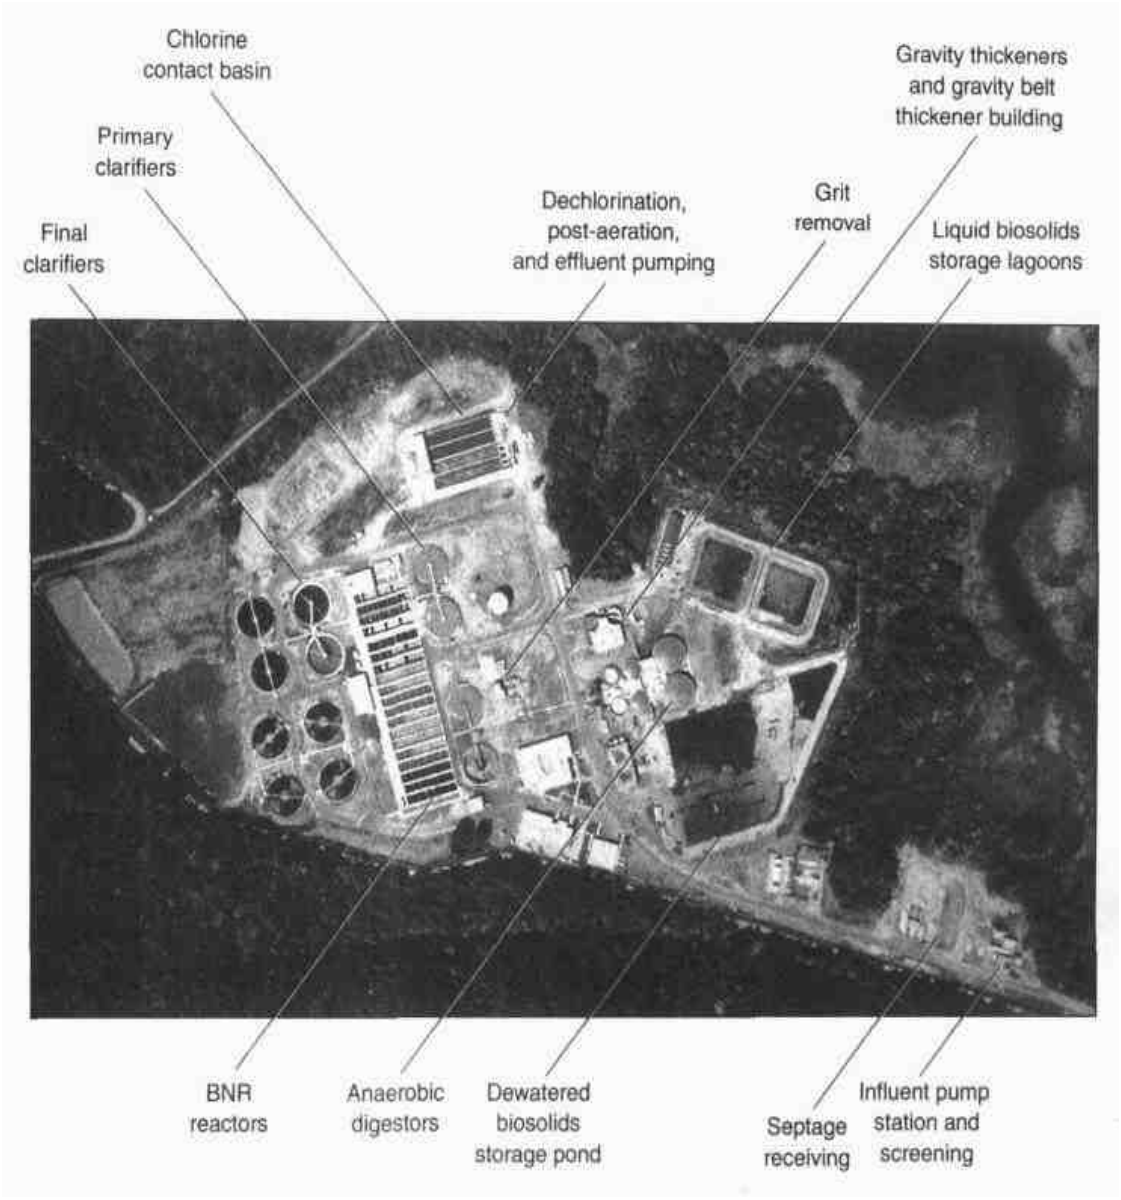

Figure 4–1

Overview of Harford County, MD, Sod Run biological nutrient removal (BNR) wastewater-treatment plant. The capacity of the plant is 76,000 m^3/d (200 Mgal/d).

reactor employed are important in the selection of treatment processes. In addition, a variety of environmental and other physical constraints must be considered in process selection. The fundamental basis for the analysis of the physical, chemical, and biological unit operations and processes used for wastewater treatment is the *materials mass balance principle* in which an accounting of mass is made before and after reactions and conversions have taken place.

Therefore, the purpose of this chapter is to introduce and discuss (1) the types of reactors used for wastewater treatment; (2) the preparation of mass balances to determine process performance; (3) modeling ideal flow in reactors; (4) the analysis of reactor hydraulics using tracers; (5) modeling nonideal flow in reactors; (6) reactions, reaction rates, and reaction rate coefficients; (7) modeling treatment kinetics, which involves the coupling of reactors and reaction rates; (8) treatment processes involving mass transfer; and (9) important factors involved in process analysis and selection. The information in this chapter is intended to serve as an introduction to the subject of process analysis, and to provide a basis for the analysis of the unit operations and processes that will be presented in subsequent chapters. By dealing with the basic concepts first, it will be possible to apply them (without repeating the details) in the remaining chapters. Processes

involving physical removal such as sedimentation and filtration are considered in Chaps. 5 and 11, respectively.

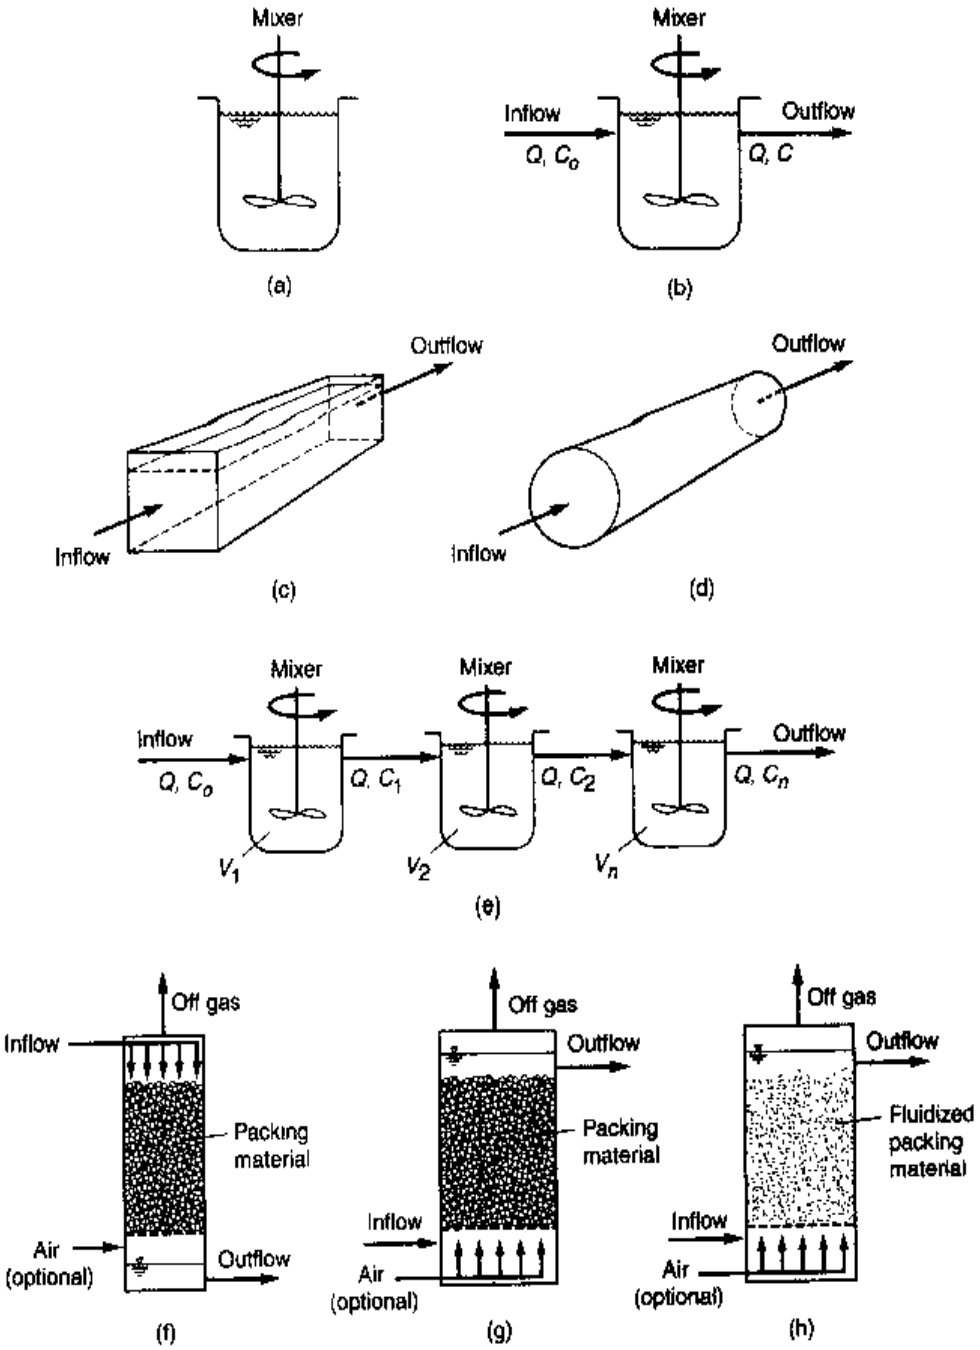
4–1 REACTORS USED FOR THE TREATMENT OF WASTEWATER

Wastewater treatment involving physical unit operations and chemical and biological unit processes is carried out in vessels or tanks commonly known as "reactors." The types of reactors that are available and their applications are introduced in this section. The analysis of the hydraulic characteristics and the performance of reactors used for wastewater treatment is considered in Secs. 4–3, 4–4, and 4–5, following the discussion of the mass-balance principle.

Types of Reactors

The principal types of reactors used for the treatment of wastewater, illustrated on Fig. 4–2, are (1) the batch reactor, (2) the complete-mix reactor [also known as the continuous-flow stirred-tank reactor (CFSTR) in the chemical engineering literature], (3) the plug-flow reactor (also known as a tubular-flow reactor), (4) complete-mix reactors in series, (5) the packed-bed reactor, and (6) the fluidized-bed reactor. Brief descriptions of these reactors are presented below.

Batch Reactor. In the batch reactor (see Fig. 4–2*a*), flow is neither entering nor leaving the reactor (i.e., flow enters, is treated, and then is discharged, and the cycle repeats). The liquid contents of the reactor are mixed completely. For example, the BOD test discussed in Chap. 2 is carried out in a batch reactor (i.e., BOD bottle as shown on Fig. 2–19), although it should be noted that the contents are not mixed completely during the incubation period. Batch reactors are often used to blend chemicals or to dilute concentrated chemicals.



Complete-Mix Reactor. In the complete-mix reactor (see Fig. 4–2*b*), it is assumed that complete mixing occurs instantaneously and uniformly throughout the reactor as fluid particles enter the reactor. Fluid particles leave the reactor in proportion to their statistical population. Complete mixing can be accomplished in round or square reactors if the contents of the reactor are uniformly and continuously redistributed. The actual time required to achieve completely mixed conditions will depend on the reactor geometry and the power input.

Plug-Flow Reactor. Fluid particles pass through the reactor with little or no longitudinal mixing and exit from the reactor in the same sequence in which they entered. The particles retain their identity and remain in the reactor for a time equal to the theoretical detention time. This type of flow is approximated in long open tanks with a high length-to-width ratio in which longitudinal dispersion is minimal or absent (see Fig. 4–2*c*) or closed tubular reactors (e.g., pipelines, see Fig. 4–2*d*).

Complete-Mix Reactors in Series. The series of complete-mix reactors (see Fig. 4–2*e*) is used to model the flow regime that exists between the ideal hydraulic flow

Figure 4–2

Definition sketch for the different types of reactors used for wastewater treatment: (*a*) batch reactor, (*b*) complete-mix reactor, (*c*) plug-flow open reactor, (*d*) plug-flow closed reactor also known as a tubular reactor, (*e*) complete-mix reactors in series, (*f*) packed-bed reactor, (*g*) packed-bed upflow reactor, and (*h*) expanded-bed upflow reactor.

patterns corresponding to the complete-mix and plug-flow reactors. If the series is composed of one reactor, the complete-mix regime prevails. If the series consists of an infinite number of reactors in series, the plug-flow regime prevails.

Packed-Bed Reactors. The packed-bed reactor is filled with some type of packing material, such as rock, slag, ceramic, or, now more commonly, plastic. With respect to flow, the packed-bed reactor can be operated in either the downflow or upflow mode. Dosing can be continuous or intermittent (e.g., trickling filter). The packing material in packed-bed reactors can be continuous (see Fig. 4–2*f*) or arranged in multiple stages, with flow from one stage to another. A packed-bed upflow anaerobic (without oxygen) reactor is shown on Fig. 4–2*g*.

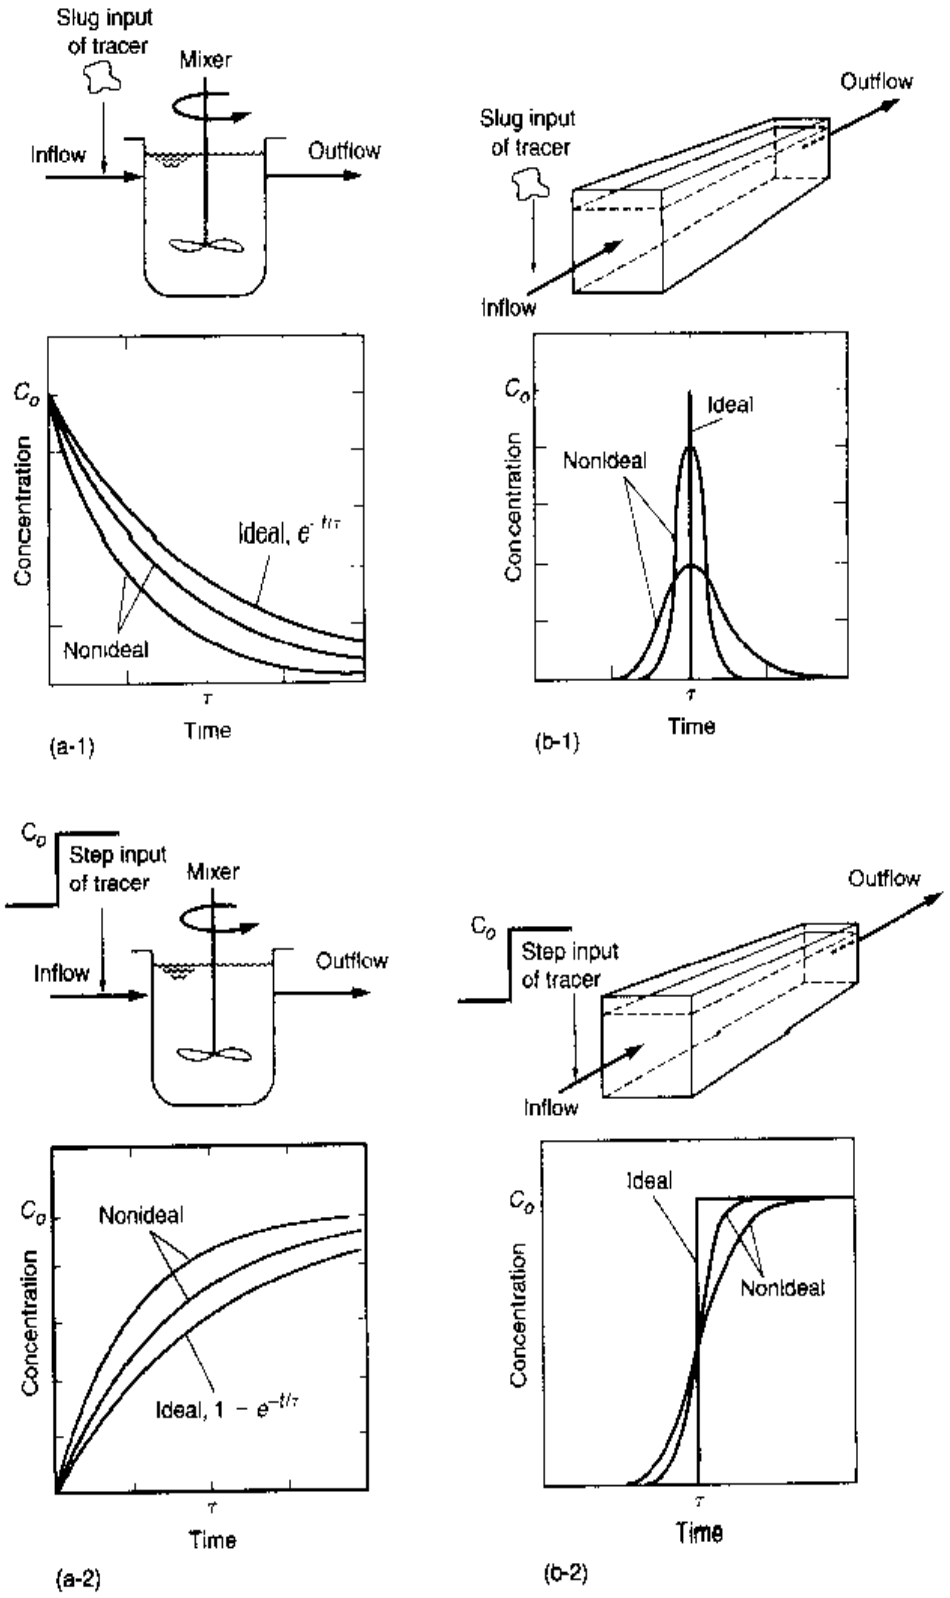
Table 4–1 Principal applications of reactor types used for wastewater treatment

Type of reactor	Application in wastewater treatment
Batch	Activated-sludge biological treatment in a sequence batch reactor, mixing of concentrated solutions into working solutions
Complete-mix	Aerated lagoons, aerobic sludge digestion
Complete-mix with recycle	Activated-sludge biological treatment
Plug-flow	Chlorine contact basin, natural treatment systems
Plug-flow with recycle	Activated-sludge biological treatment, aquatic treatment systems
Complete-mix reactors in series	Lagoon treatment systems, used to simulate nonideal flow in plug-flow reactors
Packed-bed	Nonsubmerged and submerged trickling-filter biological treatment units, depth filtration, natural treatment systems, air stripping
Fluidized-bed	Fluidized-bed reactors for aerobic and anaerobic biological treatment, upflow sludge blanket reactors, air stripping

Fluidized-Bed Reactor. The fluidized-bed reactor is similar to the packed-bed reactor in many respects, but the packing material is expanded by the upward movement of fluid (air or water) through the bed (see Fig. 4–2*h*). The expanded porosity of the fluidized-bed packing material can be varied by controlling the flowrate of the fluid.

Application of Reactors

The principal applications of reactor types used for wastewater treatment are reported in Table 4–1. Operational factors that must be considered in the selection of the type of reactor or reactors to be used in the treatment process include (1) the nature of the wastewater to be treated, (2) the nature of the reaction (i.e., homogeneous or heterogeneous), (3) the reaction kinetics governing the treatment process, (4) the process performance requirements, and (5) local environmental conditions. Homogeneous and heterogeneous reactions and reaction kinetics are discussed in Sec. 4–6. In practice, the construction costs and operation and maintenance costs also affect reactor selection. Because the relative importance of these factors varies with each application, each factor should be considered separately when the type of reactor is to be selected. Reactor selection is considered further in Sec. 4–9.



Hydraulic Characteristics of Reactors

Complete-mix and plug-flow reactors are the two reactor types used most commonly in the field of wastewater treatment. The hydraulic flow characteristics of complete-mix and plug-flow reactors can be described as varying from ideal and nonideal, depending on the relationship of the incoming flow to outgoing flow. Ideal and nonideal flow are described in the following discussion. The mathematical modeling of the flow in ideal and nonideal reactors is presented in Secs. 4–3 and 4–5, respectively, following a discussion of the mass-balance analysis and tracer studies.

Ideal Flow in Complete-Mix and Plug-Flow Reactors. The ideal hydraulic flow characteristics of complete-mix and plug-flow reactors are illustrated on Fig. 4–3 in which dye tracer response curves are presented for pulse (slug-dose) and

Figure 4–3

Output tracer response curves from reactors subject to pulse and step inputs of a tracer: (*a*) complete-mix reactor and (*b*) plug-flow reactor.

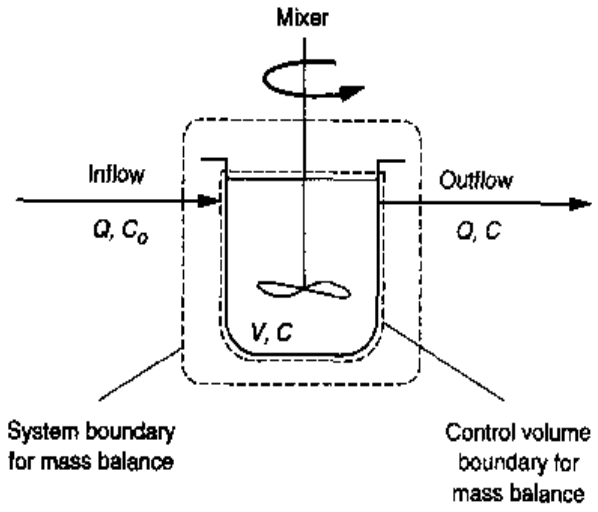
step inputs (continuous injection). On Fig. 4–3, t is the actual time and τ is equal to the theoretical hydraulic detention time defined as follows:

$$\tau = V/Q \tag{4-1}$$

where τ = hydraulic detention time, T
V = volume of the reactor, L^3
Q = volumetric flowrate, L^3T^{-1}

If a pulse (slug) input of a conservative (i.e., nonreactive) tracer is injected and dispersed instantaneously in an ideal-flow complete-mix reactor, with a continuous inflow of clear water, the output tracer concentration would appear as shown on Fig. 4–3(*a*-1). If a continuous step input of a conservative tracer at concentration C_o is injected into the inlet of an ideal complete-mix reactor, initially filled with clear water, the appearance of the tracer at the outlet would occur as shown on Fig. 4–3(*a*-2).

In the case of an ideal plug-flow reactor, the reactor is initially filled with clear water before being subjected to a pulse or a step input of tracer. If an observer were positioned at the outlet of the reactor, the appearance of the tracer in the effluent for a pulse input, distributed uniformly across the reactor cross section, would occur as shown on Fig. 4–3(*b*-1). If a continuous step input of a tracer were injected into such a reactor at an initial concentration C_o, the tracer would appear in the effluent as shown on Fig. 4–3(*b*-2).



Nonideal Flow in Complete-Mix and Plug-Flow Reactors. In practice, the flow in complete-mix and plug-flow reactors is seldom ideal. For example, when a reactor is designed, how is the flow to be introduced to satisfy the theoretical requirement of instantaneous and complete dispersion? In practice, there is always some deviation from ideal conditions, and it is the precautions taken to minimize these effects that are important. Nonideal flow occurs when a portion of the flow that enters the reactor during a given time period arrives at the outlet before the bulk of the flow that entered the reactor during the same time period arrives. Nonideal flow is illustrated on Fig. 4–3*a* and 4–3*b*. The causes of nonideal flow are considered in Sec. 4–4. The important issue with nonideal flow is that a portion of the flow will not remain in the reactor as long as may be required for a biological or chemical reaction to go to completion.

4–2 MASS-BALANCE ANALYSIS

The fundamental approach used to study the hydraulic flow characteristics of reactors and to delineate the changes that take place when a reaction is occurring in a reactor (e.g., a container), or in some definable portion of a body of liquid, is the mass-balance analysis. The basic concepts involved in such an analysis are described in this section. The application of the mass-balance approach to problem solving will be illustrated in the sections that follow and throughout this text.

The Mass-Balance Principle

The mass-balance analysis is based on the principle that mass is neither created nor destroyed, but the form of the mass can be altered (e.g., liquid to a gas). The mass-balance analysis affords a convenient way of defining what occurs within treatment reactors as a

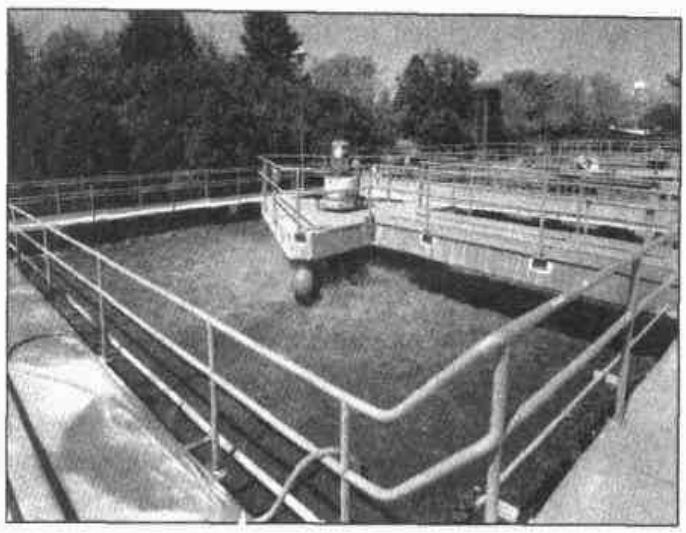


Figure 4–4

Definition sketch for the application of materials mass-balance analysis for a complete-mix reactor with inflow and outflow. The presence of a mixer is used to represent symbolically the fact that the contents of the reactor are mixed completely. The photo is of a typical complete-mix activated sludge reactor used for the biological treatment of wastewater.

function of time. To illustrate the basic concepts involved in the preparation of a mass-balance analysis, consider the reactor shown on Fig. 4–4. The *system boundary* is drawn to identify all of the liquid and constituent flows into and out of the system. The *control volume* is used to identify the actual volume in which change is occurring. In most cases, the system and control volume boundaries will coincide. For a given reactant, the general mass-balance analysis is given by

1. General word statement:

$$\begin{array}{cccccc} \text{Rate of accumulation} & & \text{rate of flow of} & & \text{rate of flow of} & \text{rate of generation} \\ \text{of reactant within} & = & \text{reactant into the} & - & \text{reactant out of the} & + \text{ of reactant within} \\ \text{the system boundary} & & \text{system boundary} & & \text{system boundary} & \text{the system boundary} \\ (1) & & (2) & & (3) & (4) \end{array} \tag{4-2}$$

2. The corresponding simplified word statement is

$$\begin{array}{ccccccc} \text{Accumulation} & = & \text{inflow} & - & \text{outflow} & + & \text{generation} \\ (1) & & (2) & & (3) & & (4) \end{array} \tag{4-3}$$

The mass balance is made up of the four terms cited above. Depending on the flow regime or treatment process, one or more of the terms can be equal to zero. For example, in a batch reactor in which there is no inflow or outflow the second and third terms will be equal to zero. In the analysis of the hydraulic characteristics of reactors, considered in the following sections, as well as in the analysis of separation processes discussed in Sec. 4–8, the fourth term, the rate of generation, will be equal to zero. In Eq. (4–2), a positive sign is used for the rate-of-generation term because the necessary

sign for the operative process is part of the rate expression (e.g., $r_c = -kC$ for a decrease in the reactant or $r_c = +kC$ for an increase in the reactant).

Preparation of Mass Balances

In preparing mass balances it is helpful if the following steps are followed, especially as the techniques involved are being mastered.

1. Prepare a simplified schematic or flow diagram of the system or process for which the mass balance is to be prepared.
2. Draw a system or control volume boundary to define the limits over which the mass balance is to be applied. Proper selection of the system or control volume boundary is extremely important because, in many situations, it may be possible to simplify the mass-balance computations.
3. List all of the pertinent data and assumptions that will be used in the preparation of the materials balance on the schematic or flow diagram.
4. List all of the rate expressions for the biological or chemical reactions that occur within the control volume.
5. Select a convenient basis on which the numerical calculations will be based.

It is recommended that the above steps be followed routinely, to avoid the errors that are often made in the preparation of mass-balance analyses.

Application of the Mass-Balance Analysis

To illustrate the application of the mass-balance analysis, consider the complete-mix reactor shown on Fig. 4–4. First, the control volume boundary must be established so that all the flows of mass into and out of the system can be identified. On Fig. 4–4*a*, the control volume boundary is shown by the inner dashed line.

To apply a mass-balance analysis to the liquid contents of the reactor shown on Fig. 4–4, it will be assumed that:

1. The volumetric flowrate into and out of the control volume is constant.
2. The liquid within the control volume is not subject to evaporation (constant volume).
3. The liquid within the control volume is mixed completely.
4. A chemical reaction involving a reactant A is occurring within the reactor.
5. The rate of change in the concentration of the reactant A that is occurring within the control volume is governed by a first-order reaction ($r_c = -kC$).

Using the above assumptions, the mass balance can be formulated as follows:

1. Simplified word statement:

   Accumulation = inflow − outflow + generation (4–4)

2. Symbolic representation (refer to Fig. 4–4):

   $$\frac{dC}{dt}V = QC_o - QC + r_cV \tag{4–5}$$

   Substituting $-kC$ for r_c yields

   $$\frac{dC}{dt}V = QC_o - QC + (-kC)V \tag{4–6}$$

where dC/dt = rate of change of reactant concentration within the control volume, $ML^{-3}T^{-1}$
V = volume contained within control volume, L^3
Q = volumetric flowrate into and out of control volume, L^3T^{-1}
C_o = concentration of reactant entering the control volume, ML^{-3}
C = concentration of reactant leaving the control volume, ML^{-3}
r_c = first-order reaction, $(-kC)$, $ML^{-3}T^{-1}$
k = first-order reaction rate coefficient, T^{-1}

Before attempting to solve any mass-balance expression, a unit check should always be made to assure that units of the individual quantities are consistent. If the following units are substituted into Eq. (4–6)

$V = m^3$

$dC/dt = g/m^3 \cdot s$

$Q = m^3/s$

$C_o, C = g/m^3$

$k = 1/s$

the resulting unit check yields

$$\frac{dC}{dt}V = QC_o - QC + (\quad kC)V$$

$(g/m^3 \cdot s)\ m^3 = m^3/s\ (g/m^3) - m^3/s\ (g/m^3) + (-1/s)(g/m^3)\ m^3$

g/s = g/s − g/s − g/s (units are consistent)

The analytical procedures that are adopted for the solution of mass-balance equations usually are governed by (1) the nature of the rate expression, (2) the type of reactor under consideration, (3) the mathematical form of the final materials-balance expression (i.e., ordinary or partial differential equation), and (4) the corresponding boundary conditions. The mass balance for a plug-flow reactor, as will be illustrated in the following section, results in a partial differential equation. A variety of solution procedures for mass balances in both ordinary and partial differential equation formats are presented in the following sections.

Steady-State Simplification

Fortunately, in most applications in the field of wastewater treatment, the solution of mass-balance equations, such as the one given by Eq. (4–6), can be simplified by noting that the steady-state (i.e., long-term) concentration is of principal concern. If it is assumed that only the steady-state effluent concentration is desired, then Eq. (4–6) can be simplified by noting that, under steady-state conditions, the rate accumulation is zero ($dC/dt = 0$). Thus, Eq. (4–6) can be written as

$$0 = QC_o - QC - r_c V \tag{4–7}$$

When solved for r_c, Eq. (4–7) yields the following expression:

$$r_c = \frac{Q}{V}(C - C_o) \tag{4–8}$$

The solution to the expression given by Eq. (4–8) will depend on the nature of the rate expression (e.g., zero-, first-, or second-order; see Sec. 4–6 for discussion of rate expressions).

4–3 MODELING IDEAL FLOW IN REACTORS

Modeling of the hydraulic characteristics of reactors is important because the results can be used to determine the actual amount of time a given volume of water will remain in the reactor and its average age. In turn, the average ages can be related to the degree of treatment achieved, based on the applicable kinetics. The coupling of reactor hydraulic characteristics and reaction rates to determine treatment process performance is considered in Sec. 4–7. Comparison of actual hydraulic characteristics of a reactor, measured using tracers, to the expected theoretical response can be used to assess the degree to which the design ideal has been achieved. The complete-mix and plug-flow reactors, as noted previously, are the reactor types used most commonly in the field of wastewater treatment. The mathematical analysis of ideal flow in complete-mix and plug-flow reactors is considered below. The modeling of nonideal flow is considered in Sec. 4–5.

Ideal Flow in Complete-Mix Reactor

If a pulse input of a conservative (i.e., nonreactive) tracer is injected into an ideal complete-mix reactor, with a continuous inflow of clear water, the output tracer concentration would appear as shown on Fig. 4–3(a-1). If a continuous step input of a conservative tracer at concentration C_o is injected into the inlet of an ideal complete-mix reactor, initially filled with clear water, the appearance of the tracer at the outlet would occur as shown on Fig. 4–3(a-2).

Analytically, using the mass-balance approach introduced in Sec. 4–2, the effluent tracer concentration as a function of time for a pulse (slug) input of tracer, which is mixed instantaneously and is purged with clear water [see Fig. 4–3(a-1)], can be determined by writing a mass balance around the reactor.

1. General word statement:

$$\begin{array}{c}\text{Rate of accumulation}\\ \text{of tracer within}\\ \text{the reactor}\end{array} = \begin{array}{c}\text{rate of flow}\\ \text{of tracer into}\\ \text{the reactor}\end{array} - \begin{array}{c}\text{rate of flow}\\ \text{of tracer out of}\\ \text{the reactor}\end{array} \qquad (4\text{–}9)$$

2. Simplified word statement:

$$\text{Accumulation} = \text{inflow} - \text{outflow} \qquad (4\text{–}10)$$

3. Symbolic representation [refer to Fig. 4–3(a-1)]:

$$\frac{dC}{dt}V = QC_o - QC \qquad (4\text{–}11)$$

Rewriting Eq. (4–11) and simplifying by noting that $C_o = 0$ yields

$$\frac{dC}{dt} = -\frac{Q}{V}C \qquad (4\text{–}12)$$

Integrating between the limits of $C = C_o$ to $C = C$, and $t = 0$ to $t = t$ yields

$$\int_{C_o}^{C} \frac{dC}{C} = -\frac{Q}{V}\int_0^t dt \tag{4-13}$$

The resulting expression after integration is

$$C = C_o e^{-t(Q/V)} = C_o e^{-t/\tau} = C_o e^{-\theta} \tag{4-14}$$

where C = concentration of the tracer in the reactor at time t, ML^{-3}
C_o = initial concentration of the tracer in the reactor, ML^{-3}
t = time, T
Q = volumetric flowrate, L^3T^{-1}
V = reactor volume, L^3
τ = theoretical detention time V/Q, T
θ = normalized detention time t/τ, unitless

The corresponding response for a continuous step input of tracer [see Fig. 4–3(a-2)] which is mixed instantaneously is given by

$$C = C_o(1-e^{-t(Q/V)}) = C_o(1-e^{-t/\tau}) = C_o(1-e^{-\theta}) \tag{4-15}$$

It will be noted that Eq. (4–15) has the same form as the BOD equation given previously in Chap. 2 [see Eq. (2-60)].

Ideal Flow in Plug-Flow Reactor

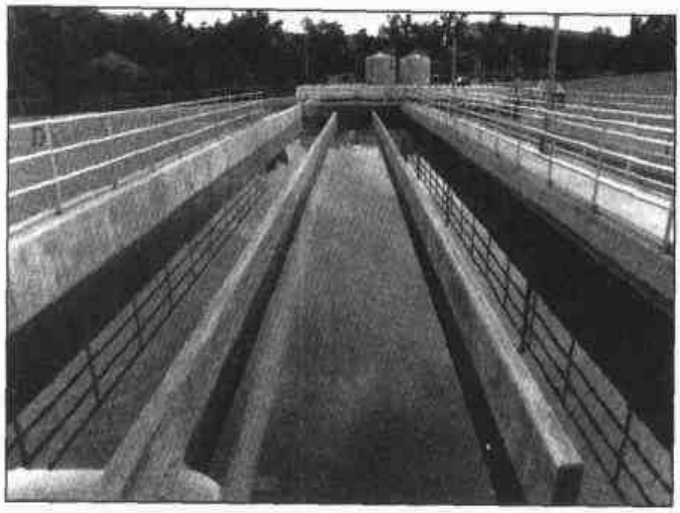
In the case of an ideal plug-flow reactor, the reactor is initially filled with clear water before being subjected to a pulse or a step input of tracer. If an observer were positioned at the outlet of the reactor, the appearance of the tracer in the effluent for a pulse input, distributed uniformly across the reactor cross section, would occur as shown on Fig. 4–3(b-1). If a continuous step input of a tracer were injected into such a reactor at an initial concentration C_o, the tracer would appear in the effluent as shown on Fig. 4–3(b-2). Under ideal plug-flow conditions t, the measured detention time should be the same as τ, the theoretical detention time (V/Q).

To verify the form of the plot given on Fig. 4–3(b-2), it will be instructive to prepare a materials balance for an ideal plug-flow reactor (no axial dispersion) in which the concentration C of a nonreactive tracer is distributed uniformly across the cross-sectional area of the control volume. The materials balance for a nonreactive tracer for the differential volume element shown on Fig. 4–5e can be written as follows:

1. General word statement:

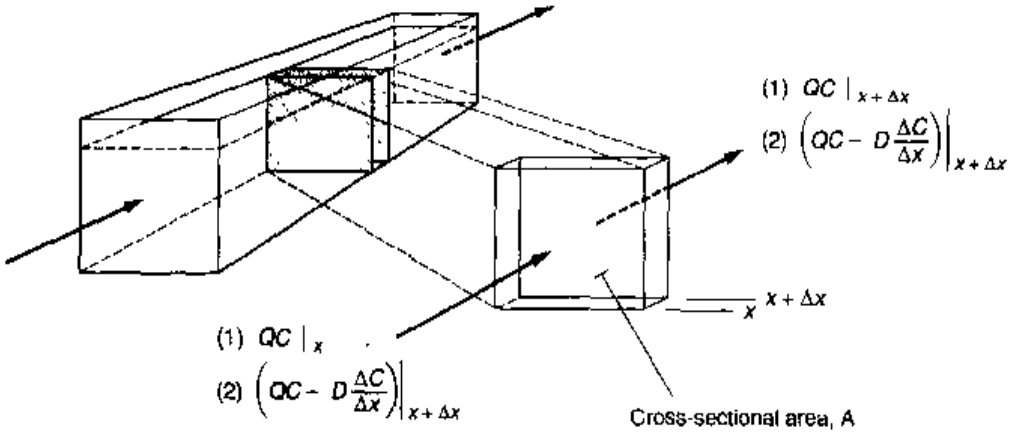
$$\begin{array}{l}\text{Rate of accumulation of}\\ \text{tracer within differential}\\ \text{volume element}\end{array} = \begin{array}{l}\text{rate of flow of tracer}\\ \text{into differential}\\ \text{volume element}\end{array} - \begin{array}{l}\text{rate of flow of tracer}\\ \text{out of differential}\\ \text{volume element}\end{array} \tag{4-16}$$

2. Simplified word statement:



$$\text{Accumulation} = \text{inflow} - \text{outflow} \tag{4-17}$$

3. Symbolic representation (refer to Fig. 4–5e)



$$\frac{\partial C}{\partial t}\Delta V = QC|_x - QC|_{x+\Delta x} \tag{4-18}$$

(a)

(b)

(c)

Figure 4–5

Views of plug-flow reactors and definition sketch: (a) empty plug-flow activated sludge process reactor, (b) plug-flow chlorine contact basin with long narrow channels, and (c) definition sketch for the hydraulic analysis of a plug-flow reactor with (1) advection only and (2) with advection and axial dispersion.

where $\partial C/\partial t$ = constituent concentration, ML^{-3}, (g/m^3)
ΔV = differential volume element, L^3, (m^3)
t = time T, (s)
Q = volumetric flow rate, L^3T^{-1}, (m^3/s)
x = some point along the reactor length L, (m)
Δx = differential distance L, (m)

The change in concentration with time term ($\partial C/\partial t$) is written as partial differential because the concentration is also changing with distance (i.e., the change in concentration is a function of both time and distance).

Substituting the differential form for the terms $QC|_x$ and $QC|_{x+\Delta x}$ in Eq. (4–18) results in

$$\frac{\partial C}{\partial t}\Delta V = QC - Q\left(C + \frac{\Delta C}{\Delta x}\Delta x\right) \tag{4–19}$$

Substituting $A\Delta x$ for ΔV, where A is the cross-sectional area in the x direction, and simplifying yields

$$\frac{\partial C}{\partial t} A\Delta x = -Q\frac{\Delta C}{\Delta x}\Delta x \tag{4-20}$$

where $\Delta C/\Delta t$ = change in constituent concentration C with time, $ML^{-3}T^{-1}$, (g/m^3)

Dividing by A and Δx yields

$$\frac{\partial C}{\partial t} = -\frac{Q}{A}\frac{\Delta C}{\Delta x} \tag{4-21}$$

Taking the limit as Δx approaches zero yields

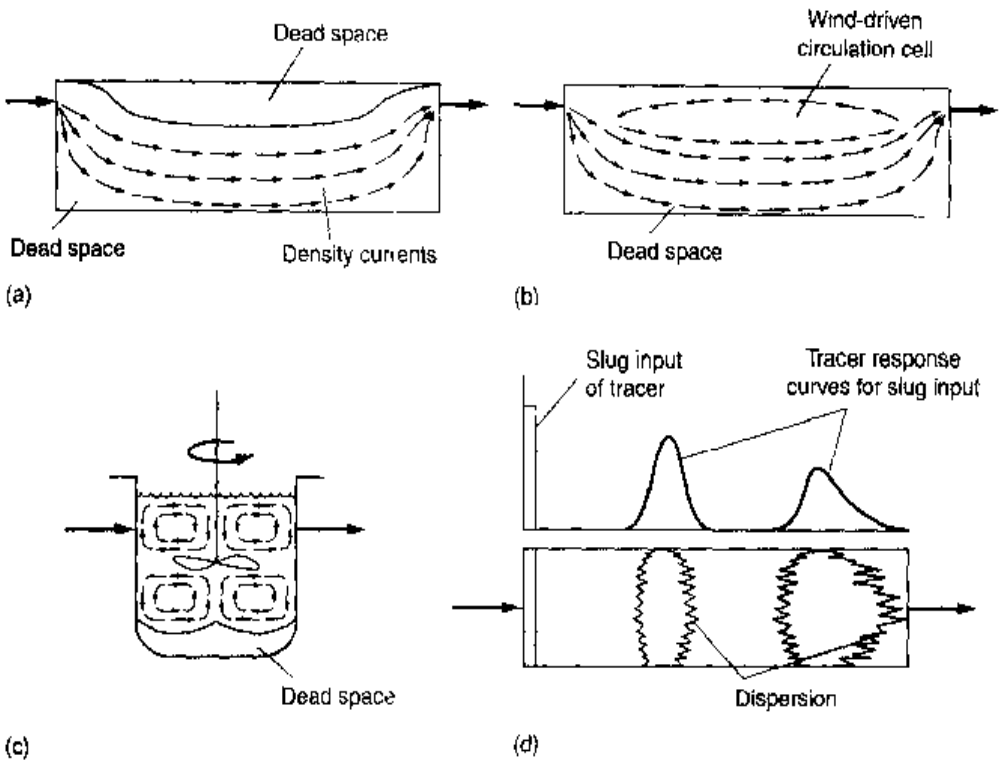
$$\frac{\partial C}{\partial t} = -\frac{Q}{A}\frac{\partial C}{\partial x} = -v\frac{\partial C}{\partial x} \tag{4-22}$$

where v = velocity of flow, LT^{-1}, (m/s)

Because both sides of the equation are the same (note $\partial t = \partial x/v$), except for the minus sign, the only way that the equation can be satisfied is if the change in concentration with distance is equal to zero. Thus, the effluent concentration must be equal to the influent concentration, which is consistent with the depiction on Fig. 4–3(*b*-2).

4–4 ANALYSIS OF NONIDEAL FLOW IN REACTORS USING TRACERS

Although many of the practical aspects of process and reactor design are discussed in detail in the chapters that follow, the analysis of reactor hydraulic performance using tracers is considered in this section. The discussion of nonideal flow in this section will serve as an introduction to the modeling of nonideal flow considered in the following section. Attention is called to this subject because often it is neglected or not considered properly. Because of a lack of appreciation for the hydraulics of reactors, many of the treatment plants that have been built do not perform hydraulically as designed. Included in this section is a discussion of (1) the factors leading to nonideal flow in reactors, (2) the need for tracer analysis, (3) the conduct of tracer tests, (4) the types of tracers used, (5) the analysis of tracer response curves, and (6) the practical interpretation of tracer measurements.



Factors Leading to Nonideal Flow in Reactors

As noted previously, nonideal flow is often defined as short circuiting that occurs when a portion of the flow that enters the reactor during a given time period arrives at the outlet before the bulk of the flow that entered the reactor during the same time period arrives. Factors leading to nonideal flow in reactors include:

1. Temperature differences In complete-mix and plug-flow reactors, nonideal flow (short circuiting) can be caused by density currents due to temperature differences. When the water entering the reactor is colder or warmer than the water in the tank, a portion of the water can travel to the outlet along the bottom of or across the top of the reactor without mixing completely (see Fig. 4–6*a*).

Figure 4–6

Definition sketch for short circuiting caused by (a) density currents caused by temperature differences, (b) wind circulation patterns, (c) inadequate mixing, (d) fluid advection and dispersion.

2. Wind-driven circulation patterns. In shallow reactors, wind-circulation patterns can be set up that will transport a portion of the incoming water to the outlet in a fraction of the actual detention time (see Fig. 4–6*b*).
3. Inadequate mixing. Without sufficient energy input, portions of the reactor contents may not mix with the incoming water (see Fig. 4–6*c*).
4. Poor design. Depending on the design of the inlet and outlet of the reactor relative to the reactor aspect ratio, dead zones may develop within the reactor that will not mix with the incoming water (see Fig. 4–6*d*).
5. Axial dispersion in plug-flow reactors. In plug-flow reactors the forward movement of the tracer is due to advection and dispersion. *Advection* is the term used to describe the movement of dissolved or colloidal material with the current velocity. *Dispersion* is the term used to describe the axial and longitudinal transport of material brought about by velocity differences, turbulent eddies, and molecular diffusion. The distinction between molecular diffusion, turbulent diffusion, and dispersion is considered in the subsequent discussion dealing with "Modeling Nonideal Flow In Reactors." In a tubular plug-flow reactor (e.g., a pipeline), the early arrival of the tracer at the outlet can be reasoned partially by remembering that the velocity distribution in the pipeline will be parabolic.

Ultimately, the inefficient use of the reactor volume due to short circuiting resulting from temperature differences, the presence of dead zones resulting from poor design, inadequate mixing, and dispersion (see Fig. 4–6) can result in reduced treatment performance. The subject of short circuiting in a series of complete-mix reactors was examined extensively in early papers by MacMullin and Weber (1935); Fitch (1956); and Morrill (1932). Morrill examined the effects of short circuiting on the performance of sedimentation tanks.

Need for Tracer Analysis

One of the more important practical considerations involved in reactor design is how to achieve the ideal conditions postulated in the analysis of their performance. The use of dyes and tracers for measuring the residence time distribution curves is one of the simplest and most successful methods now used to assess the hydraulic performance of full-scale reactors. Important applications of tracer studies include (1) the assessment of short circuiting in sedimentation tanks and biological reactors, (2) the assessment of the contact time in chlorine contact basins, (3) the assessment of the hydraulic approach conditions in UV reactors, and (4) the assessment of flow patterns in constructed wetlands and other natural treatment systems. Tracer studies are also of critical importance in assessing the degree of success that has been achieved with corrective measures.

Types of Tracers

Over the years, a number of tracers have been used to evaluate the hydraulic performance of reactors. Important characteristics for a tracer include (adapted in part from Denbigh and Turner, 1965):

- The tracer should not affect the flow (should have essentially the same density as water when diluted).
- The tracer must be conservative so that a mass balance can be performed.
- It must be possible to inject the tracer over a short time period.
- The tracer should be able to be analyzed conveniently.
- The molecular diffusivity of the tracer should be low.
- The tracer should not be absorbed on or react with the exposed reactor surfaces.
- The tracer should not be absorbed on or react with the particles in wastewater.

Dyes and chemicals that have been used successfully in tracer studies include congo red, fluorescein, fluorosilicic acid (H_2SiF_6), hexafluoride gas (SF_6), lithium chloride (LiCl), Pontacyl Brilliant Pink B, potassium, potassium permanganate, rhodamine WT, and sodium chloride (NaCl). Pontacyl Brilliant Pink B (the acid form of rhodamine WT) is especially useful in the conduct of dispersion studies because it is not readily adsorbed onto surfaces. Because fluorescein, rhodamine WT, and Pontacyl Brilliant Pink B can be detected at very low concentrations using a fluorometer (see Fig. 4–7), they are the dye tracers used most commonly in the evaluation of wastewater-treatment facilities. Lithium chloride is commonly used for the study of natural systems. Sodium chloride, used commonly in the past, has a tendency to form density currents unless mixed. Hexafluoride gas (SF_6) is used most commonly for tracing the movement of groundwater.

Conduct of Tracer Tests

In tracer studies, typically a tracer (i.e., a dye, most commonly) is introduced into the influent end of the reactor or basin to be studied. The time of its arrival at the effluent end is determined by collecting a series of grab samples for a given period of time or by measuring the arrival of a tracer using instrumental methods (see Fig. 4–8). The method used to introduce the tracer will control the type of response observed at the downstream end. Two types of dye input are used, the choice depending on the influent

Figure 4–7

Schematic of setup used to conduct tracer studies of plug-flow reactors: (*a*) slug of tracer added to flow and (*b*) continuous input of tracer added to flow. Tracer response curve is measured continuously (see Fig. 4–8).

(a)

(b)

and effluent configurations. The first method involves the injection of a quantity of dye (sometimes referred to as a pulse or slug of dye) over a short period of time. Initial mixing is usually accomplished with a static mixer or an auxiliary mixer. With the slug injection method it is important to keep the initial mixing time short relative to the detention time of the reactor being measured. The measured output is as described on Fig. 4–3(*a*-1 and *b*-1). In the second method, a continuous step input of dye is intro-

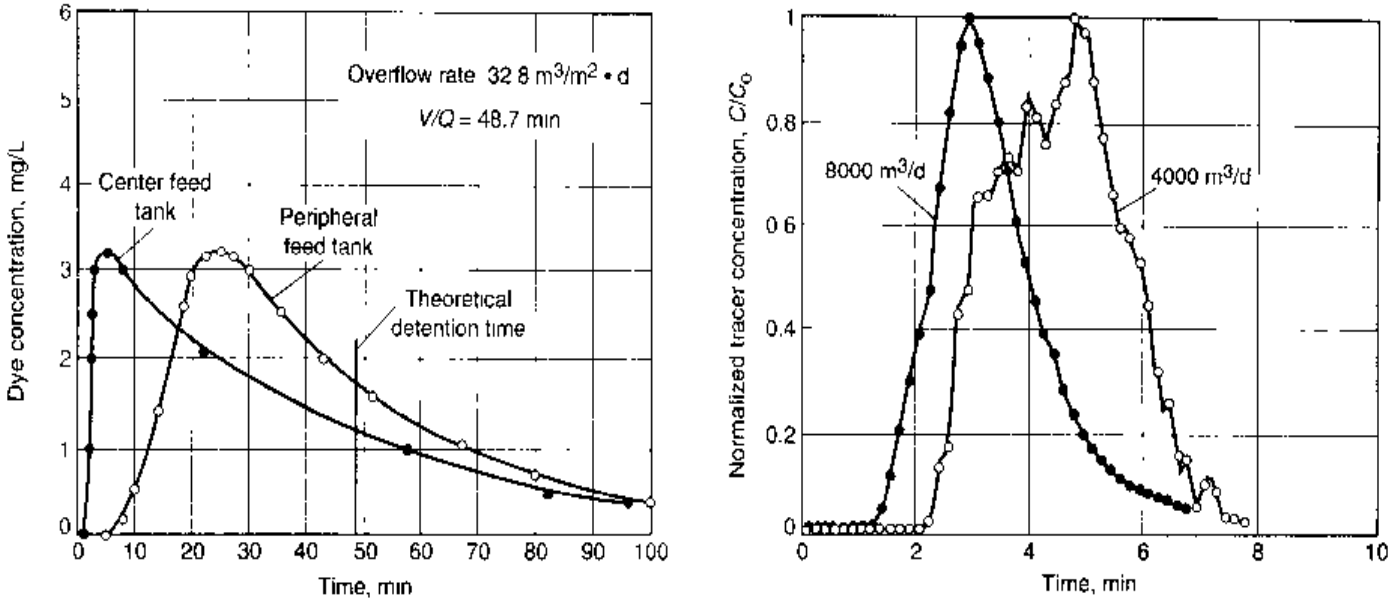

Figure 4–9

Typical tracer response curves: two different types of circular clarifiers (adapted from Dague and Baumann, 1961) and open channel UV disinfection system. *(Courtesy Andy Salveson, Whitley Burchett & Associates.)*

duced until the effluent concentration matches the influent concentration. The measured response is as shown on Fig. 4–3(*a*-2 and *b*-2). Another response curve can be measured after the dye injection has ceased and the dye in the reactor is flushed out.

Analysis of Tracer Response Curves

Tracers of various types are used commonly to assess the hydraulic performance of reactors used for wastewater treatment. Typical examples of tracer response curves are shown on Fig. 4–9. Tracer response curves, measured using a short-term and continuous injection of tracer, are known as C (concentration versus time) and F (fraction of tracer remaining in the reactor versus time) curves, respectively. The fraction remaining is based on the volume of water displaced from the reactor by the step input of tracer. The analysis of tracer response curves is considered in detail in the following discussion. The terms used to characterize tracer response curves, the analysis of concentration versus time, and the development of residence time distribution (RTD) curves are described below. The material to be discussed below will be used in the subsequent analysis of the hydraulic characteristics of nonideal reactors.

Terms Used to Characterize Tracer Response Curves. Because of the complexity of the hydraulic response of full-scale reactors, tracer response curves are used to analyze the hydraulics of reactors. Over the years, a number of numerical values have been used to characterize output tracer curves (see Table 4–2). As reported in Table 4–2, τ, as given previously, is the theoretical detention (residence) time defined as V/Q, where V is the volume and Q is the flowrate in consistent units. As noted in Table 4–2, various other symbols have been used in the literature for the theoretical detention time.

Table 4–2 Various terms used to describe the hydraulic performance of reactors used for wastewater treatment[a]

Term	Definition
τ, θ, θ_h[b]	Theoretical hydraulic residence time (V, volume/Q, flowrate)
t_i	Time at which tracer first appears
t_p	Time at which the peak concentration of the tracer is observed (mode)
t_g	Mean time to reach centroid of the RTD curve
t_{10}, t_{50}, t_{90}	Time at which 10, 50, and 90 percent of the tracer had passed through the reactor
t_{90}/t_{10}	Morrill dispersion index, MDI
1/MDI	Volumetric efficiency as defined by Morrill (1932)
t_i/τ	Index of short circuiting. In an ideal plug-flow reactor, the ratio is 1, and approaches zero with increased mixing
t_p/τ	Index of modal retention time. Ratio will approach 1 in a plug-flow reactor, and 0 in a complete-mix reactor. For values of the ratio greater than or less than 1.0, the flow distribution in the reactor is not uniform
t_g/τ	Index of average retention time. A value of 1 would indicate that full use is being made of the volume. A value of the ratio greater than or less than 1.0 indicates the flow distribution is not uniform
t_{50}/τ	Index of mean retention time. The ratio t_{50}/τ to is a measure of the skew of the RTD curve. In an effective plug-flow reactor, the RTD curve is very similar to a normal or Gaussian distribution (U.S. EPA, 1986). A value of t_{50}/τ of less than 1.0 corresponds to an RTD curve that is skewed to the left. Similarly, for values greater than 1.0 the RTD curve is skewed to the right

[a] Adapted from Morrill (1932), Fair and Geyer (1954), and U.S. EPA (1986).

[b] The symbols θ and θ_h have also been used for the theoretical hydraulic residence time.

The relationships of the terms in Table 4–2 and a typical tracer response curve are illustrated on Fig. 4–10.

Concentration versus Time Tracer Response Curves. As noted previously, tracer response curves measured using a short-term and continuous injection of tracer are known as C curves (concentration versus time). To characterize C curves, such as those shown on Fig. 4–9, the mean value is given by the centroid of the distribution. For C curves, the theoretical mean residence time is determined as follows.

$$\bar{t}_c = \frac{\int_0^\infty tC(t)dt}{\int_0^\infty C(t)dt} \qquad (4\text{–}23)$$

where $\bar{t}_c$ = mean residence time derived from tracer curve, T
t = time, T
$C(t)$ = tracer concentration at time t, ML^{-3}

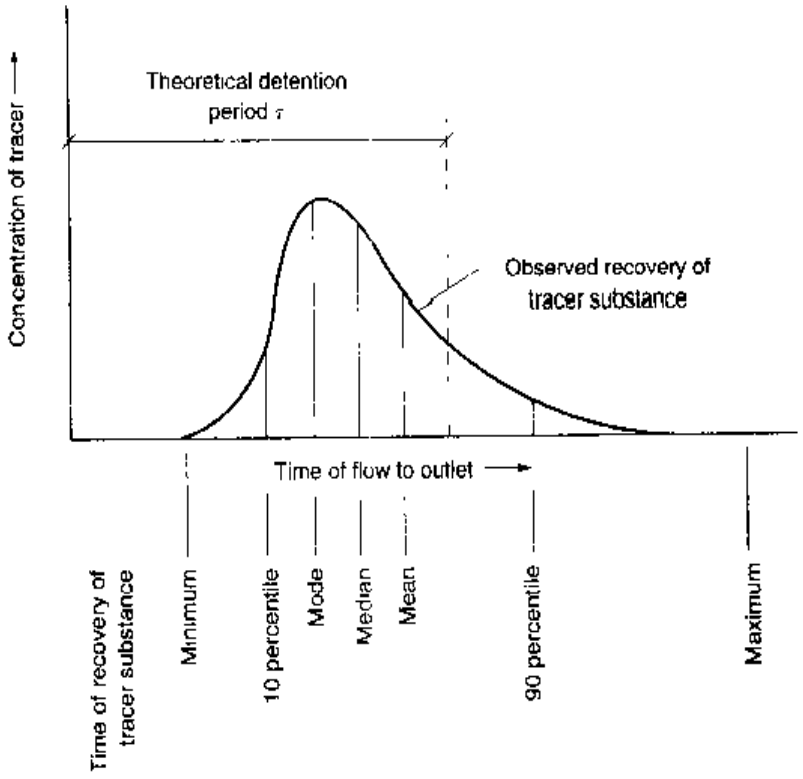

Figure 4–10
Definition sketch for the parameters used in the analysis of concentration versus time tracer response curves.

The variance σ_c^2 used to define the spread of the distribution is defined as

$$\sigma_c^2 = \frac{\int_0^\infty (t - \bar{t})^2 C(t)dt}{\int_0^\infty C(t)dt} = \frac{\int_0^\infty t^2 C(t)dt}{\int_0^\infty C(t)dt} - (\bar{t}_c)^2 \tag{4–24}$$

It will be recognized that the integral term in the denominator in Eqs. (4–23) and (4–24) corresponds to the area under the concentration versus time curve. It will also be recognized that the mean and variance are equal to the *first* and *second moments* of the distribution about the y axis.

If the concentration versus time tracer response curve is defined by a series of discrete time step measurements, the theoretical mean residence time is typically approximated as

$$\bar{t}_{\Delta c} \approx \frac{\Sigma t_i C_i \Delta t_i}{\Sigma C_i \Delta t_i} \tag{4–25}$$

where $\bar{t}_{\Delta c}$ = mean detention time based on discrete time step measurements, T
t_i = time at ith measurement, T
C_i = concentration at ith measurement, ML^{-3}
Δt_i = time increment about C_i, T

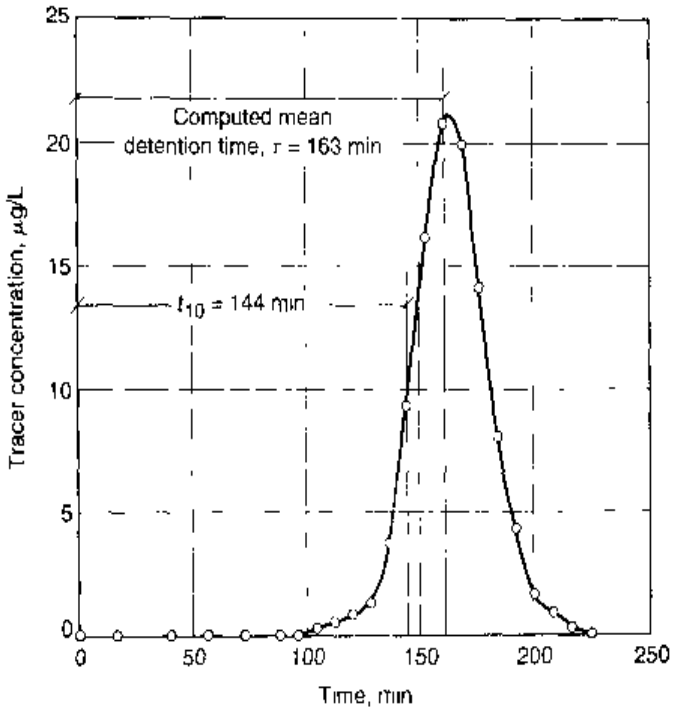

Figure 4–11
Concentration versus time tracer response curve for a long narrow chlorine contact basin.

The variance for a concentration versus time tracer response curve, defined by a series of discrete time step measurements, is defined as

$$\sigma_{\Delta t}^2 = \frac{\Sigma t_i^2 C_i \Delta t_i}{\Sigma C_i \Delta t_i} - (t_{\Delta t})^2 \tag{4-26}$$

where $\sigma_{\Delta}^2 t$ = variance based on discrete time measurements, T^2

A typical concentration versus time tracer curve for a chlorine contact basin is presented on Fig. 4–11. Additional details on the physical features for the chlorine contact basin used to develop Fig. 4–11 are presented in Example 4–1. The application of Eqs. (4–25) and (4–26) is illustrated in Example 4–1. Additional details on the analysis of tracer response curves may be found in Levenspiel (1972).

EXAMPLE 4–1 Determination of the Mean Residence Time and Variance for a Plug-Flow Chlorine Contact Basin The following data were obtained from a dye tracer test to evaluate the hydraulic performance of a long chlorine contact basin, such as shown on Fig. 4–5. The chlorine contact system is designed to provide a minimum contact time of 2 h at a flowrate of 300,000 m^3/d (80 Mgal/d). The flowrate at the time when the tracer test was conducted was 240,000 m^3/d. The chlorine contact system consists of four chlorine contact tanks. Each of the four chlorine contact tanks is baffled into 13 individual contact channels. Each channel is 36.6 m (120 ft) long, 3.0 m (10 ft) wide, and has a normal water depth of 4.9 m (16 ft). Using these data and the tracer test data, determine the mean residence time and variance for the tracer response curve.

Time, min	Concentration, μg/L	Time, min	Concentration, μg/L
0	0.0	144	9.333
16	0.0	152	16.167
40	0.0	160	20.778
56	0.0	168	19.944
72	0.0	176	14.111
88	0.0	184	8.056
96	0.056	192	4.333
104	0.333	200	1.556
112	0.556	208	0.889
120	0.833	216	0.278
128	1.278	224	0.000
136	3.722		

Solution

1. Determine the mean residence time and variance for the tracer response curve using Eqs. (4–25) and (4–26).
   a. Set up computation table to solve Eqs. (4–25) and (4–26). In setting up the computation table given below, the Δt value was omitted as it appears in both the numerator and the denominator of Eqs. (4–25) and (4–26).

Time t, min	Conc. C, μg/L	$t \times C$	$t^2 \times C$
88	0.000	0.000	0
96	0.056	5.338	512.41
104	0.333	34.663	3,604.97
112	0.556	62.227	6,969.45
120	0.833	99.996	11,999.52
128	1.278	163.558	20,935.48

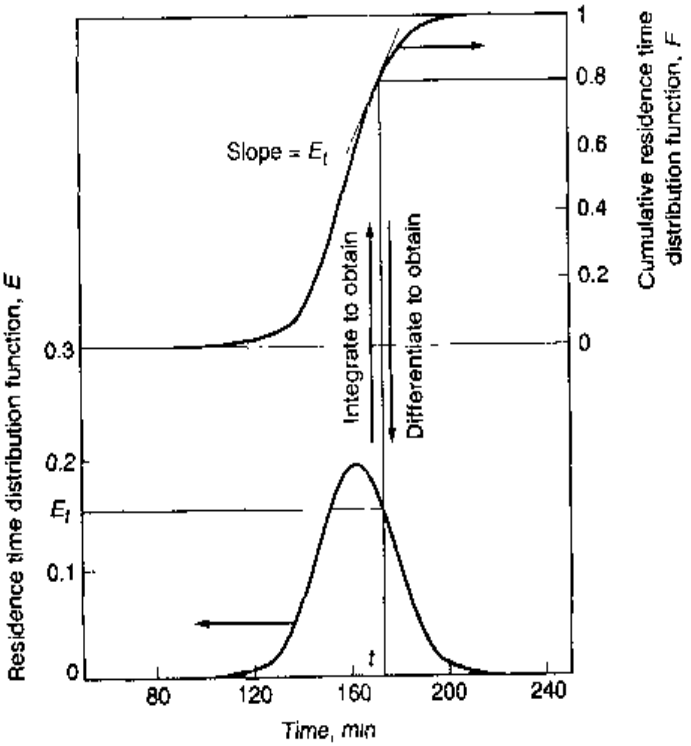
200	1.556	311.120	62,224.00
208	0.889	184.891	38,457.37
216	0.278	60.005	12,961.04
224	0.000	0.000	
Total	102.222	16,702.229	2,757,959.48

b. Determine the mean residence time and variance

$$\bar{t}_{\Delta c} = \frac{\Sigma t_i C_i \Delta t_i}{\Sigma C_i \Delta t_i} = \frac{16{,}702.23}{102.22} = 163.4 \text{ min} = 2.7 \text{ h}$$

c. Determine the variance

$$\sigma^2_{\Delta c} = \frac{\Sigma t_i^2 C_i \Delta t_i}{\Sigma C_i \Delta t_i} - (\bar{t}_{\Delta c})^2 = \frac{2{,}757{,}959.48}{102.22} - (163.4)^2 = 280.5 \text{ min}^2$$



$$\sigma_{\Delta c} = 16.7 \text{ min}$$

Comment The mean and variance determined in this analysis will be used in Example 4–4 to determine the dispersion number and the coefficient of dispersion.

Residence Time Distribution (RTD) Curves. To standardize the analysis of output concentration versus time curves for a pulse input, such as those shown on Fig. 4–9, the output concentration measurements are often normalized by dividing the measured concentration values by an appropriate function such that the area under the normalized curve is equal to 1. The normalized curves are known, more formally, as *residence time distribution (RTD) curves* (see Fig. 4–12). When a pulse addition of tracer is used, the area under the normalized curve is known as an E curve (also known

Figure 4–12

Normalized residence time distribution curves. The curve on the bottom, known as the exit age curve, is identified as the E curve. The curve on the top, known as the cumulative residence time curve, is identified as the F curve.

as the exit age curve). The most important characteristic of an E curve is that the area under the curve is equal to 1, as defined by the following integral:

$$\int_0^\infty E(t)dt = 1 \tag{4-27}$$

where $E(t)$ is the residence time distribution function. The $E(t)$ value is related to the $C(t)$ value as follows:

$$E(t) = \frac{C(t)}{\int_0^\infty C(t)dt} \tag{4-28}$$

As in Eqs. (4–23) and (4–24), the integral term in the denominator in Eq. (4–28) corresponds to the area under the concentration versus time curve. Applying Eq. (4–28) to the expression, obtained previously, for the complete-mix reactor, the exit age curve $E(t)$ for a complete-mix reactor is obtained as follows:

$$E(t) = \frac{C(t)}{\int_0^\infty C(t)dt} = \frac{C_o e^{-t/\tau}}{\int_0^\infty C_o e^{-t/\tau}\,dt} = \frac{e^{-t/\tau}}{\tau} \tag{4-29}$$

and the corresponding value based on normalized time, $\theta = t/\tau$, is

$$E(\theta) = \tau E(t) = e^{-\theta} \tag{4-30}$$

The mean residence time for the $E(t)$ curve, given by Eq. (4–30), can be derived by applying Eq. (4–23); the resulting expression is given by

$$t_m = \frac{\int_0^\infty tE(t)dt}{\int_0^\infty E(t)dt} = \int_0^\infty tE(t)dt \tag{4-31}$$

In a similar manner when a step input is used, the normalized concentration curve is known as the cumulative residence time distribution curve and is designated as the F curve. The F curve is defined as

$$F(t) = \int_0^t E(t)dt \tag{4-32}$$

where $F(t)$ is the cumulative residence time distribution function. As shown on Fig. 4–12, the $F(t)$ curve is the integral of the $E(t)$ curve while the $E(t)$ curve is the derivative of the $F(t)$ curve. In effect, $F(t)$ represents the amount of tracer that has been in the reactor for less than the time t. The development of E and F RTD curves is illustrated in Example 4–2. Additional details on the analysis of E and F curves may be found in Denbigh and Turner (1965), Fogler (1999), Levenspiel (1972), and in the chemical engineering literature.

EXAMPLE 4–2 Development of Residence Time Distribution (RTD) Curves from Concentration versus Time Tracer Curves Use the concentration versus time tracer data given in Example 4–1 to develop E and F residence time distribution (RTD) curves for the chlorine contact basin. Using the E curve, compute the residence time and compare to the value obtained in Example 4–1. Plot the resulting E and F curves.

Solution

1. Using the values for time and concentration from Example 4–1, set up a computation table to calculate $E(t)$ values. The computation table is shown below. The $E(t)$ values are calculated by finding the sum of the $C \times \Delta t$ values, which corresponds to the area under the C (concentration) curve, and dividing the original concentrations by the sum as illustrated below.

   Area under C curve $= \Sigma C \Delta t$

   and

   $$E(t) = \frac{C}{\Sigma C \Delta t}$$

   a. For each time interval, multiply the concentration by the time step ($\Delta t = 8$ min) and obtain the sum of the multiplied values. As shown in the computation table, the sum (which is the approximate area under the curve) is 817.778 (μg/L)·min.
   b. Calculate the $E(t)$ values by dividing the original concentration values by the area under the curve.
   c. Confirm that the $E(t)$ values are correct by multiplying each one by the time step, and calculating the sum. According to Eq. (4–28) written in differential form, the sum should be 1.00.

   $$\Sigma E(t)\Delta t = \Sigma\left(\frac{C\Delta t}{\Sigma C \Delta t}\right) = \Sigma\left(\frac{C}{\Sigma C}\right) = 1$$

Time t, min	Conc. C, μg/L	$C \times \Delta t$ μg/L·min	$E(t)$, min^{-1}	$E(t) \times \Delta t$, unitless	$t \times E(t) \times \Delta t$, min

2. Determine the mean residence time using the following summation form of Eq. (4–28).

   $$\bar{t} = \Sigma(t)E(t)\Delta t$$

   The required computation is presented in the final column of the computation table given above. As shown, the computed mean residence time (163.6 min) is essentially the same as the value (163.4 min) determined in Example 4–1.

3. Develop the F RTD curve. The values for plotting the F curve are obtained by summing cumulatively the $E(t)\Delta t$ values to obtain the coordinates of the F curve.

4. Plot the resulting E and F curves. The plot of the E (column 3) and F (column 4) curves using the values determined above is shown below.

Comment The use of normalized RTD curves to obtain coefficients of dispersion is included in the discussion of the Hydraulic Characteristics of Reactors. Additional details may be found in Denbigh and Turner (1965) and Levenspiel (1972).

Practical Interpretation of Tracer Measurements

In 1932, based on his studies of sedimentation basins, Morrill (1932) suggested that the ratio of the 90 percentile to the 10 percentile value from the cumulative tracer curve could be used as a measure of the dispersion index, and that 1 over the dispersion index

is a measure of the volumetric efficiency. The dispersion index as proposed by Morrill is given by

$$\text{Morrill dispersion index, MDI} = \frac{P_{90}}{P_{10}} \tag{4–33}$$

where P_{90} = 90 percentile value from log-probability plot
P_{10} = 10 percentile value from log-probability plot

The percentile values are obtained from a log-probability plot of the time (log scale) versus the cumulative percentage of the total tracer which has passed out of the basin (on probability scale). The value of the MDI for an ideal plug-flow reactor is 1.0 and about 22 for a complete-mix reactor. A plug-flow reactor with an MDI value of 2.0 or less is considered by the U.S. EPA to be an effective plug-flow reactor (U.S. EPA, 1986). The volumetric efficiency is given by the following expression:

$$\text{Volumetric efficiency, \%} = \frac{1}{\text{MDI}} \times 100 \tag{4–34}$$

The determination of the Morrill dispersion index and the volumetric efficiency is illustrated in Example 4–3.

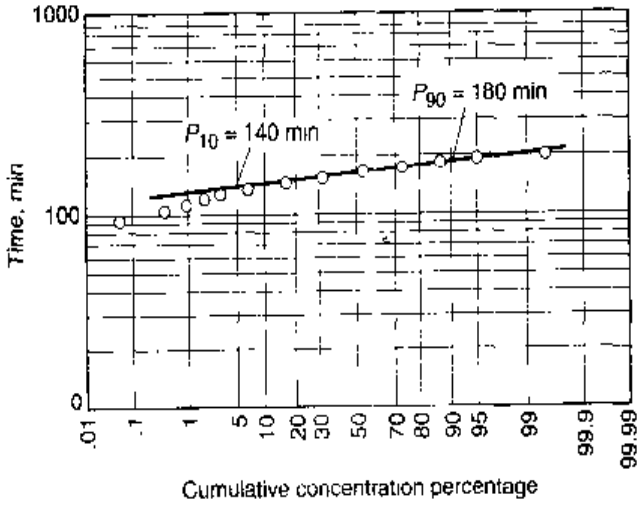
EXAMPLE 4–3 Determination of the Morrill Dispersion Index and Volumetric Efficiency for a Plug-Flow Chlorine Contact Basin Determine the MDI and the corresponding basin volumetric efficiency for the chlorine contact basin given in Example 4–1.

Solution

1. Determine the MDI and the volumetric efficiency using the tracer response data given in Example 4–1.
   a. Set up a computation table to obtain cumulative concentration and percentage values.

Time t, min	Conc. C, ppb	Cumulative concentration	Cumulative percentage
88	0.000		
96	0.056	0.05	0.05
104	0.333	0.39[a]	0.38[b]
112	0.556	0.94	0.92
120	0.833	1.78	1.74
128	1.278	3.06	2.99
136	3.722	6.78	6.63
144	9.333	16.11	15.75
152	16.167	32.28	31.58

(continued)



(*Continued*)

Time *t*, min	Conc. *C*, ppb	Cumulative concentration	Cumulative percentage
160	20.778	53.06	51.91
168	19.944	73.00	71.41
176	14.111	87.11	85.22
184	8.056	95.17	93.10
192	4.333	99.50	97.34
200	1.556		
208	0.889		
216	0.278		
224	0.000		
Total	102.222		

[a]0.056 + 0.333 − 0.39

[b](0.39/102.222) × 100 = 0.38.

b. Plot the cumulative concentration as a percentage on log-probability paper. The cumulative percentage is plotted on the probability scale and the time is plotted on the log scale. The required plot is shown below.

c. Determine the Morrill dispersion index from the plot prepared in the previous step.

$$\text{Morrill dispersion index, MDI} = \frac{P_{90}}{P_{10}} = \frac{180}{140} = 1.29$$

d. Determine the volumetric efficiency.

$$\text{Volumetric efficiency, \%} = \frac{1}{\text{MDI}} \times 100 = \frac{1}{1.29} \times 100 = 78\%$$

Comment The MDI value (1.29) for the chlorine contact basin is very low. As noted above, an MDI value below 2.0 has been established as an effective design (U.S. EPA, 1986). Similarly the volumetric efficiency is very high, signifying essentially plug flow with small amounts of axial dispersion.

4–5 MODELING NONIDEAL FLOW IN REACTORS

The hydraulic characteristics of nonideal reactors can be modeled by taking dispersion into consideration. For example, if dispersion becomes infinite, the plug-flow reactor with axial dispersion is equivalent to a complete-mix reactor. However, before considering nonideal flow in reactors it will be helpful to examine the distinction between the coefficient of molecular diffusion, turbulent diffusion, and dispersion as applied to the analysis of reactors used for wastewater treatment. Both the plug-flow reactor with axial dispersion and complete-mix reactors in series are considered in the following discussion.

The Distinction between Molecular Diffusion, Turbulent Diffusion, and Dispersion

Under quiescent flow conditions (i.e., no flow), the mass transfer of material is brought about by "molecular diffusion." The transfer of mass by molecular diffusion in stationary systems can be represented as a function of the concentration gradient as follows:

$$r = -D_m \frac{\partial C}{\partial x} \tag{4–35}$$

where r = rate of mass transfer per unit area per unit time, $ML^{-2}T^{-1}$
D_m = coefficient of molecular diffusion in the x direction, L^2T^{-1}
C = concentration of constituent being transferred, ML^{-3}
x = distance, L

In the chemical engineering literature the symbol J is used to denote mass transfer in concentration units whereas the symbol N, as used in Eq. (4–73), is used to denote the transfer of mass expressed as moles. The negative sign in Eq. (4–35) is used to denote the fact that diffusion takes place in the direction of decreasing concentration (Shaw, 1966). Equation (4–35) is known as Fick's first law of diffusion. Fick derived the first and second laws of diffusion [Eqs. (4–35) and (4–140)] in the 1850s by direct analogy to the equations used to describe the conduction of heat in solids as proposed by Fourier (Crank, 1957). Determination of numerical values for the coefficient of molecular diffusion is illustrated in Sec. 4–8.

Under turbulent conditions (e.g., mixing) without flow, the transfer of mass is brought about by microscale turbulence known as "turbulent or eddy diffusion." For this case, the molecular diffusion term D_m in Eq. (4–35) is replaced by the turbulent diffusion term D_e or E.

Table 4–3
Typical range of values for molecular diffusion, turbulent diffusion, and dispersion[a]

Item	Symbol	Range of values, cm^2/s
Molecular diffusion	D_m	10^{-8}–10^{-4}
Turbulent or eddy diffusion	D_e, E	10^{-4}–10^{-2}
Dispersion	D	10^{2}–10^{6}

[a] Adapted from Schnoor (1996), Shaw (1966), and Thibodeaux (1996).

Under turbulent-flow conditions, the longitudinal spreading of a tracer is caused by dispersion, in which case the molecular diffusion term D_m is replaced by the "coefficient of dispersion" D. The coefficient of dispersion is an inclusive term which includes the effects of dispersion caused by advection (i.e., transport caused by differences in the fluid velocity), turbulent eddies (i.e., eddy diffusion), and molecular diffusion. While the magnitude of the molecular diffusion depends primarily on the chemical and fluid properties, turbulent or eddy diffusion and dispersion depend primarily on the flow regime.

In general, the following relationship holds between the numerical values of the various terms described above.

$$D >> D_e >> D_m \tag{4–36}$$

Typical observed ranges for the coefficient of molecular diffusion, turbulent or eddy diffusion, or dispersion are reported in Table 4–3. In all cases, it is important to remember that regardless of whether the coefficient of molecular diffusion, turbulent or eddy diffusion, or dispersion is operative, the driving force for mass transfer is the concentration gradient.

Plug-Flow Reactor with Axial Dispersion

In the following analysis only the one-dimensional problem is considered. However, it should be noted that all dispersion problems are three-dimensional, with the dispersion coefficient varying with direction and the degree of turbulence. Using the relationship given above [Eq. (4–35)] and referring to Fig. 4–5*c*, given previously, the one-dimensional materials mass balance for the transport of a conservative dye tracer by advection and dispersion is

Accumulation = inflow − outflow

$$\frac{\partial C}{\partial t} A\Delta x = \left(vAC - AD\frac{\Delta C}{\Delta x}\right)\Bigg|_x - \left(vAC - AD\frac{\Delta C}{\Delta x}\right)\Bigg|_{x+\Delta x} \tag{4–37}$$

where $\partial C/\partial t$ = change in concentration with time, $ML^{-3}T^{-1}$, $(g/m^3 \cdot s)$
A = cross-sectional area in x direction, L^2, (m^2)
Δx = differential distance, L, m
v = average velocity in x direction, LT^{-1}, (m/s)
C = constituent concentration, ML^{-3}, (g/m^3)
D = coefficient of axial dispersion, L^2T^{-1}, (m^2/s)

In Eq. (4–37) the term vAC represents the transport of mass due to advection and the term $AD(\Delta C/\Delta x)$ represents the transport brought about by dispersion. Taking the limit of Eq. (4–37) as Δx approaches zero results in the following two expressions:

$$\frac{\partial C}{\partial t} = -D\frac{\partial^2 C}{\partial x^2} - v_x\frac{\partial C}{\partial x} \tag{4–38}$$

$$\frac{\partial C}{\partial t} = -D\frac{\partial^2 C}{\partial x^2} - \frac{\partial C}{\partial t} \tag{4–39}$$

In Eq. (4–39) the hydraulic detention time ∂t has been substituted for the term $\partial x/v_x$. Equation (4–39) has been solved for small amounts of axial dispersion (see below). The solution for a unit pulse input leading to symmetrical output tracer response curves for small amounts of axial dispersion is given by Levenspiel (1972).

$$C_\theta = \frac{1}{2\sqrt{\pi(D/uL)}}\exp\left[-\frac{(1-\theta)^2}{4(D/uL)}\right] \tag{4–40}$$

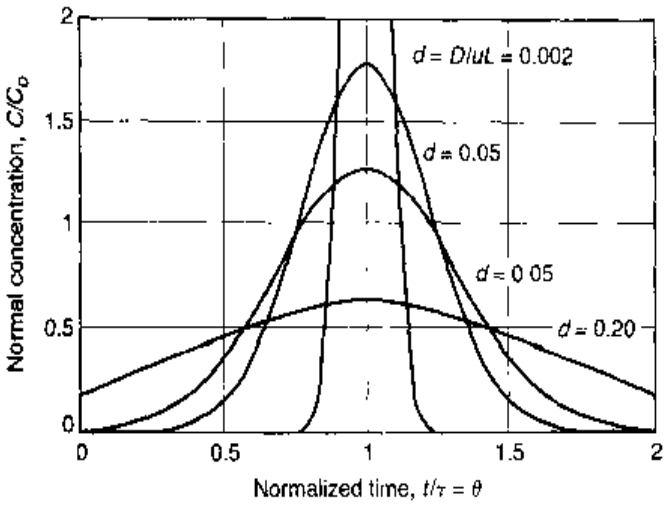
where C_θ = normalized tracer response C/C_o, unitless
θ = normalized time t/τ, unitless
t = time T, (s)
τ = theoretical detention time V/Q, T, (s)
D = coefficient of axial dispersion L^2T^{-1}, (m^2/s)
u = fluid velocity LT^{-1}, (m/s)
L = characteristic length L, (m)

The solution given by Eq. (4–40) is for what is known as a *closed system* in which it is assumed that there is no dispersion upstream or downstream of the boundaries of the reactor (i.e., ideal plug flow). Nevertheless, for small amounts of dispersion, Eq. (4–40) can be used to approximate the performance of an open or closed reactor, regardless of the boundary conditions.

It will be noted that Eq. (4–40) has the same general form as the equation for the normal probability distribution. Thus, the corresponding mean and variance are

$$\bar{\theta} = \frac{\bar{t}_c}{\tau} = 1 \tag{4–41}$$

$$\sigma_\theta^2 = \frac{\sigma_c^2}{\tau^2} = 2\frac{D}{uL} \tag{4–42}$$



where $\bar{\theta}$ = normalized mean detention time $\bar{t}_c/\tau$, unitless
$\bar{t}_c$ = mean detention (or residence) time derived from C curve [see Eq. (4–26)], T, h, min
τ = theoretical detention (or residence) time T, (s)
σ_θ^2 = variance of normalized tracer response C curve T^2, (s^2)
σ_c^2 = variance derived from C curve [see Eq. (4–24)] T^2, (s^2)

Defining the exact extent of axial dispersion is difficult. To provide an estimate of dispersion, the following unitless dispersion number has been defined:

$$d = \frac{D}{uL} = \frac{Dt}{L^2} \tag{4–43}$$

Figure 4–13

Typical concentration versus time tracer response curves for a plug-flow reactor with small amounts of axial dispersion subject to a pulse (slug) input of tracer.

where d = dispersion number, unitless
D = coefficient of axial dispersion L^2T^{-1}, (m^2/s)
u = fluid velocity LT^{-1}, (m/s)
L = characteristic length L, (m)
t = travel time (L/u), T, (s)

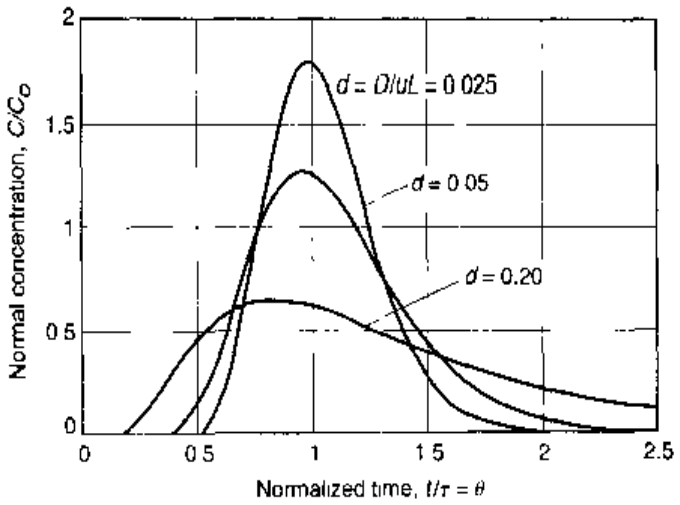
Normalized effluent concentration versus time curves, obtained using Eq. (4–40), for a plug-flow reactor with limited axial dispersion for various values of the dispersion number are shown on Fig. 4–13.

When dispersion is large, the output curve becomes increasingly nonsymmetrical, and the problem becomes sensitive to the boundary conditions. In environmental problems, a wide variety of entrance and exit conditions are encountered, but most can be considered approximately open; that is, the flow characteristics do not change greatly as the boundaries are crossed. The solution to Eq. (4–39) for a unit pulse input in an *open system* with larger amounts of dispersion is as follows (Fogler, 1999; Levenspiel, 1972):

$$C_\theta = \frac{1}{2\sqrt{\pi\theta(D/uL)}} \exp\left[-\frac{(1-\theta)^2}{4\theta(D/uL)}\right] \tag{4–44}$$

The corresponding mean and variance are

$$\bar{\theta} = \frac{\bar{t}_c}{\tau} = 1 + 2\frac{D}{uL} \tag{4–45}$$



$$\sigma_\theta^2 = \frac{\sigma_c^2}{\tau^2} = 2\frac{D}{uL} + 8\left(\frac{D}{uL}\right)^2 \tag{4–46}$$

where the terms are as defined previously for Eqs. (4–41), (4–42), and (4–43).

The mean as given by Eq. (4–45) is greater than the hydraulic detention time because of the forward movement of the tracer due to dispersion. Effluent concentration versus time curves, obtained using Eq. (4–44), for a plug-flow reactor with significant axial dispersion for various dispersion factors are shown on Fig. 4–14. A more

Figure 4–14

Typical concentration versus time tracer response curves for a plug-flow reactor with large amounts of axial dispersion subject to a pulse (slug) input of tracer.

detailed discussion of closed and open reactors may be found in Fogler (1999) and Levenspiel (1972).

In the literature, the inverse of Eq (4–43), as given below, is often identified as the Peclet number of longitudinal dispersion (Kramer and Westererp, 1963).

$$P_e = \frac{uL}{D} \tag{4-47}$$

In effect, the Peclet number represents the ratio of the mass transport brought about by advection and dispersion. If the Peclet number is significantly greater than 1, advection is the dominant factor in mass transport. If the Peclet number is significantly less than 1, dispersion is the dominant factor in mass transport. Although beyond the scope of this presentation, it can also be shown that the number of complete-mix reactors in series required to simulate a plug-flow reactor with axial dispersion is approximately equal to the Peclet number divided by 2. Thus, for a dispersion factor of 0.025, the Peclet number is equal to 40 and the corresponding number of reactors in series needed to simulate the dispersion in a plug-flow reactor is equal to 20. This relationship will be illustrated in the following discussion dealing with complete-mix reactors in series. The Peclet number is also used to define transverse diffusion in packed-bed plug-flow reactors (Denbigh and Turner, 1965).

For practical purposes, the following dispersion values can be used to assess the degree of axial dispersion in wastewater-treatment facilities.

No dispersion	$d = 0$ (ideal plug-flow)
Low dispersion	$d = < 0.05$
Moderate dispersion	$d = 0.05$ to 0.25
High dispersion	$d = > 0.25$
	$d \rightarrow \infty$ (complete-mix)

Typical dispersion numbers determined for actual treatment facilities are given in Table 4–4. The considerable range in the dispersion numbers reported in Table 4–4 for

Table 4–4
Typical dispersion numbers for various wastewater treatment facilities[a]

Treatment facility	Range of values for dispersion number, cm^2/s
Rectangular sedimentation tanks	0.2–2.0
Activated-sludge aeration reactors	
Long plug-flow	0.1–1.0
Complete-mix	3.0–4.0+
Oxidation ditch activated-sludge process	3.0–4.0+
Waste-stabilization ponds	
Single ponds	1.0–4.0+
Multiple cells in series	0.1–1.0
Mechanically aerated lagoons	
Long rectangular shaped	1.0–4.0+
Square shaped	3.0–4.0+
Chlorine contact basins	0.02–0.004

[a] Adapted from Arceivala (1998).

individual and similar treatment facilities is due, most often, to one or more of the following factors (Arceivala. 1983):

1. The scale of the mixing phenomenon
2. Geometry (i.e., aspect ratio) of the unit
3. Power input per unit volume (i.e., mechanical and pneumatic)
4. Type and disposition of the inlets and outlets of the treatment units
5. Inflow velocity and its fluctuations
6. Density and temperature differences between the inflow and the contents of the reactor

Because of the wide range of dispersion numbers that can result for individual treatment processes, special attention must be devoted to the factors cited above in the design of treatment facilities. Determination of the dispersion number and the coefficient of dispersion using the tracer response curves is illustrated in Example 4–4.

Evaluation of the coefficient of axial dispersion D for existing facilities is done experimentally using the results of tracer tests, as discussed previously. Because the systems encountered in wastewater treatment are large, experimental work is often difficult and expensive, and is, unfortunately, usually after the fact. To take into account axial dispersion in the design of treatment facilities both scaled models and empirical relationships have been developed for a variety of treatment units including oxidation ponds (Polprasert and Bhattarai, 1985) and chlorine contact basins (Montgomery, 1985). An approximate value of D for water for large Reynolds numbers is (Davies, 1972)

$$D = 1.01\nu N_R^{0.875} \tag{4-48}$$

where D = coefficient of dispersion, L^2T^{-1}, (m^2/s)
ν = kinematic viscosity, L^2T^{-1}, m^2/s (see Appendix C)
N_R = Reynolds number, unitless
$= 4vR/\nu$
v = velocity in open channel, LT^{-1}, (m/s)
R = hydraulic radius = area/wetted perimeter, L, (m)

Values for N_R found in open channel flow in wastewater-treatment plants are typically in the range from 10^3 to 10^4. The corresponding values for D range from 0.0004 to 0.003 m^2/s (4 to 30 cm^2/s).

EXAMPLE 4–4 Determination of the Dispersion Number and the Coefficient of Dispersion from Concentration versus Time Tracer Response Curves Use the concentration versus time tracer data given in Example 4–1 to determine the dispersion number and the coefficient of dispersion for the chlorine contact basin described in Example 4–1. Compare the value of the coefficient of dispersion computed, using the tracer data, to the value computed using Eq. (4–48). Assume the following data are applicable:

1. The flowrate at the time when the tracer test was conducted = 240,000 m^3/d
2. Number of chlorine contact basin = 4
3. Number of channels per contact basin = 13
4. Channel dimensions
   a. Length = 36.6 m
   b. Width = 3.0 m
   c. Depth = 4.9 m
5. Temperature = 20°C

Solution

1. From Example 4–1, the mean value and variance for the tracer response C curve are:
   a. Mean, $t_{\Delta c} = 2.7$ h
   b. Variance, $\sigma^2_{\Delta c} = 280.5\ h^2$
2. Determine the theoretical detention time for the chlorine contact basin using the given data.

$$\tau = \frac{4 \times 13 \times (36.6\ m \times 3.0\ m \times 4.9\ m)}{(240{,}000\ m^3/d)}$$

$$= 0.1166\ d = 2.8\ h = 167.9\ min$$

3. Determine the mean detention time using Eq. (4–41). Use the approximate value of $\bar{t}_{\Delta c}$ for $\bar{t}_c$.

$$\bar{\theta}_\Delta = \frac{\bar{t}_{\Delta c}}{\tau} \approx \frac{2.7}{2.8} \approx 0.96 \approx 1.0$$

4. Determine the dispersion number using Eq. (4–42). Use the approximate value of $\sigma^2_{\Delta c}$ for σ^2_c.

$$\sigma^2_{\Delta\theta} = \frac{\sigma^2_{\Delta c}}{\tau^2} \approx 2\frac{D}{uL} = 2d$$

$$d \approx \frac{1}{2}\frac{\sigma^2_{\Delta t}}{\tau^2} \approx \frac{1}{2}\frac{(280.5\text{ min})^2}{(167.9\text{ min})^2} = 0.00498$$

5. Using Eq. (4–40), determine the coefficient of dispersion

$$D = d \times u \times L$$

$$u = \frac{Q}{A} = \frac{(240{,}000\text{ m}^3/\text{d})}{(4 \times 13 \times 3.0\text{ m} \times 4.9\text{ m})} = 314.0\text{ m/d} = 0.00363\text{ m/s}$$

$$D = (0.00498)(0.00363\text{ m/s})(36.6\text{ m}) = 6.62 \times 10^{-4}\text{ m}^2/\text{s}$$

6. Compare the value of the coefficient of dispersion computed in Step 5 with the value computed using Eq. (4–48).

$$D = 1.01\,\nu N_R^{0.875}$$

a. Compute the Reynolds number

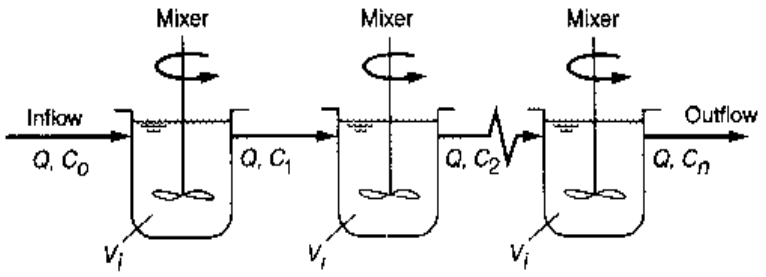
$$N_R = 4vR/\nu$$

$$\nu = 1.002 \times 10^{-6}\text{ m}^2/\text{s}$$

$$N_R = \frac{(4)(0.000363\text{ m/s})[(3.0\text{ m} \times 4.9\text{ m})/(2 \times 4.9\text{ m} + 3.0\text{ m})]}{(1.002 \times 10^{-6}\text{ m}^2/\text{s})} = 1664$$

b. Compute the coefficient of dispersion

$$D = 1.002 \times 10^{-6}(1664)^{0.875} = 6.60 \times 10^{-4}\text{ m}^2/\text{s}$$



Comment Based on the computed value of the dispersion number (0.00498), the chlorine contact basin would be classified as having low dispersion (i.e., $d = < 0.05$). The coefficients of dispersion determined using the results of the tracer study and Eq. (4–48) are remarkably close, given the nature of such measurements.

Complete-Mix Reactors in Series

When varying amounts of axial dispersion are encountered, the flow is sometimes identified as *arbitrary flow*. The output from a plug-flow reactor with axial dispersion (arbitrary flow) is often modeled using a number of complete-mix reactors in series, as outlined below. In some situations, the use of a series of complete-mix reactors may have certain advantages with respect to treatment. To understand the hydraulic characteristics of reactors in series (see Figs. 4–2*e* and 4–15), assume that a pulse input (i.e., a slug) of tracer is injected into the first reactor in a series of equally sized reactors so that

Figure 4–15

Definition sketch for the analysis of complete-mix reactors in series.

the resulting instantaneous concentration of tracer in the first reactor is C_o. The total volume of all the reactors is V, the volume of an individual reactor is V_i, and the hydraulic residence time V_i/Q is τ_i. The effluent concentration from the first reactor as given by Eq. (4–14) is

$$C_1 = C_o e^{-1/\tau_i} \tag{4–49}$$

Writing a materials balance for the second reactor results in the following:

Accumulation = inflow − outflow

$$\frac{dC_2}{dt} + \frac{1}{\tau_i} C_1 - \frac{1}{\tau_i} C_2 \tag{4–50}$$

Rearranging the terms in Eq. (4–47) and substituting Eq. (4–46) for C_1 results in

$$\frac{dC_2}{dt} + \frac{C_2}{\tau_i} = \frac{C_o}{\tau_i} e^{-n\theta} \tag{4–51}$$

The general non-steady-state solution for Eq. (4–51) is obtained by first noting that Eq. (4–51) has the form of the standard first-order linear differential equation. The solution procedure outlined in Eqs. (4–52) through (4–59) involves the use of an integrating factor. It should be noted that Eq. (4–51) can also be solved using the separation of variables method. The solution to Eq. (4–51) is included here because these types of equations are encountered frequently in the field of environmental engineering and in this text. The first step in the solution is to rewrite Eq. (4–51) in the form

$$C_2' + \frac{C_2}{\tau_i} = \frac{C_o}{\tau_i} e^{-t/\tau_i} \tag{4–52}$$

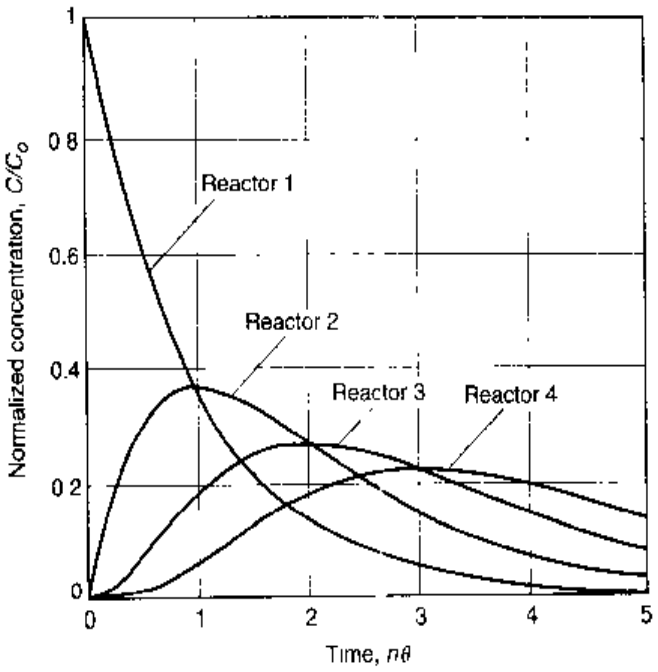
where C_2' is used to denote the derivative dC_2/dt. In the next step, both sides of the expression are multiplied by the integrating factor $e^{\beta t}$, where $\beta = (1/\tau_i)$.

$$e^{\beta t}(C_2' + \beta C_2) = (\beta C_o e^{-\beta t}) = \beta C_o \tag{4–53}$$

The left-hand side of the above expression can be written as a differential as follows:

$$(C_2 e^{\beta t})' = \beta C_o \tag{4–54}$$

The differential sign is removed by integrating the above expression



$$C_2 e^{\beta t} = \beta C_o \int dt \tag{4–55}$$

Integration of Eq. (4–55) yields

$$C_2 e^{\beta t} = \beta C_o t + K \text{ (constant of integration)} \tag{4–56}$$

Figure 4–16

Effluent concentration curves for each of four complete-mix reactors in series subject to a slug input of tracer into the first reactor of the series.

Dividing by $e\beta t$ yields

$$C_2 = \beta C_o t e^{-\beta t} + K e^{-\beta t} \tag{4–57}$$

But when $t = 0$, $C_2 = 0$ and K is equal to 0. Thus,

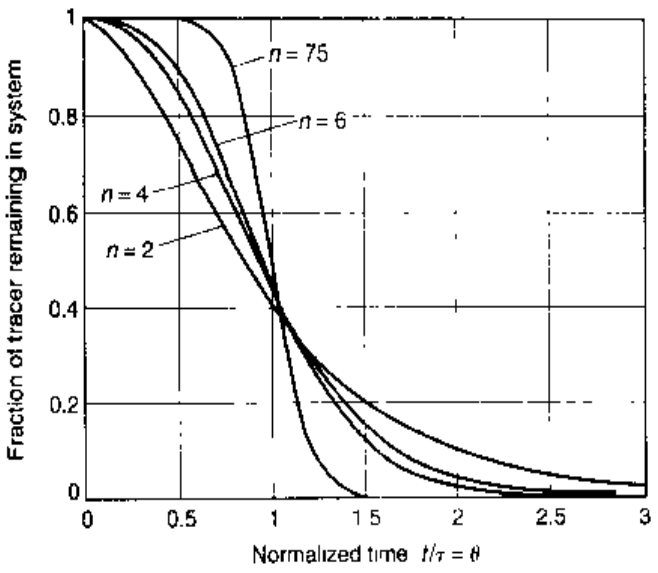
$$C_2 = C_o \frac{t}{\tau_i} e^{-t/\tau_i} \tag{4–58}$$

Following the same solution procedure, the generalized expression for the effluent concentration for the ith reactor is

$$C_i = \frac{C_o}{(i-1)!} \cdot \left(\frac{t}{\tau_i}\right)^{i-1} e^{-t/\tau_i} \tag{4–59}$$

The effluent concentration from each of four complete-mix reactors in series is shown on Fig. 4–16.

The generalized RTD for n reactors in series, obtained using Eq. (4–59), is



$$E(t) = \frac{t^{n-1}}{(n-1)\tau_i^n} e^{-t/\tau_i} \tag{4–60}$$

Fraction Remaining. Equation (4–59) can also be used to obtain the fraction of tracer remaining in a series of complete-mix reactors at any time t. The fraction of tracer remaining, F, at time t, is equal to

$$F = \frac{C_1 + C_2 + \cdots + C_n}{C_o} \tag{4–61}$$

Figure 4–17

Fraction of tracer remaining in a system comprised of reactors in series.

Using Eq. (4–59) to obtain the individual effluent concentrations, the fraction remaining in four equal-sized reactors in series is given by:

$$F_{4R} = \frac{C_o e^{-4t/\tau_i} + C_o(4t/\tau_i)e^{-4t/\tau_i} + (C_o/2)(4t/\tau_i)^2 e^{-4t/\tau_i} + (C_o/6)(4t/\tau_i)^3 e^{-4t/\tau_i}}{C_o}$$

$$F_{4R} = \left[1 + (4t/\tau_i) + \frac{(4t/\tau_i)^2}{2} + \frac{(4t/\tau_i)^3}{6}\right] e^{-4t/\tau_i} \qquad (4\text{–}62)$$

The fraction of a tracer remaining in a series of 2, 4, 6, and 75 complete-mix reactors in series is given on Fig. 4–17.

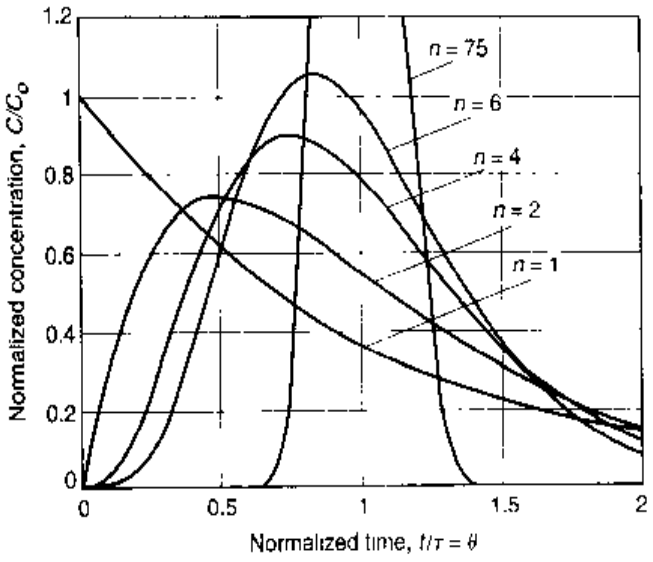
Comparison of Nonideal Plug-Flow Reactor and Complete-Mix Reactors in Series. In many cases it will be useful to model the performance of plug-flow reactors with axial dispersion, as discussed previously, with a series of complete-mix reactors in series. To obtain the normalized residence time distribution curve for n reactors in series, Eq. (4–60) can be written as follows by noting that the total volume is nV_i and $\tau_i = \tau/n$:

$$E(\theta) = \frac{n}{(n-1)!}(n\theta)^{n-1}e^{-n\theta} \qquad (4\text{–}63)$$

In effect, in Eq. (4–63) it is assumed that the same amount of tracer is always added to the first reactor in series. Effluent residence time distribution curves, obtained using Eq. (4–63), for 1, 2, 4, 6, and 75 reactors in series are shown on Fig. 4–18. It is interesting to note that a model comprised of four complete-mix reactors in series is often used to describe the hydraulic characteristics of constructed wetlands. On Fig. 4–18, the concentration increases as the number of reactors in series increases because the same amount of tracer is used regardless of the number of reactors in series. It should also be

Figure 4–18

Effluent tracer concentration curves for reactors in series, subject to a slug input of tracer into the first reactor of the series. Concentration values greater than 1 occur because the same amount of tracer is placed in the first reactor in each series of reactors.



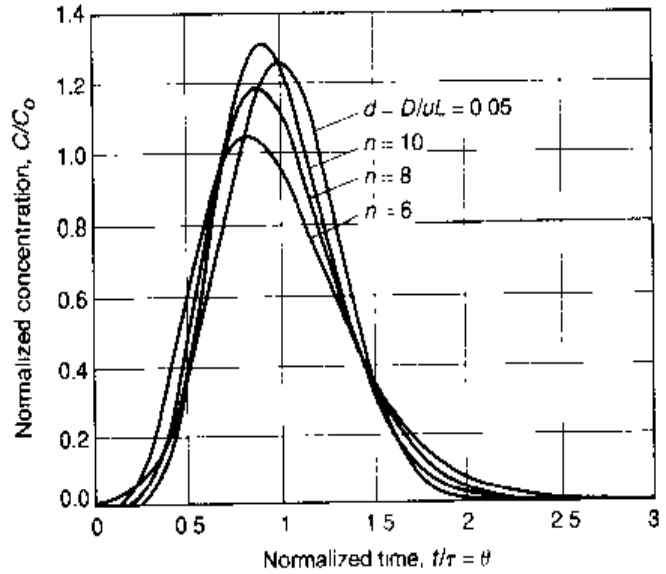


Figure 4–19

Comparison of effluent response curves for a plug-flow reactor with a dispersion factor of 0.05 and reactor systems comprised of six, eight, and ten reactors in series subject to a pulse input of tracer.

noted that the F curves shown on Fig. 4–17 can also be obtained by integrating the E curves given on Fig. 4–18.

A comparison of the residence time distribution curves obtained for a plug-flow reactor, with a dispersion number of 0.05, to the residence time distribution curves obtained for six, eight, and ten complete-mix reactors in series is shown on Fig. 4–19. As shown, all three of the complete-mix reactors in series can be used, for practical purposes, to simulate a plug-flow reactor with a dispersion factor of 0.05. As noted previously, the number of reactors in series needed to simulate a plug-flow reactor with dispersion is approximately equal to the Peclet number divided by 2. Thus, for a dispersion factor of 0.05, the Peclet number is equal to 20 and the corresponding number of reactors in series needed to simulate the dispersion in a plug-flow reactor is equal to 10. As shown on Fig. 4–19, the response curves computed using ten reactors in series and Eq. (4–44) with a dispersion number $d = 0.05$ are essentially the same.

4–6 REACTIONS, REACTION RATES, AND REACTION RATE COEFFICIENTS

From the standpoint of process selection and design, the controlling stoichiometry and the rate of the reaction are of principal concern. The number of moles of a substance entering into a reaction and the number of moles of the substances produced are defined by the stoichiometry of a reaction. The *stoichiometry* of reaction refers to the definition of the quantities of chemical compounds involved in a reaction. The rate at which a substance disappears or is formed in any given stoichiometric reaction is defined as the rate of reaction. These and other related topics are discussed in this section. The rate expressions discussed in this section will be integrated with the hydraulic characteristics of the reactors, discussed previously, to define treatment kinetics.

Types of Reactions

The two principal types of reactions that occur in wastewater treatment are classified as homogeneous and heterogeneous (nonhomogeneous).

Homogeneous Reactions. In homogeneous reactions, the reactants are distributed uniformly throughout the fluid so that the potential for reaction at any point within the fluid is the same. Homogeneous reactions are usually carried out in the batch, complete-mix, and plug-flow reactors (see Figs. 4–2*a, b, c,* and *d*). Homogeneous reactions may be either irreversible or reversible.

Examples of irreversible reactions are

a. Simple reactions

$$A \rightarrow \text{B} \tag{4-64}$$

$$A + A \rightarrow \text{C} \tag{4-65}$$

$$aA + bB \rightarrow \text{C} \tag{4-66}$$

b. Parallel reactions

$$A + B \rightarrow \text{C} \tag{4-67}$$

$$A + B \rightarrow \text{D} \tag{4-68}$$

c. Consecutive reactions

$$A + B \rightarrow \text{C} \tag{4-69}$$

$$A + C \rightarrow \text{D} \tag{4-70}$$

Examples of reversible reactions are

$$A \leftrightarrow B \tag{4-71}$$

$$A + B \leftrightarrow C + D \tag{4-72}$$

As will be discussed subsequently, for both irreversible and reversible reactions, the rate of reaction will be an important consideration in the design of the treatment facilities in which these reactions will be carried out. Special attention must be given to the design of mixing facilities, especially for reactions that are rapid.

Heterogeneous Reactions. Heterogeneous reactions occur between one or more constituents that can be identified with specific sites, such as those on an ion-exchange resin in which one or more ions is replaced by another ion.

Reactions that require the presence of a solid-phase catalyst are also classified as heterogeneous. Heterogeneous reactions are usually carried out in packed and fluidized-bed reactors (see Fig. 4–2*f*, *g*, and *h*). These reactions are more difficult to study because a number of interrelated steps may be involved. The typical sequence of these steps, as quoted from Smith (1981), is as follows:

1. Transport of reactants from the bulk fluid to the fluid-solid interface (external surface of catalyst particle)
2. Intraparticle transport of reactants into the catalyst particle (if it is porous)
3. Adsorption of reactants at interior sites of the catalyst particle
4. Chemical reaction of adsorbed reactants to adsorbed products (surface reaction)
5. Desorption of adsorbed products
6. Transport of products from the interior sites to the outer surface of the catalyst particle

Rate of Reaction

The rate of reaction is the term used to describe the change (decrease or increase) in the number of moles of a reactive substance per unit volume per unit time (for homogeneous reactions), or per unit surface area or mass per unit time (for heterogeneous reactions) (Denbigh and Turner, 1965).

For homogeneous reactions, the rate of reaction r is given by

$$r = \frac{1}{V}\frac{d[N]}{dt} = \frac{\text{moles}}{(\text{volume})(\text{time})} \tag{4–73}$$

If N is replaced by the term VC, where V is the volume and C is the concentration, Eq. (4–73) becomes

$$r = \frac{1}{V}\frac{d(VC)}{dt} = \frac{1}{V}\frac{VdC + CdV}{dt} \tag{4–74}$$

If the volume remains constant (i.e., isothermal conditions, no evaporation), Eq. (4–74) reduces to

$$r = \pm\frac{dC}{dt} \tag{4–75}$$

where the plus sign indicates an increase or accumulation of the substance, and the minus sign indicates a decrease of the substance.

For heterogeneous reactions where S is the surface area, the corresponding expression is

$$r = \frac{1}{S}\frac{d[N]}{dt} = \frac{\text{moles}}{(\text{area})(\text{time})} \tag{4–76}$$

For reactions involving two or more reactants with unequal stoichiometric coefficients, the rate expressed in terms of one reactant will not be the same as the rate for the other reactants. For example, for the reaction

$$aA + bB \rightarrow cC + dD \tag{4–77}$$

the concentration changes for the various reactants are given by

$$-\frac{1}{a}\frac{d[A]}{dt} = -\frac{1}{b}\frac{d[B]}{dt} = \frac{1}{c}\frac{d[C]}{dt} = \frac{1}{d}\frac{d[D]}{dt} \tag{4–78}$$

Thus, for reactions in which the stoichiometric coefficients are not equal, the rate of reaction is given by

$$r = \frac{1}{c_i}\frac{d[C_i]}{dt} \tag{4–79}$$

where the coefficient term $(1/c_i)$ is negative for reactants and positive for products.

The rate at which a reaction proceeds is an important consideration in wastewater treatment. For example, in many cases the reaction usually takes too long to go to completion. In such cases, treatment processes are designed on the basis of the rate at which the reaction proceeds rather than the equilibrium position of the reaction. Often, quantities of chemicals in excess of the stoichiometric or exact reacting amount may be used to accomplish the treatment step in a shorter period of time by driving the reaction to completion.

Reaction Order

The rate at which reactions occur usually is determined by measuring the concentration of either a reactant or a product as the reaction proceeds to completion. The measured results are then compared to the corresponding results obtained from various standard rate equations by which the reaction under study is expected to proceed.

The order of a reaction with respect to a specified compound is equal to the stoichiometric coefficient for that compound. For example, in the following reaction, the reaction order for compound A is a, for compound B is b, and so on.

$$aA + bB + \cdots \rightarrow pP + qQ + \cdots \tag{4–80}$$

If the rate is experimentally found to be proportional to the first power of the concentration of A (i.e., $a = 1$), then the reaction is said to be first-order with respect to A.

When the mechanism of reaction is not known, the reaction rate for Eq. (4–80) may be approximated with the following expression:

$$r = kC_A^a C_B^b C_C^c \cdots C_P^p = kC_A^n \tag{4–81}$$

where a and b are the reaction orders with respect to reactants A and B, and n is the overall reaction order ($n = a + b + \cdots + p$). The sum of the exponents to which the concentration(s) are raised is known as the *order* of the reaction. The following discussion of other types of rate expressions illustrates the relationships that are used to identify reactions of various orders.

Types of Rate Expressions

Other types of rate expressions that have been used to describe the conversion of wastewater constituents in treatment processes and the fate of constituents released in the environment include the following:

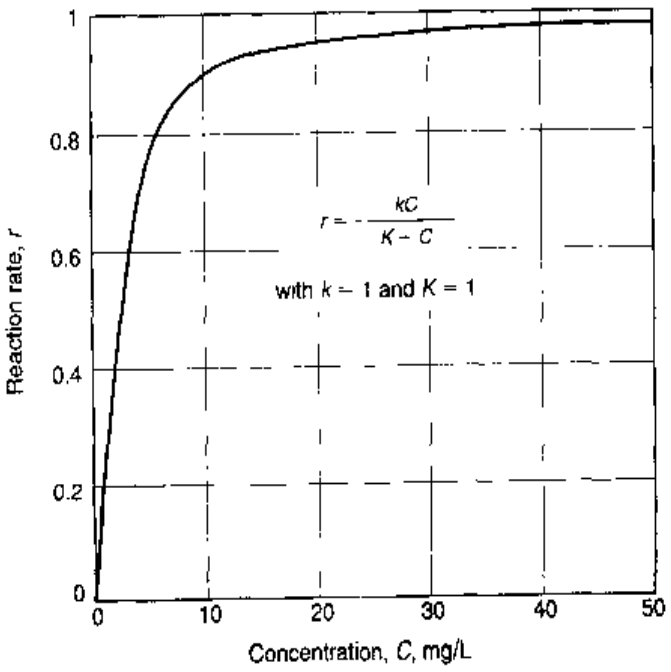
$$r = \pm k \quad \text{(zero-order)} \tag{4-82}$$

$$r = \pm kC \quad \text{(first-order)} \tag{4-83}$$

$$r = \pm k(C - C_s) \quad \text{(first-order)} \tag{4-84}$$

$$r = \pm kC^2 \quad \text{(second-order)} \tag{4-85}$$

$$r = \pm kC_AC_B \quad \text{(second-order)} \tag{4-86}$$



$$r = \pm \frac{kC}{K + C} \quad \text{(saturation or mixed-order)} \tag{4-87}$$

$$r = \pm \frac{kC}{(1 + r_t t)^n} \quad \text{(first-order retarded)} \tag{4-88}$$

Zero-order reactions [Eq. (4–82)] proceed at a rate independent of the concentration of the reactants, whereas first-order reactions [Eqs. (4–83) and (4–84)] proceed at a rate directly proportional to the concentration of one of the reactants. For example, the first-order reaction ($r_c = -kC$) is used to model the exertion of BOD and bacterial decay, as discussed in Chap. 2. Second-order reactions [Eq. (4–85)] proceed at a rate proportional to the second power of a single reactant. Although Eq. (4–86) is second-order overall, it is first-order with respect to C_A and C_B, individually. Equation (4–87), known as a saturation type of equation, is illustrated on Fig. 4–20. As shown on Fig. 4–20, when the concentration C is large, the rate of reaction is zero-order, and when the concentration is low, the rate of reaction is first-order.

Figure 4-20

Rate of reaction versus concentration for a saturation-type expression. Beyond a concentration of about 20 mg/L the rate of reaction is essentially zero-order.

The rate expression given by Eq. (4–88) is known as a retarded first-order rate expression, because the rate constant changes with distance or time or with the degree of treatment which, in turn, can be related to distance or time. The term r_f in the denominator is the retardation factor. In wastewater-treatment applications, the exponent n in Eq. (4–88) is related to the particle size distribution. For example, if all of the particles are the same size and composition, the value of the exponent n is equal to 1 and the retardation factor r_f is equal to zero. The retarded rate expression is also applied to the removal of organic matter from mixtures where the biodegradability of the individual constituents comprising the organic matter is different (Tchobanoglous et al., 2000). Application of the retarded first-order rate expression is considered further in Sec. 4–7.

Rate Expressions Used in Environmental Modeling

The physical, chemical, and biological processes that control the fate of the constituents dispersed to the environment are numerous and varied. Important constituent transformations and removal processes (i.e., fate processes) operative in the environment, along with the constituents affected, are reported in Table 4–5. The various processes listed in Table 4–5 will be referred to throughout this text. For example, bacterial conversion was considered previously in Chap. 2 in the analysis of the BOD reaction, and will be considered in greater detail in the chapters dealing with biological treatment. Because all of the processes summarized in Table 4–5 are rate-dependent, representative rate expressions used to model these processes are presented in Table 4–6. The important thing to note about Table 4–6 is the variety of different rate expressions that have been used to model constituent transformation and removal processes. The application of various rate expressions will be illustrated in this chapter. Additional details on the application of the rate expressions in environmental engineering modeling may be found in Hemond and Fechner (1994), Orlob (1983), Schnoor (1996), Thibodeaux (1996), and Thomann and Mueller (1987).

Effects of Temperature on Reaction Rate Coefficients

The temperature dependence of the specific reaction rate constants is important because of the need to adjust for other temperatures. The temperature dependence of the rate constant is given by the van't Hoff–Arrhenius relationship presented previously in Chap. 2.

$$\ln \frac{k_2}{k_1} = \frac{E(T_2 - T_1)}{RT_1T_2} = \frac{E}{RT_1T_2} = \frac{E}{RT_1T_2}(T_2 - T_1) \qquad (2\text{–}21)$$

where k_2 = reaction rate constant at temperature T_2, (1/s, 1/min, etc.)
k_1 = reaction rate constant at temperature T_1, (1/s, 1/min, etc.)
T = temperature, K = 273.15 + °C
E = a constant characteristic of the reaction (e.g., activation energy), J/mol
R = ideal gas constant, 8.314 J/mol·K (1.99 cal/mol·K)

As noted previously in the discussion of temperature in Chap. 2, most wastewater-treatment operations and processes are carried out over a relatively narrow temperature range. Given that the temperature differences are not great, the following relationship, developed from the van't Hoff–Arrhenius relationship (see discussion of temperature in

Table 4–5
Constituent transformation and removal processes (i.e., fate processes) in the environment

Process	Comments	Constituents affected
Adsorption/ desorption	Many chemical constituents tend to attach or sorb onto solids. The implication for wastewater discharges is that a substantial fraction of some toxic chemicals is associated with the suspended solids in the effluent. Adsorption combined with solids settling results in the removal from the water column of constituents that might not otherwise decay	Metals, trace organics, NH_4^+, PO_4^{3-}
Algal synthesis	The synthesis of algal cell tissue using the nutrients found in wastewater	NH_4^+, NO_3^-, PO_4^{3-}, pH, etc.
Bacterial conversion	Bacterial conversion (both aerobic and anaerobic) is the most important process in the transformation of constituents released to the environment. The exertion of BOD and NOD is the most common example of bacterial conversion encountered in water-quality management. The depletion of oxygen in the aerobic conversion of organic wastes is also known as deoxygenation. Solids discharged with treated wastewater are partly organic. Upon settling to the bottom, they decompose bacterially either anaerobically or aerobically, depending on local conditions. The bacterial transformation of toxic organic compounds is also of great significance	BOD_5, nitrification, denitrification, sulfate reduction, anaerobic fermentation (in bottom sediments), conversion of priority organic pollutants, etc.
Chemical reactions	Important chemical reactions that occur in the environment include hydrolysis, photochemical, and oxidation-reduction reactions. Hydrolysis reactions occur between contaminants and water	Chemical disinfection, decomposition of organic compounds, specific ion exchange, element substitution
Filtration	Removal of suspended and colloidal solids by straining (mechanical and chance contact), sedimentation, interception, impaction, and adsorption	TSS, colloidal particles
Flocculation	Flocculation is the term used to describe the aggregation of smaller particles into larger particles that can be removed by sedimentation and filtration. Flocculation is brought about by Brownian motion, differential velocity gradients, and differential settling in which large particles overtake smaller particles and form larger particles	Colloidal and small particles
Gas absorption/ desorption	The process whereby a gas is taken up by a liquid is known as absorption. For example, when the dissolved oxygen concentration in a body of water with a free surface is below the saturation concentration in the water, a net transfer of oxygen occurs from the atmosphere to the water. The rate of transfer (mass per unit time per unit surface area) is proportional to the amount by which the dissolved oxygen is below saturation. The addition of oxygen to water is also known as reaeration. Desorption occurs when the concentration of the gas in the liquid exceeds the saturation value, and there is a transfer from the liquid to the atmosphere	O_2, CO_2, CH_4, NH_3, H_2S

(continued)

Table 4–5 *(Continued)*

Process	Comments	Constituents affected
Natural decay	In nature, contaminants will decay for a variety of reasons, including mortality in the case of bacteria and photooxidation for certain organic constituents. Natural and radioactive decay usually follow first-order kinetics	Plants, animals, algae, fungi, protozoa, eubacteria (most bacteria), archaebacteria, viruses, radioactive substances, plant mass
Photochemical reactions	Solar radiation is known to trigger a number of chemical reactions. Radiation in the near-ultraviolet (UV) and visible range is known to cause the breakdown of a variety of organic compounds	Oxidation of inorganic and organic compounds
Photosynthesis/ respiration	During the day, algal cells in water bodies will produce oxygen by means of photosynthesis. Dissolved oxygen concentrations as high as 30 to 40 mg/L have been measured. During the evening hours algal respiration will consume oxygen. Where heavy growths of algae are present, oxygen depletion has been observed during the evening hours	Algae, duckweed, submerged macrophytes, NH_4^+, PO_4^{3-}, pH, etc.
Sedimentation	The suspended solids discharged with treated wastewater ultimately settle to the bottom of the receiving water body. This settling is enhanced by flocculation and hindered by ambient turbulence. In rivers and coastal areas, turbulence is often sufficient to distribute the suspended solids over the entire water depth	TSS
Sediment oxygen demand	The residual solids discharged with treated wastewater will, in time, settle to the bottom of streams and rivers. Because the particles are partly organic, they can be decomposed anaerobically as well as aerobically, depending on conditions. Algae which settle to the bottom will also be decomposed, but much more slowly. The oxygen consumed in the aerobic decomposition of material in the sediment represents another dissolved oxygen demand in the water body	O_2, particulate BOD
Volatilization	Volatilization is the process whereby liquids and solids vaporize and escape to the atmosphere. Organic compounds that readily volatilize are known as VOCs (volatile organic compounds). The physics of this phenomenon are very similar to gas absorption, except that the net flux is out of the water surface	VOCs, NH_3, CH_4, H_2S, other gases

Chap. 2), can be used to adjust the value of the operative rate constant to reflect the effect of temperature:

$$\frac{k_2}{k_1} = \theta^{(T_2 - T_1)} \tag{2-25}$$

Typical values for θ vary from about 1.020 to 1.10 for some biological treatment systems.

Table 4–6
Typical rate expressions for selected processes given in Table 4–5[a]

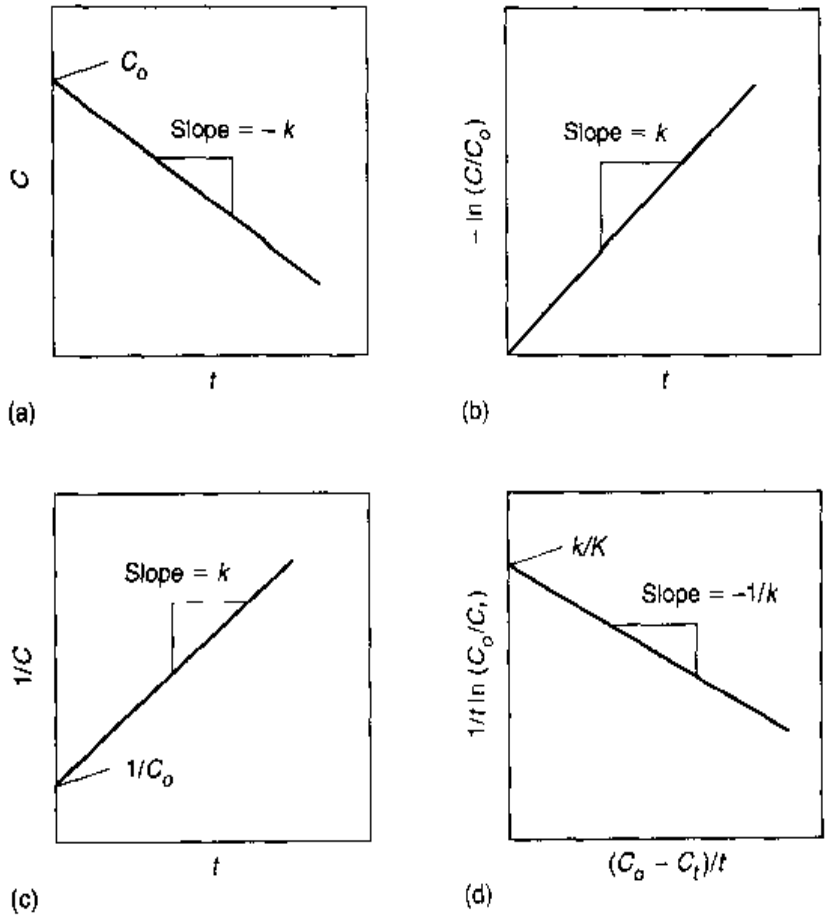
Process	Rate expression	Comments
Bacterial conversion	$r_c = -kC$	r_c rate of conversion, M/L^3T k = first-order reaction rate coefficient, $1/T$ C concentration of organic material remaining, M/L^3
Chemical reactions	$r_c = \pm kC^n$	r_c rate of conversion, M/L^3T k - reaction rate coefficient, $(M/L^3)^n\ ^1/T$ C - concentration of constituent, $(M/L^3)^n$ n - reaction order (e.g., for second-order $n = 2$)
Gas absorption/ desorption	$r_{ab} = k_{ab}\frac{A}{V}(C_s - C)$ $r_{de} = k_{de}\frac{A}{V}(C - C_s)$	r_{ab} - rate of absorption, M/L^3T r_{de} = rate of desorption, M/L^3T k_{ab} = coefficient of absorption, L/T k_{de} = coefficient of desorption, L/T A = area, L^2 V = volume, L^3 C_s - saturation concentration of constituent in liquid, M/L^3 [see Eq. (2–49)] C = concentration of constituent in liquid, M/L^3
Natural decay	$r_d = -k_d N$	r_d - rate of decay, no./T k_d - first-order reaction rate coefficient, $1/T$ N amount of organisms remaining, no.
Sedimentation	$r_s = \frac{v_s}{H}(SS)$	r_s - rate of sedimentation, $1/T$ v_s = settling velocity, L/T H = depth, L SS settleable solids, L^3/L^3
Volatilization	$r_v = -k_v(C - C_s)$	r_v - rate of volatilization per unit time per unit volume, M/L^3T k_v = volatilization constant, $1/T$ C = concentration of constituent in liquid, M/L^3 C_s - saturation concentration of constituent in liquid, M/L^3 [see Eq. (2–49)]

[a]Adapted in part from Ambrose et al. (1988), Tchobanoglous and Burton (1991).

Analysis of Reaction Rate Coefficients

Typically, reaction rate coefficients are determined using the results obtained from batch experiments (i.e., no inflow or outflow), from continuous-flow experiments, and from pilot- and field-scale experiments. Using the data from batch experiments, the

Table 4–7
Integration and differential methods used to determine reaction rate coefficients



Rate expression		Method used to determine the reaction rate coefficient
Integration method		
Zero-order reaction	Integrated form	
$r_c = \frac{dC}{dt} = k$	$C - C_o = -kt$	Graphically, by plotting C versus t (see Fig. 4–21*a*)
First-order reaction		
$r_c = \frac{dC}{dt} = kC$	$\ln \frac{C}{C_o} = kt$	Graphically, by plotting $-\ln (C/C_o)$ versus t (see Fig. 4–21*b*)
Second-order reaction		
$r_c = \frac{dC}{dt} = kC^2$	$\frac{1}{C} - \frac{1}{C_o} = kt$	Graphically, by plotting $1/C$ versus t (see Fig. 4–21*c*)
Saturation reaction		
$r_c = \frac{dC}{dt} = \frac{kC}{K + C}$	$kt = K \ln \frac{C_o}{C_t} + (C_o - C_t)$	Graphically, by plotting $1/t \ln (C_o/C_t)$ versus $(C_o - C_t)/t$ (see Fig. 4–21*d*)
Differential method		
$r_c = \frac{dC}{dt} = kC^n$		Analytically, by solving for n $n = \frac{\log (-d[C_1]/dt) - \log (-d[C_2]/dt)}{\log [C_1] - \log [C_2]}$ Once the order of the reaction is known, the reaction rate coefficient can be determined by substitution

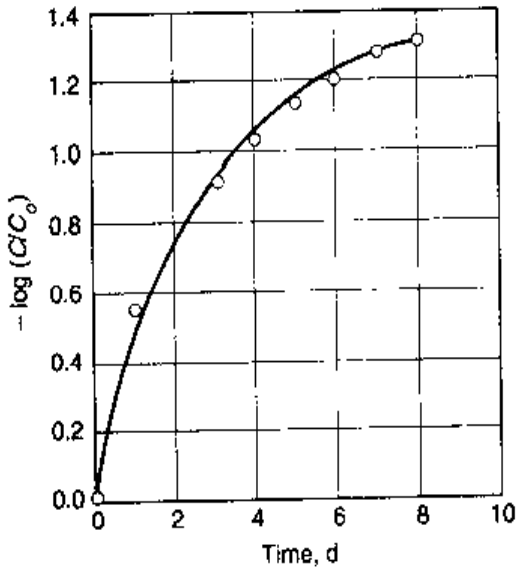
coefficients can be determined using a variety of methods including (1) the method of integration and (2) the differential method (see Table 4–7).

As summarized in Table 4–7, the method of integration involves the substitution of the measured data on the amount of reactant remaining at various times into the integrated form of the rate expression. Plots of the integrated forms of the reaction rate expressions used to determine the reaction rate coefficients are shown on Fig. 4–21. In the differential method, where the order of the reaction is unknown, the concentrations remaining at two different times are used to solve the differential form of the rate expression for the order of the reaction. Once the reaction order is known, the reaction rate coefficient is determined by substitution using the test data. The application of these two methods is illustrated in Example 4–5.

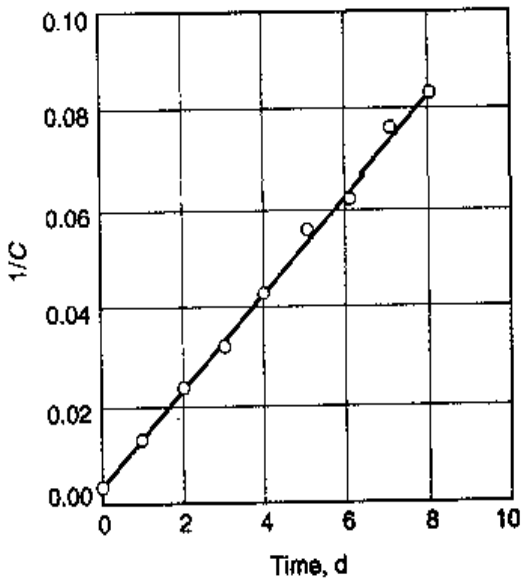
Figure 4–21

Graphical analysis for the determination of reaction order and reaction rate coefficients; (a) zero-order reaction, (b) first-order reaction, (c) second-order reaction, and (d) saturation-type reaction.

EXAMPLE 4–5 Determination of the Reaction Order and the Reaction Rate Coefficient Given the following set of data obtained using a batch reactor (see Fig. 4–2*a*), determine the order of the reaction and the reaction rate coefficient using the integration and differential methods.



Time, t	Concentration, [C], mole/L
0	250
1	70
2	42
3	30
4	23
5	18
6	16
7	13
8	12



Solution—Part 1

1. Determine the reaction order and the reaction rate constant using the integration method. Develop the data needed to plot the experimental data functionally, assuming the reaction is either first- or second-order.

Time, d	$[C]$, mole/L	$-\log [C/C_o]$	$1/[C]$
0	250	0	0.004
1	70	0.553	0.014
2	42	0.775	0.024
3	30	0.921	0.033
4	23	1.036	0.044
5	18	1.143	0.056
6	16	1.194	0.063
7	13	1.284	0.077
8	12	1.319	0.083

2. To determine whether the reaction is first- or second-order, plot log $[C/C_o]$ and $1/[C]$ versus t as shown below. Because the plot of $1/C$ versus t is a straight line, the reaction is second-order with respect to the concentration C.

3. Determine the reaction rate coefficient.

Slope $= k$

$$\text{The slope from the plot} = \frac{0.084 - 0.024}{8d - 2d} = 0.010/d$$

$$k = 0.010/d$$

Solution—Part 2

1. Determine the reaction order and the reaction rate constant using the differential method.

$$n = \frac{\log(-d[C_1]/dt) - \log(-d[C_2]/dt)}{\log[C_1] - \log[C_2]}$$

a. Use the experimental data obtained at day 2 and 5.

Time, d	$[C]$, mole/L	$\frac{C_{t+1} - C_{t-1}}{2} \approx \frac{dC_t}{dt}$	
0	250		
1	70		
2	42	(30 − 70)/2	−20.0
3	30		
4	23		
5	18	(16 − 23)/2	−3.5
6	16		
7	13		
8	12		

b. Substitute and solve for n.

$$n = \frac{\log(20.0) - \log(3.5)}{\log(42.0) - \log(18.0)} = 2.06 \qquad \text{use } n = 2$$

c. The reaction is second-order

d. The reaction rate constant is

$$\frac{1}{C} - \frac{1}{C_o} = kt$$

$$\frac{1}{42} - \frac{1}{250} = k(2)$$

$$k = 0.0103/d \quad \text{use } k = 0.010/d$$

In the applications described above, the initial concentration of a constituent is generally known. However, in the conventional BOD test, described previously in Chap. 2, both UBOD and k_1 are unknown. To determine these values, the usual procedure is to run a series of BOD measurements with time. Using these measurements, the UBOD and k_1 values can be determined using a number of methods including the method of least squares, the method of moments, the daily-difference method, the rapid-ratio method, the Thomas method, and the Fujimoto method, as discussed in Sec. 2–6. The

application of the least squares and the Fujimoto methods is illustrated in Example 2–9 in Chap. 2.

4–7 MODELING TREATMENT PROCESS KINETICS

In wastewater treatment, the chemical and biological reactions that are needed to bring about the treatment of wastewater are carried out in the reactors described previously in Sec. 4–1. Treatment process kinetics involves the coupling of reactors and reaction rates to determine treatment process performance. In this section, the focus is on modeling the reactions that occur in the reactors used for wastewater treatment. The reactors considered include (1) batch, (2) complete-mix, (3) complete-mix reactors in series, (4) ideal plug-flow, (5) ideal plug-flow with retarded reaction rate, and (6) plug-flow with axial dispersion.

Batch Reactor with Reaction

The derivation of the materials-balance equation for a batch reactor (see Fig. 4–2*a*) for a reactive constituent is written as follows:

Accumulation = inflow − outflow + generation

$$\frac{dC}{dt}V = QC_o - QC + r_C V \tag{4–89}$$

Because $Q = 0$ the resulting equation for a batch reactor is

$$\frac{dC}{dt} = r_C \tag{4–90}$$

Before proceeding further, it will be instructive to explore the difference between the rate of change term that appears as part of the accumulation term and the rate of generation or utilization or decay term. In general, these terms are not equal, except in the special case of a batch reactor in which there is no inflow or outflow from the control volume. The key point to remember is that when flow is not occurring, the concentration per unit volume is changing according to the applicable rate expression. On the other hand, when flow is occurring, the concentration in the reactor is also being modified by the inflow and outflow from the reactor.

If the rate of reaction is defined as first-order (i.e., $r_c = -kC$), integrating between the limits $C = C_o$ and $C = C$ and $t = 0$ and $t = t$ yields

$$\int_{C=C_o}^{C=C} \frac{dC}{C} = -k\int_{t=0}^{t=t} dt = kt \tag{4–91}$$

The resulting expression is

$$\frac{C}{C_o} = e^{-kt} \tag{4–92}$$

Equation (4–92) is the same as the BOD equation [Eq. (2–59)] considered previously in Chap. 2.

Complete-Mix Reactor with Reaction

The general form of the mass-balance equation for a complete-mix reactor as shown on Figs. 4–2*a* and 4–4, in which the liquid in the reactor is mixed completely, is given below.

Accumulation = inflow − outflow + generation

$$\frac{dC}{dt}V = QC_o - QC + r_cV \tag{4–93}$$

Assuming first-order removal kinetics ($r_c = -kC$), Eq. (4–93) can be rearranged and written as follows:

$$C' + \beta C = \frac{Q}{V}C_o \tag{4–94}$$

where $C' = dC/dt$

$\beta = k + Q/V$

To solve Eq. (4–94) both sides of the expression are multiplied by the integrating factor $e^{\beta t}$:

$$e^{\beta t}(C' + \beta C) = \frac{Q}{V}C_o e^{\beta t} \tag{4–95}$$

The left-hand side of the above expression can be written as a differential as follows:

$$(Ce^{\beta t})' = \frac{Q}{V}C_o e^{\beta t} \tag{4–96}$$

The differential sign is removed by integrating the above expression

$$Ce^{\beta t} = \frac{Q}{V}C_o \int^{e^{\beta t}} dt \tag{4–97}$$

Integration of Eq. (4–97) yields

$$Ce^{\beta t} = \frac{Q}{V}\frac{C_o}{\beta}e^{\beta t} + K \tag{4–98}$$

Dividing by $e^{\beta t}$ yields

$$C = \frac{Q}{V}\frac{C_o}{\beta} + Ke^{-\beta t} \tag{4–99}$$

But when $t = 0$, $C = C_o$ and K is equal to

$$K = C_o - \frac{Q}{V}\frac{C_o}{\beta} \tag{4–100}$$

Substituting for K in Eq. (4–99) and simplifying yields the following expression, which is the non-steady-state solution of Eq. (4–93):

$$C = \frac{Q}{V}\frac{C_o}{\beta}(1 - e^{-\beta t}) + C_o e^{-\beta t} \tag{4–101}$$

The solution to Eq. (4–93) under steady-state conditions [i.e., the rate accumulation term is equal to zero ($dC/dt = 0$)] is given below.

$$C = \frac{C_o}{[1 + k(V/Q)]} = \frac{C_o}{[1 + k\tau]} \tag{4–102}$$

It should also be noted that when $t \rightarrow \infty$, Eq. (4–101) becomes the same as Eq. (4–99).

Complete-Mix Reactors in Series with Reaction

When complete-mix reactors are used in series, the steady-state solution is of concern as it is used for design. Two approaches are presented for the analysis of reactors in series: (1) analytical and (2) graphical. The graphical approach also applies to cascades of reactors, as discussed in Sec. 4–5 when dealing with mass-transfer equilibria.

Analytical Solution. The steady-state form of the mass balance for the second reactor of the two-reactor system (see Fig. 4–15), is given by

Accumulation = inflow − outflow + generation

$$\frac{dC_2}{dt}\frac{V}{2} = 0 = QC_1 - QC_2 + r_c\frac{V}{2} \tag{4–103}$$

Assuming first-order removal kinetics ($r_c = -kC_2$), Eq. (4–103) can be rearranged and solved for C_2, yielding

$$C_2 = \frac{C_1}{[1 + (kV/2Q)]} \tag{4–104}$$

But from Eq. (4–102), the value of C_1 is equal to

$$C_1 = \frac{C_o}{[1 + (kV/2Q)]} \tag{4–105}$$

Combining the above two expressions yields

$$C_2 = \frac{C_o}{[1 + (kV/2Q)]^2} \tag{4–106}$$

For n reactors in series the corresponding expression is

$$C_n = \frac{C_o}{[1 + (kV/nQ)]^n} = \frac{C_o}{[1 + (k/n\tau)]^n} \tag{4–107}$$

For example, consider three 1000 m^3 complete-mix reactors in series with a flowrate of 100 m^3/d and first-order kinetics with a reaction rate coefficient value of $k = 0.1/d$. Using Eq. (4–107), the effluent concentration from the third reactor, assuming the starting concentration was 100 mg/L, is

$$C_3 = \frac{C_o}{[1 + (kV/3Q)]^3} = \frac{100}{\left\{1 + \left[\dfrac{(0.1/\text{d})(3000\ \text{m}^3)}{(3 \times 100\ \text{m}^3/\text{d})}\right]\right\}^3} = 12.5\ \text{mg/L}$$

Solving Eq. (4–107) for the detention time yields

$$t_o = \frac{V}{Q} = \left[\frac{1}{(C_n/C_o)^{1/n}} - 1\right]\left(\frac{n}{k}\right) \quad \text{or} \quad t_o = \left[\left(\frac{C_o}{C_n}\right)^{1/n} - 1\right]\left(\frac{n}{k}\right) \tag{4-108}$$

Graphical Solution. The graphical solution for 3 (or for n) reactors in series is obtained as follows. For a single reactor, Eq. (4–93) can be written as follows:

Accumulation = inflow − outflow + generation

$$0 = QC_o - QC_1 - r_c V \tag{4-109}$$

The first step in developing a graphical solution is to draw a graph of r_c versus C (see Fig. 4–22). To plot r_c versus C, Eq. (4–109) is now rewritten as follows:

$$r_c = -\frac{Q}{V}(C_1 - C_o) = -\frac{1}{\tau}(C_1 - C_o) \tag{4-110}$$

The above equation can be represented graphically by a straight line drawn from the point $r_c = 0$ and $C = 100$ mg/L with a slope of $-1/\tau$. The line drawn will intersect the graph of r_c versus C at $r_c = 5.0$ and $C_1 = 50$ mg/L as shown on Fig. 4–22. The value $C_1 = 50$ mg/L is the solution of Eq. (4–110) for a single reactor for the stated conditions used to derive the analytical solution, presented previously. If the procedure is repeated for a second and a third reactor, the final effluent concentration from the third reactor is found to be 12.5 mg/L, which is the same as the analytical solution determined above. The graphical approach is especially useful in solving phase-separation processes as described in Sec. 4–8. To use the graphical procedure, the reaction rate coefficient must be a function of a single variable (e.g., C). Additional details on the graphical solution of design equations may be found in Eldridge and Piret (1950) and Smith (1981).

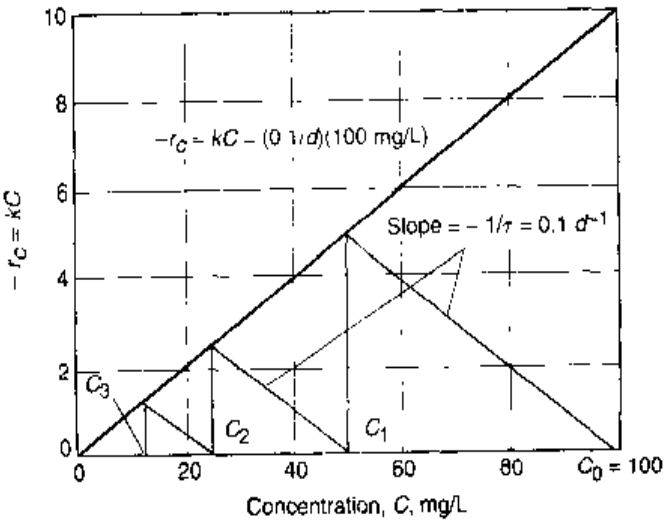


Figure 4–22

Graphical analysis used to determine the effluent concentration from a series of complete-mix reactors.

EXAMPLE 4-6 Analysis of Reactors in Series Using Both an Analytical and Graphical Approach Two 1000 m^3 complete-mix reactors are to be used in series with a flowrate of 500 m^3/d and second-order kinetics with a k value of 0.01/d. Determine the effluent concentration from the second reactor assuming the starting concentration is 100 mg/L.

Solution

1. Determine the effluent concentration from the series of two complete-mix reactors analytically.
   a. At steady state, the mass balance for the first complete-mix reactor is

   $$0 = QC_o - QC_1 - kC_1^2V$$

   Substituting the given values and solving for C_1 yields

   $$0 = \frac{(500\ m^3/d)}{1000\ m^3}(100\ mg/L) - \frac{(500\ m^3/d)}{1000\ m^3}C_1 - (0.01/d)C_1^2$$

   $$C_1 = 50\ mg/L$$

   b. At steady state, the mass balance for the second complete-mix reactor is

   $$0 = QC_1 - QC_2 - kC_2^2V$$

   Substituting the given values and solving for C_2 yields

   $$0 = \frac{(500\ m^3/d)}{1000\ m^3}(50\ mg/L) - \frac{(500\ m^3/d)}{1000\ m^3}C_2 - (0.01/d)C_2^2$$

   $$C_2 = 30\ mg/L$$

2. Determine the effluent concentration from the series of two complete-mix reactors graphically.
   a. Prepare a plot of r_c versus C as shown below.

b. Linearize the mass-balance equation from Step 1a

$$r_c = -\frac{Q}{V}(C_1 - C_o)$$

c. On the plot prepared above draw a straight line from the point $r_c = 0$ and $C = 100$ mg/L with a slope of $-Q/V$ equal to -0.5/d [$-(500\ m^3/d)/1000\ m^3$]. The line drawn intersects the graph of r_c versus C at $r_c = 0.25$ and $C_1 = 50$ mg/L. Repeating the above procedure the final effluent concentration from the second reactor is found to be 30 mg/L, which is the same as the analytical solution determined in Step 1.

Ideal Plug-Flow Reactor with Reaction

The derivation of the materials-balance equation for an ideal plug-flow reactor, in which the concentration C of the constituent is uniformly distributed across the cross-sectional area of the control volume and there is no longitudinal dispersion, can be illustrated by considering the differential volume element shown on Fig. 4–5. For the differential volume element ΔV shown on Fig. 4–5, the materials balance on a reactive constituent C is written as follows:

Accumulation = inflow − outflow + generation

$$\frac{\partial C}{\partial t}\Delta V = QC|_x - QC|_{x-\Delta x} + r_c\Delta V \qquad (4\text{–}111)$$

Accumulation = inflow − outflow + generation

where $\partial C/\partial t$ = change in average concentration with time, $ML^{-3}T^{-1}$ ($g/m^3 \cdot s$)
C = constituent concentration, ML^{-3} (g/m^3)
ΔV = differential volume element, L^3 (m^3)
Q = volumetric flow rate, L^3T^{-1} (m^3/s)
r_c = reaction rate for constituent C, $ML^{-3}T^{-1}$, ($g/m^3 \cdot s$)

Substituting the differential form for the term $QC|_{x+\Delta x}$ in Eq. (4–111) results in

$$\frac{\partial C}{\partial t}\Delta V = QC - Q\left(C + \frac{\Delta C}{\Delta x}\Delta x\right) + r_C\Delta V \qquad (4\text{–}112)$$

Substituting $A\Delta x$ for ΔV and dividing by A and Δx yields

$$\frac{\partial C}{\partial t} = \frac{Q}{A}\frac{\Delta C}{\Delta x} + r_C \qquad (4\text{–}113)$$

Taking the limit as Δx approaches zero yields

$$\frac{\partial C}{\partial t} = -\frac{Q}{A}\frac{\partial C}{\partial x} + r_C \qquad (4\text{–}114)$$

If steady-state conditions are assumed ($\partial C/\partial t = 0$) and the rate of reaction is defined as $r_c = -kC^n$, integrating between the limits $C = C_o$ and $C = C$ and $x = 0$ and $x = L$ yields

$$\int_{C_o}^{C} \frac{dC}{C^n} = -k\frac{A}{Q}\int_0^L dx = -k\frac{AL}{Q} = -k\frac{V}{Q} = -k\tau \qquad (4\text{–}115)$$

Equation (4–115) is the steady-state solution to the materials-balance equation for a plug-flow reactor without dispersion. If it is assumed that n is equal to 1, Eq. (4–115) becomes

$$\frac{C}{C_o} = e^{-k\tau} \qquad (4\text{–}116)$$

which is equivalent to Eq. (4–92), derived previously for the batch reactor.

Comparison of Complete-Mix and Plug-Flow Reactors with Reaction

The combined effect of reactor type (e.g., complete-mix versus plug-flow) and kinetics is also of interest. The total volume required for various removal efficiencies for first-order kinetics, using 1, 2, 4, 6, 8, or 10 reactors in series, is reported in Table 4–8 and shown graphically on Fig. 4–23. The corresponding volume required for a plug-flow reactor is also reported in Table 4–8. As shown in Table 4–8, as the number of reactors in series is increased, the total reactor volume required approaches that of a plug-flow reactor. A comparison of reactor types for second-order kinetics is examined in Example 4–7.

It should be noted, however, that for zero-order kinetics the volume of the two reactors will be the same. It is also important to note that biological processes do not obey the results presented in Table 4–8 (i.e., plug-flow is more efficient than complete-mix) because biological processes are modeled using BOD and COD, which includes

Table 4–8 Required reactor volumes expressed in terms of Q/k for complete-mix reactors in series and plug-flow reactors for various removal efficiencies for first-order kinetics[a]

No. of reactors in series	K values where V = K(Q/k)			
	85% removal efficiency	90% removal efficiency	95% removal efficiency	98% removal efficiency
1	5.67	9.00	19.00	49.00
2	3.16	4.32	6.94	12.14
4	2.43	3.11	4.46	6.64
6	2.23	2.81	3.89	5.52
8	2.14	2.67	3.63	5.05
10	2.09	2.59	3.49	4.79
Plug flow	1.90	2.30	3.00	3.91

[a]Volume of individual reactors equals value in table divided by the number of reactors in series.

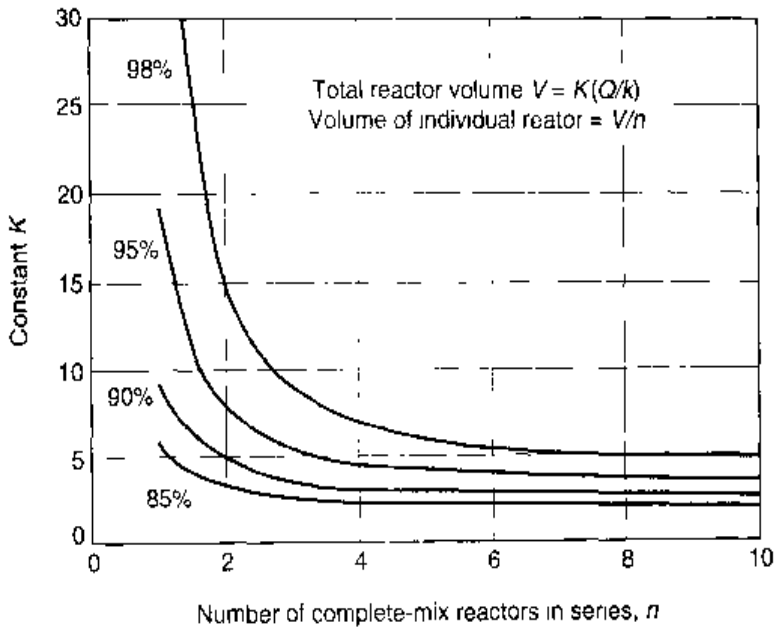

Figure 4–23

Definition sketch for the total volume required versus the number of complete-mix reactors in series for various removal efficiencies. The K value on the vertical axis is multiplied by the flowrate and divided by the reaction coefficient to obtain the total volume required. The volume of an individual reactor is equal to the total volume divided by the number of reactors in series.

microbial products in addition to any residual substrate. As a result, the volumes required for the two reactors will be the same. The use of a plug-flow reactor, or mixed cells in series, is often favored to help control the growth of filamentous organisms (see discussion in Chap. 7).

EXAMPLE 4–7 Comparison of Required Reactor Volumes for Second-Order Kinetics Assuming that second-order kinetics apply ($r_c = -kC^2$), compare the required volume of a complete-mix reactor to the volume of a plug-flow reactor to achieve a 90 percent reduction in the concentration ($C_o = 1$ and $C_e = 0.1$).

Solution

1. Compute the required volume for a complete-mix reactor in terms of Q/k.
   a. At steady state, a mass balance for a complete-mix reactor yields

$$0 = QC_o - QC_e - kC_e^2V$$

   b. Simplify and substitute the given data.

$$V = \frac{Q}{k}\left(\frac{C_o - C_e}{C_e^2}\right) = \frac{Q}{k}\,\frac{1 - 0.1}{(0.1)^2} = 90\,\frac{Q}{k}$$

2. Compute the required volume for a plug-flow reactor in terms of Q/k.
   a. At steady state, a mass balance for a plug-flow reactor yields

$$0 = -Q\frac{dC}{dx}dx + Adx(-kC^2)$$

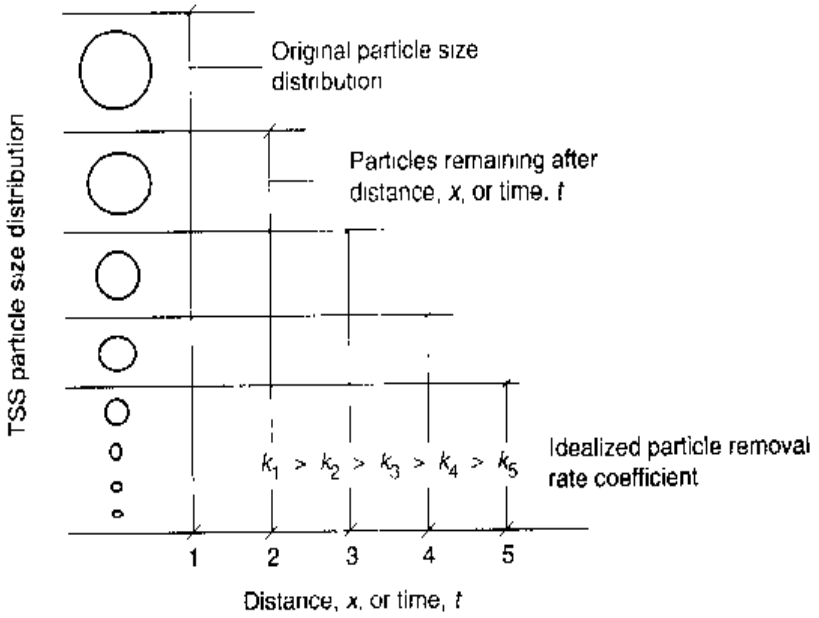
b. The integrated form of the steady-state equation is

$$V = \frac{Q}{k}\int_{C_o}^{C_e}\frac{dC}{C^2} = \frac{Q}{k}\left.\frac{1}{C}\right|_{C_o}^{C_e} = \frac{Q}{k}\left(\frac{1}{C_e} - \frac{1}{C_o}\right)$$

c. Substituting the given concentration values yields

$$V = \frac{Q}{k}\left(\frac{1}{0.1} - \frac{1}{1}\right) = \frac{9Q}{k}$$

3. Determine the volume ratio.



$$\frac{V_{CMR}}{V_{PFR}} = \frac{(90\,Q/k)}{(9\,Q/k)} = 10$$

Ideal Plug-Flow Reactor with Retarded Reaction

A retarded rate expression is used when the rate constant is changing with distance or time. To illustrate the concept, consider the removal of total suspended solids in an overland flow-treatment system. As shown on Fig. 4–24, the removal rate constant for the original particle size distribution is k_1. If it is assumed that the largest particle size will be removed after the wastewater has passed a unit distance, then the new removal rate constant for the remaining particle size distribution will be k_2. Based on actual observations, it has been found that k_1 is greater than k_2, and that k_2 will be greater than k_3, and so on. It is interesting to note that the same analysis can be applied to the settling of the particulate matter found in wastewater.

Figure 4–24

Definition sketch to illustrate the change that can occur in the removal rate coefficient with treatment for an influent wastewater with a particle size distribution *(Tchobanoglous, 1969)*.

The expression for a plug-flow reactor in which a retarded first-order reaction is occurring can be written as follows:

$$\int_{C_o}^{C} \frac{dC}{C} = -\int_0^t \frac{k}{(1 + r_t t)^n} dt \qquad (4\text{–}117)$$

The integrated forms of Eq. (4–114) for $n = 1$ (all of the particles are of the same size and composition) and $n \neq 1$ are as given below

$$C = C_o \exp\left[-\frac{k}{r_t} \ln (1 + r_t t)\right] \qquad (\text{for } n = 1) \qquad (4\text{–}118)$$

$$C = C_o \exp\left\{-\frac{k}{r_t(n-1)}\left[1 - \frac{1}{(1 + r_t t)^{n-1}}\right]\right\} \qquad (\text{for } n \neq 1) \qquad (4\text{–}119)$$

EXAMPLE 4–8 Analysis of Impact of Reaction Rate Retardation. Determine the effluent concentration from a treatment system, designed as an ideal plug-flow reactor, assuming the removal of the constituent in question can be described by a retarded first-order equation. Assume the exponent in the retardation term is equal to 1.5. If the value of the retardation coefficient is 0.2, compare the effluent concentration with and without retardation after 2 days. Determine the retarded effluent concentration if the value of n is equal to 1.0.

Solution

1. Determine the effluent concentration using Eq. (4–119) for the given conditions.

$$C = C_o \exp\left[-\frac{k}{r_t(n-1)}\left(1 - \frac{1}{(1 + r_t t)^{n-1}}\right)\right]$$

where $C_o = 1.0$ (assumed)
$k = 0.3$/d
$r_t = 0.8$/d
$n = 1.5$ (unitless)
$t = 2.0$ d

$$C = 1.0 \exp\left[-\frac{0.3}{0.8(1.5-1)}\left(1 - \frac{1}{(1 + 0.8 \times 2.0)^{1.5-1}}\right)\right] = 0.75$$

2. Determine the effluent concentration without retardation using Eq. (4–116).

$$\frac{C}{C_o} = e^{-kt}$$

where $C_o = 1.0$ (assumed)
$k = 0.3$/d
$t = 2.0$ d

$$C_{(\text{unretarded})} = 1.0\, e^{-0.3 \times 2.0} = 0.55$$

3. Determine the effluent concentration for a wastewater with an n value of 1.0 using Eq. (4–118).

$$C = C_o \exp\left[-\frac{k}{r_t} \ln (1 + r_t t)\right]$$

where $C_o = 1.0$ (assumed)
$k = 0.3/\text{d}$
$r_t = 0.8/\text{d}$
$t = 2.0\ \text{d}$

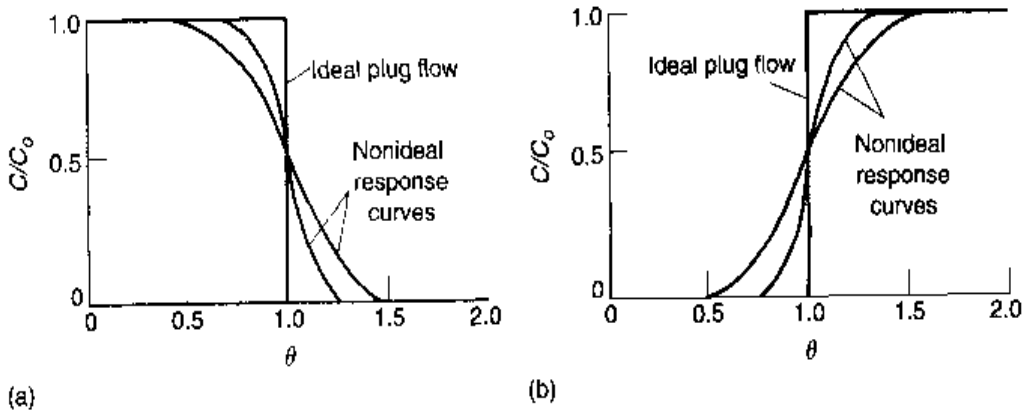
$$C = 1.0 \exp\left[-\frac{0.3}{0.8} \ln (1 + 0.8 \times 2.0)\right] = 0.69$$

Comment From the above computations it can be seen that the effect of retardation can be significant for a first-order reaction. If the value of n were equal to 1, the corresponding effluent concentration would be equal to 0.54. In this example, the retardation coefficient has the greatest impact. The impact of retardation is not as great for second-order reactions. By assuming that an unretarded removal rate coefficient applies throughout, the performance of the treatment system would be overestimated.

Plug-Flow Reactor with Axial Dispersion and Reaction

In most full-scale plug-flow reactors, the flow usually is nonideal because of entrance and exit flow disturbances and axial dispersion. Depending on the magnitude of these effects, the ideal effluent-tracer curves may look like the curves shown on Fig. 4–25. Using first-order removal kinetics, Wehner and Wilhelm (1958) developed a solution for a plug-flow reactor with dispersion numbers varying from complete-mix ($d = \infty$) to ideal plug-flow ($d = 0$). The equation developed by Wehner and Wilhelm is as follows:

$$\frac{C}{C_o} = \frac{4a \exp(1/2d)}{(1 + a)^2 \exp(a/2d) - (1 - a)^2 \exp(-a/2d)} \qquad (4\text{–}120)$$



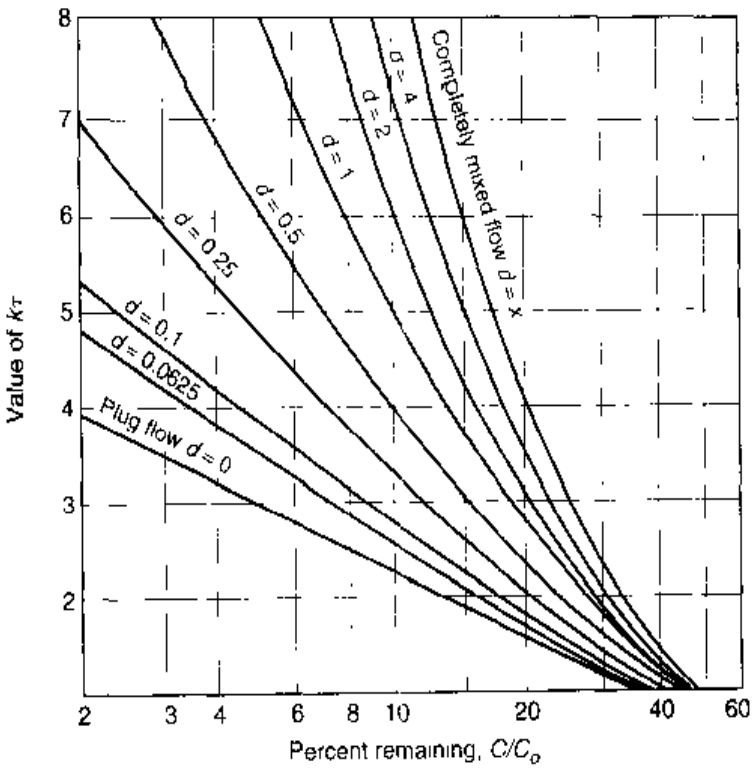


Figure 4–25
Theoretical and generalized nonideal response curves for a reactor with axial dispersion.

Figure 4–26

Values of $k\tau$ in the Wehner and Wilhelm equation [Eq. (4–100)] versus percent remaining for various dispersion factors and first-order kinetics. *(After Thirumurthi, 1969.)*

where C = effluent concentration, ML^{-3}
C_o = influent concentration, ML^{-3}
$a = \sqrt{1 + 4k\tau d}$
d = dispersion factor = D/uL [see Eq. (4–40)]
k = first-order reaction constant, T^{-1}, (1/h)
τ = hydraulic detention time V/Q, T, (h)

To facilitate the use of Eq. (4–120) for the design of treatment processes such as stabilization ponds and natural systems, Thirumurthi (1969) developed Fig. 4–26, in which the term $k\tau$ is plotted against C/C_o for dispersion factors varying from zero for an ideal plug-flow reactor to infinity for a complete-mix reactor. The application of Fig. 4–26 is illustrated in Example 4–9.

EXAMPLE 4–9 Comparison of the Performance of a Treatment Process Occurring in a Plug-Flow Reactor without and with Axial Dispersion A treatment process reactor was designed assuming ideal plug flow with a first-order BOD removal rate constant of 0.5/d at 20°C and a detention time of 5 d. Once in operation, a considerable amount of axial dispersion was observed in the reactor. What effect will the observed axial dispersion have on the performance of the treatment process? The dispersion factor for the reactor d has been estimated to be about 0.5. Determine how much longer the detention time must be for a reactor with a dispersion factor of 0.5 to achieve the same degree of treatment as expected initially with the ideal plug-flow reactor.

Solution

1. Estimate the percentage removal for an ideal plug-flow reactor using Eq. (4–116).
   a. The BOD remaining is

$$\frac{C}{C_o} = e^{-k\tau}$$

$$\frac{C}{C_o} = e^{-0.5\times5} = 0.082 = 8.2\%$$

   b. The percentage removal is

   Percentage removal $100 - 8.2 = 91.8\%$

2. Determine the percentage removal for the reactor using Fig. 4–26.
   a. The value of $k\tau$ equals

   $k\tau = (0.5/\text{d} \times 5\ \text{d}) = 2.5$

   b. The percent remaining from Fig. 4–26 is equal to

   $C/C_o = 0.20 = 20\%$

   Percentage removal $100 - 20 = 80.0\%$

3. Determine the required detention time to achieve 91.8 percent removal.
   a. The value of $k\tau$ from Fig. 4–26 for a C/C_o value of 8.2% is 4.6.
   b. The required detention time is

   $k\tau = 4.6$

   $\tau = 4.6/0.5 = 9.2\ \text{d}$

Comment Clearly, axial dispersion can affect the predicted performance of a treatment process designed to function as an ideal plug-flow reactor. Because of axial dispersion and temperature effects, the actual performance of the treatment process will generally be less than expected.

Other Reactor Flow Regimes and Reactor Combinations

In the previous discussions of complete-mix and plug-flow reactors, a single-pass straight-through flow pattern has been used for the purpose of analysis. In practice, other flow regimes and reactor combinations are also used. Some of the more common alternative flow regimes are shown schematically on Fig. 4–27. The flow regime shown on Fig. 4–27*a* is used to achieve intermediate levels of treatment by blending various amounts of treated and untreated wastewater. The flow regime used on Fig. 4–27*b* is often adopted to achieve greater process control and will be considered specifically in Chaps. 7 and 8, which deal with biological wastewater treatment. The flow regime shown on Fig. 4–27*c* is used to reduce the loading applied to the process. On Fig. 4–27*d*,

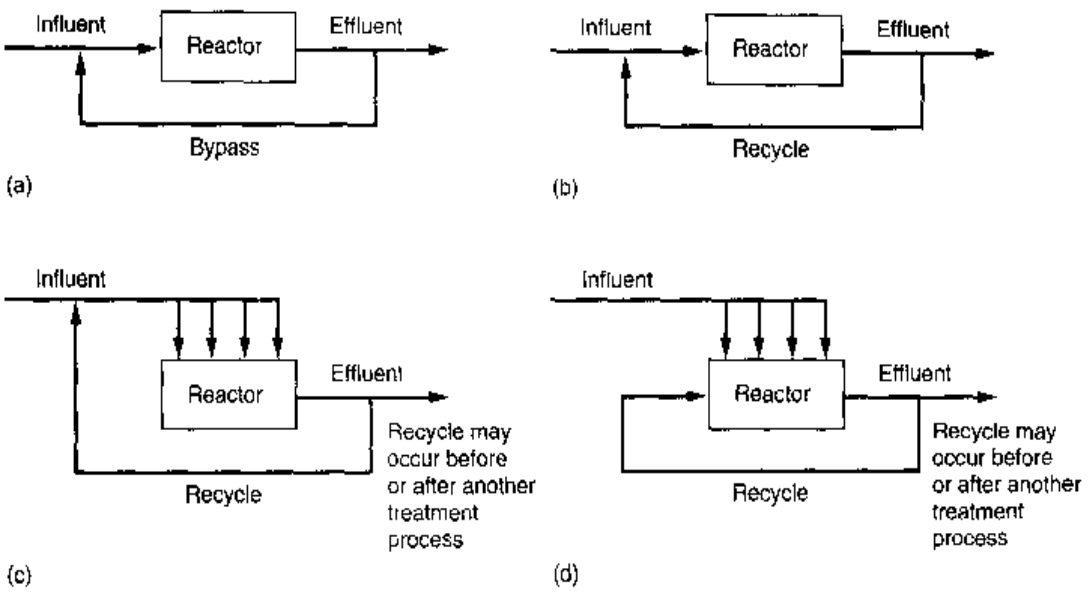

Figure 4–27

Flow regimes commonly used in the treatment of wastewater. (*a*) Direct input with bypass flow (plug-flow or complete-mix reactor), (*b*) direct input with recycle flow (plug-flow or complete-mix reactor), (*c*) stepped input with recycle (recycle flow mixed with influent, recycle type 1), and (*d*) stepped input with recycle (recycle flow introduced at influent end of reactor, recycle type 2).

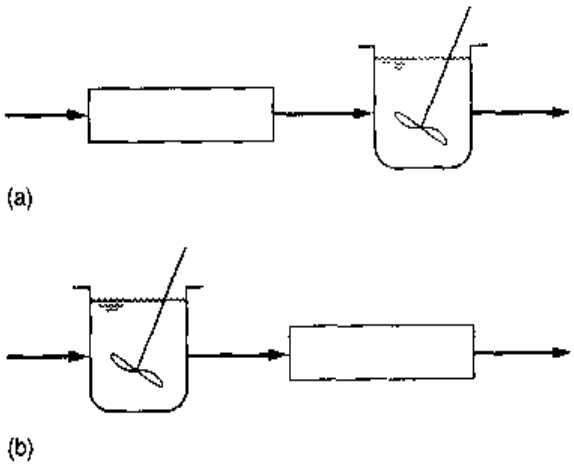

Figure 4–28

Hybrid reactor systems. (*a*) Plug-flow reactor followed by complete-mix reactor and (*b*) complete-mix reactor followed by plug-flow reactor.

the return flow is not mixed with the influent but is introduced at the entrance of the reactor to achieve greater initial dilution of the wastewater to be treated. Each of these hydraulic regimes is considered further in the following chapters.

Among the numerous types of reactor combinations that are possible and that have been used, two combinations using a plug-flow reactor and a continuous-flow stirred-tank reactor are shown on Fig. 4–28. In the arrangement shown on Fig. 4–28*a*, complete mixing takes place second; in the arrangement shown on Fig. 4–28*b*, it occurs first. If no reaction takes place and the reactors are used only to equalize temperature, for example, the result will be identical. If a reaction is occurring, however, the product yields of the two reactor systems can be different. The use of such hybrid reactor systems will depend on the specific product requirements. Additional details on the analysis of such processes may be found in Denbigh and Turner (1965), Kramer and Westererp (1963), and Levenspiel (1972).

4–8 TREATMENT PROCESSES INVOLVING MASS TRANSFER

In the previous section, the removal of constituents was accomplished using chemical and/or biological conversion reactions. In this section, a group of separation operations based on the transfer of material from one homogeneous phase to another is considered. The operations are designed to reduce the concentration of a given component in one stream and to increase the concentration in another stream. Unlike mechanical separations, the driving force for the transfer of material is a pressure or concentration gradient (McCabe and Smith, 1976). The separation operations are sometimes identified as equilibrium phase separations or equilibrium contact separations, because the transfer of a component will cease when equilibrium conditions prevail (Treybal, 1980).

Common operations and processes in wastewater treatment involving mass transfer are identified in Table 4–9. The most important mass transfer operations in wastewater treatment involve (1) the transfer of material across gas-liquid interfaces as in aeration and in the removal of unwanted gaseous constituents found in wastewater by air stripping, and (2) the removal of unwanted constituents from wastewater by adsorption onto solid surfaces such as activated carbon and ion exchange. To introduce the concepts involved in mass transfer, the basic principle of mass transfer is reviewed followed by a consideration of gas-liquid and liquid-solid mass transfer operations.

Basic Principle of Mass Transfer

The transfer of mass is represented by Eq. (4–35), given previously, and repeated here for easy reference.

$$r = -D_m \frac{\partial C}{\partial x} \tag{4–35}$$

Table 4–9
Principal applications of mass transfer operations and processes in wastewater treatment[a]

Type of reactor	Phase equilibria	Application
Absorption	Gas → liquid	Addition of gases to water (e.g., O_2, O_3, CO_2, Cl_2, SO_2), NH_3 scrubbing in acid
Adsorption	Gas → solid	Removal of organics with activated carbon
	Liquid → solid	Removal of organics with activated carbon, dechlorination
Desorption	Solid → liquid	Sediment scrubbing
	Solid → gas	Reactivation of spent activated carbon
Drying (evaporation)	Liquid → gas	Drying of sludges
Gas stripping (also known as desorption)	Liquid → gas	Removal of gases (e.g., CO_2, O_2, H_2S, NH_3, volatile organic compounds, NH_3 from digester supernatant)
Ion exchange	Liquid → solid	Selective removal of chemical constituents, demineralization

[a]Adapted from Crittenden (1999), McCabe and Smith (1976), and Montgomery (1985).

where r = rate of mass transfer per unit area per unit time, $ML^{-2}T^{-1}$
D_m = coefficient of molecular diffusion in the x direction, L^2T^{-1}
C = concentration of constituent being transferred, ML^{-3}
x = distance, L

The coefficient of molecular diffusion is related to the frictional coefficient of a particle by Stokes-Einstein's law of diffusion. For spherical particles the coefficient of diffusion is given by the following expression (Shaw, 1966):

$$D \simeq \frac{kT}{6\pi\eta r_p} = \frac{RT}{6\pi\eta r_p N} \tag{4-121}$$

where D = coefficient of diffusion, m^2/s
k = Boltzmann constant 1.3805×10^{-23} J/K
T = temperature, K = 273.15 + °C
R = universal gas law constant, 8.3145 J/mol·K
η = dynamic viscosity, N·s/m^2
r_p = radius of particle, m
N = Avogadro's number, 6.02×10^{23} molecules/g-mol

The terms in the denominator in Eq. (4–121) correspond to the coefficient of friction for a particle as defined by Stokes' law. The coefficient of diffusion for a particle with a radius of 10^{-7} m (0.01 μm), which corresponds to the size of the smallest bacteria, for the following conditions is

$T = 20°C$

$\eta = 1.002 \times 10^{-3}$ N·s/m^2

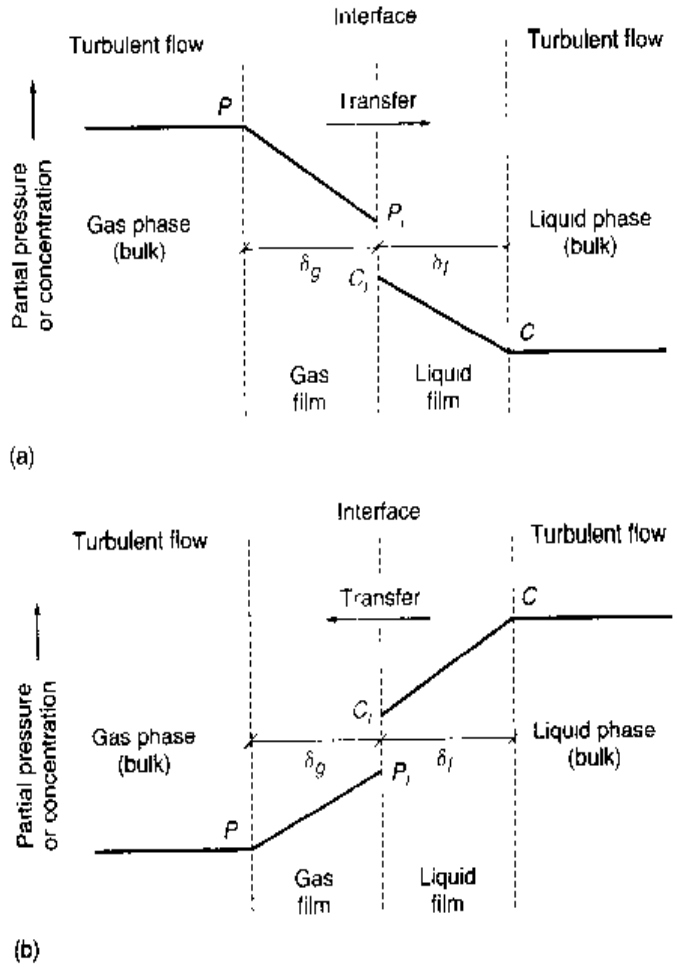
$$D = \frac{RT}{6\pi\eta r_p A} = \frac{(8.3145 \text{ J/mol·K})[(273.15 + 20)\text{K}]}{6(3.14)(1.002 \times 10^{-3}\text{N·s/m}^2)(10^{-7}\text{m})(6.02 \times 10^{23}/\text{mol})}$$

$$= 21.43 \times 10^{-13} \text{ m}^2/\text{s} = 2.143 \times 10^{-8} \text{ cm}^2/\text{s}$$

From the above computation it is easy to see that as the particles get smaller the coefficient of molecular diffusion increases. Depending on the fluid regime, the coefficient of molecular diffusion in Eq. (4–121) will be replaced by the turbulent coefficient of diffusion or the coefficient of dispersion. Determination of the turbulent coefficient of diffusion and the coefficient of dispersion was considered previously in Sec. 4.5.

Typically, the concentration gradient arises from the difference in the equilibrium concentrations in the two streams (phases). In practice, the approach to equilibrium is brought about in a number of contact stages so that the concentration of the material being transferred changes progressively from one stream to another. Thus, two features common to all equilibrium contact operations are the attainment of, or approach to, equilibrium conditions and the provision of contact stages, which may occur in a continuous packed bed or in separated discrete stages.

Gas-Liquid Mass Transfer



Over the past 50 years a number of mass transfer theories have been proposed to explain the mechanism of gas transfer across gas-liquid interfaces. The simplest and most com-

monly used is the two-film theory proposed by Lewis and Whitman (1924). The penetration model proposed by Higbie (1935) and the surface-renewal model proposed by Danckwerts (1951) are more theoretical and take into account more of the physical phenomena involved. The two-film theory remains popular because, in more than 95 percent of the situations encountered, the results obtained are essentially the same as those obtained with the more complex theories. Even in the 5 percent where there is some disagreement between the two-film theory and other theories, it is not clear which approach is more correct. For these reasons, the two-film theory will be described in the following discussion.

The Two-Film Theory. The two-film theory is based on a physical model in which two films exist at the gas-liquid interface, as shown on Fig. 4–29. Two conditions are shown on Fig. 4–29: (*a*) "absorption," in which a gas is transferred from the gas phase to the liquid phase, and (*b*) "desorption," in which a gas is transferred out of the liquid phase into the gas phase. The two films, one liquid and one gas, provide the resistance to the passage of gas molecules between the bulk-liquid and the bulk-gaseous phases. It is very important to note that in the application of the two-film theory it is assumed that the concentration and partial pressure in both the bulk-liquid and bulk-gas phase are uniform (i.e., mixed completely).

Figure 4–29

Definition sketch for the two-film theory of gas transfer: (a) absorption and (b) desorption.

Under steady-state conditions, the rate of mass transfer of a gas through the gas film must be equal to the rate transfer through the liquid film. Using Fick's first law [Eq. (4–35)], the mass flux for each phase for absorption (gas addition) is written as follows:

$$r = k_G(P_G - P_i) = k_L(C_i - C_L) \tag{4–122}$$

where r = rate of mass transferred per unit area per unit time
k_G = gas film mass transfer coefficient
P_G = partial pressure of constituent A in the bulk of the gas phase
P_i = partial pressure of constituent A at the interface in equilibrium with concentration C_i of constituent A in liquid
k_L = liquid film mass transfer coefficient
C_i = concentration of constituent A at the interface in equilibrium with partial pressure P_i of constituent A in the gas
C_L = concentration of constituent A in the bulk liquid phase

It should be noted that the gas and liquid film mass transfer coefficients depend on the conditions at the interface. The terms $(P_G - P_i)$ and $(C_i - C_L)$ represent the driving force causing transfer in the gas and liquid phase, respectively. If the terms $(P_G - P_i)$ and $(C_i - C_L)$ are divided by their respective film thickness values (δ_G and δ_L), the driving force can be expressed in terms of unit thickness. Thus, the degree of mass transport can be enhanced by reducing the thickness of the film, depending on which is the controlling film.

However, because it is difficult to measure the values of k_G and k_L at the interface, it is common to use overall coefficients K_G and K_L, depending on whether the resistance to mass transfer is on the gas or liquid side. If it is assumed that all of the resistance to mass transfer is caused by the liquid film, then the rate of mass transfer can be defined as follows in terms of the overall liquid mass transfer coefficient:

$$r = K_L(C_s - C_L) \tag{4–123}$$

where r = rate of mass transferred per unit area per unit time
K_L = overall liquid mass transfer coefficient
C_s = concentration of constituent A at the interface in equilibrium with the partial pressure of constituent A in the bulk gas phase
C_L = concentration of constituent A in the bulk liquid phase

If the two expressions given by Eqs (4–123) and (4–122) above are equated, the following relationship can be derived between the overall liquid mass transfer coefficient and the gas and liquid film coefficients:

$$r = K_L(C_s - C_i) = k_G(P_G - P_i) = k_L(C_i - C_L) \tag{4–124}$$

Because it was assumed that all of the resistance to mass transfer is caused by the liquid film, the following relationships, based on Henry's law (see Chap. 2), must apply at the interface:

$$P_G = HC_s \quad \text{and} \quad P_i = HC_i$$

It will now be noted that the overall driving force $(C_s - C_L)$ in Eq. (4–124) can be written as

$$(C_s - C_L) = (C_s - C_i) + (C_i - C_L) \tag{4–125}$$

Substituting for P_G and P_i in Eq. (4–145) and combining Eq. (4–125) and Eq. (4–124), the following relationship is obtained where the liquid film controls the mass transfer:

$$\frac{r}{K_L} = \frac{r}{k_L} + \frac{r}{Hk_G} \qquad \text{or} \qquad \frac{1}{K_L} = \frac{1}{k_L} + \frac{1}{Hk_G} \tag{4–126}$$

In a similar manner it can be shown that the following relationship holds if the transfer of mass is controlled by the gas film:

$$\frac{1}{K_G} = \frac{1}{k_G} + \frac{H}{k_L} \tag{4–127}$$

The relationship between the overall liquid and gas phase transfer coefficients is

$$\frac{1}{K_L} = \frac{1}{K_G H} \tag{4–128}$$

It should be noted that in Eqs. (4–126) and (4–127) the overall transfer coefficients include the resistance to mass transfer offered by both the gas and liquid phases. The fact that the overall resistance to mass transfer is the sum of the gas and liquid phase resistances was first demonstrated by Lewis and Whitman (1924). Referring to Eq. (4–126), it is interesting to note that if the Henry's constant is large, then the liquid phase resistance will typically control the mass transfer process. For the transfer of gas molecules from the gas phase to the liquid phase, slightly soluble gases (e.g., O_2, N_2, and CO_2 in water) encounter the primary resistance to transfer from the liquid film, and very soluble gases (e.g., NH_3 in water) encounter the primary resistance to transfer from the gaseous film. Gases of intermediate solubility (e.g., H_2S in water) encounter significant resistance from both films.

To estimate the flux of a slightly soluble gas from the gas to the liquid phase (liquid film controls transfer rate), Eq. (4–123) can be approximated by substituting C_t for C_L as follows:

$$r = K_L(C_s - C_t) \tag{4–129}$$

where r = rate of mass transferred per unit area per unit time, $ML^{-2}T^{-1}$
K_l = overall liquid mass transfer coefficient, LT^{-1}
C_t = concentration in liquid bulk phase at time t, ML^{-3}
C_s = concentration in equilibrium with gas as given by Henry's law, ML^{-3}

The corresponding rate of mass transfer per unit volume per unit time is obtained by multiplying Eq. (4–129) by the area A and dividing by the volume V.

$$r_v = K_L \frac{A}{V}(C_s - C_t) = K_L a(C_s - C_t) \tag{4–130}$$

where r_v = rate of mass transfer per unit volume per unit time, $ML^{-3}T^{-1}$
$K_L a$ = volumetric mass transfer coefficient, T^{-1}
A = area through which mass is transferred, L^2
V = volume in which constituent concentration is increasing, L^3
a = interfacial area for mass transfer per unit volume, A/V, L^{-1}

The term $K_L a$, known as the volumetric mass transfer coefficient, depends on water quality and the type of aeration equipment and is unique for each situation. Numerical values for $K_L a$ are usually determined experimentally (see Chap. 5, Sec. 5–11). Equation (4–127) is the basic relationship used in solving problems involving the addition of oxygen to water as in aeration, the removal of volatile organics from wastewater by bubbling air through the wastewater, and for the stripping of dissolved constituents such as ammonia from digested supernatant.

Absorption of Gases. The application of the gas-liquid mass transfer relationship developed above will be illustrated by considering the absorption of a gas in a liquid (see Fig. 4–30*a*). Consider, for example, a storage basin open to the atmosphere with surface area A and depth h. If the concentration of dissolved oxygen in the basin is initially undersaturation, how long would it take for the oxygen concentration to increase by a given amount? The approach to this mass transfer problem can be outlined as follows.

First, a mass balance is written for the open basin as follows:

1. General word statement:

$$\begin{array}{l}\text{Rate of accumulation}\\ \text{of a gas within the}\\ \text{system boundary}\end{array} = \begin{array}{l}\text{rate of flow of}\\ \text{a gas into the}\\ \text{system boundary}\end{array} - \begin{array}{l}\text{rate of flow of}\\ \text{a gas out of the}\\ \text{system boundary}\end{array} + \begin{array}{l}\text{amount of gas}\\ \text{absorbed through}\\ \text{system boundary}\end{array} \quad (4\text{–}131)$$

2. Simplified word statement:

$$\text{Accumulation} = \text{inflow} - \text{outflow} + \text{increase due to absorption} \quad (4\text{–}132)$$

3. Symbolic representation at equilibrium (refer to Fig. 4–29*a*):

$$\frac{dC}{dt}(V) = 0 - 0 + r_L V \quad (4\text{–}133)$$

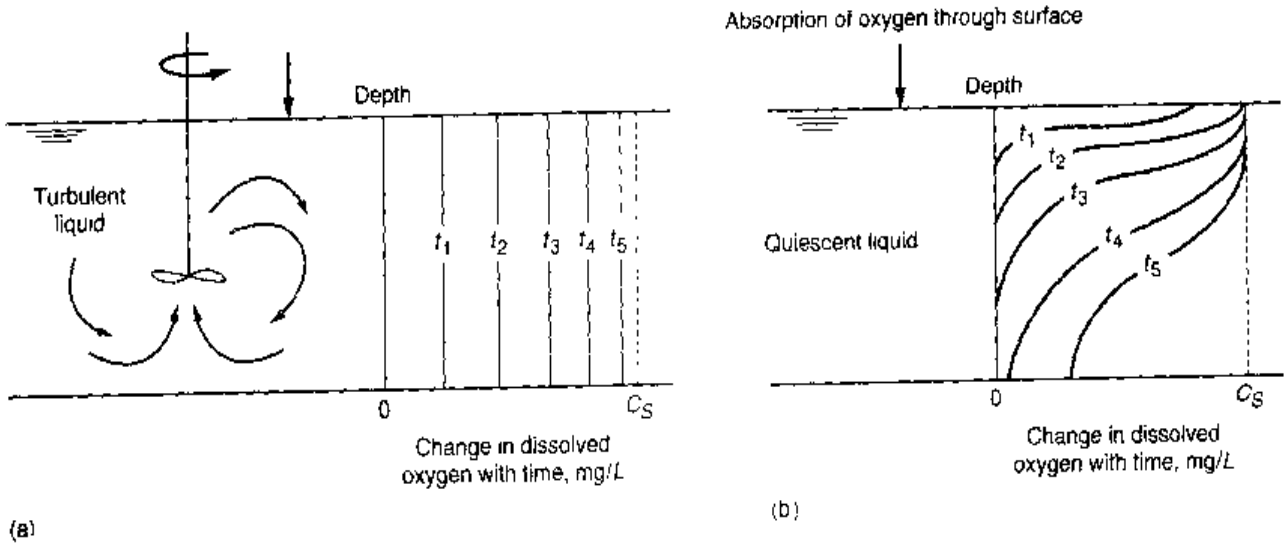


Figure 4–30

Definition sketch for the absorption of a gas: (*a*) under turbulent conditions where the concentration of gas in the gaseous and liquid phases is uniform and (*b*) under quiescent conditions. *(Adapted from Tchobanoglous and Schroeder, 1985.)*

where dC/dt = change in concentration with time, $ML^{-3}T^{-1}$, ($g/m^3 \cdot s$)
V = volume in which constituent concentration is increasing, L^3, (m^3)
r_v = mass of constituent transferred per unit volume per unit time, $ML^{-3}T^{-1}$, ($g/m^3 \cdot s$)

Using Eq. (4–130) to describe the mass transfer through the surface of the basin, Eq. (4–133) can be written as follows, which is the same as Eq. (4–130):

$$\frac{dC}{dt} = K_L a(C_s - C_t) \tag{4–134}$$

Integrating Eq. (4–134) between the limits of $C = C_o$ and $C = C_t$ and $t = 0$ and $t = t$, where C_o is the initial concentration and C_t is the concentration at some time t

$$\int_{C_o}^{C_t} \frac{dC}{C_s - C_t} = K_L a \int_0^t dt \tag{4–135}$$

yields

$$\frac{C_s - C_t}{C_s - C_o} = e^{-(K_L a)t} \tag{4–136}$$

In Eq. (4–136), the term $(C_s - C_t)$ represents, as noted above, the degree of undersaturation at any time t and the term $(C_s - C_o)$ represents the initial degree of undersaturation. The application of Eq. (4–136) is illustrated in Example 4–10.

EXAMPLE 4–10 Time Required to Absorb a Gas Dechlorinated secondary effluent is placed in a storage basin until needed for reuse. If the initial dissolved oxygen concentration is 1.5 mg/L, estimate the time required for the dissolved oxygen concentration to increase to 8.5 mg/L due to surface reaeration, assuming the water in the storage basin is circulated and not stagnant. Assume the K_L value for oxygen is equal to 0.03 m/h. The surface area of the storage basin is 400 m^2 and the depth is 3 m. Assume the temperature is 20°C and that the saturation value estimated in Example 2–6 can be used.

Solution

1. The time required for the concentration of oxygen to be increased from 1.5 to 8.5 can be estimated using Eq. (4–136).

$$\frac{C_s - C_t}{C_s - C_o} = e^{-(K_L a)t}$$

   a. The oxygen saturation value from Example 2–6 is 9.09 mg/L.
   b. Solve for the term $(K_L a)t$.

$$\ln\left(\frac{9.09 - 8.5}{9.09 - 1.5}\right) = -2.55 = -(K_L a)t$$

2. The time required is
   a. The value for a, the interfacial area for mass transfer per unit volume

      $a = A/V = 400\ m^2/10\ m^3 = 40\ m^2/m^3$

   b. Solve for t.

      $t = 2.55/[(0.03\ m/h)(40\ m^2/m^3)] = 2.12\ h$

Comment The importance of the surface area exposed to the atmosphere is illustrated in this example. The larger the surface area relative to the depth, the greater the rate of oxygen transfer. In biological wastewater treatment either many small gas bubbles, released at the bottom of a reactor, are used to transfer oxygen to the active biomass or small droplets of water containing the active biomass are sprayed into the atmosphere to maximize the rate of oxygen transfer.

Absorption of Gases under Quiescent Conditions. The transfer of a slightly soluble gas into a liquid under quiescent conditions (see Fig. 4–30*b*) occurs as a result of molecular diffusion. Applying the materials-balance approach to the control volume shown on Fig. 4–31, the quiescent transfer of a gas across the open surface can be modeled as follows:

First, a mass balance is written for the open basin as follows:

1. General word statement:

Rate of accumulation of a gas within the system boundary	=	rate of diffusion of gas into the system boundary	−	rate of diffusion of gas out of the system boundary	(4–137)

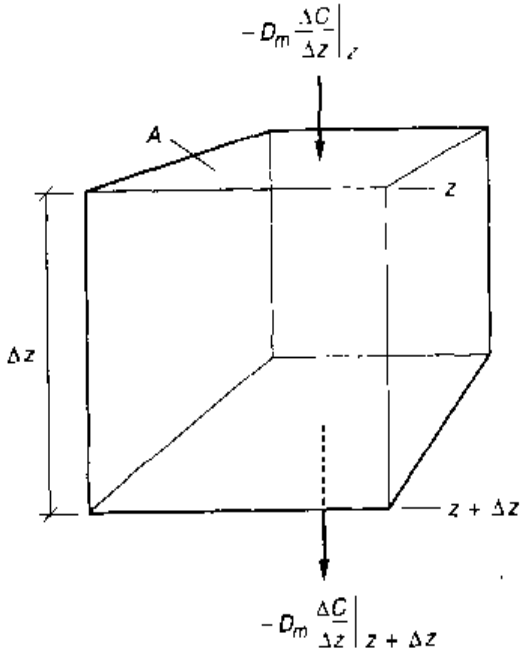

Figure 4–31
Definition sketch for the absorption of a gas under quiescent conditions due to molecular diffusion.

2. Simplified word statement:

$$\text{Accumulation} = \text{inflow} \quad \text{outflow} \tag{4–138}$$

3. Symbolic representation at equilibrium (refer to Fig. 4–31):

$$\frac{\partial C}{\partial t}(A\Delta z) = -D_m A \left.\frac{\Delta C}{\Delta z}\right|_{z} + D_m A \left.\frac{\Delta C}{\Delta z}\right|_{z+\Delta z} \tag{4–139}$$

where $\partial C/\partial t$ = change in concentration per unit time, $ML^{-3}T^{-1}$, $(g/m^3 \cdot s)$
A = surface area through which mass is transferred, L^2, (m^2)
Δz = distance in z direction, L, (m)
D_m = coefficient of molecular diffusion, L^2T^{-1}, (m^2/s)
$\Delta C/\Delta z$ = change in concentration with distance, $ML^{-3}L^{-1}$, $(g/m^3 \cdot s)$

Taking the limit as Δz approaches zero yields

$$\frac{\partial C}{\partial t} = D_m A \frac{\partial^2 C}{\partial z^2} \tag{4–140}$$

Equation (4–140) is also known as Fick's second law of diffusion (Crank, 1957). Typical values for the coefficient of molecular diffusion for gases of low solubility are reported in Table 4–10. Solutions to Eq. (4–140) for a variety of boundary conditions may be found in Carlslaw and Jaeger (1947), Crank (1957), Danckwertz (1970), and Thibodeaux (1996).

Desorption (Removal) of Gases. The application of the gas-liquid mass transfer relationship for the removal of a gas from a liquid will be illustrated by considering the volatilization of a constituent from a liquid. The same approach used for the addition of a gas will be followed, but noting that for the removal of a gas from a liquid Eq. (4–134) is written as follows:

$$\frac{dC}{dt} = -K_L a(C_t - C_s) \tag{4–141}$$

where the term $(C_t - C_s)$ represents the degree of supersaturation at any time t. If Eq. (4–141) is integrated between the limits of $C = C_s$ and $C = C_t$ and $t = 0$ and $t = t$, the

Table 4–10 Approximate coefficients of molecular diffusion and coefficients of diffusion for gases of low solubility in water at 20°C[a]

Gas	Coefficient of molecular, diffusion, cm^2/h	Gas transfer coefficient, cm/h	Estimated film thickness, cm
Oxygen, O_2	6.7×10^{-2}	$32.3 \times 1.018^{T-20}$	$\sim 2 \times 10^{-3}$
Nitrogen, N_2	6.4×10^{-2}	$34.0 \times 1.019^{T-20}$	$\sim 2 \times 10^{-3}$
Carbon dioxide, CO_2	$\sim 6.5 \times 10^{-2}$		$\sim 2 \times 10^{-3}$
Air		$32.1 \times 1.019^{T-20}$	$\sim 2 \times 10^{-3}$

[a] Adapted from Adeney and Becker (1919), Becker (1924).

integrated form of Eq. (4–141), corresponding to Eq. (4–136), for the volatilization of a gas from a supersatured liquid is given by

$$\frac{C_t - C_s}{C_o - C_s} = e^{-(K_L a)t} \tag{4-142}$$

In Eq. (4–142), the term $(C_o - C_s)$ represents the initial degree of supersaturation. The application of Eq. (4–141) is illustrated in Example 4–11.

EXAMPLE 4–11 Time Required for a Gas to Volatilize from a Liquid A quantity of benzene was spilled accidentally into a treated wastewater-storage basin. Estimate the time required for the concentration of benzene to drop by 50 percent from the initial concentration due to volatilization.

Solution

1. If it is assumed that the concentration of the specific volatile chemical is not common to the atmosphere, then $C_s = 0$, and Eq. (4–142) can be written as follows:

$$\frac{C_t}{C_o} = e^{-(K_L a)t}$$

2. Knowing the value of $K_L a$, the time for the concentration to dissipate to one half of the initial concentration can be determined by rewriting the equation developed in Step 1 as

$$\frac{0.5\,C_o}{1.0\,C_o} = e^{-(K_L a)t_{1/2}}$$

Solving for $t_{1/2}$ yields

$$t_{1/2} = \frac{0.69\ \text{h}}{K_L a}$$

3. Using a $K_L a$ value of 0.144 m/h for benzene, the time for 50 percent of the initial concentration to dissipate is

$$t_{1/2} = \frac{0.69 \times 2\ \text{m}}{(0.144\ \text{m/h})} = 9.6\ \text{h}$$

The application of gas-liquid mass transfer is considered further in the discussion of the aeration in Chap. 5, in the discussion of the aeration system in Chap. 9, in the discussion of gas stripping in Chap.11, and in the discussion of the control of volatile organic compounds (VOCs) in Chap 15.

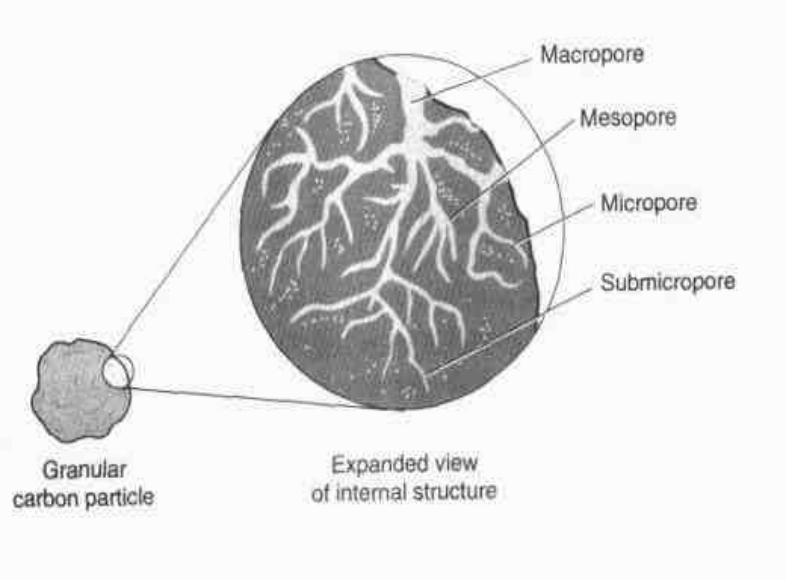
Liquid-Solid Mass Transfer

In the discussion of gas-liquid mass transfer, it was found that mass could be transferred from either phase to the other phase. In liquid-solid mass transfer operations, constituents from the liquid phase are transferred (adsorbed) to a solid phase. Adsorption and ion exchange mass transfer processes are introduced in the following discussion. The application of liquid-solid mass transfer is considered further in the discussion of adsorption and ion exchange in Chap. 11.

Adsorption. The process of accumulating substances that are in solution on a suitable interface is termed *adsorption.* The *adsorbate* is the substance that is being removed from liquid phase at the interface. The *adsorbent* is the solid, liquid, or gas phase onto which the adsorbate accumulates. The adsorption process takes place in three steps: macrotransport, microtransport, and sorption. Macrotransport involves the movement of the adsorbate (e.g., organic matter) through the water to the liquid/solid interface by advection and diffusion. Microtransport involves the diffusion of the organic material through the macropore system of the solid adsorbent, such as activated carbon, to the adsorption sites in the micropores and the solid adsorbent (see Fig. 4–32). Although adsorption also occurs on the surface of the solid adsorbent and in the macropores and mesopores, the surface area of these parts of most solid adsorbents is so extremely small compared with the surface area of the micropores that the amount of material adsorbed there is usually considered negligible.

Two important characteristics of the solid adsorbent are (1) its extremely large surface area to volume ratio and (2) its preferential affinity for certain constituents in the liquid phase. The purpose of the following discussion is to introduce the basic concept of adsorption as a liquid-solid mass transfer operation. Adsorption, in particular carbon adsorption, is considered in detail in Chap. 11. Additional details on activated carbon adsorption may be found in Snoeyink and Summers (1999) and Sontheimer et al. (1988).

As noted above, adsorption is the process of accumulating substances that are in solution on a suitable interface. Granular or powdered activated carbon (GAC or PAC)



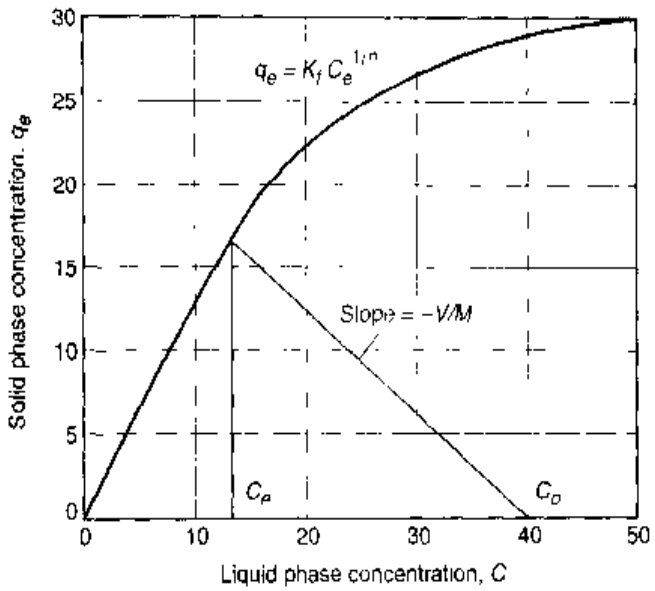


Figure 4–32
Macropore, mesopore, micropore, and submicropore adsorption sites on activated carbon.

Figure 4–33

Typical plot of a Freundlich adsorption isotherm.

is used most commonly for the removal of selected constituents from wastewater. The accumulation of material is described by what is known as an adsorption isotherm, which is used to define the mass of material adsorbed per unit mass of adsorbing material. A common adsorption isotherm is the Freundlich isotherm. Derived from empirical considerations, the Freundlich isotherm is defined as follows:

$$q_e = \frac{x}{m} = K_f C_e^{1/n} \tag{4–143}$$

where q_e = mass of material adsorbed (x) per unit mass of adsorbent (m) at equilibrium
K_f = Freundlich capacity factor
C_e = equilibrium concentration of adsorbate in liquid phase after adsorption, mg/L
$1/n$ = Freundlich intensity parameter

A plot of a typical Freundlich isotherm is shown on Fig. 4–33. It should be noted that in the case of activated carbon adsorption, the expression governing the mass transfer is the adsorption isotherm. The coefficients in the Freundlich isotherm are determined by linearizing Eq. (4–143) and plotting the experimental results on loglog paper. Determination of the Freundlich isotherm coefficients is illustrated in Sec. 11–7 in Chap. 11.

The removal of a constituent in solution with powdered activated carbon (PAC) can be used to illustrate the adsorption process. If a mass balance is performed for a batch reactor into which a quantity of powdered activated carbon has been added (see Fig. 4–34), the resulting expression at equilibrium, at the completion of the mass transfer process, is given by

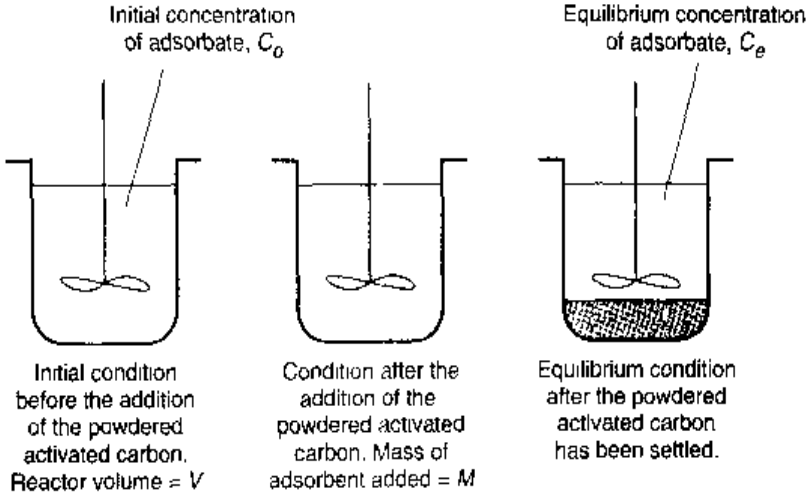

Figure 4–34
Definition sketch for mass-balance analysis of carbon adsorption.

1. General word statement:

$$\begin{array}{l}\text{Amount of reactant}\\ \text{adsorbed within the}\\ \text{system boundary}\end{array} = \begin{array}{l}\text{initial amount of}\\ \text{reactant within the}\\ \text{system boundary}\end{array} - \begin{array}{l}\text{final amount of}\\ \text{reactant within the}\\ \text{system boundary}\end{array} \qquad (4\text{–}144)$$

2. Simplified word statement:

$$\begin{array}{l}\text{Amount}\\ \text{adsorbed}\end{array} = \begin{array}{l}\text{initial amount}\\ \text{of absorbate}\\ \text{present}\end{array} - \begin{array}{l}\text{final amount}\\ \text{of absorbate}\\ \text{present}\end{array} \qquad (4\text{–}145)$$

3. Symbolic representation at equilibrium (refer to Fig. 4–34):

$$q_e M = VC_o - VC_e \qquad (4\text{–}146)$$

where q_e = adsorbent phase concentration after equilibrium, mg adsorbate/g adsorbent [see Eq (4–143)]
M = mass of adsorbent, g
V = volume of liquid in the reactor, L
C_o = initial concentration of adsorbate, mg/L
C_e = final equilibrium concentration of adsorbate after absorption has occurred, mg/L

Equation (4–146) can be written as follows:

$$q_e = -\frac{V}{M}(C_e - C_o) \qquad (4\text{–}147)$$

Because the form of Eq. (4–147) is the same as Eq. (4–110), used previously to develop graphical solutions for reactor design equations, the same graphical approach can be applied to obtain the graphical solution of Eq. (4–147). If a straight line is drawn on the

plot of the Freundlich isotherm, presented previously on Fig. 4–33, from the point $q_e = 0$ and $C = C_o$ mg/L with a slope of $-V/M$, as given by the above equation, the intersection of the line and plot of the adsorption isotherm corresponds to the final equilibrium concentration of organic compound that can be achieved with an activated carbon dose of V/M. The straight line on Fig. 4–33 is known as the *operating line* for the equilibrium adsorption of an organic constituent from solution (Sontheimer et al., 1988).

EXAMPLE 4–12 Activated Carbon Required to Treat a Wastewater As a result of effluent chlorination, the amount of chloroform formed was found to be 0.12 mg/L. How much powdered activated carbon will be required to treat an effluent flowrate of 4000 m^3/d to reduce the chloroform concentration to 0.05 mg/L? The Freundlich adsorption isotherm coefficients for chloroform are: $K_f = 2.6$ and $1/n = 0.73$.

Solution

1. Combine Eqs. (4–143) and (4–147) to obtain an expression for V/M as follows:

$$q_e = \frac{x}{m} = K_f C_e^{1/n}$$

$$q_e = -\frac{V}{M}(C_e - C_o)$$

$$-\frac{V}{M} = \frac{K_f C_e^{1/n}}{(C_e - C_o)}$$

2. Substitute the isotherm coefficients and solve for M/V:

$$-\frac{V}{M} = \frac{K_f C_e^{1/n}}{(C_e - C_o)} = \frac{2.6(0.05)^{0.73}}{0.05 - 0.12} = -4.17 \text{ L/g}$$

$$M/V = 1/4.17 = 0.24 \text{ g/L}$$

3. Determine the amount of carbon required to treat 4000 m^3/d:

$$\text{PAC required} = \frac{(0.24 \text{ g/L})(4000 \text{ m}^3/\text{d})(10^3 \text{ L/m}^3)}{(10^3 \text{ g/kg})} = 960 \text{ kg/d}$$

Comment Given the amount of PAC required to treat the effluent to reduce the residual chloroform to 0.05 mg/L, carbon adsorption is a poor choice for the removal of residual chloroform. Carbon adsorption is examined in greater detail in Sec. 11–7 in Chap. 11.

Ion Exchange. Ion exchange is a mass transfer process in which ions of a given species are displaced from an insoluble exchange material by ions of a different species in solution. In water treatment, ion exchange is used most commonly to soften hard

water through the removal of multivalent cations. In wastewater treatment, the principal uses are for (1) the removal of nitrogen and phosphorus, (2) the removal of heavy metals, and (3) the removal of total dissolved solids (i.e., demineralization) for reuse applications.

The reactions for the removal of sodium (Na^+) and calcium (Ca^{2+}) ions from water using a strong acid synthetic cationic exchange resin R, and the regeneration of the exhausted resins with hydrochloric acid (HCl) and sodium chloride (NaCl) are as follows:

Reaction:

$$R^-H^+ + Na^+ \rightarrow R^-Na^+ + H \qquad (4\text{–}148)$$

$$2\,R^-Na^+ + Ca^{2+} \rightarrow R_2^-Ca^{2+} + 2Na^+ \qquad (4\text{–}149)$$

Regeneration:

$$R^-Na^+ + HCl \rightarrow R^-H^+ + NaCl \qquad (4\text{–}150)$$

$$R_2Ca^{2+} + 2NaCl \rightarrow 2R^-Na^+ + CaCl_2 \qquad (4\text{–}151)$$

As illustrated in the reaction given in Eq. (4–148), the Na^+ ion in solution is exchanged for the H^+ ion on the resin. Similarly, in Eq. (4–149) the Ca^{2+} in solution is exchanged for two Na^+ ions on the resin. To recover the capacity of the resin, the process is reversed during regeneration. The subject of ion exchange is considered in detail in Chap. 11, Sec. 11–9.

4–9 INTRODUCTION TO PROCESS SELECTION

Process selection involves the detailed evaluation of the various factors that must be considered when evaluating unit operations and processes and other treatment methods to meet current and future treatment objectives. The purpose of process analysis is to select the most suitable unit operations and processes and the optimum operational criteria. The purpose of this section is to introduce the important factors that must be considered in process selection and to consider the basis for process design.

Important Factors in Process Selection

The most important factors that must be evaluated in process analysis and selection are identified in Table 4–11. Each factor is important in its own right, but some factors require additional attention and explanation. The first factor, "process applicability," stands out above all others and reflects directly upon the skill and experience of the design engineer. Many resources are available to the designer to determine applicability, including past experience in similar types of projects. Available resources include performance data from operating installations, published information in technical journals, manuals of practice published by the Water Environment Federation, process design manuals published by EPA, and the results of pilot-plant studies. Where the applicability of a process to a given situation is unknown or uncertain, pilot-plant studies must be conducted to determine performance capabilities and to obtain design data upon which a full-scale design can be based.

Table 4–11
Important factors that must be considered when evaluating and selecting unit operations and processes

Factor	Comment
1. Process applicability	The applicability of a process is evaluated on the basis of past experience, data from full-scale plants, published data, and from pilot-plant studies. If new or unusual conditions are encountered, pilot-plant studies are essential
2. Applicable flow range	The process should be matched to the expected range of flowrates. For example, stabilization ponds are not suitable for extremely large flowrates in highly populated areas
3. Applicable flow variation	Most unit operations and processes have to be designed to operate over a wide range of flowrates. Most processes work best at a relatively constant flowrate. If the flow variation is too great, flow equalization may be necessary
4. Influent wastewater characteristics	The characteristics of the influent wastewater affect the types of processes to be used (e.g., chemical or biological) and the requirements for their proper operation
5. Inhibiting and unaffected constituents	What constituents are present and may be inhibitory to the treatment processes? What constituents are not affected during treatment?
6. Climatic constraints	Temperature affects the rate of reaction of most chemical and biological processes. Temperature may also affect the physical operation of the facilities. Warm temperatures may accelerate odor generation and also limit atmospheric dispersion
7. Process sizing based on reaction kinetics or process loading criteria	Reactor sizing is based on the governing reaction kinetics and kinetic coefficients. If kinetic expressions are not available, process loading criteria are used. Data for kinetic expressions and process loading criteria usually are derived from experience, published literature, and the results of pilot-plant studies
8. Process sizing based on mass transfer rates or process loading criteria	Reactor sizing is based on mass transfer coefficients. If mass transfer rates are not available, process loading criteria are used. Data for mass transfer coefficients and process loading criteria usually are derived from experience, published literature, and the results of pilot-plant studies
9. Performance	Performance is usually measured in terms of effluent quality and its variability, which must be consistent with the effluent discharge requirements
10. Treatment residuals	The types and amounts of solid, liquid, and gaseous residuals produced must be known or estimated. Often, pilot-plant studies are used to identify and quantify residuals
11. Sludge processing	Are there any constraints that would make sludge processing and disposal infeasible or expensive? How might recycle loads from sludge processing affect the liquid unit operations or processes? The selection of the sludge processing system should go hand in hand with the selection of the liquid treatment system
12. Environmental constraints	Environmental factors, such as prevailing winds and wind directions and proximity to residential areas, may restrict or affect the use of certain processes, especially where odors may be produced. Noise and traffic may affect selection of a plant site. Receiving waters may have special limitations, requiring the removal of specific constituents such as nutrients
13. Chemical requirements	What resources and what amounts must be committed for a long period of time for the successful operation of the unit operation or process? What effects might the addition of chemicals have on the characteristics of the treatment residuals and the cost of treatment?
14. Energy requirements	The energy requirements, as well as probable future energy cost, must be known if cost-effective treatment systems are to be designed

(continued)

Table 4–11 (*Continued*)

Factor	Comment
15. Other resource requirements	What, if any, additional resources must be committed to the successful implementation of the proposed treatment system using the unit operation or process being considered?
16. Personnel requirements	How many people and what levels of skills are needed to operate the unit operation or process? Are these skills readily available? How much training will be required?
17. Operating and maintenance requirements	What special operating or maintenance requirements will need to be provided? What spare parts will be required and what will be their availability and cost?
18. Ancillary processes	What support processes are required? How do they affect the effluent quality, especially when they become inoperative?
19. Reliability	What is the long-term reliability of the unit operation or process being considered? Is the operation or process easily upset? Can it stand periodic shock loadings? If so, how do such occurrences affect the quality of the effluent?
20. Complexity	How complex is the process to operate under routine or emergency conditions? What levels of training must the operators have to operate the process?
21. Compatibility	Can the unit operation or process be used successfully with existing facilities? Can plant expansion be accomplished easily?
22. Adaptability	Can the process be modified to meet future treatment requirements?
23. Economic life-cycle analysis	Cost evaluation must consider initial capital cost and long-term operating and maintenance costs. The plant with lowest initial capital cost may not be the most effective with respect to operating and maintenance costs. The nature of the available funding will also affect the choice of process
24. Land availability	Is there sufficient space to accommodate not only the facilities currently being considered but possible future expansion? How much of a buffer zone is available to provide landscaping to minimize visual and other impacts?

Some of the factors (items 2 through 6) listed in Table 4–11 have been discussed previously in Chaps. 2 and 3. The following discussion will deal briefly with process design based on reaction kinetics, mass transfer, and the use of loading criteria, the subjects considered in this chapter. As part of the discussion, the conduct of bench and pilot-plant studies is considered along with process variability. The other factors in Table 4–11 will be discussed throughout the remainder of the book. They are identified here to indicate the diverse nature of the information that must be available to make a proper evaluation of unit operations and processes used for the treatment of wastewater.

Process Selection Based on Reaction Kinetics

In process selection and sizing based on reaction kinetics, particular emphasis is placed on defining the nature of the reactions occurring within the process, the appropriate values of the kinetic coefficients, and the selection of the reactor type.

Nature of the Kinetic Reactions. The nature of the reactions occurring within a process must be known to apply the reaction kinetics approach to design. Selection of

reaction rate expressions for the process that is to be designed is typically based on (1) information obtained from the literature, (2) experience with the design and operation of similar systems, or (3) data derived from pilot-plant studies. For example, it is of critical importance to know if the reaction is zero-, first-, retarded first-, or second-order, or if the reaction is a saturation type. Clearly, as demonstrated in this chapter, the order of the reaction will have a significant effect on the type and size of the reactor. The total volume required for various removal efficiencies for first-order kinetics, using 1, 2, 4, 6, 8, or 10 complete-mix reactors in series, was compared to the volume required for a plug-flow reactor previously in Table 4–8. As indicated in Table 4–8, greater reactor volume is required for complete-mix reactors to achieve the same removal efficiencies as plug-flow reactors. It should be noted, however, that for zero-order kinetics the volume of the two reactors will be the same.

Selection of Appropriate Kinetic Rate Coefficients. Selection of appropriate kinetic rate coefficients for the process that is to be designed is also based on (1) information obtained from the literature, (2) experience with the design and operation of similar systems, or (3) data derived from pilot-plant studies. In cases where significantly different wastewater characteristics occur or new applications of existing technology or new processes are being considered, pilot-plant testing is recommended. The various rate expressions that have been developed for biological waste treatment, based on the method of analysis presented in this chapter, are considered in Chaps. 8 through 10.

Selection of Reactor Types. Operational factors that must be considered in the type of reactor or reactors to be used in the treatment process include (1) the nature of the wastewater to be treated, (2) the nature of the reaction kinetics governing the treatment process, (3) special process requirements, and (4) local environmental conditions. As noted previously, for biological treatment with the activated sludge process there is no difference in the size of the reactor required (i.e., $V_{\text{complete-mix}} = V_{\text{plug-flow}}$). For example, a complete-mix reactor might be selected over a plug-flow reactor, because of its dilution capacity, if the influent wastewater is known to contain toxic constituents that cannot be removed by pretreatment. Alternatively, a plug-flow or multistage reactor might be selected over a complete-mix reactor to control the growth of filamentous microoganisms. In practice, the construction costs and operation and maintenance costs also affect reactor selection.

Process Selection Based on Mass Transfer

In addition to process selection based on reaction kinetics and loading criteria, a number of treatment processes will be based on mass transfer considerations, as introduced in this chapter. The principal operations in wastewater treatment involving mass transfer are aeration, especially the addition of oxygen to water; the drying of biosolids and sludge; the removal of volatile organics from wastewater; the stripping of dissolved constituents such as ammonia from digested supernatant; and the exchange of dissolved constituents as in ion exchange. Fortunately, there is a considerable body of literature on these subjects as well as a vast amount of practical experience. Additional details on these subjects are presented in the subsequent chapters.

Process Design Based on Loading Criteria

If appropriate reaction rate expressions and/or mass transfer coefficients cannot be developed, generalized loading criteria are frequently used. Early design loading criteria for activated sludge biological treatment systems were based on aeration tank capacity [e.g., kg of BOD/m^3 (lb BOD/10^3 ft^3)]. For example, if a process that is loaded at 10 kg/m^3 produces an acceptable effluent and one loaded at 20 kg/10^3 m^3 does not, the successful experience tends to be repeated. Unfortunately, records often are not well maintained, and the limits of such loading criteria are seldom defined. Examples of loading criteria are presented in the design chapters for unit operations and processes. It should be noted that with the new activated-sludge biological treatment process variations and new aeration equipment, the use of loading factors should be avoided.

Bench Tests and Pilot-Plant Studies

Where the applicability of a process for a given situation is unknown, but the potential benefits of using the process are significant, bench-scale or pilot-scale tests must be conducted. The purpose of conducting pilot-plant studies is to establish the suitability of the process in the treatment of a specific wastewater under specific environmental conditions and to obtain the necessary data on which to base a full-scale design. Factors that should be considered in planning pilot-plant studies for wastewater treatment are presented in Table 4–12. The relative importance of the factors presented in Table 4–12 will depend on the specific application and the reasons for conducting the testing program. For example, testing of UV disinfection systems is typically done: (1) to verify manufacturers' performance claims, (2) to quantify effects of effluent water quality constituents on UV performance, (3) to assess the effect(s) of system and reactor hydraulics on UV performance, (4) to assess the effect(s) of effluent filtration on UV performance, and (5) to investigate photoreactivation and impacts.

Bench-scale tests are conducted in the laboratory with small quantities of the wastewater in question. Pilot-scale tests are typically conducted with flows that are 5 to 10 percent of the design flows (see Fig. 4–35). In some instances full-scale tests have been conducted, especially where scale-up issues are complex and computational methods are too complex. A discussion of scale-up issues may be found in Johnstone and Thring (1957) and Schmidtke and Smith (1983).

Reliability Considerations in Process Selection

Important factors in process selection and design are treatment plant performance and reliability in meeting permit requirements. In most permits, effluent constituent requirements based on 7-day and 30-day average concentrations are specified. Because wastewater treatment effluent quality is variable for a number of reasons (varying organic loads, changing environmental conditions, etc.), it is necessary to ensure that the treatment system is designed to produce effluent concentrations equal to or less than the permit limits.

Two approaches in process selection and design are (1) the use of arbitrary safety factors, and (2) statistical analysis of treatment plant performance to determine a functional relationship between effluent quality and the probable frequency of occurrence. The latter approach, termed the "reliability concept," is preferred because it can be used

Table 4-12
Considerations in setting up pilot-plant testing programs

Item	Consideration
Reasons for conducting pilot testing	Test new process
	Simulation of another process
	Predict process performance
	Document process performance
	Optimize system design
	Satisfy regulatory agency requirements
	Satisfy legal requirements
Pilot-plant size	Bench- or laboratory-scale model
	Pilot-scale tests
	Full- (prototype) scale tests
Nonphysical design factors	Available time, money, and labor
	Degree of innovation and motivation involved
	Quality of water or wastewater
	Location of facilities
	Complexity of process
	Similar testing experience
	Dependent and independent variables
Physical design factors	Scale-up factors
	Size of prototype
	Flow variations expected
	Facilities and equipment required and setup
	Materials of construction
Design of pilot testing program	Dependent variables including ranges
	Independent variables including ranges
	Time required
	Test facilities
	Test protocols
	Statistical design of data acquisition program

to provide a consistent basis for analysis of uncertainty and a rational basis for the analysis of performance and reliability. Treatment plant reliability can be defined as the probability that a system can meet established performance criteria consistently over extended periods of time. Thus, reliability is comprised of two components: inherent reliability and mechanical reliability. These subjects are considered further in Chap. 15.

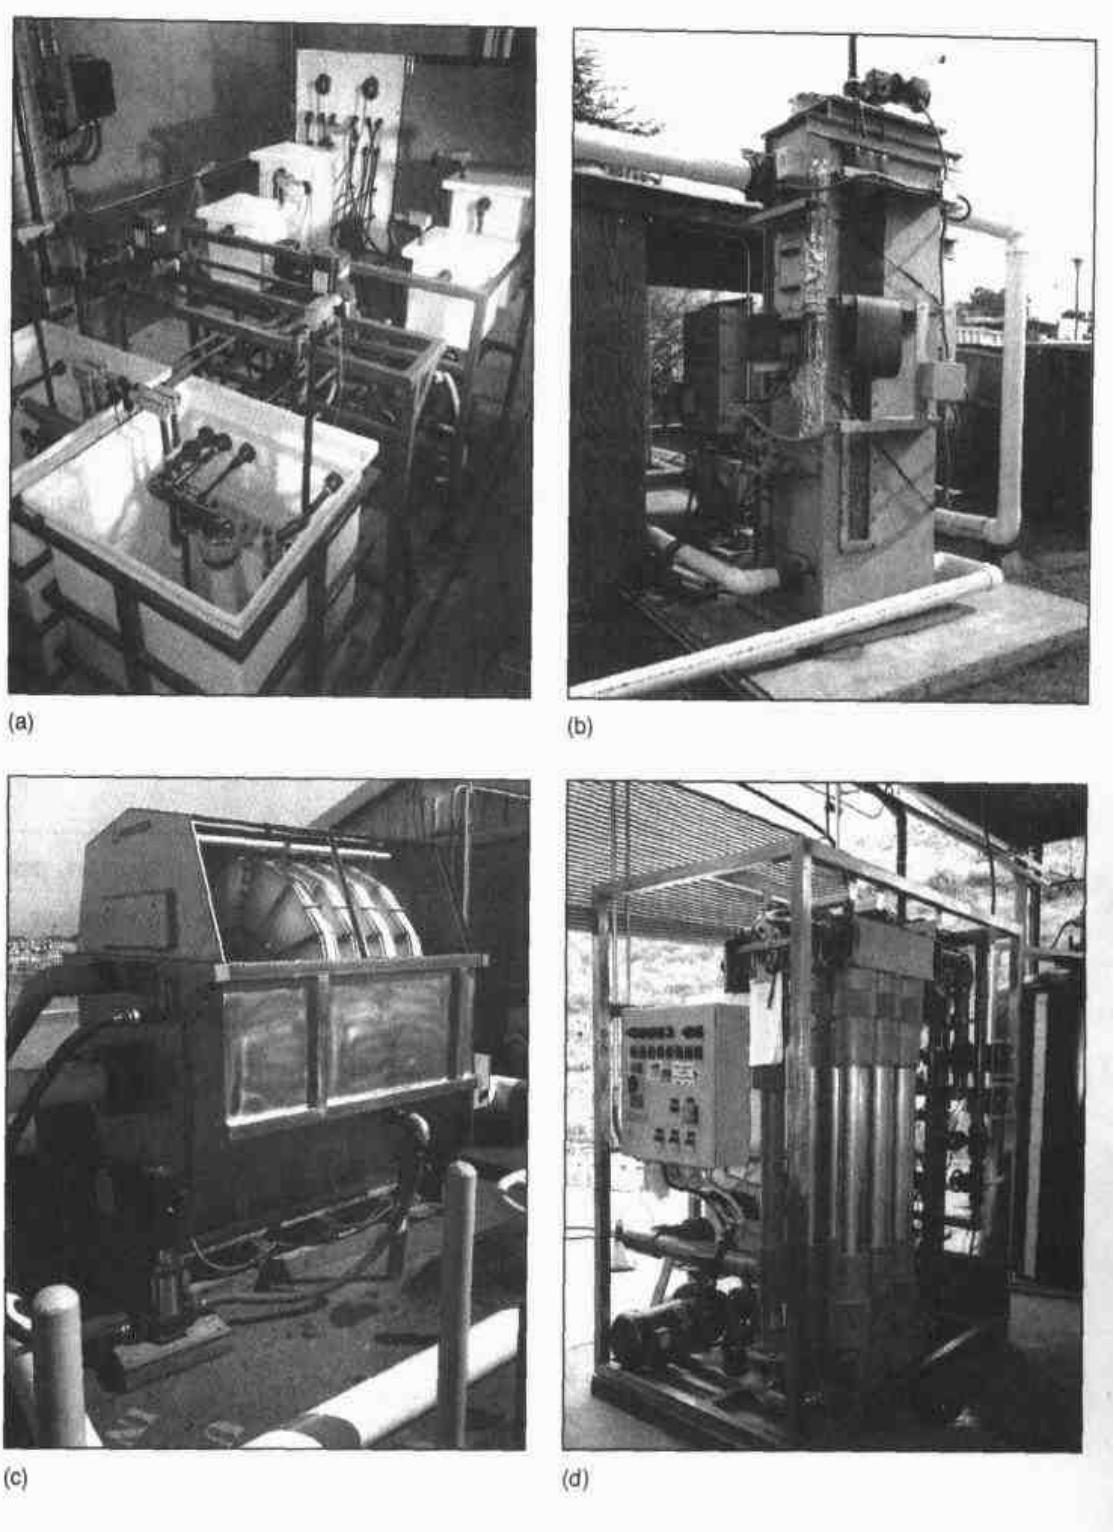

Figure 4–35

Typical pilot plants used to develop design criteria: (*a*) activated sludge, (*b*) effluent filtration with depth filter, (*c*) effluent filtration with cloth surface filter, and (*d*) effluent filtration with membrane microfilter.

PROBLEMS AND DISCUSSION TOPICS

4–1 A water storage tank receives a constant feed rate of 0.2 m^3/s and the demand varies according to the relationship $0.2[1 - \cos \pi t/(43{,}200)]$ m^3/s. The tank is cylindrical with a cross-sectional area of 1000 m^2. If the depth at $t = 0$ is 5 m, plot the water depth as a function of time.

4–2 Solve Problem 4–1 assuming the feed rate is 0.33 m^3/s and that the storage tank is a square with a cross-sectional area of 1600 m^2.

4–3 A large tank having a floor area of 1000 m^2 and a sidewall depth of 10 m is used as an equalization reservoir. Flow out of the basin is 0.3 m^3/s, while flow into the basin is $0.28[1 + \cos \pi t/(43{,}200)\ m^3/s)]$. Plot the hourly values of water depth versus time, assuming $h = h_o = 5$ m at $t = 0$.

4–4 Solve Problem 4–3 assuming the feed rate is 0.35 m^3/s and that the floor area for the storage tank is 2000 m^2. Plot the hourly values of water depth versus time, assuming $h = h_0 = 2.0$ m at $t = 0$.

4–5 Wastewater is being pumped into a 4.2 m diameter tank at the rate of 0.5 m^3/min. At the same time, water leaves the tank at a rate that is dependent on the height of the liquid in the tank. The relationship governing the flow from the tank is $q = [2.1\ (m^2/min) \times h(m)]$. If the tank was initially empty, develop a relationship that can be used to define the height of the liquid in the tank as a function of time. What is the steady-state height of the liquid in the tank?

4–6 Solve Problem 4–5 assuming the feed rate is 0.75 m^3/min and the tank outflow is $q = [2.7\ (m^2/min) \times h(m)]$.

4–7 The following data were obtained from dye tracer studies of five different chlorine contact basins. Using these data, determine the mean detention time and the corresponding variance for one of the basins (to be selected by instructor).

	Concentration, ppb				
	Basin number				
Time, min	A	B	C	D	E
0	0.0	0.0	0.0	0.0	0.0
6	0.0	0.0	0.0	0.0	0.0
12	3.5	0.1	0.1	0.0	0.0
18	7.6	2.1	2.1	0.0	0.7
24	7.8	7.5	10.0	0.3	4.0
30	6.9	10.1	12.0	1.8	9.0
36	5.9	10.2	10.2	4.5	12.5
42	4.8	9.7	8.0	8.0	11.5
48	3.8	8.1	6.0	11.0	8.8
54	3.0	6.0	4.3	11.0	5.5
60	2.4	4.4	3.0	9.0	3.0
66	1.9	3.0	2.1	4.3	1.8
72	1.5	1.9	1.5	2.0	0.8
78	1.0	1.0	1.0	1.0	0.4
84	0.6	0.4	0.5	0.2	0.1
90	0.3	0.1	0.1	0.0	0.0
96	0.1	0.0	0.0	0.0	0.0
102	0.0	0.0	0.0	0.0	0.0

4–8 Using the tracer data given in Problem 4–1, develop residence time distribution curves (E and F) for one of the chlorine contact basins (to be selected by instructor).

4–9 Using the tracer data given in Problem 4–1, determine the Morrill dispersion index and the volumetric efficiency for one of the chlorine contact basins (to be selected by instructor).

4–10 Using the tracer data given in Problem 4–1, determine the dispersion number, the Peclet number, and the number of complete-mix reactors in series that would be needed to simulate the tracer curve for one of the chlorine contact basins (to be selected by instructor). Also, plot the tracer curve and the simulated curve.

4–11 When a slug of tracer is added to a series of complete-mix reactors, a maximum value of $C(\theta)$ occurs at $t > 0$ for all reactors except the first. Determine the time, θ, when the peak concentration of tracer occurs in reactor number 5 in a reactor system comprised of 6 reactors in series.

4–12 Solve Problem 4–11 for the nth reactor in a reactor system comprised of n complete-mix reactors in series.

4–13 The following data were obtained for four different reactants for the reaction $A \rightarrow B + C$. Determine the order of the reaction for one reaction (to be selected by instructor) and the value of the reaction rate constant k.

	Concentration, mg/L			
Time, t, min	A	B	C	D
0	90			
10	72			
20	57			
24	36			
60	23			

4–14 A bimolecular reaction $A + B \rightarrow P$ is 10 percent complete in 10 min. If the initial concentration of A and B is equal to 1.0 mole/L, determine the reaction rate constant and how long it will take for the reaction to be 90 percent complete.

4–15 A bimolecular reaction $A + B \rightarrow P$ is 8 percent complete in 12 min. If the initial concentration of A and B is equal to 1.33 mole/L, determine the reaction rate constant and how long it will take for the reaction to be 96 percent complete.

4–16 The following values have been obtained for the rate constant for the reaction $A + B \rightarrow P$. Using these data, determine the activation energy E and the value of the rate constant at 15°C.

$k_{25°C} = 1.5 \times 10^{-2}$ L/mole·min

$k_{45°C} = 4.5 \times 10^{-2}$ L/ mole·min

4–17 Solve Problem 4–16 for the following rate constant values:

$k_{20°C} = 1.25 \times 10^{-2}$ L/mole·min

$k_{35°C} = 3.55 \times 10^{-2}$ L/ mole·min

4–18 An aqueous reaction is being studied in a laboratory-sized complete-mix reactor with a volume of 5 L. The stoichiometry of the reaction is $A \rightarrow 2R$, and reactant A is introduced into the reactor at a concentration of 1 mole/L. From the results given in the following table, find the rate expression for this reaction. Assume steady-state flow.

Run	Feed rate, cm^3/s	Temperature, °C	Concentration R in effluent, mole/L
1	2	13	1.8
2	15	13	1.5
3	15	84	1.8

4–19 The rate of reaction for an enzyme-catalyzed substrate in a batch reactor can be described by the following relationship.

$$r_C = -\frac{kC}{K + C}$$

where k = maximum reaction rate, mg/L·min
C = substrate concentration, mg/L
K = constant, mg/L

Using this rate expression, derive an equation that can be used to predict the reduction of substrate concentration with time in a batch reactor. If k equals 40 mg/L·min and K = 100 mg/L, determine the time required to decrease the substrate concentration from 1000 to 100 mg/L.

4–20 Solve problem 4–19 for the following values: k equals 28 mg/L·min and K = 116 mg/L.

4–21 A wastewater is to be treated in a continuous-flow stirred-tank reactor. Assuming that the reaction is irreversible and first-order ($r = -kC$) with a reaction rate coefficient equal to 0.15 d, determine the flowrate that can be treated if the reactor has a volume of 20 m^3 and 98 percent treatment efficiency is required. What volume would be required to treat the flowrate determined above if the required treatment efficiency is 92 percent?

4–22 For first-order removal kinetics, demonstrate that the maximum treatment efficiency in a series of complete-mix reactors occurs when all the reactors are the same size.

4–23 Determine the number of completely mixed chlorine contact chambers each having a detention time of 30 min that would be required in a series arrangement to reduce the bacterial count of a treated effluent from 10^6 to 14.5 organisms/mL if the first-order removal rate constant is equal to 6.1 h^{-1}. If a plug-flow chlorine contact chamber were used with the same detention time as the series of completely mixed chambers, what would the bacterial count be after treatment?

4–24 The concentration of UBOD in a river entering the first of two lakes that are connected in a series is equal to 20 mg/L. If the first-order BOD reaction rate constant (K) equals 0.35 d^{-1} and complete mixing occurs in each lake, what is the concentration of UBOD at the outlet of each lake? The flow in the river is equal to 4000 m^3/d and the volume of the first and second lake is 20,000 and 12,000 m^3, respectively. Assume steady-state conditions.

4–25 In Prob. 4–24, if the length of the river connection between the two lakes is equal to 3 km and the velocity in the river is equal to 0.4 m/s, determine the concentration of the UBOD in the effluent from the second lake.

4–26 Plot the ratio of required tank volume for a plug-flow reactor to that of a continuous-flow stirred-tank reactor (VPFR/VCMR) versus the fraction of the original substrate that is converted for the following reaction rates.

$r = -k$

$r = -kC^{0.5}$

$r = -kC$

$r = -kC^2$

What is the value of the required volume ratio for each of these rates when $C = 0.25$ mg/L and $C_o = 1.0$ mg/L?

4–27 Solve problem 4–26 for the following values: $C = 0.17$ mg/L and $C_o = 1.25$ mg/L.

4–28 If second-order reaction kinetics are applicable ($r = -kC^2$), determine the effluent concentration for each of the reactor systems shown on Fig. 4–28. To simplify the computations, assume that the following data apply:

$k = 1.0$ m^3/kg·d

$Q = 1.0$ m^3/d

$V_{PFR} = 1.0$ m^3

$V_{CMR} = 1.0$ m^3

$C_o = 1.0$ kg/m^3

Explain your results. What would happen if first- or zero-order kinetics are applicable?

4–29 A portion of the outflow, αQ, from an ideal plug-flow reactor is recycled around the reactor where $\alpha \geq 0$. Assume that the rate of conversion can be defined as $r_c = -kC$.

a. Sketch the generalized curve of conversion versus the recycle ratio.
b. Sketch a family of curves showing the effect of the recycle ratio α on the longitudinal concentration gradient.
c. If a continuous-flow stirred-tank reactor were substituted for the plug-flow reactor, what effect would the recycle have on conversion?

4–30 Determine the effect of recycle on the performance of a complete-mix reactor for first- and second-order reactions.

4–31 Derive an expression that can be used to compute the effluent concentration from an overland flow treatment system, designed as an ideal plug-flow reactor, assuming the removal of the constituent in question can be described by a retarded second-order equation. Assume the exponent n in the retardation term is equal to one. If the value of the retardation coefficient is 0.2, compare the effluent concentration with and without retardation.

4–32 For first-order removal kinetics demonstrate that the maximum treatment efficiency in a series of complete-mix reactors occurs when all of the reactors are of the same size.

4–33 A treated effluent flows in a 0.3 m deep open channel for a distance of 1000 m. Estimate the concentration of dissolved oxygen in the effluent at the end of the channel, assuming ideal plug-flow if the average flow velocity in the channel is 0.33 m/s and that the mass transfer coefficient, K, for oxygen is 0.05 m/h. Assume the initial concentration of dissolved oxygen is 0.5 mg/L and the temperature is 20°C.

4–34 Solve Problem 4–33 for a 0.45 m deep open channel, an average flow velocity of 0.25 m/s, and an oxygen mass transfer coefficient value of 0.06 m/h.

4–35 A treated effluent flows in a 0.25 m deep open channel for a distance of 1500 m at a velocity of 0.25 m/h. If the initial concentration of dissolved oxygen is 0.8 mg/L and the concentration at the end of the channel is 2.9 mg/L, estimate the value of the mass transfer coefficient, K, for oxygen at 20°C.

4–36 Solve Problem 4–35 if the initial concentration of dissolved oxygen is 0.6 mg/L and the concentration at the end of the channel is 2.7.

4–37 How much powdered activated carbon will be required to treat an effluent flowrate of 6500 m^3/d to reduce the bromoform concentration from 0.09 to 0.025 mg/L? The Freundlich adsorption isotherm coefficients for bromoform are: $K_f = 20$ and $1/n = 0.52$ (see Table 11–32 in Chap. 11).

4–38 Solve Problem 4–37 for a toluene. Assume the initial concentration is 0.067 mg/L and that the final concentration is to be 0.01 mg/L. The Freundlich adsorption isotherm coefficients for toluene are: $K_f = 100$ and $1/n = 0.45$ (see Table 11–32 in Chap. 11).

4–39 Wastewater containing 0.8 g/m^3 of total pesticide percolates through a soil treatment system. Adsorption has been determined to follow a Langmuir isotherm with the following coefficients: $a = 1.0$ and $b = 0.003$ m^3/g. Determine the mass of pesticide that will potentially accumulate in the soil per 1.0 m^2 of cross-sectional and the effective depth is 4 m. The dry density of the soil is approximately 2400 kg/m^3. What is the effluent concentration and the volume of wastewater that can be applied assuming all of the available adsorption capacity will be utilized?

4–40 Solve Problem 4–39 for a water containing 0.75 mg/L g/m^3 of total pesticide. Assume the Langmuir isotherm coefficients are $a = 0.9$ and $b = 0.0025$ m^3/g.

Operations used for the treatment of wastewater in which change is brought about by means of or through the application of physical forces are known as *physical unit operations*. Because physical unit operations were derived originally from observations of the physical world, they were the first treatment methods to be used. Today, physical unit operations, as shown on Fig. 5–1, are a major part of most wastewater-treatment systems.

The unit operations most commonly used in wastewater treatment include (1) screening, (2) coarse solids reduction (comminution, maceration, and screenings grinding), (3) flow equalization, (4) mixing and flocculation, (5) grit removal, (6) sedimentation, (7) high-rate clarification, (8) accelerated gravity separation (vortex separators), (9) flotation, (10) oxygen transfer, (11) aeration, and (12) volatilization and stripping of volatile organic compounds (VOCs). The principal applications of these operations and treatment devices used are summarized in Table 5–1. Physical unit operations that apply to advanced wastewater-treatment systems such as packed-bed filters, membrane separation systems, and ammonia stripping are discussed separately in Chap. 11. Unit operations associated with the processing of solids and biosolids (sludge) are covered in Chap. 14.

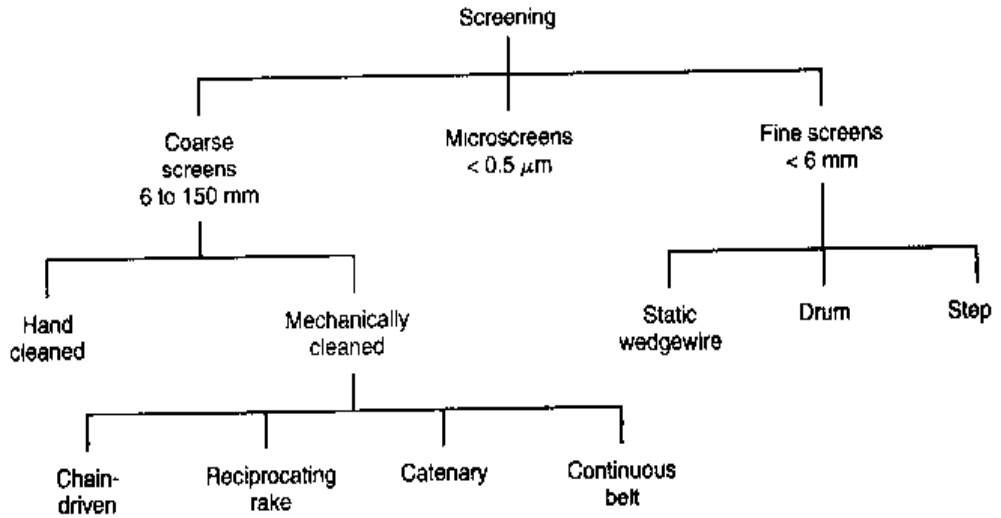
	Removal of oil and grease	Induced-air flotation	5–10
Aeration	Addition of oxygen to biological process	Diffused-air aeration Mechanical aerator	5–12 5–12
	Postaeration of treated effluent	Cascade aerator	5–12
VOC control	Removal of volatile and semivolatile organic compounds from wastewaters	Gas stripper Diffused-air and mechanical aeration	5–13 5–12, 5–13
Depth filtration	Removal of supended solids	Depth filters	11–4
Membrane filtration	Removal of suspended and colloidal solids and dissolved organic and inorganic matter	Reverse osmosis and other membrane systems	11–6
Air stripping	Removal of ammonia, hydrogen sulfide, and other gases from wastewater and digester supernatant	Packed tower	11–8

5–1 SCREENING

The first unit operation generally encountered in wastewater-treatment plants is screening. A screen is a device with openings, generally of uniform size, that is used to retain solids found in the influent wastewater to the treatment plant or in combined wastewater-collection systems subject to overflows, especially from stormwater. The principal role of screening is to remove coarse materials from the flow stream that could (1) damage subsequent process equipment, (2) reduce overall treatment process reliability and effectiveness, or (3) contaminate waterways. Fine screens are sometimes used in place of or following coarse screens where greater removals of solids are required to (1) protect process equipment or (2) eliminate materials that may inhibit the beneficial reuse of biosolids.

All aspects of screenings removal, transport, and disposal must be considered in the application of screening devices, including (1) the degree of screenings removal required because of potential effects on downstream processes, (2) health and safety of the operators as screenings contain pathogenic organisms and attract insects, (3) odor potential, and (4) requirements for handling, transport, and disposal, i.e., removal of organics (by washing) and reduced water content (by pressing), and (5) disposal options. Thus, an integrated approach is required to achieve effective screenings management.



Classification of Screens

The types of screening devices commonly used in wastewater treatment are shown on Fig. 5–2. Two general types of screens, coarse screens and fine screens, are used in preliminary treatment of wastewater. Coarse screens have clear openings ranging from 6 to 150 mm (0.25 to 6 in); fine screens have clear openings less than 6 mm (0.25 in). Microscreens, which generally have screen openings less than 50 μm, are used principally in removing fine solids from treated effluents.

The screening element may consist of parallel bars, rods or wires, grating, wire mesh, or perforated plate, and the openings may be of any shape but generally are circular or rectangular slots. A screen composed of parallel bars or rods is often called a "bar rack" or a coarse screen and is used for the removal of coarse solids. Fine screens are devices consisting of perforated plates, wedgewire elements, and wire cloth that have smaller openings. The materials removed by these devices are known as *screenings*.

Figure 5–2

Definition sketch for types of screens used in wastewater treatment.

Coarse Screens (Bar Racks)

In wastewater treatment, coarse screens are used to protect pumps, valves, pipelines, and other appurtenances from damage or clogging by rags and large objects. Industrial waste-treatment plants may or may not need them, depending on the character of the wastes. According to the method used to clean them, coarse screens are designated as either hand-cleaned or mechanically cleaned.

Hand-Cleaned Coarse Screens. Hand-cleaned coarse screens are used frequently ahead of pumps in small wastewater pumping stations and sometimes used at the headworks of small- to medium-sized wastewater-treatment plants. Often they are used for standby screening in bypass channels for service during high-flow periods, when mechanically cleaned screens are being repaired, or in the event of a power failure. Normally, mechanically cleaned screens are provided in lieu of hand-cleaned screens to minimize manual labor required to clean the screens and to reduce flooding due to clogging.

Where used, the length of the hand-cleaned bar rack should not exceed the distance that can be conveniently raked by hand, approximately 3 m (10 ft). The screen bars are welded to spacing bars located at the rear face, out of the way of the tines of the rake. A perforated drainage plate should be provided at the top of the rack where the rakings may be stored temporarily for drainage.

The screen channel should be designed to prevent the accumulation of grit and other heavy materials in the channel ahead of the screen and following it. The channel floor should be level or should slope downward through the screen without pockets to trap solids. Fillets may be desirable at the base of the sidewalls. The channel preferably should have a straight approach, perpendicular to the bar screen, to promote uniform distribution of screenable solids throughout the flow and on the screen. Typical design information for hand-cleaned bar screens is provided in Table 5–2.

Table 5–2
Typical design information for manually and mechanically cleaned bar racks

	U.S. customary units			SI units

Mechanically Cleaned Bar Screens. The design of mechanically cleaned bar screens has evolved over the years to reduce the operating and maintenance problems and to improve the screenings removal capabilities. Many of the newer designs include extensive use of corrosion-resistant materials including stainless steel and plastics. Mechanically cleaned bar screens are divided into four principal types: (1) chain-driven, (2) reciprocating rake, (3) catenary, and (4) continuous belt. Cable-driven bar screens were used extensively in the past but largely have been replaced in wastewater applications by the other types of screens. Typical design information for mechanically cleaned is also included in Table 5–2. Examples of the different types of mechanically cleaned bar screens are shown on Fig. 5–3 and the advantages and disadvantages of each type are presented in Table 5–3.

Chain-Driven Screens Chain-driven mechanically cleaned bar screens can be divided into categories based on whether the screen is raked to clean from the front (upstream) side or the back (downstream) side and whether the rakes return to the bottom of the

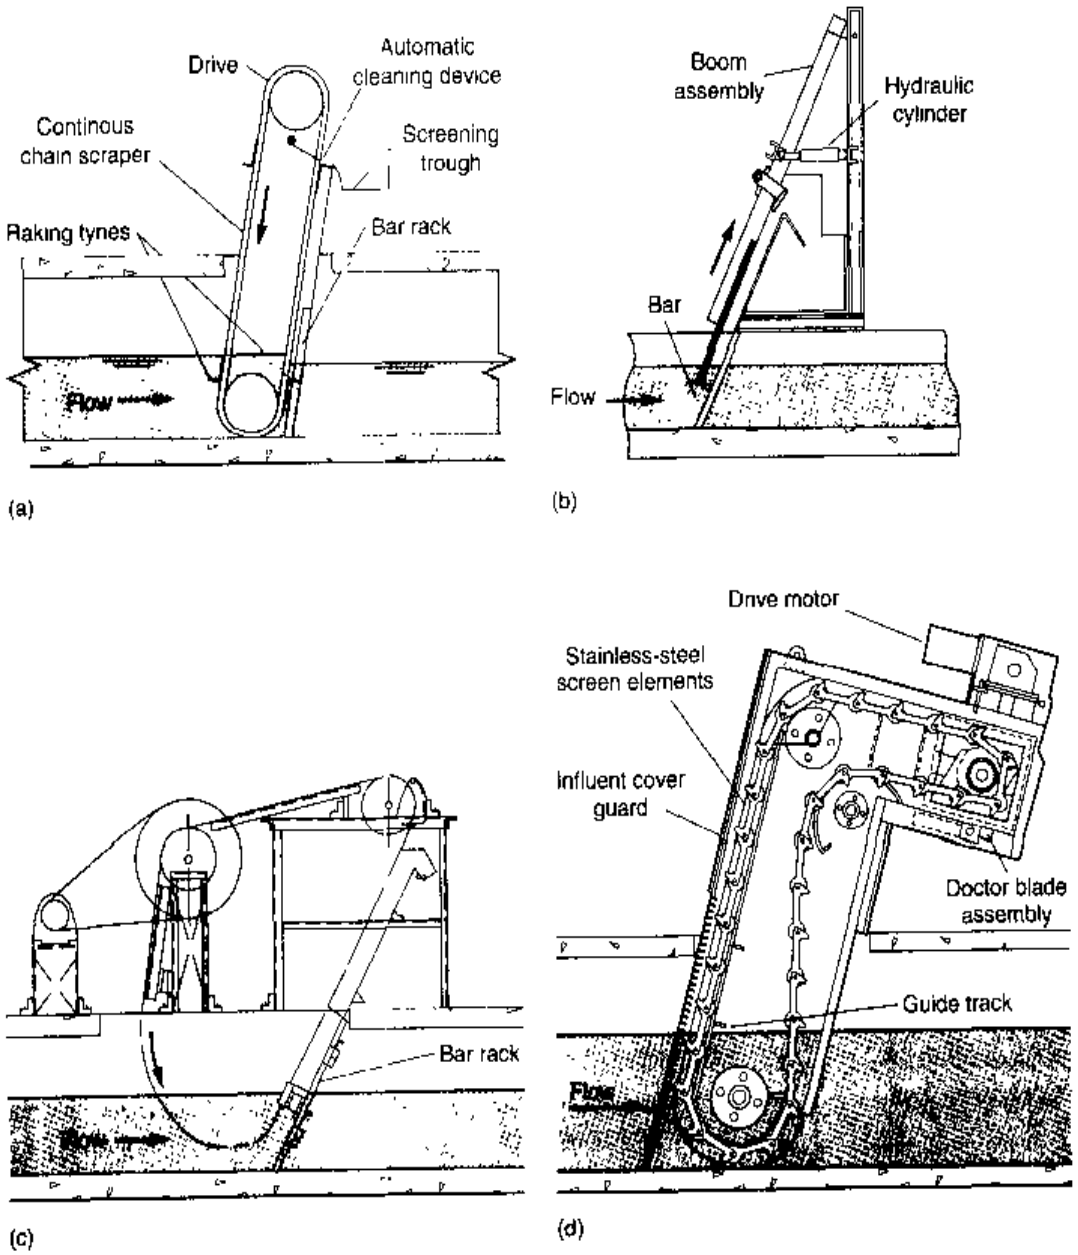

Figure 5–3
Typical mechanically cleaned coarse screens: (*a*) front-cleaned, front-return chain-driven, (*b*) reciprocating rake, (*c*) catenary, and (*d*) continuous belt.

Table 5–3
Advantages and disadvantages of various types of bar screens

Type of screen	Advantages	Disadvantages
Chain-driven screen		
Front clean/ back return	Multiple cleaning elements (short cleaning cycle)	Unit has submerged moving parts that require channel dewatering for maintenance
	Used for heavy-duty applications	Less efficient screenings removal, i.e., carryover of residual screenings to screened wastewater channel
Front clean/ front return	Multiple cleaning elements (short cleaning cycle)	Unit has submerged moving parts that require channel dewatering for maintenance
	Very little screenings carryover	Submerged moving parts (chains, sprockets, and shafts) are subject to fouling
		Heavy objects may cause rake to jam
Back clean/ back return	Multiple cleaning elements (short cleaning cycle)	Unit has submerged moving parts that require channel dewatering for maintenance
	Submerged moving parts (chains, sprockets, and shafts) are protected by bar rack	Long rake teeth are susceptible to breakage
		Some susceptibility to screenings carryover
Reciprocating rake	No submerged moving parts; maintenance and repairs can be done above operating floor	Unaccounted for high channel water level can submerge rake motor and cause motor burnout
	Can handle large objects (bricks, tires, etc.)	Requires more headroom than other screens
	Effective raking of screenings and efficient discharge of screenings	Long cycle time; raking capacity may be limiting
	Relatively low operating and maintenance costs	Grit accumulation in front of bar may impede rake movement
	Stainless-steel construction reduces corrosion	Relatively high cost due to stainless-steel construction
	High flow capacity	
Catenary	Sprockets are not submerged, most maintenance can be done above the operating floor	Because design relies on weight of chain for engagement of rakes with bars, chains are very heavy and difficult to handle
	Required headroom is relatively low	Because of the angle of inclination of the screen (45 to 75°), screen has a large footprint
	Multiple cleaning elements (short cleaning cycle)	Misalignment and warpage can occur when rakes are jammed
	Can handle large objects	May emit odors because of open design
	Very little screenings carryover	
Continuous belt	Most maintenance can be done above operating floor	Overhaul or replacement of the screening elements is a time-consuming and expensive operation
	Unit is difficult to jam	

bar screen from the front or back. Each type has its advantages and disadvantages, although the general mode of operation is similar. In general, front cleaned, front return screens (see Fig. 5–3*a*) are more efficient in terms of retaining captured solids, but they are less rugged and are susceptible to jamming by solids that collect at the base of the rake. Front cleaned, front return screens are seldom used for plants serving combined sewers where large objects can jam the rakes. In front cleaned, back return screens, the cleaning rakes return to the bottom of the bar screen on the downstream side of the screen, pass under the bottom of the screen, and clean the bar screen as the rake rises. The potential for jamming is minimized, but a hinged plate, which is also subject to jamming, is required to seal the pocket under the screen.

In back cleaned screens, the bars protect the rake from damage by the debris. However, a back cleaned screen is more susceptible to solids carryover to the downstream side, particularly as rake wipers wear out. The bar rack of the back cleaned, back return screens is less rugged than the other types because the top of the rack is unsupported so the rake tines can pass through. Most of the chain-operated screens share the disadvantage of submerged sprockets that require frequent operator attention and are difficult to maintain. Additional disadvantages include the adjustment and repair of the heavy chains, and the need to dewater the channels for inspection and repair of submerged parts.

Reciprocating Rake (Climber) Screen The reciprocating-rake-type bar screen (see Fig. 5–3*b*) imitates the movements of a person raking the screen. The rake moves to the base of the screen, engages the bars, and pulls the screenings to the top of the screen where they are removed. Most screen designs utilize a cogwheel drive mechanism for the rake. The drive motors are either submersible electric or hydraulic type. A major advantage is that all parts requiring maintenance are above the waterline and can be easily inspected and maintained without dewatering the channel. The front cleaned, front return feature minimizes solids carryover. The screen uses only one rake instead of multiple rakes that are used with other types of screens. As a result, the reciprocating rake screen may have limited capacity in handling heavy screenings loads, particularly in deep channels where a long "reach" is necessary. The high overhead clearance required to accommodate the rake mechanism can limit its use in retrofit applications.

Catenary Screen A catenary screen is a type of front cleaned, front return chain-driven screen, but it has no submerged sprockets. In the catenary screen (see Fig. 5–3*c*), the rake is held against the rack by the weight of the chain. If heavy objects become jammed in the bars, the rakes pass over them instead of jamming. The screen, however, has a relatively large "footprint" and thus requires greater space for installation.

Continuous Belt Screen The continuous belt screen is a relatively new development for use in screening applications in the United States. It is a continuous, self-cleaning screening belt that removes fine and coarse solids (see Fig. 5–3*d*). A large number of screening elements (rakes) are attached to the drive chains; the number of screening elements depends on the depth of the screen channel. Because the screen openings can range from 0.5 to 30 mm (0.02 to 1.18 in), it can be used as either a coarse or a fine screen. Hooks protruding from the belt elements are provided to capture large solids such as cans, sticks, and rags. The screen has no submerged sprocket.

Design of Coarse Screen Installations. Considerations in the design of screening installations include (1) location; (2) approach velocity; (3) clear openings between bars or mesh size; (4) headloss through the screens; (5) screenings handling, processing, and disposal; and (6) controls.

Because the purpose of coarse screens is to remove large objects that may damage or clog downstream equipment, in nearly all cases, they should be installed ahead of the grit chambers. If grit chambers are placed before screens, rags and other stringy material could foul the grit chamber collector mechanisms, wrap around air piping, and settle with the grit. If grit is pumped, further fouling or clogging of the pumps will likely occur.

In hand-cleaned installations, it is essential that the velocity of approach be limited to approximately 0.45 m/s (1.5 ft/s) at average flow to provide adequate screen area for accumulation of screenings between raking operations. Additional area to limit the velocity may be obtained by widening the channel at the screen and by placing the screen at a flatter angle to increase the submerged area. As screenings accumulate, partially plugging the screen, the upstream head will increase, submerging new areas for the flow to pass through. The structural design of the screen should be adequate to prevent collapse if it becomes plugged completely.

For most mechanically cleaned coarse screen installations, two or more units should be installed so that one unit may be taken out of service for maintenance. Slide gates or recesses in the channel walls for the insertion of stop logs should be provided ahead of, and behind, each screen so that the unit can be dewatered for screen maintenance and repair. If only one unit is installed, it is absolutely essential that a bypass channel with a manually cleaned bar screen be provided for emergency use. Sometimes the manually cleaned bar screen is arranged as an overflow device if the mechanical screen should become inoperative, especially during unattended hours. Flow through the bypass channel normally would be prevented by a closed slide or sluice gate. The screen channel should be designed to prevent the settling and accumulation of grit and other heavy materials. An approach velocity of at least 0.4 m/s (1.25 ft/s) is recommended to minimize solids deposition in the channel. To prevent the pass-through of debris at peak flowrates, the velocity through the bar screen should not exceed 0.9 m/s (3 ft/s).

The velocity through the bar screen can be controlled by installation of a downstream head control device such as a Parshall flume, or, for screens located upstream of a pumping station, by controlling the wetwell operating levels. If the channel velocities are controlled by wetwell levels, lower velocities can be tolerated provided flushing velocities occur during normal operating conditions.

Headloss through mechanically cleaned coarse screens is typically limited to about 150 mm (6 in) by operational controls. The raking mechanisms are operated normally based on differential headloss through the screen or by a time clock. For time clock operation, a cycle length of approximately 15 min is recommended; however, either a high-water or high-differential contact should be provided that will place the screen in continuous operation when needed.

Hydraulic losses through bar screens are a function of approach velocity and the velocity through the bars. The headloss through coarse screens can be estimated using the following equation:

$$h_L = \frac{1}{C}\left(\frac{V^2 - v^2}{2g}\right) \qquad (5\text{–}1)$$

where h_L = headloss, m
C = an empirical discharge coefficient to account for turbulence and eddy losses, typically 0.7 for a clean screen and 0.6 for a clogged screen
V = velocity of flow through the openings of the bar screen, m/s
v = approach velocity in upstream channel, m/s
g = acceleration due to gravity, 9.81 m/s^2

The headloss calculated using Eq. (5–1) applies only when the bars are clean. Headloss increases with the degree of clogging. The buildup of headloss can be estimated by assuming that a part of the open space in the upper portion of the bars in the flow path is clogged. The use of Eq. (5–1) is illustrated in Example 5–1.

EXAMPLE 5–1 Headloss Buildup in Coarse Screens Determine the buildup of headloss through a bar screen when 50 percent of the flow area is blocked off due to the accumulation of coarse solids. Assume the following conditions apply:

Approach velocity = 0.6 m/s
Velocity through clean bar screen = 0.9 m/s
Open area for flow through clean bar screen = 0.19 m^2
Headloss coefficient for a clean bar screen = 0.7

Solution

1. Compute the clean water headloss through bar screen using Eq. (5–1).

$$h_L = \frac{1}{C}\left(\frac{V^2 - v^2}{2g}\right)$$

$$h_L = \frac{1}{0.7}\left[\frac{(0.9\text{ m/s})^2 - (0.6\text{ m/s})^2}{2(9.81\text{ m/s}^2)}\right] = 0.033\text{ m}$$

2. Estimate the headloss through the clogged bar screen (reducing the screen area by 50 percent results in a doubling of the velocity).

The velocity through the clogged bar screen is

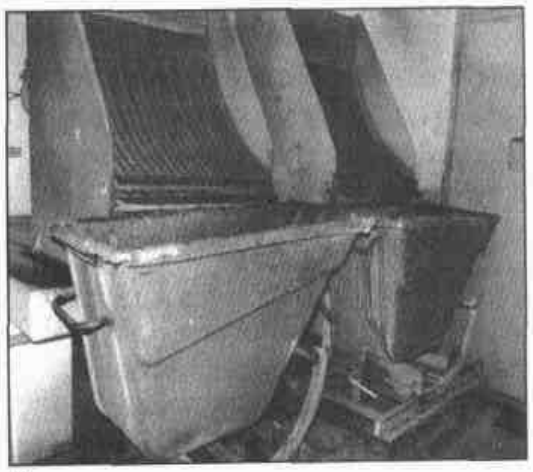
$$V_c = 0.9\text{ m/s} \times 2 = 1.8\text{ m/s}$$

Assuming the flow coefficient for the clogged bar screen is approximately 0.6, the estimated headloss is

$$h_L = \frac{1}{0.6}\left[\frac{(1.8\text{ m/s})^2 - (0.6\text{ m/s})^2}{2(9.81\text{ m/s}^2)}\right] = 0.24\text{ m}$$

Comment Where mechanically cleaned coarse screens are used, the cleaning mechanism typically is actuated by the buildup of headloss. Headloss is determined by measuring the water level before and after the screen. In some cases, the screen is cleaned at predetermined time intervals, as well as at a maximum head differential.

Although most screens use rectangular bars, optional shapes, i.e., "teardrop" and trapezoidal, are available. For the optional shapes, the wider width dimension is located



on the upstream side of the bar rack to make it easier to dislodge materials trapped between the bars. The alternative shapes also reduce headloss through the rack.

Screenings from the rake mechanism are usually discharged directly into a hopper or container or into a screenings press. For installations with multiple units, the screenings may be discharged onto a conveyor or into a pneumatic ejector system and transported to a common screenings storage hopper. As an alternative, screenings grinders may be used to grind and shred the screenings. Ground screenings are then returned to the wastewater; however, ground screenings may adversely affect operation and maintenance of downstream equipment such as clogging weir openings on sedimentation tanks or wrapping around air diffusers. Application of screenings grinders is discussed in Sec. 5–3.

Fine Screens

The applications for fine screens range over a broad spectrum; uses include preliminary treatment (following coarse bar screens), primary treatment (as a substitute for primary clarifiers), and treatment of combined sewer overflows. Fine screens can also be used to remove solids from primary effluent that could cause clogging problems in trickling filters.

Screens for Preliminary and Primary Treatment. Fine screens used for preliminary treatment are of the (1) static (fixed), (2) rotary drum, or (3) step type. Typically, the openings vary from 0.2 to 6 mm (0.01 to 0.25 in). Examples of fine screens are illustrated on Fig. 5–4, descriptive information is provided in Table 5–4, and addi-

(a)

(b)

(c)

Figure 5–4

Typical fine screens: (a) static wedgewire, (b) drum, and (c) step. In step screens, screenings are moved up the screen by means of movable and fixed vertical plates.

Table 5–4
Description of screening devices used in wastewater treatment

Type of screening device	Screening surface: Size classification	Size range: in	Size range: mm[a]	Screen medium	Application	See fig.
Inclined (fixed)	Medium	0.01–0.1	0.25–2.5	Stainless-steel wedgewire screen	Primary treatment	5–4a

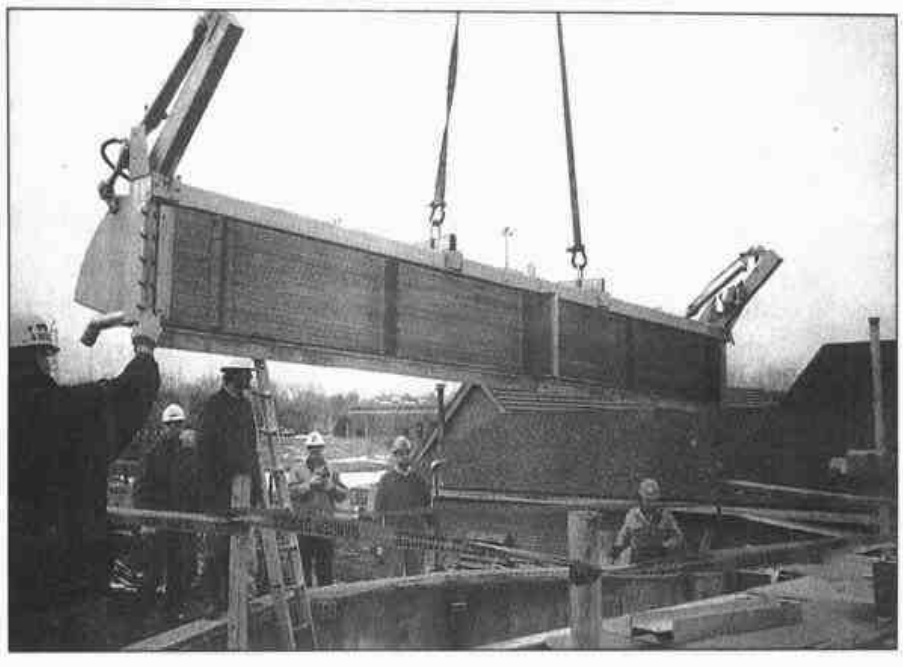
[a]The actual removal achieved will depend on the nature of the wastewater-collection system and the wastewater travel time.

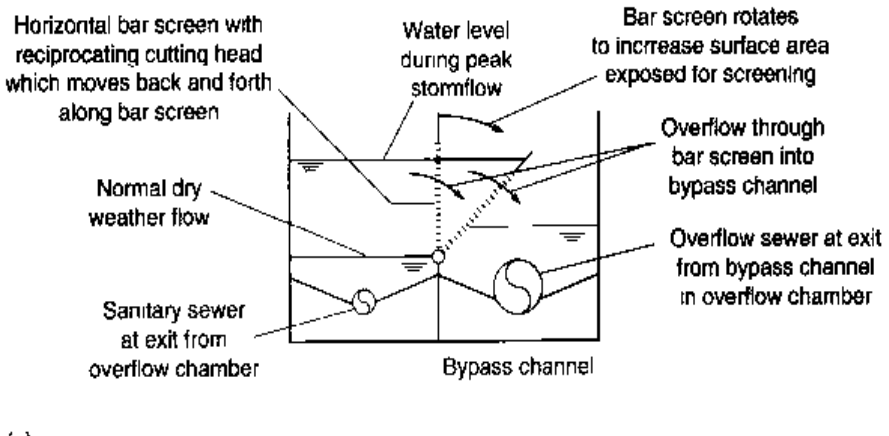
tional information is given below. In many cases, application of fine screens is limited to plants where headloss through the screens is not a problem.

Fine screens may be used to replace primary treatment at small wastewater-treatment plants, up to 0.13 to m^3/s (3 Mgal/d) in design capacity. Typical removal rates of BOD and TSS are reported in Table 5–5. Stainless-steel mesh or special wedge-shaped bars are used as the screening medium. Provision is made for the continuous removal of the collected solids, supplemented by water sprays to keep the screening medium clean. Headloss through the screens may range from about 0.8 to 1.4 m (2.5 to 4.5 ft).

Static Wedgewire Screens Static wedgewire screens (see Fig. 5–4*a*) customarily have 0.2 to 1.2 mm (0.01 to 0.06 in) clear openings and are designed for flowrates of about 400 to 1200 L/m^2·min (10 to 30 gal/ft^2·min) of screen area. Headloss ranges from 1.2 to 2 m (4 to 7 ft). The wedgewire medium consists of small, stainless-steel wedge-shaped bars with the flat part of the wedge facing the flow. Appreciable floor area is required for installation and the screens must be cleaned once or twice daily with high-pressure hot water, steam, or degreaser to remove grease buildup. Static wedgewire screens are generally applicable to smaller plants or for industrial installations.



Drum Screens For the drum-type screen (see Fig. 5–4*b*), the screening or straining medium is mounted on a cylinder that rotates in a flow channel. The construction varies, principally with regard to the direction of flow through the screening medium. The wastewater flows either into one end of the drum and outward through the screen with the solids collection on the interior surface, or into the top of the unit and passing through to the interior with solids collection on the exterior. Internally fed screens are applicable for flow ranges of 0.03 to 0.8 m^3/s (0.7 to 19 Mgal/d) per screen, while externally fed screens are applicable for flowrates less than 0.13 m^3/s (3 Mgal/d) (Laughlin and Roming, 1993). Drum screens are available in various sizes, from 0.9 to 2 m (3 to 6.6 ft) in diameter and from 1.2 to 4 m (4 to 13.3 ft) in length.



Step Screens Step screens, although widely used in Europe, are a relatively new technology in fine screening in the United States. The design consists of two step-shaped sets of thin vertical plates, one fixed and one movable (see Fig. 5–4*c*). The fixed and movable step plates alternate across the width of an open channel and together form a single screen face. The movable plates rotate in a vertical motion. Through this motion, solids captured on the screen face are automatically lifted up to the next fixed step landing, and are eventually transported to the top of the screen where they are discharged to a collection hopper. The circular pattern of the moving plates provides a self-cleaning feature for each step. Normal ranges of openings between the screen plates are 3 to 6 mm (0.12 or 0.24 in); however, openings as small as 1 mm (0.04 in) are available. Solids trapped on the screen also create a "filter mat" that enhances solids removal performance. In addition to wastewater screening, step screens can be used for removal of solids from septage, primary sludge, or digested biosolids.

Fine Screens for Combined Sewer Overflows. Screens have also been developed specifically for the removal of floatable and other solids from combined sewer overflows. Two basic types are used: horizontal reciprocating screens and tangential flow screens. The horizontal reciprocating screen is a rigid, weir-mounted screen configured of narrow stainless-steel bars that run the length of the device (see Fig. 5–5*a*). The screening bars are parallel to the normal direction of flow and are designed in continuous runs with no intermediate supports to collect solids. As the water in the screen channel rises, wastewater begins to pass through the openings in the screen bars. Solids are trapped on the screen, and, as the level continues to rise in the channel due to the entrapped solids on the screen, a hydraulically driven rake assembly is automatically activated to remove the accumulated solids from the screen. The rake carriage travels back and forth across the screen, combing the entrapped solids. The combing tines of the rake assembly carry the solids to one end of the screen for disposal either

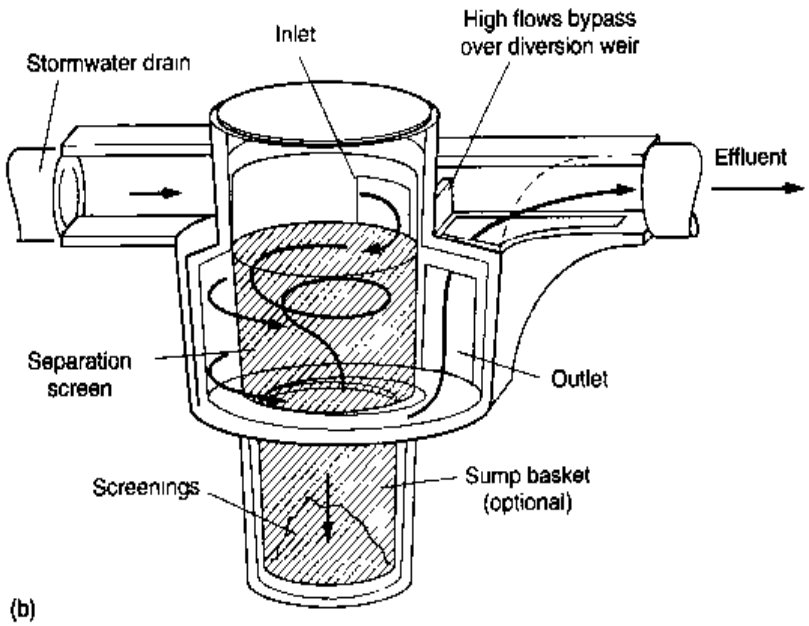


Figure 5–5

Devices used for the screening of combined sewer overflows: (a) horizontal type in which the cutting mechanism travels back and forth horizontally along the bars *(Photo courtesy of Parkson)* and (b) tangential flow in which the flow passes through a cylindrical screen leaving the solids to accumulate in a sump. *(Adapted from CDS Technologies Catalog.)*

(a)

(b)

into the wastewater channel that carries flow to the wastewater-treatment plant or to a solids-collection pit.

In the tangential flow screen, the technology relies on the natural motion of water to screen and trap solids. The separation process is effected using a fine-mesh cylindrical screen and requires no moving parts (see Fig. 5–5*b*). As the wastewater flows into the separation chamber, a circular motion is generated that is designed to allow water to pass through the cylindrical screen while forcing solids to swirl toward the center of the chamber. The swirling water is regulated so that the tangential flow around the chamber is greater than the radial force attempting to push the solids outward. Thus, the accumulation of solids on the screen is minimized. The solids settle into a central sump where they can be removed. Floatables are trapped in the separation chamber until the flow stops, when they can be removed (Williams, 2000).

Design of Fine-Screen Installations. Mechanically cleaned coarse screens should precede some types of fine screens. Newer designs of internally fed rotary screens that use wedgewire instead of screen fabric are structurally more rugged. These designs can handle coarse solids that are transported through wastewater pumps; thus upstream protective devices may not be required.

An installation should have a minimum of two screens, each with the capability of handling peak flowrates. Flushing water should be provided nearby so that the buildup of grease and other solids on the screen can be removed periodically. In colder climates, hot water or steam is more effective for grease removal.

The calculation of headloss through fine screens differs from that of coarse screens. The clear water headloss through fine screens may be obtained from manufacturers' rating tables, or calculated using Eq. (5–2):

$$h_L = \frac{1}{2g}\left(\frac{Q}{CA}\right)^2 \qquad (5\text{–}2)$$

where h_L = headloss, m
C = coefficient of discharge for the screen (a typical value for a clean screen is 0.60)
g = acceleration due to gravity, 9.81 m/s^2
Q = discharge through screen, m^3/s
A = effective open area of submerged screen, m^2

Values of C and A depend on screen design factors, such as the size and milling of slots, the wire diameter and weave, and particularly the percent of open area, and must be obtained from the screen manufacturer or determined experimentally. The important determination is the headloss during operation; headloss depends on the size and amount of solids in the wastewater, the size of the apertures, and the method and frequency of cleaning.

Microscreens

Microscreening involves the use of variable low-speed (up to 4 r/min), continuously backwashed, rotating-drum screens operating under gravity-flow conditions (see Fig. 5–6). The filtering fabrics have openings of 10 to 35 μm and are fitted on the drum periphery. The wastewater enters the open end of the drum and flows outward through

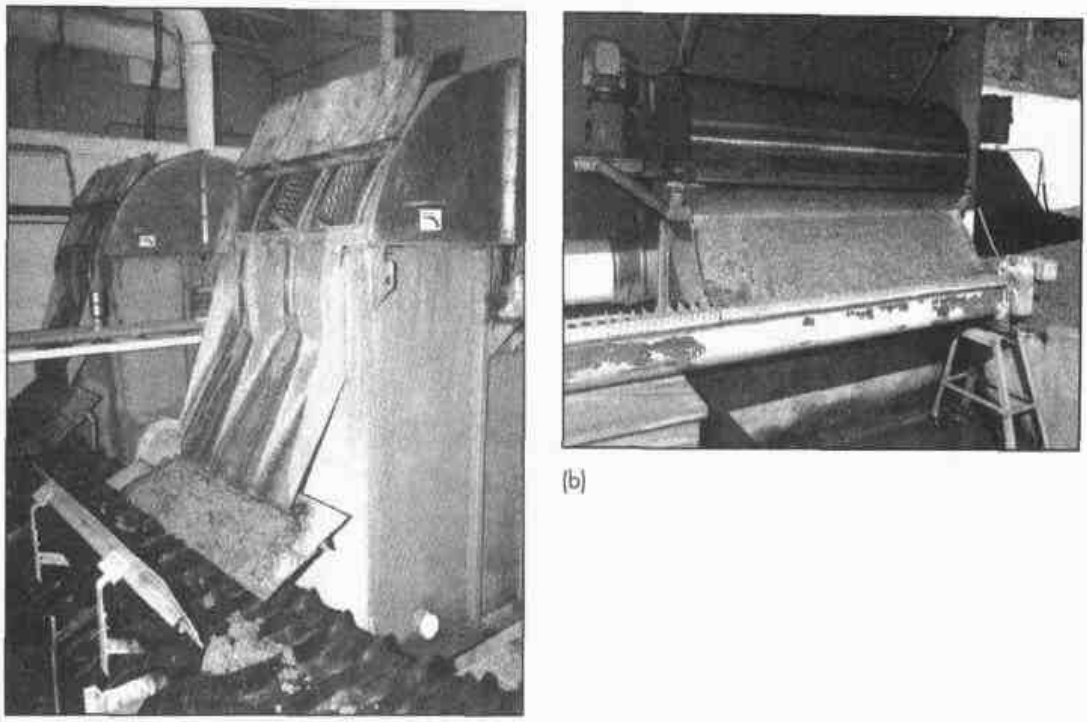

Figure 5–6

Microscreens used in wastewater treatment as a replacement for primary treatment: (a) disk type with stainless-steel fabric and (b) drum type with wedgewire screen. The size of the openings on both screens is 250 μm (0.010 in).

the rotating-drum screening cloth. The collected solids are backwashed by high-pressure jets into a trough located within the drum at the highest point of the drum. (See also Sec. 11–5 for cloth medium surface filters used in advanced wastewater treatment.) The principal applications for microscreens are to remove suspended solids from secondary effluent and from stabilization-pond effluent.

Typical suspended-solids removal achieved with microscreens ranges from 10 to 80 percent, with an average of 55 percent. Problems encountered with microscreens include incomplete solids removal and inability to handle solids fluctuations. Reducing the rotating speed of the drum and less frequent flushing of the screen have resulted in increased removal efficiencies but reduced capacity.

The functional design of a microscreen involves (1) characterizing the suspended solids with respect to the concentration and degree of flocculation, (2) selecting design parameters that will not only assure sufficient capacity to meet maximum hydraulic loadings with critical solids characteristics but also meet operating performance requirements over the expected range of hydraulic and solids loadings, and (3) providing backwash and cleaning facilities to maintain the capacity of the screen. Typical design information for microscreens is presented in Table 5–6. Because of the variable performance of microscreens, pilot-plant studies are recommended, especially if the units are to be used to remove solids from stabilization-pond effluent, which may contain significant amounts of algae.

Screenings Characteristics and Quantities

Screenings are the material retained on bar racks and screens. The smaller the screen opening, the greater will be the quantity of collected screenings. While no precise definition of screenable material exists, and no recognized method of measuring quantities of screenings is available, screenings exhibit some common properties.

Table 5-6
Typical design information for microscreens used for screening secondary settled effluent[a]

Item	Typical value: U.S. customary units	Typical value: SI units	Remarks
Screen size	20–35 μm	20–35 μm	Stainless-steel or polyester screen cloths are available in sizes ranging from 15 to 60 μm
Hydraulic loading rate	75–150 gal/ft^2·min	3–6 m^3/m^2·min	Based on submerged surface area of drum
Headloss through screen	3–6 in	75–150 mm	Bypass should be provided when headloss exceeds 200 mm (8 in)
Drum submergence	70–75% of height; 60–70% of area	70–75% of height; 60–70% of area	Varies depending on screen design
Drum diameter	8–16 ft	2.5–5 m	3 m (10 ft) is most commonly used size; smaller sizes increase backwash requirements
Drum speed	15 ft/min at 3 in headloss	4.5 m/min at 75 mm headloss	Maximum rotational speed is limited to 45 m/min (150 ft/min)
Backwash requirements	2% of throughput at 50 lb$_f$/in^2; 5% of throughput at 15 lb$_f$/in^2	2% of throughput at 350 kPa; 5% of throughput at 100 kPa	

[a] Adapted in part from Tchobanoglous, 1988

Screenings Retained on Coarse Screens. Coarse screenings, collected on coarse screens of about 12 mm (0.5 in) or greater spacing, consist of debris such as rocks, branches, pieces of lumber, leaves, paper, tree roots, plastics, and rags. Organic matter can collect as well. The accumulation of oil and grease can be a serious problem, especially in cold climates. The quantity and characteristics of screenings collected for disposal vary, depending on the type of bar screen, the size of the bar screen opening, the type of sewer system, and the geographic location. Typical data on the characteristics and quantities of coarse screenings to be expected at wastewater-treatment plants served by conventional gravity sewers are reported in Table 5–7.

Combined storm and sanitary collection systems may produce volumes of screenings several times the amounts produced by separate systems. The quantities of screenings have also been observed to vary widely, ranging from large quantities during the "first flush" to diminishing amounts as the wet weather flows persist. The quantities of screenings removed from combined sewer flows are reported to range from 3.5 to 84 L/1000 m^3 of flow (0.5 to 11.3 ft^3/Mgal) (WEF, 1998*b*).

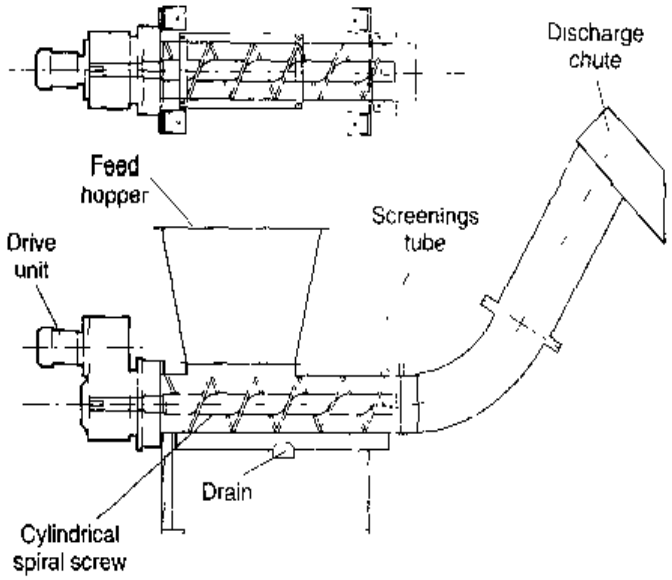
Screenings Retained on Fine Screens. Fine screenings consist of materials that are retained on screens with openings less than 6 mm (0.25 in). The materials retained on fine screens include small rags, paper, plastic materials of various types, razor blades, grit, undecomposed food waste, feces, etc. Compared to coarse screen-

Table 5–7
Typical information on the characteristics and quantities of screenings removed from wastewater with coarse screens

Size of opening between bars, mm	Moisture content, %	Specific weight, kg/m³	Volume of screenings			
			ft³/Mgal		L/1000 m³	
			Range	Typical	Range	Typical
12.5	60–90	700–1100	5–10	7	37–74	50
25	50–80	600–1000	2–5	3	15–37	22
37.5	50–80	600–1000	1–2	1.5	7–15	11
50	50–80	600–1000	0.5–1 5	0.8	4–11	6

Note: mm × 0.3937 = in
kg/m³ × 8.3492 = lb/1000 gal

Table 5–8
Typical information on the characteristics and quantities of screenings removed from wastewater with fine bar and rotary-drum screens



Operation	Size of opening, mm	Moisture content, %	Specific weight, kg/m³	Volume of screenings			
				ft³/Mgal		L/1000 m³	
				Range	Typical	Range	Typical
Fine bar screens	12.5	80–90	900–1100	6–15	10	44–110	75
Rotary drum[a]	6.25	80–90	900–1100	4–8	6	30–60	45

[a] Following coarse screening.
Note: mm × 0.3937 = in
kg/m³ × 8.3492 = lb/1000 gal

ings, the specific weight of the fine screenings is slightly lower and the moisture content is slightly higher (see Table 5–8). Because putrescible matter, including fecal material, is contained within screenings, they must be handled and disposed of properly. Fine screenings contain substantial grease and scum, which require similar care, especially if odors are to be avoided.

Screenings Handling, Processing, and Disposal. In mechanically cleaned screen installations, screenings are discharged from the screening unit directly into a screenings grinder, a pneumatic ejector, or a container for disposal; or onto a conveyor for transport to a screenings compactor or collection hopper. Belt conveyors and pneumatic ejectors are generally the primary means of mechanically transporting screenings. Belt conveyors offer the advantages of simplicity of operation, low maintenance, freedom from clogging, and low cost. Belt conveyors give off odors and may have to be provided

Figure 5–7
Typical device used for compacting screenings.

with covers. Pneumatic ejectors are less odorous and typically require less space; however, they are subject to clogging if large objects are present in the screenings.

Screenings compactors can be used to dewater and reduce the volume of screenings (see Fig. 5–7). Such devices, including hydraulic ram and screw compactors, receive screenings directly from the bar screens and are capable of transporting the compacted screenings to a receiving hopper. Compactors can reduce the water content of the screenings by up to 50 percent and the volume by up to 75 percent. As with pneumatic ejectors, large objects can cause jamming, but automatic controls can sense jams, automatically reverse the mechanism, and actuate alarms and shut down equipment.

Means of disposal of screenings include (1) removal by hauling to disposal areas (landfill) including codisposal with municipal solid wastes, (2) disposal by burial on the plant site (small installations only), (3) incineration either alone or in combination with sludge and grit (large installations only), and (4) discharge to grinders or macerators where they are ground and returned to the wastewater. The first method of disposal is most commonly used. In some states, screenings are required to be lime stabilized for the control of pathogenic organisms before disposal in landfills. Grinding the screenings and returning them to the wastewater flow shares many of the disadvantages cited under comminution, as discussed in the following section.

5–2 COARSE SOLIDS REDUCTION

As an alternative to coarse bar screens or fine screens, comminutors and macerators can be used to intercept coarse solids and grind or shred them in the screen channel. High-speed grinders are used in conjunction with mechanically cleaned screens to grind and shred screenings that are removed from the wastewater. The solids are cut up into a smaller, more uniform size for return to the flow stream for subsequent removal by downstream treatment operations and processes. Comminutors, macerators, and grinders can theoretically eliminate the messy and offensive task of screenings handling and disposal. The use of comminutors and macerators is particularly advantageous in a pumping station to protect the pumps against clogging by rags and large objects and to

eliminate the need to handle and dispose of screenings. They are particularly useful in cold climates where collected screenings are subject to freezing.

There is a wide divergence of views, however, on the suitability of using devices that grind and shred screenings at wastewater-treatment plants. One school of thought maintains that once coarse solids have been removed from wastewater, they should not be returned, regardless of the form. The other school of thought maintains that once cut up, the solids are more easily handled in the downstream processes. Shredded solids often present downstream problems, particularly with rags and plastic bags, as they tend to form ropelike strands. Rag and plastic strands can have a number of adverse impacts, such as clogging pump impellers, sludge pipelines, and heat exchangers, and accumulating on air diffusers and clarifier mechanisms. Plastics and other nonbiodegradable material may also adversely affect the quality of biosolids that are to be beneficially reused.

Approaches to using comminutors, macerators, and grinders are applicable in many retrofit situations. Examples of retrofit applications include plants where a spare channel has been provided for the future installation of a duplicate unit or in very deep influent pumping stations where the removal of screenings may be too difficult or costly to achieve. Alternative approaches may also be possible, such as using chopper pumps at pumping stations (see Sec. 14–4) or installing grinders ahead of sludge pumps.

Comminutors

Comminutors are used most commonly in small wastewater-treatment plants, less than 0.2 m^3/s (5 Mgal/d). Comminutors are installed in a wastewater flow channel to screen and shred material to sizes from 6 to 20 mm (0.25 to 0.77 in) without removing the shredded solids from the flow stream. A typical comminutor uses a stationary horizontal screen to intercept the flow (see Fig. 5–8) and a rotating or oscillating arm that

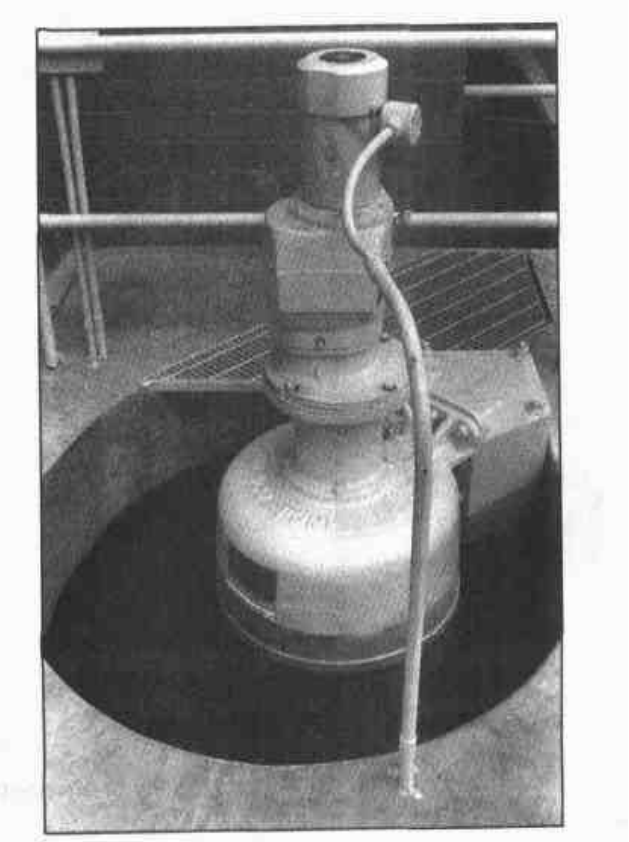


Figure 5–8

Typical comminutor used for particle size reduction of solids.

contains cutting teeth to mesh with the screen. The cutting teeth and the shear bars cut coarse material. The small sheared particles pass through the screen and into the downstream channel. Comminutors may create a string of material, namely, rags, that can collect on downstream treatment equipment. Because of operating problems and high maintenance with comminutors, newer installations generally use a screen or a macerator described below.

Macerators

Macerators are slow-speed grinders that typically consist of two sets of counterrotating assemblies with blades (see Fig. 5–9*a*). The assemblies are mounted vertically in the flow channel. The blades or teeth on the rotating assemblies have a close tolerance that effectively chops material as it passes through the unit. The chopping action reduces the potential for producing ropes of rags or plastic that can collect on downstream equipment. Macerators can be used in pipeline installations to shred solids, particularly ahead of wastewater and sludge pumps, or in channels at smaller wastewater-treatment plants. Sizes for pipeline applications typically range from 100 to 400 mm (4 to 16 in) in diameter. Grinders for solids (sludge) applications are discussed in Chap. 14.

Another type of macerator used in channel applications is a moving, linked screen that allows wastewater to pass through the screen while diverting screenings to a

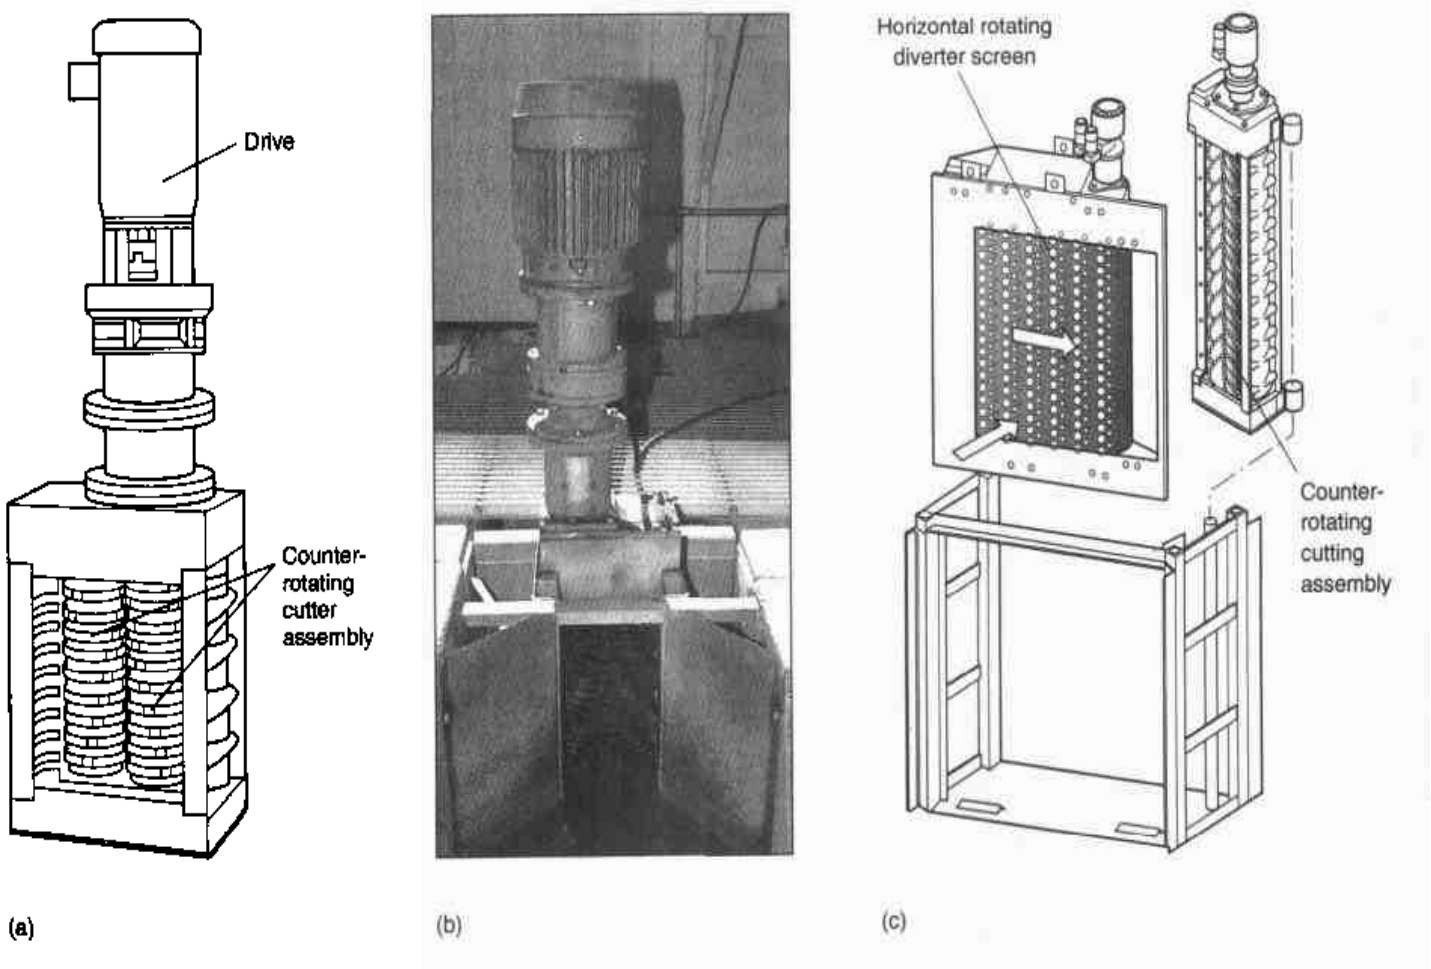

Figure 5–9

Typical macerators: (*a*) schematic of in-channel type slow-speed grinder/macerator, (*b*) view of a macerator mounted in an open channel, and (*c*) schematic of linked-screen macerator.

grinder located at one side of the channel (see Fig. 5–9*c*). Standard sizes of this device are available for use in large channels ranging from widths of 750 to 1800 mm (30 to 72 in) and depths of 750 to 2500 mm (30 to 100 in). The headloss is lower than that of the units with counterrotating blades shown on Fig. 5–9*a*.

Grinders

High-speed grinders, typically referred to as hammermills, receive screened materials from bar screens. The materials are pulverized by a high-speed rotating assembly that cuts the materials passing through the unit. The cutting or knife blades force screenings through a stationary grid or louver that encloses the rotating assembly. Washwater is typically used to keep the unit clean and to help transport materials back to the wastewater stream. Discharge from the grinder can be located either upstream or downstream of the bar screen.

Design Considerations

Comminuting and macerating devices may be preceded by grit chambers to prolong the life of the equipment and to reduce the wear on the cutting surfaces. Comminutors should be constructed with a bypass arrangement so that a manual bar screen is used in case flowrates exceed the capacity of the comminutor or when there is a power or mechanical failure. Stop gates and provisions for dewatering the channel should also be included to facilitate maintenance. Headloss through a comminutor usually ranges from 0.1 to 0.3 m (4 to 12 in), and can approach 0.9 m (3 ft) in large units at maximum flowrates.

In cases where a comminutor or macerator precedes grit chambers, the cutting teeth are subject to high wear and require frequent sharpening or replacement. Units that use cutting mechanisms ahead of the screen grid should be provided with rock traps in the channel upstream of the comminutor to collect material that could jam the cutting blade.

Because these units are complete in themselves, no detailed design is necessary. Manufacturers' data and rating tables for these units should be consulted for recommended channel dimensions, capacity ranges, headloss, upstream and downstream submergence, and power requirements. Because manufacturers' capacity ratings are usually based on clean water, the ratings should be decreased by approximately 80 percent to account for partial clogging of the screen.

5–3 FLOW EQUALIZATION

The variations of influent wastewater flowrate and characteristics at wastewater-treatment facilities were discussed in Chap. 3. Flow equalization is a method used to overcome the operational problems caused by flowrate variations, to improve the performance of the downstream processes, and to reduce the size and cost of downstream treatment facilities.

Description/Application

Flow equalization simply is the damping of flowrate variations to achieve a constant or nearly constant flowrate and can be applied in a number of different situations, depending on the characteristics of the collection system. The principal applications are for the

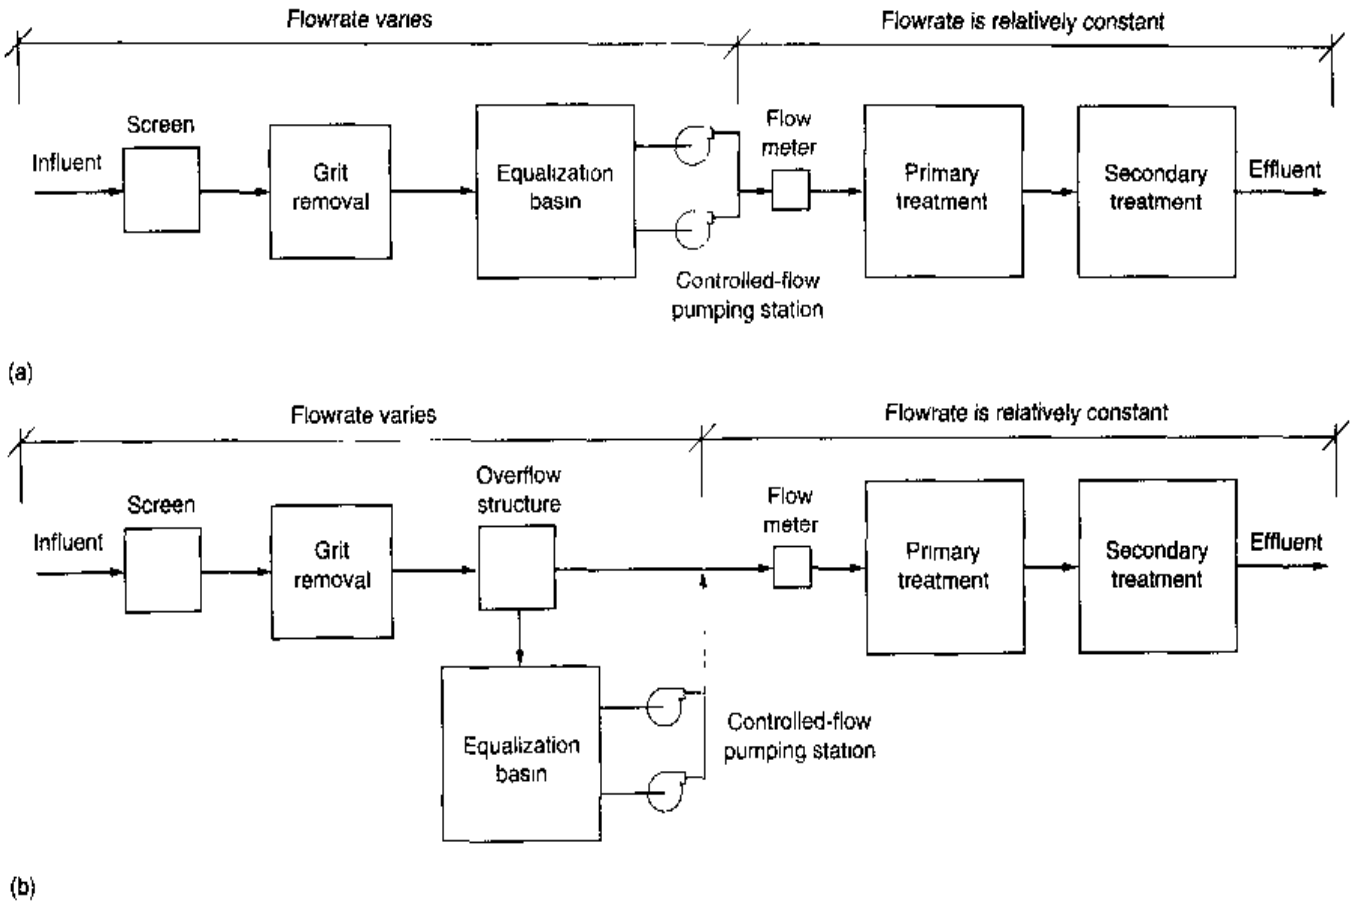

Figure 5–10

Typical wastewater-treatment plant flow diagram incorporating flow equalization: (*a*) in-line equalization and (*b*) off-line equalization. Flow equalization can be applied after grit removal, after primary sedimentation, and after secondary treatment where advanced treatment is used.

equalization of (1) dry-weather flows to reduce peak flows and loads, (2) wet-weather flows in sanitary collection systems experiencing inflow and infiltration, or (3) combined stormwater and sanitary system flows.

The application of flow equalization in wastewater treatment is illustrated in the two flow diagrams given on Fig. 5–10. In the in-line arrangement (Fig. 5–10*a*), all of the flow passes through the equalization basin. This arrangement can be used to achieve a considerable amount of constituent concentration and flowrate damping. In the off-line arrangement (Fig. 5–10*b*), only the flow above some predetermined flow limit is diverted into the equalization basin. Although pumping requirements are minimized in this arrangement, the amount of constituent concentration damping is considerably reduced. Off-line equalization is sometimes used to capture the "first flush" from combined collection systems.

The principal benefits that are cited as deriving from application of flow equalization are: (1) biological treatment is enhanced, because shock loadings are eliminated or can be minimized, inhibiting substances can be diluted, and pH can be stabilized; (2) the effluent quality and thickening performance of secondary sedimentation tanks following biological treatment is improved through improved consistency in solids loading; (3) effluent filtration surface area requirements are reduced, filter performance

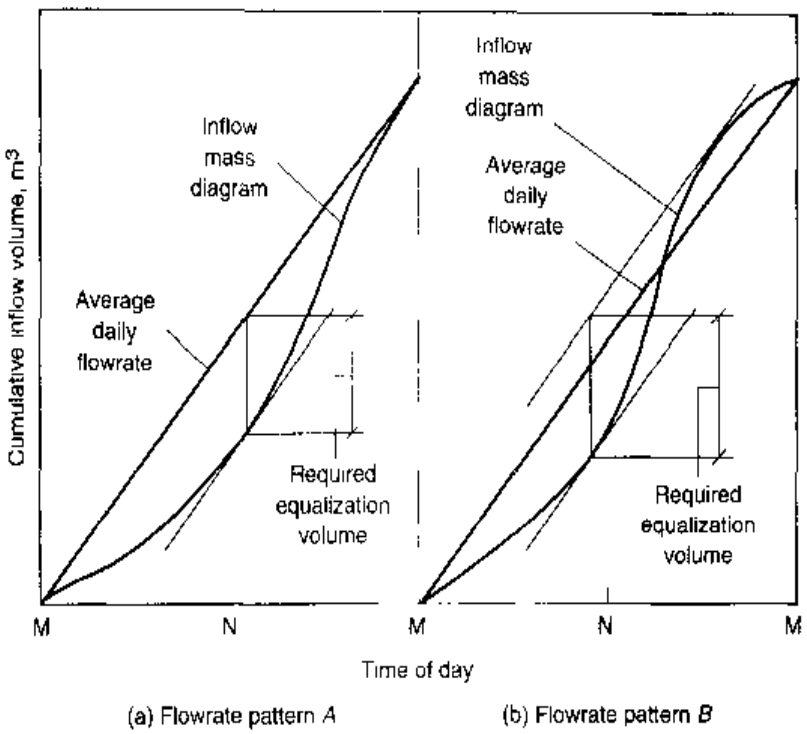
is improved, and more uniform filter-backwash cycles are possible by lower hydraulic loading; and (4) in chemical treatment, damping of mass loading improves chemical feed control and process reliability. Apart from improving the performance of most treatment operations and processes, flow equalization is an attractive option for upgrading the performance of overloaded treatment plants. Disadvantages of flow equalization include (1) relatively large land areas or sites are needed, (2) equalization facilities may have to be covered for odor control near residential areas, (3) additional operation and maintenance is required, and (4) capital cost is increased.

Design Considerations

The design of flow equalization facilities is concerned with the following questions:

1. Where in the treatment process flowsheet should the equalization facilities be located?
2. What type of equalization flowsheet should be used, in-line or off-line?
3. What is the required basin volume?
4. What are the features that should be incorporated into design?
5. How can the deposition of solids and potential odors be controlled?

Location of Equalization Facilities. The best location for equalization facilities must be determined for each system. Because the optimum location will vary with the characteristics of the collection system and the wastewater to be handled, land requirements and availability, and the type of treatment required, detailed studies should be performed for several locations throughout the system. Where equalization facilities are considered for location adjacent to the wastewater-treatment plant, it is necessary to evaluate how they could be integrated into the treatment process flowsheet. In some cases, equalization after primary treatment and before biological treatment may be appropriate. Equalization after primary treatment causes fewer problems with solids deposits and scum accumulation. If flow-equalization systems are to be located ahead of primary settling and biological systems, the design must provide for sufficient mixing to prevent solids deposition and concentration variations, and aeration to prevent odor problems.



In-Line or Off-Line Equalization. As shown on Fig. 5–10, it is possible to achieve considerable damping of constituent mass loadings to the downstream processes with in-line equalization, but only slight damping is achieved with off-line equalization. The analysis of the effect of in-line equalization on the constituent mass loading is illustrated in Example 5–2.

Volume Requirements for the Equalization Basin. The volume required for flowrate equalization is determined by using an inflow cumulative volume diagram in which the cumulative inflow volume is plotted versus the time of day. The average daily flowrate, also plotted on the same diagram, is the straight line drawn from the origin to the endpoint of the diagram. Diagrams for two typical flowrate patterns are shown on Fig. 5–11.

To determine the required volume, a line parallel to the coordinate axis, defined by the average daily flowrate, is drawn tangent to the mass inflow curve. The required

Figure 5–11

Schematic mass diagrams for the determination of the required equalization basin storage volume for two typical flowrate patterns.

volume is then equal to the vertical distance from the point of tangency to the straight line representing the average flowrate (see Fig. 5–11*a*). If the inflow mass curve goes above the line representing the average flowrate (see Fig. 5–11*b*), the inflow mass diagram must be bounded with two lines that are parallel to the average flowrate line and tangent to extremities of the inflow mass diagram. The required volume is then equal to the vertical distance between the two lines. The determination of the required volume for equalization is also illustrated in Example 5 2. The procedure is exactly the same as if the average hourly volume were subtracted from the volume flow occurring each hour, and the resulting cumulative volumes were plotted. In this case, the low and high points of the curve would be determined using a horizontal line.

The physical interpretation of the diagrams shown on Fig. 5–11 is as follows. At the low point of tangency (flowrate pattern *A*) the storage basin is empty. Beyond this point, the basin begins to fill because the slope of the inflow mass diagram is greater than that of the average daily flowrate. The basin continues to fill until it becomes full at midnight. For flowrate pattern *B*, the basin is filled at the upper point of tangency.

In practice, the volume of the equalization basin will be larger than that theoretically determined to account for the following factors:

1. Continuous operation of aeration and mixing equipment will not allow complete drawdown, although special structures can be built.
2. Volume must be provided to accommodate the concentrated plant recycle streams that are expected, if such flows are returned to the equalization basin (a practice that is not recommended unless the basin is covered because of the potential to create odors).
3. Some contingency should be provided for unforeseen changes in diurnal flow.

Although no fixed value can be given, the additional volume will vary from 10 to 20 percent of the theoretical value, depending on the specific conditions.

EXAMPLE 5-2 Determination of Flowrate Equalization Volume Requirements and Effects on BOD Mass Loading For the flowrate and BOD concentration data (derived from Fig. 3–5) given in the following table, determine (1) the in-line storage volume required to equalize the flowrate, and (2) the effect of flow equalization on the BOD mass loading rate.

	Given data		Derived data

10–11	0.380	245	25,308	335
11–M	0.345	180	26,550	224
Average	0.307			213

Note: $m^3/s \times 35.3147 = ft^3/s$
$m^3 \times 35.3147 = ft^3$
$mg/L = g/m^3$

Solution

1. Determine the volume of the basin required for the flow equalization.
   a. The first step is to develop a cumulative volume curve of the wastewater flowrate expressed in cubic meters. The cumulative volume curve is obtained

by converting the average flowrate (q^i) during each hourly period to cubic meters, using the following expression, and then cumulatively by summing the hourly values to obtain the cumulative flow volume.

Volume, m^3 = (q_i, m^3/s)(3600 s/h)(1.0 h)

For example, for the first three time periods shown in the data table, the corresponding hourly volumes are as follows:

For the time period M–1:

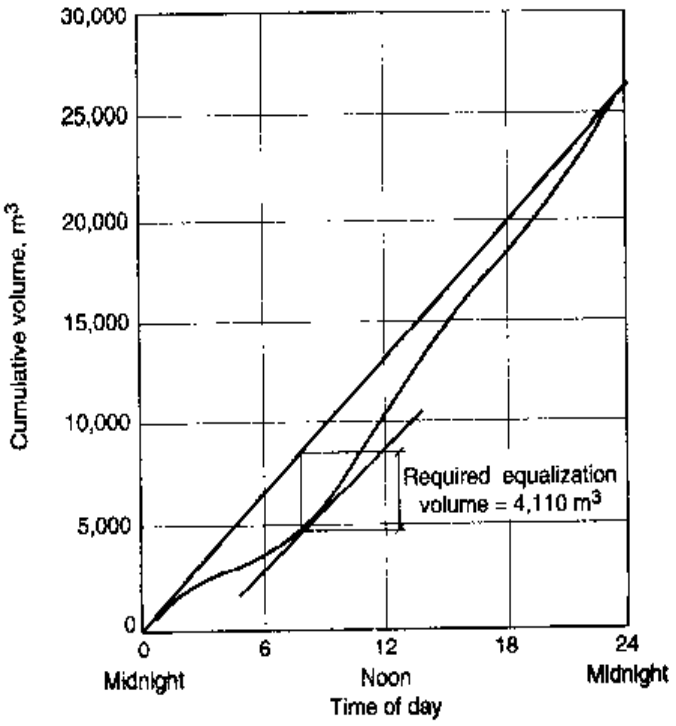
V_{M-1} = (0.275 m^3/s)(3600 s/h)(1.0 h) = 990 m^3

For the time period 1–2:

V_{1-2} = (0.220 m^3/s)(3600 s/h)(1.0 h) = 792 m^3

The cumulative flow, expressed in m^3, at the end of each time period is determined as follows:

At the end of the first time period M–1:



V_1 = 990 m^3

At the end of the second time period 1–2:

V_2 = 990 + 792 = 1782 m^3

The cumulative flows for all the hourly time periods are computed in a similar manner (see derived data in data table).

b. The second step is to prepare a plot of the cumulative flow volume, as shown in the following diagram. As will be noted, the slope of the line drawn from the origin to the endpoint of the inflow mass diagram represents the average flowrate for the day, which in this case is equal to 0.307 m^3/s.

c. The third step is to determine the required storage volume. The required storage volume is determined by drawing a line parallel to the average flowrate tangent to the low point of the inflow mass diagram. The required volume is represented by the vertical distance from the point of tangency to the straight line representing the average flowrate. Thus, the required volume is equal to

Volume of equalization basin, $V = 4110\ m^3$ (145,100 ft^3)

2. Determine the effect of the equalization basin on the BOD mass loading rate. Although there are alternative computation methods, perhaps the simplest way is to perform the necessary computations starting with the time period when the equalization basin is empty. Because the equalization basin is empty at about 8:30 A.M., the necessary computations will be performed starting with the 8–9 time period.

a. The first step is to compute the liquid volume in the equalization basin at the end of each time period. The volume required is obtained by subtracting the equalized hourly flowrate expressed as a volume from the inflow flowrate also expressed as a volume. The volume corresponding to the equalized flowrate for a period of 1 h is 0.307 $m^3/s \times 3600$ s/h = 1106 m^3. Using this value, the volume in storage is computed using the following expression:

$$V_{sc} = V_{sp} + V_{ic} - V_{oc}$$

where V_{sc} = volume in the equalization basin at the end of current time period
V_{sp} = volume in the equalization basin at the end of previous time period
V_{ic} = volume of inflow during the current time period
V_{oc} = volume of outflow during the current time period

Thus, using the values in the original data table, the volume in the equalization basin for the time period 8–9 is as follows:

$$V_{sc} = 0 + 1278\ m^3 - 1106\ m^3 = 172\ m^3$$

For time period 9–10:

$$V_{sc} = 172\ m^3 + 1476\ m^3 - 1106\ m^3 = 542\ m^3$$

The volume in storage at the end of each time period has been computed in a similar way (see the following computation table).

Time period	Volume of flow during time period, m^3	Volume in storage at end of time period, m^3	Average BOD concentration during time period, mg/L	Equalized BOD concentration during time period, mg/L	Equalized BOD mass loading during time period, kg/h
8–9	1278	172	175	175	193
9–10	1476	542	200	197	218
10–11	1530	966	215	210	232
11–N	1548	1408	220	216	239

(continued)

(*Continued*)

Time period	Volume of flow during time period, m^3	Volume in storage at end of time period, m^3	Average BOD concentration during time period, mg/L	Equalized BOD concentration during time period, mg/L	Equalized BOD mass loading during time period, kg/h
N–1	1530	1832	220	218	241
1–2	1458	2184	210	214	237
2–3	1386	2464	200	209	231
3–4	1260	2618	190	203	224
4–5	1170	2680	180	196	217
5–6	1170	2746	170	188	208
6–7	1188	2828	175	184	203
7–8	1314	3036	210	192	212
8–9	1440	3370	280	220	243
9–10	1440	3704	305	245	271
10–11	1368	3966	245	245	271
11–M	1242	4102	180	230	254

3–4	468	2522	50	162	179
4–5	378	1794	45	147	162
5–6	360	1048	60	132	146
6–7	432	374	90	119	132
7–8	738	0	130	126	139
Average					213

Note: $m^3 \times 35.3147 = ft^3$
$kg \times 2.2046 = lb$
$g/m^3 = mg/L$

b. The second step is to compute the average concentration leaving the storage basin. Using the following expression, which is based on the assumption that the contents of the equalization basin are mixed completely, the average concentration leaving the storage basin is

$$X_{oc} = \frac{(V_{ic})(X_{ic}) + (V_{sp})(X_{sp})}{V_{ic} + V_{sp}}$$

where X_{oc} = average concentration of BOD in the outflow from the storage basin during the current time period, g/m^3 (mg/L)
V_{ic} = volume of wastewater inflow during the current period, m^3

X_{ic} = average concentration of BOD in the inflow wastewater volume, g/m^3

V_{sp} = volume of wastewater on storage basin at the end of the previous time period, m^3

X_{sp} = concentration of BOD in wastewater in storage basin at the end of the previous time period, g/m^3

Using the data given in column 2 of the above computation table, the effluent concentration is computed as follows:

For the time period 8–9:

$$X_{oc} = \frac{(1278\ \text{m}^3)(175\ \text{g/m}^3) + (0)(0)}{1278\ \text{m}^3} = 175\ \text{g/m}^3$$

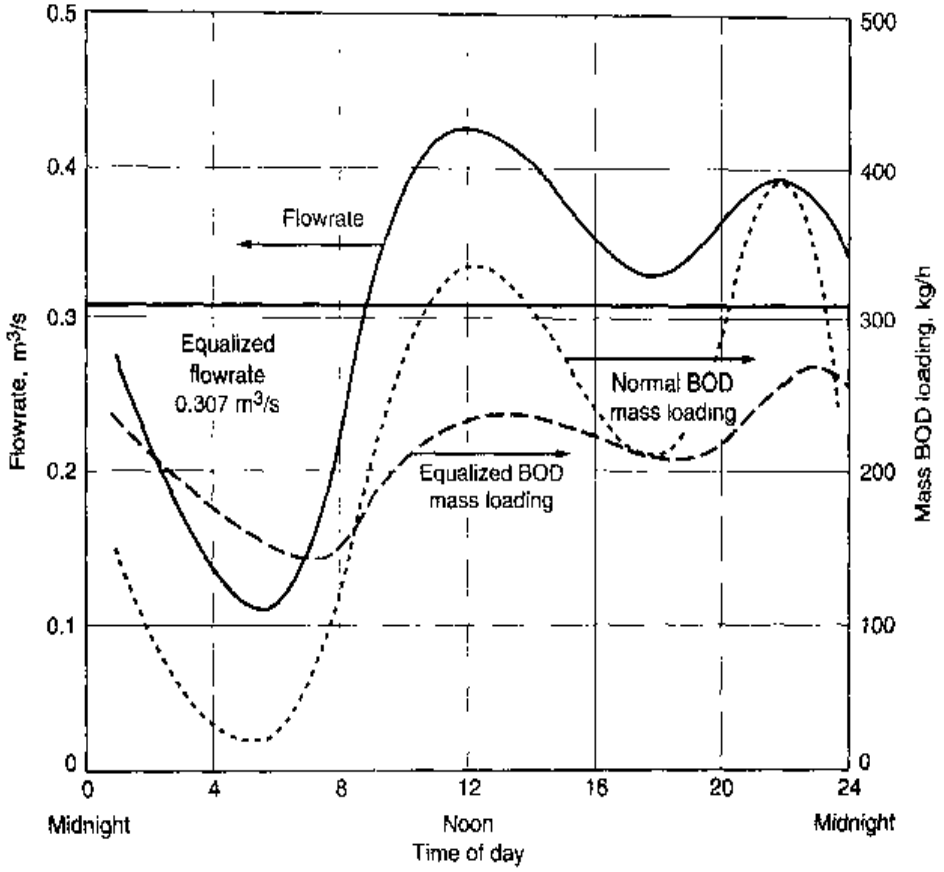
For the time period 9–10:

$$X_{oc} = \frac{(1476\ \text{m}^3)(200\ \text{g/m}^3) + (172\ \text{m}^3)(175\ \text{g/m}^3)}{(1476 + 172)\ \text{m}^3} = 197\ \text{g/m}^3$$

All the concentration values computed in a similar manner are reported in the above computation table.

c. The third step is to compute the hourly mass loading rate using the following expression:

$$\text{Mass loading rate, kg/h} = \frac{(X_{oc}, \text{g/m}^3)(q_i, \text{m}^3/\text{s})(3600\ \text{s/h})}{(10^3\ \text{g/kg})}$$



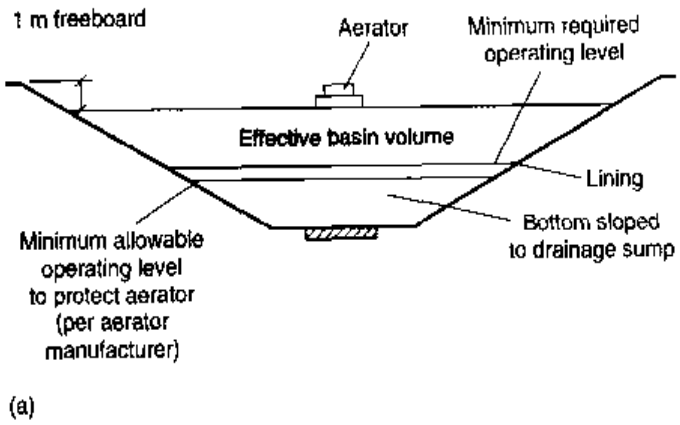
For example, for the time period 8–9, the mass loading rate is

$$\frac{(175\ \text{g/m}^3)(0.307\ \text{m}^3/\text{s})(3600\ \text{s/h})}{(10^3\ \text{g/kg})} = 193\ \text{kg/h}$$

All hourly values are summarized in the computation table. The corresponding values without flow equalization are reported in the original data table.

d. The effect of flow equalization can be shown best graphically by plotting the hourly unequalized and equalized BOD mass loading (see the following plot). The following flowrate ratios, derived from the data presented in the table given in the problem statement and the computation table prepared in Step 2a, are also helpful in assessing the benefits derived from flow equalization:

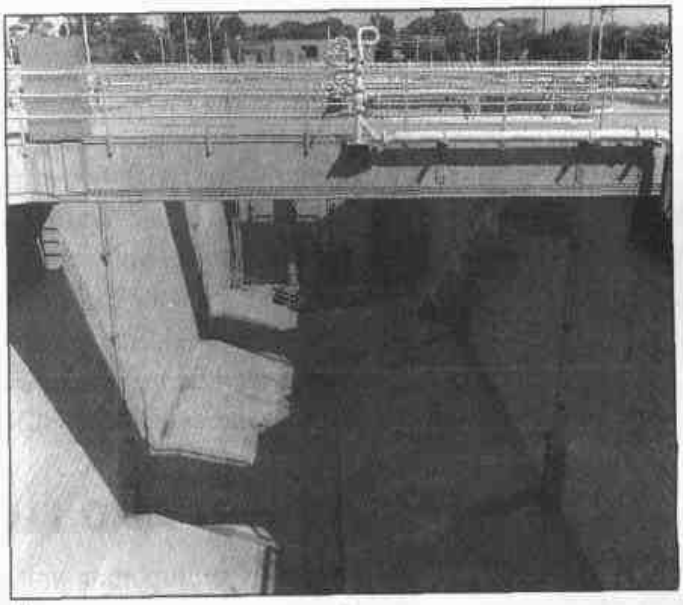
	BOD mass loading	
Ratio	**Unequalized**	**Equalized**
$\frac{\text{Peak}}{\text{Average}}$	$\frac{439}{213} = 2.06$	$\frac{271}{213} = 1.27$
$\frac{\text{Minimum}}{\text{Average}}$	$\frac{17}{213} = 0.08$	$\frac{132}{213} = 0.62$
$\frac{\text{Peak}}{\text{Minimum}}$	$\frac{439}{17} = 25.82$	$\frac{271}{132} = 2.05$



Comment Where in-line equalization basins are used, additional damping of the BOD mass loading rate can be obtained by increasing the volume of the basins. Although the flow to a treatment plant was equalized in this example, flow equalization would be used, more realistically, in locations with high infiltration/inflow or peak stormwater flows.

Basin Configuration and Construction. In equalization basin design, the principal factors that must be considered are (1) basin geometry; (2) basin construction including cleaning, access, and safety; (3) mixing and air requirements; (4) operational appurtenances; and (5) pump and pump control systems.

Basin Geometry The importance of basin geometry varies somewhat, depending on whether in-line or off-line equalization is used. If in-line equalization is used to dampen both the flow and the mass loadings, it is important to use a geometry that allows the basin to function as a continuous-flow stirred-tank reactor insofar as possible. Therefore, elongated designs should be avoided, and the inlet and outlet configurations should be arranged to minimize short circuiting. Discharging the influent near the mixing equipment usually minimizes short circuiting. If the geometry of the basins is controlled by the available land area and an elongated geometry must be used, it may be necessary to use multiple inlets and outlets. Provisions should be included in the basin design for access by cleaning equipment such as front-end loaders. Multiple compartments are also desirable to reduce cleaning costs and for odor control.



Basin Construction New basins may be of earthen, concrete, or steel construction; earthen basins are generally the least expensive. Depending on local conditions, the interior side slopes may vary between 3:1 and 2:1. A section through a typical earthen basin is shown on Fig. 5–12. In most installations, a liner is required to prevent groundwater contamination. Basin depths will vary depending on land availability, groundwater level, and topography. If a liner is used in areas of high groundwater, the effects of hydraulic uplift on the liner must be considered. The freeboard required depends on the surface area of the basin and local wind conditions. If a floating aerator is used to provide mixing and prevent septicity and odor formation, a minimum operating level is needed to protect the aerator. Typically, the minimum water depth can vary from 1.5 to 2 m (5 to 6 ft). With floating aerators, a concrete pad should be provided below the aerators to minimize erosion. To prevent wind-induced erosion in the upper portions of the basin, it may be necessary to protect the slopes with riprap, soil cement, or a partial concrete layer. Fencing should also be provided to prevent public access to the basins.

(a)

(b)

(c)

Figure 5–12

Typical open type flow equalization basins: (a) typical section through a lined earthen basin, (b) shallow concrete basin, and (c) deep concrete basin.

In areas of high groundwater, drainage facilities should be provided to prevent embankment failure. To further ensure a stable embankment, the tops of the dikes should be of adequate width. The use of an adequate dike width will facilitate the use of mechanical equipment for maintenance and will also reduce construction costs, especially where mechanical compaction equipment is used.

Mixing and Air Requirements The proper operation of both in-line and off-line equalization basins generally requires proper mixing and aeration. Mixing equipment should be sized to blend the contents of the tank and to prevent deposition of solids in the basin. To minimize mixing requirements, grit-removal facilities should precede equalization basins where possible. Mixing requirements for blending a medium-strength municipal wastewater (see Table 3–15), having a suspended solids concentration of approximately 210 mg/L, range from 0.004 to 0.008 kW/m^3 (0.02 to 0.04 hp/10^3 gal) of storage. Aeration is required to prevent the wastewater from becoming septic and odorous. To maintain aerobic conditions, air should be supplied at a rate of 0.01 to 0.015 m^3/m^3·min (1.25 to 2.0 ft^3/10^3 gal·min). In equalization basins that follow primary sedimentation and have short detention times (less than 2 h), aeration may not be required.

Where mechanical aerators are used, baffling may be necessary to ensure proper mixing, particularly with a circular tank configuration. To protect the aerators in the event of excessive level drawdown, low-level shutoff controls should be provided. Because it may be necessary to dewater the equalization basins periodically, the aerators should be equipped with legs or draft tubes that allow them to come to rest on the bottom of the basin without damage. Various types of diffused air systems may also be used for mixing and aeration including static tube, jet, and aspirating aerators (see Sec. 5–12).

Operational Appurtenances Among the appurtenances that should be included in the design of equalization basins are (1) facilities for flushing any solids and grease that may tend to accumulate on the basin walls; (2) a high-water takeoff for the removal of floating material and foam; (3) water sprays to prevent the accumulation of foam on the sides of the basin and to aid in scum removal; and (4) separate odor control facilities (see Chap. 15) where covered equalization basins must be used. Solids removed from equalization basins should be returned to the head of the plant for processing.

Pumps and Pump Control Because flow equalization imposes an additional head requirement within the treatment plant, pumping facilities are frequently required. Pumping may precede or follow equalization, but pumping into the basin is generally preferred for reliability of treatment operation. In some cases, pumping of both basin influent and equalized flows will be required.

An automatically controlled flow-regulating device will be required where gravity discharge from the basin is used. Where basin effluent pumps are used, instrumentation should be provided to control the preselected equalization rate. Regardless of the discharge method used, a flow-measuring device should be provided on the outlet of the basin to monitor the equalized flow.

5–4 MIXING AND FLOCCULATION

Mixing is an important unit operation in many phases of wastewater treatment including (1) mixing of one substance completely with another, (2) blending of miscible liq-

uids, (3) flocculation of wastewater particles, (4) continuous mixing of liquid suspensions, and (5) heat transfer. Most mixing operations in wastewater can be classified as continuous-rapid (less than 30 s) or continuous (i.e., ongoing). Continuous rapid mixing and continuous mixing are considered in this section. Each unit operation is described separately below followed by a description of the types of mixers and flocculation devices and an analysis of the energy requirements for these operations.

Continuous Rapid Mixing in Wastewater Treatment

Continuous rapid mixing is used, most often, where one substance is to be mixed with another. The principal applications of continuous rapid mixing are in (1) the blending of chemicals with wastewater (e.g., the addition of alum or iron salts prior to flocculation and settling or for dispersing chlorine and hypochlorite into wastewater for disinfection), (2) the blending of miscible liquids, and (3) the addition of chemicals to sludge and biosolids to improve their dewatering characteristics. Typical examples of the types of mixers used in wastewater-treatment facilities for rapid mixing are reported in Table 5–9.

Continuous Mixing in Wastewater Treatment

Continuous mixing is used where the contents of a reactor or holding tank or basin must be kept in suspension such as in equalization basins, flocculation basins, suspended-growth biological treatment processes, aerated lagoons, and aerobic digesters. The two applications considered in the following discussion are flocculation and the maintenance of material in suspension.

Flocculation in Wastewater Treatment. The purpose of wastewater flocculation is to form aggregates or flocs from finely divided particles and from chemically destabilized particles. Flocculation is a transport step that brings about the collisions between the destabilized particles needed to form larger particles that can be removed readily by settling or filtration. Although not used routinely, flocculation of wastewater by mechanical or air agitation may be considered for (1) increasing removal of suspended solids and BOD in primary settling facilities, (2) conditioning wastewater containing certain industrial wastes, (3) improving performance of secondary settling tanks following the activated-sludge process, and (4) as a pretreatment step for the filtration of secondary effluent. When used, flocculation can be accomplished in separate tanks or basins specifically designed for the purpose, in in-line facilities such as in the conduits and pipes connecting the treatment units, or in combination with flocculator-clarifiers.

Flocculation typically follows rapid mixing where chemicals have been added to destabilize the particles. The destabilization of particles resulting from the addition of chemicals is defined as "coagulation" and is considered in Chap. 6. There are two types of flocculation: (1) microflocculation and (2) macroflocculation. The distinction between these two types of flocculation is based on the particle sizes involved.

Microflocculation (also known as *perikinetic flocculation*) is the term used to refer to the aggregation of particles brought about by the random thermal motion of fluid molecules. The random thermal motion of fluid molecules is also known as *Brownian motion* or *movement* (see Fig. 5–13*a*). Microflocculation is significant for particles that are in the size range from 0.001 to about 1 μm.

Table 5–9
Typical mixing times and applications for different mixing and flocculation devices used in wastewater-treatment facilities

Mixing device	Typical mixing times, s	Applications/remarks
Mixing and blending devices		
Static in-line mixers	<1	Used for chemicals requiring instantaneous mixing such as alum (Al^{3+}), ferric chloride (Fe^{3+}), cationic polymer, chlorine (Cl_2)
In-line mixers	<1	Used for chemicals requiring instantaneous mixing such as alum (Al^{3+}), ferric chloride (Fe^{3+}), cationic polymer, chlorine (Cl_2)
High-speed induction mixers	<1	Used for chemicals requiring instantaneous mixing such as alum (Al^{3+}), ferric chloride (Fe^{3+}), cationic polymer, chlorine (Cl_2)
Pressurized water jets	<1	Used in water-treatment practice and for reclaimed water applications
Turbine and propeller mixers	2–20	Used in back mix reactors for the mixing of alum in sweep floc applications. Actual time depends on the configuration of the vessel in which mixing is taking place. Mixing of chemicals in solution feed tanks
Pumps	<1	Chemicals to be mixed are introduced in the suction ntake of the pump
Other hydraulic mixing devices	1–10	Hydraulic jumps, weirs, Parshall flumes, etc.
Flocculation devices		
Static mixers	600–1800	Used for flocculation of coagulated colloidal particles
Paddle mixers	600–1800	Used for flocculation of coagulated colloidal particles
Turbine mixers	600–1800	Used for flocculation of coagulated colloidal particles
Continuous mixing		
Mechanical aerators	Continuous	Used to provide oxygen and to maintain mixed liquor suspended solids in suspension in suspended-growth biological treatment processes
Pneumatic mixing	Continuous	Used to provide oxygen and to maintain mixed liquor suspended solids in suspension in suspended-growth biological treatment processes

Macroflocculation (also known as *orthokinetic flocculation*) is the term used to refer to the aggregation of particles greater than 1 or 2 μm. *Macroflocculation* can be brought about by (1) induced velocity gradients and (2) differential settling.

Particles can be brought together (i.e., flocculated) by inducing velocity gradients in a fluid containing the particles to be flocculated. As illustrated on Fig. 5–13*b*, faster-moving particles will overtake slower-moving particles in a velocity field. If the parti-

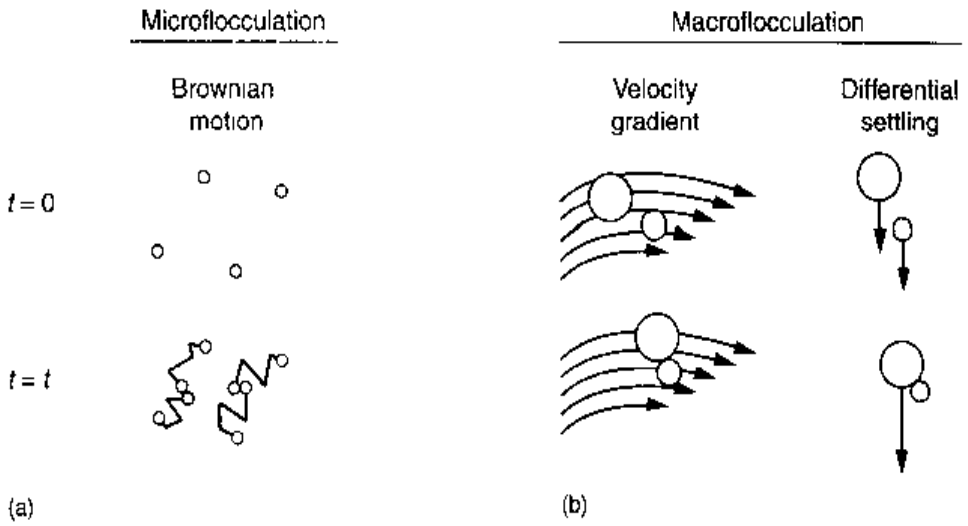


Figure 5–13
Schematic illustration of the two types of flocculation: (*a*) microflocculation (due to Brownian motion, also known as perikinetic flocculation) and (*b*) macroflocculation (also known as orthokinetic flocculation) due to (i) fluid shear and (ii) differential settling. (*Adapted from Pankow, 1991; Logan, 2000.*)

cles that collide stick together, a larger particle will be formed that will be easier to remove by gravity separation.

In macroflocculation by differential settling (see Fig. 5–13*b*), large particles overtake smaller particles during gravity settling. When the two particles collide and stick together, a larger particle is formed that settles at a rate that is greater than that of the larger particle before the two particles collided. Flocculent settling in the absence of induced velocity gradients is considered in the following section.

It should be noted that flocculation brought about by induced velocity gradients is ineffectual until the colloidal particles reach a size of 1 or 2 μm through contacts produced by Brownian motion. For example, macroflocculation cannot be used to aggregate viruses, which are 0.1 μm in size or smaller, until they are microflocculated or adsorbed or enmeshed in larger flocs or particles. Typical examples of the types of mixers used in wastewater-treatment facilities for flocculation are reported in Table 5–9.

Maintaining Material in Suspension. Continuous mixing operations are used in biological treatment processes such as the activated-sludge process to maintain the mixed liquor suspended solids in suspension. In biological treatment systems the mixing device is also used to provide the oxygen needed for the process. Thus, the aeration equipment must be able to provide the oxygen needed for the process and must be able to deliver the energy needed to maintain mixed conditions within the reactor. Both mechanical aerators and dissolved aeration devices are used. In both aerobic and anaerobic digestion, mixing is used to homogenize the contents of the digester to accelerate the biological conversion process, and to distribute uniformly the heat generated from biological conversion reactions.

Energy Dissipation in Mixing and Flocculation

Mixing with an impeller in a reactor or mixing chamber causes two actions to occur: circulation and shearing of the fluid. The power input per unit volume of liquid can be used as a rough measure of mixing effectiveness, based on the reasoning that more input power creates greater turbulence, and greater turbulence leads to better mixing.

Camp and Stein (1943) studied the establishment and effect of velocity gradients in coagulation tanks of various types and developed the following equations for use in the design and operation of systems with mechanical mixing devices (e.g., paddles).

$$G = \sqrt{\frac{P}{\mu V}} \tag{5-3}$$

where G = average velocity gradient, T^{-1}, 1/s
P = power requirement, W
μ = dynamic viscosity, N·s/m^2
V = flocculator volume, m^3

In Eq. (5–3), it is important to note that the velocity gradient G is a measure of the average velocity gradient in the fluid. High G values will be observed near the blades of the mechanical mixing device, while significantly lower values will be observed at some distance from the blades of the mixing device.

As shown, the value of G depends on the power input, the viscosity of the fluid, and the volume of the basin. Multiplying both sides of Eq. (5–3) by the detention time $\tau = V/Q$ yields

$$G\tau = \frac{V}{Q}\sqrt{\frac{P}{\mu V}} = \frac{1}{Q}\sqrt{\frac{PV}{\mu}} \tag{5-4}$$

where τ = detention time, s
Q = flowrate, m^3/s

Typical values that have been used for G for various mixing operations are reported in Table 5–10. The power required for various types of mixers is considered in the following discussion. The use of Eq. (5–3) is illustrated in Example 5–3.

Table 5–10 Typical detention time and velocity gradient G values for mixing and flocculation in wastewater[a]

Process	Range of values	
	Detention time	G value, s^{-1}
Mixing		
Typical rapid mixing operations in wastewater treatment	5–30 s	500–1500
Rapid mixing for effective initial contact and dispersion of chemicals	<1 s	1500–6000
Rapid mixing of chemicals in contact filtration processes	<1 s	2500–7500
Flocculation		
Typical flocculation processes used in wastewater treatment	30–60 min	50–100
Flocculation in direct filtration processes	2–10 min	25–150
Flocculation in contact filtration processes	2–5 min	25–200

[a]The limitations associated with the use of the velocity gradient concept, as discussed in the text, must be considered in applying the G values given in this table.

EXAMPLE 5–3 Power Requirement to Develop Velocity Gradients Determine the theoretical power requirement to achieve a G value of 100/s in a tank with a volume of 2800 m^3 (~10^5 ft^3). Assume that the water temperature is 15°C. What is the corresponding value when the water temperature is 5°C?

Solution

1. Determine the theoretical power requirement at 15°C using Eq. (5–3) rearranged as follows.
   $P = G^2\mu V$
   μ at 15°C = 1.139×10^{-3} N·s/m^2 (see Appendix C)
   $P = (100/s)^2(1.139 \times 10^{-3}$ N·s/$m^2)(2800$ $m^3)$
   = 31,892 W
   = 31.9 kW
2. Determine the theoretical power requirement at 5°C
   μ at 5°C = 1.518×10^{-3} N·s/m^2 (see Appendix C)
   $P = (100/s)^2(1.518 \times 10^{-3}$ N·s/$m^2)(2800$ $m^3)$
   = 42,504 W
   = 42.5 kW

While the use of the velocity gradient G has been popular in the water and wastewater field, it should be noted that use of the velocity gradient concept does not apply to microflocculation and, as will be discussed later, cannot be used as design parameter for some types of mixing devices. Insight into the reason that the velocity gradient G is not an effective measure for microflocculation can be gained by considering the following relationship developed by Kolmogoroff (1941) to describe the size of eddies formed as result of power input to a fluid (Davies, 1972).

$$l_K = \left(\frac{\upsilon^3}{P_M}\right)^{1/4} \tag{5–5}$$

where l_K = Kolmogoroff microscale length, m
υ = kinematic viscosity, m^2/s
P_M = power per unit mass, W/kg, [(kg·m^2/s^3)/kg]
= $G^2\upsilon$

Substituting $G^2\upsilon$ in Eq. (5–5) yields

$$l_K = \left(\frac{\upsilon^2}{G^2}\right)^{1/4} \tag{5–6}$$

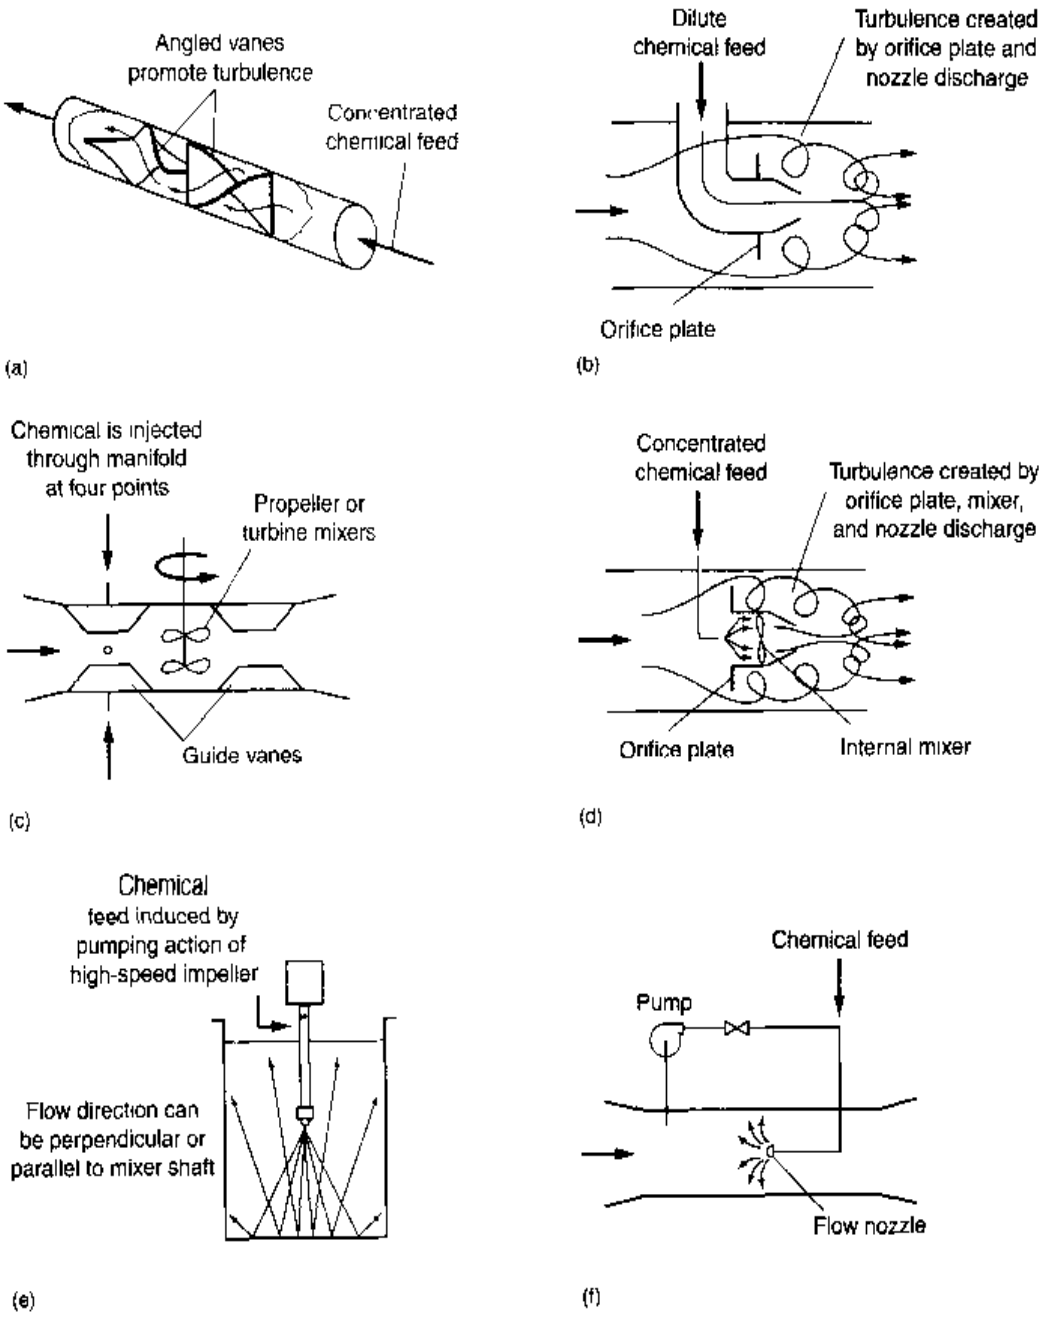
Equation (5–6) can now be used to estimate the smallest eddy that can be produced for a given average G value. For example, if G = 1000/s, and $\upsilon = 1.003 \times 10^{-6}$ m^2/s at 20°C, the corresponding value of the microscale length is 31.7 μm. Thus, particles smaller than 31.7 μm will not be affected. In fact, if the G value were increased to 10,000/s, the corresponding microscale length is 10.0 μm. Based on this analysis, it is clear that if particles smaller than 1 to 10 μm are to be removed they must first be destabilized and allowed

to undergo microflocculation caused by Brownian motion. It can be argued that effective mixing is critical in keeping the particles in suspension so that collisions can occur by Brownian motion (Han and Lawler, 1992). Further, because the G value is an average value, the effectiveness of the mixing, which will depend on the pumping characteristics of the mixer and the geometry of the mixing basin, must be evaluated carefully.

Timescale in Mixing

The timescale for mixing is an important consideration in the design of mixing facilities and operations. For example, if the reaction rate between the substance being mixed into a liquid and the liquid is rapid, the time of mixing is extremely important. For slowly reacting substances, the time of mixing is not as critical. The rationale for mixing times for various chemicals is considered in Chap. 6. Typical mixing times may be found in Table 6–19 in Chap. 6. As reported in Table 6–19, recommended mixing times for coagulants such as alum or iron salts and for dispersing chlorine and hypochlorite into solution are less than 1 s. Typical mixing times achievable for various mixing devices are presented in Table 5–9. It should be noted that achieving extremely short mixing times becomes increasingly difficult as the flowrate increases. In some applications, it may be preferable to use multiple mixing devices to achieve optimal mixing times.

Types of Mixers Used for Rapid Mixing in Wastewater Treatment



Many types of mixing devices are available, depending on the application and the timescale required for mixing (see Table 5–9). The principal devices used for rapid mixing in wastewater-treatment applications include static in-line mixers, in-line mixers, high-speed induction mixers, pressurized water jets, and propeller and turbine mixers. Mixing can also be accomplished in pumps and with the aid of hydraulic devices such as hydraulic jumps, Parshall flumes, or weirs. Although hydraulic mixing can sometimes be highly efficient, the principal problem is that the energy input varies with the flowrate, and incomplete and ineffective mixing can occur at low flowrates.

Static Mixers. Static in-line mixers contain internal vanes or orifice plates that bring about sudden changes in the velocity patterns as well as momentum reversals. Static mixers are principally identified by their lack of moving parts. Typical examples include in-line static mixers that contain elements that bring about sudden changes in the velocity patterns as well as momentum reversals (see Fig. 5–14*a*) and mixers that contain orifice plates and nozzles (see Fig. 5–14*b*). Static in-line mixers are used most commonly for mixing of chemicals with wastewater. In-line mixers are available in sizes varying from about 12 mm to 3 m × 3 m open channels. Low-pressure-drop round, square, and rectangular in-line static mixers have been developed for chlorine mixing in open channels and tunnels for flowrates varying from 0.22 to over 8.76 m^3/s (5 to over 200 Mgal/d) (Carlson, 2000).

For static in-line mixers with vanes, the longer the mixing elements, the better the mixing; however, the pressure loss increases. It should also be noted that the shear rate and the scale (i.e., size) of the turbulent eddies formed in static mixers with vanes are more limited in range as compared to the wide range of values obtained with mechanical mixers. Mixing also occurs in a plug-flow regime in static in-line mixers. Mixing times in static mixers are quite short, typically less than 1 s. The actual mixing time will vary with the length of the mixer, which depends on the number of mixing elements used, and the

Figure 5-14

Typical mixers used in wastewater treatment for rapid mixing: (*a*) in-line static mixer with internal vanes, (*b*) in-line static mixer with orifice for mixing dilute chemicals, (*c*) in-line mixer, (*d*) in-line mixer with internal mixer, (*e*) high-speed induction mixer, (*f*) pressurized water jet mixer with reactor tube.

internal volume occupied by the mixing element. Thus, because the nature of the mixing that occurs in static mixers is quite different from that of mechanical mixers, use of the velocity gradient concept [see Eq. (5–3)] is inappropriate for static mixers.

For static mixers, the degree of mixing is related to the headloss (i.e., pressure drop) through the mixer. The headloss through the mixer can be estimated using the following expression:

$$h \approx k\left(\frac{v^2}{2g}\right) \approx K_{SM}v^2 \qquad (5\text{–}7)$$

where h = headloss dissipated as liquid passes through mixing device, m
k = empirical coefficient characteristic of the mixing
v = approach velocity, m/s
K_{SM} = overall coefficient for mixing device, s^2/m
g = acceleration due to gravity, 9.81 m/s^2

Typical values for K_{SM} vary from about 1.0 to 4.0, with a value of 2.5 being typical for the mixers used in wastewater. However, because the specific geometry of the internal mixing vanes used in such mixers varies with each manufacturer, the headloss or pressure-drop curves provided by the manufacturer must be used for estimation purposes. The power dissipated by static mixing devices can be computed using the following equation:

$$P = \gamma Q h \tag{5-8}$$

where P = power dissipated, kW
γ = specific weight of water, kN/m^3
Q = flowrate, m^3/s

In-line Mixers. In-line mixers are similar to static mixers but contain a rotating mixing element to enhance the mixing process. Typical examples of in-line mixers are illustrated on Fig. 5–14c and *d*. In the in-line mixer shown on Fig. 5–14*c*, the power required for mixing is supplied by an external source. For the mixer shown on Fig. 5–14*d*, the power for mixing is supplied by the energy dissipation caused by the orifice plate and by the power input to the propeller mixer.

High-Speed Induction Mixer. The high-speed induction mixer is an efficient mixing device for a variety of chemicals. A proprietary device, shown on Fig. 5–14*e* for chlorine mixing, consists of a motor-driven open propeller that creates a vacuum in the chamber directly above the propeller. The vacuum created by the impeller induces the chemical to be mixed directly from the storage container without the need for dilution water. The high operating speed of the impeller (3450 r/min) provides a thorough mixing of the chemical that is being added to the water by the high velocity of the fluid leaving the impeller of the mixing device.

Pressurized Water Jets. Pressurized water jet mixers, such as illustrated on 5.14*f*, can also be used to mix chemicals. An important design feature of pressurized water jet mixers is that the velocity of the jet containing the chemical to be mixed must be sufficient to achieve mixing in all parts of the pipeline (Chao and Stone, 1979; Pratte and Baines, 1967). As shown on Fig. 5–14*f*, a reactor tube has been added to achieve effective mixing. With pressurized water jet mixers, the power for mixing is provided by an external source (i.e., the solution feed pump).

Turbine and Propeller Mixers. Turbine and propeller mixers are used commonly in wastewater-treatment processes for mixing and blending of chemicals, for keeping material in suspension, and for aeration. Turbine or propeller mixers are usually constructed with a vertical shaft driven by a speed reducer and electric motor. Two types of impellers are used for mixing: (1) radial-flow impellers and (2) axial-flow impellers. Radial-flow impellers generally have flat or curved blades located parallel to the axis of the shaft. The vertical flat-blade turbine impeller is a typical example of a radial-flow impeller. Axial-flow impellers make an angle of less than 90° with the drive shaft. Axial-flow impellers are further classified as variable pitch–constant angle of attack and constant pitch–variable angle of attack. Propellers and hydrofoils are typical examples. Propeller mixers may be provided with more than one set of propeller blades

on a shaft. Typical impellers used for mixing are shown on Fig. 5–15, and information on the different types of impellers is presented in Table 5–11.

Rapid mixing in wastewater-treatment processes usually occurs in the regime of turbulent flow in which inertial forces predominate. As a general rule, the higher the velocity and the greater the turbulence, the more efficient the mixing. On the basis of inertial and viscous forces, the following mathematical relationships can be used to estimate the power requirements for mixing and the pumping capacity of the mixer.

Figure 5–15

Typical impellers used for mixing in wastewater-treatment facilities: (*a*) disk-type radial-flow impeller, (*b*) axial-flow pitched (typically 45°) blade impeller, (*c*) axial-flow hydrofoil-type impeller, and (*d*) propeller mixer. Note: The flat blade radial-flow turbine mixer looks like the axial-flow impeller (*b*) with the exception that the blades are set parallel to the axis of the shaft.

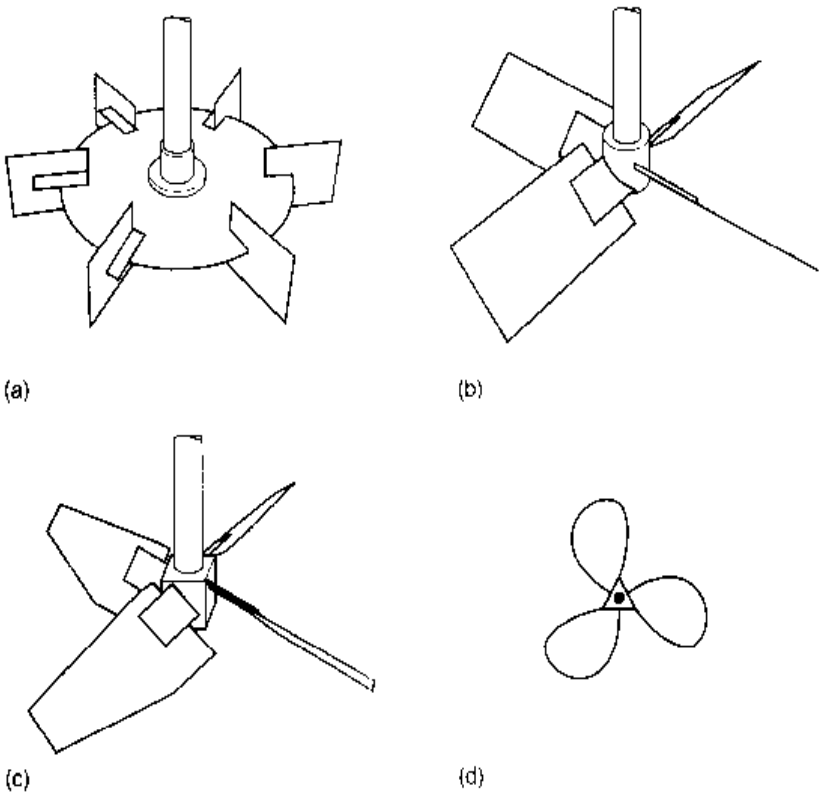


Table 5–11
Typical types of mixing impellers used in wastewater treatment[a]

Type of impeller	Flow	Shear	Pumping capacity	Applications
Vertical flat blade turbine (VFBT)	Radial	High	Low	Vertical-flow flash mixing, suspension of solids, gas dispersion
Disk turbine	Radial	High	Low	Mixing, gas dispersion
Surface impeller	Radial	High	Moderate	Gas transfer
Pitched-blade turbine (45 or 32° PBT)	Axial	Moderate	Moderate	Horizontal flash mixing, suspension of solids
Low-shear hydrofoil (LS)	Axial	Low	High	Horizontal-flow flash mixing, suspension of solids, blending, flocculation
Propeller	Axial	Very low	High	Horizontal-flow flash mixing, suspension of solids, blending, flocculation

Power for mixing

$$P = N_P \rho n D^3 \tag{5-9}$$

Pumping capacity

$$Q_i = N_Q n D^3 \tag{5-10}$$

where P = power input, W ($kg \cdot m^2/s^3$)
N_P = power number for impeller, unitless
ρ = density, kg/m^3
n = revolutions per second, r/s
D = diameter of impeller, m
Q_i = pump discharge, m^3/s
N_Q = flow number for impeller, unitless

Typical values for N_P and N_Q are presented in Table 5–12 for various types of impellers. It is important to consult manufacturers' catalogs for the appropriate values for N_P and N_Q for a specific piece of equipment. The values of N_P and N_Q must be adjusted for viscosity, blade characteristics, and the number of impellers on a single shaft.

Based on Eqs. (5–9) and (5–10), for a constant input of power as the impeller size is increased, more power is expended on flow and less on turbulence or shear. Thus, a small impeller operating at a high rotational speed will produce greater fluid shear and less pumping, whereas a large impeller operating at a slow speed will result in a high pumping capacity and low fluid shear. Mixers with small impellers operating at high speeds are best for dispersing gases or small amounts of chemicals in wastewater. Mixers with slow-moving impellers are best for blending two fluid streams, or for flocculation.

Typically, Eq. (5–9) applies if the Reynolds number is in the turbulent range (greater than 10,000). For intermediate values of the Reynolds number, manufacturers' catalogs should be consulted. The Reynolds number is given by

$$N_R = \frac{D^2 n \rho}{\mu} \tag{5-11}$$

Table 5–12
Typical power and flow numbers for various impellers[a]

Type of impeller	Power number, N_P	Flow number, N_Q	Pumping capacity
Vertical flat-blade turbine (VFBT)	3.5–4.0	0.84–0.86	Low
Disk turbine			Low
Pitched-blade turbine (45° PBT)	1.6	0.84–0.86	
Pitched-blade turbine (32° PBT)	1.1	0.84–0.86	Moderate
Low-shear hydrofoil (LS, 3-blade)	0.30	0.50	High
Low-shear hydrofoil (LS, 4-blade)	0.60	0.55	High
Propeller			High

[a] Adapted from Philadelphia Mixer Catalog.

where D = diameter of impeller, m
n = rotational speed, r/s
ρ = mass density of fluid, kg/m^3
μ = dynamic viscosity of fluid, N·s/m^2
Note: N = kg·m/s^2

Mixers are selected on the basis of laboratory or pilot-plant tests or similar data provided by manufacturers. No satisfactory method exists for scaling up from an agitator of one design to a unit of a different design. Geometrical similarity should be preserved, and the power input per unit volume should be kept the same.

Where propeller or turbine mixers are used, it is imperative that vortexing or mass swirling of the liquid be eliminated. Vortexing, in which the liquid to be mixed rotates with the impeller, causes a reduction in the difference between the fluid velocity and the impeller velocity and thus decreases the effectiveness of mixing. If the mixing vessel is fairly small, vortexing can be prevented by mounting the impellers off-center or at an angle with the vertical, or by having them enter the side of the basin at an angle. In circular and rectangular tanks the usual method used to limit vortexing is to install four or more vertical baffles extending approximately one-tenth the diameter out from the wall (see Fig. 5–16). These baffles effectively break up the mass rotary motion and promote vertical mixing.

Typical design criteria for turbine and propeller mixers are given in Table 5–13. As reported in Table 5–13, important design considerations include (1) the velocity gradient G, subject to the caveats discussed previously, (2) the rotational speed, and (3) the ratio of the impeller diameter to the equivalent tank diameter. The rotation speed will vary considerably, depending on whether the flow through the mixer is horizontal or vertical (see Fig. 5–17).

Types of Mixers Used for Flocculation in Wastewater Treatment

The principal types of mixers used for flocculation can be classified as (1) static mixers, (2) paddle mixers, and (3) turbine and propeller mixers. Each of these types of mixers is considered briefly in the following discussion.

Static Mixers. In the most common type of static mixer, the liquid to be treated is subjected to a series of flow reversals in which the direction of flow is changed. Static

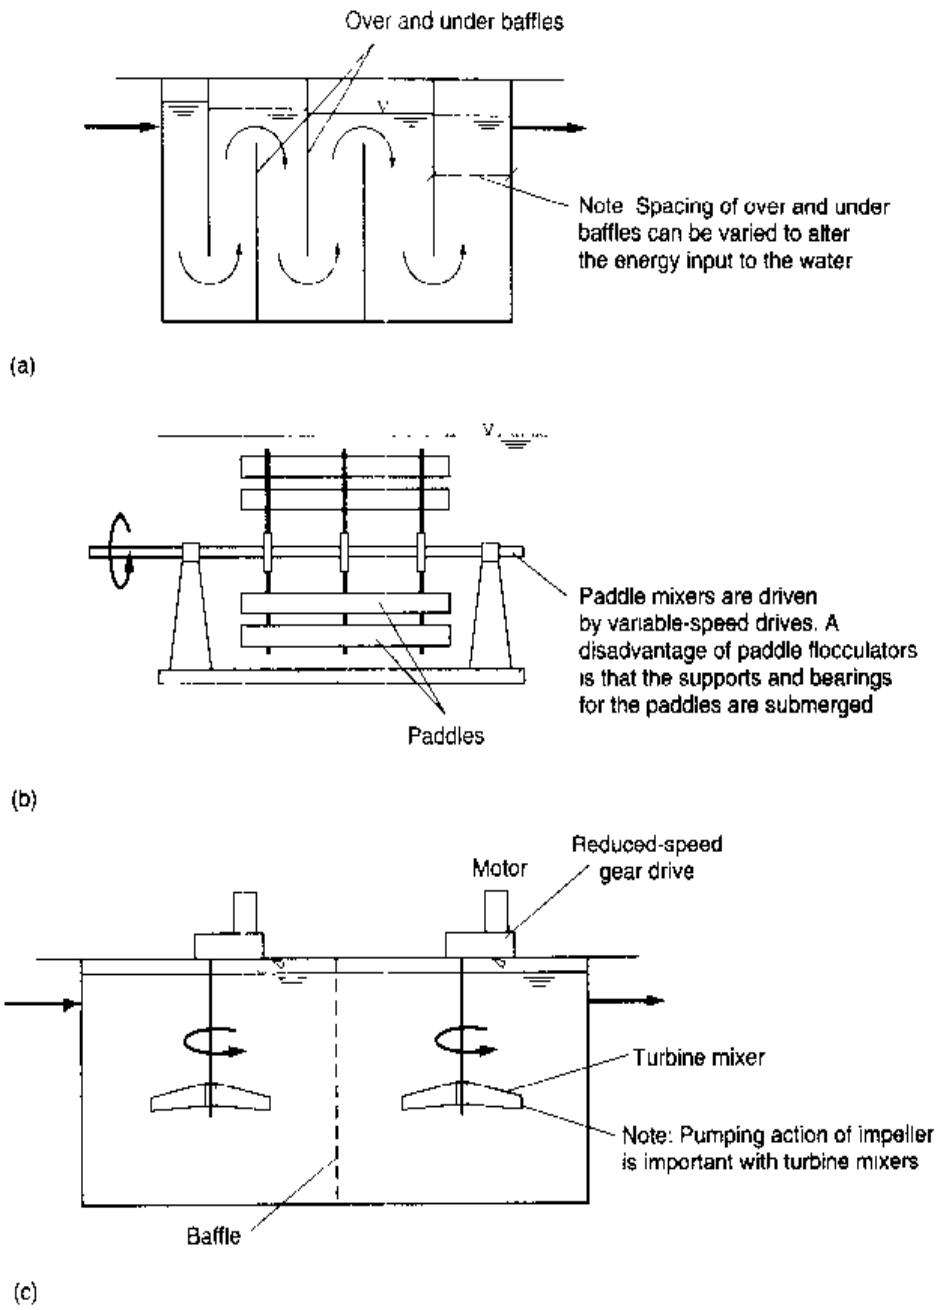
Ratio impeller diameter to equivalent tank diameter	D/T_e	unitless	0.40–0.60

[a] Adapted from Philadelphia Mixer Catalog.
[b] $T_e = 1.13\sqrt{L \times W}$ where L = length and W = width.

Figure 5–17
Definition sketch for mixing: (*a*) horizontal flow through a mixing tank equipped with an axial-flow impeller mixer and (*b*) vertical flow through a mixing tank equipped with a radial-flow impeller mixer.



mixers can be comprised of over and under narrow flow channels, such as shown on Fig. 5–18*a*, or the narrow flow channels can be laid out horizontally. The headloss caused by frictional resistance offered by the flow channels and the flow reversals provides the energy for flocculation. In some designs, the channel spacing is varied to provide a decreasing energy gradient so that the large floc particles formed toward the end of the flocculation basin will not be broken apart.

Paddle Mixers. Paddle mixers are used as flocculation devices when coagulants, such as aluminum or ferric sulfate, and coagulant aids, such as polyelectrolytes and lime, are added to wastewater or solids (sludge). Paddle flocculators consist of a series of appropriately spaced paddles mounted on either a horizontal or vertical shaft. Flocculation is promoted by gentle mixing brought about by the slow-moving paddles, which, as shown on Fig. 5–18*b*, rotate the liquid and promote mixing. Increased particle contact promotes floc growth, but, if the mixing is too vigorous, the increased shear

Figure 5–18

Typical mixers used for flocculation in wastewater-treatment facilities (*a*) over and under baffled reactor, (*b*) paddle mixed in baffled tank, and (*c*) turbine mixer in a baffled tank.

forces will break up the floc into smaller particles. Agitation should be controlled carefully so that the floc particles will be of suitable size and will settle readily. Variable-speed drives are often used to regulate the paddle speed. There has been a movement away from paddle flocculators to the use of turbine flocculators because of the maintenance problems associated with paddle flocculators.

Power in a mechanical paddle system can be related to the drag force on the paddles as follows.

$$F_D = \frac{C_D A \rho v_p^2}{2} \tag{5–12}$$

$$P = F_D v_p = \frac{C_D A \rho v_p^3}{2} \tag{5–13}$$

where F_D = drag force, N
C_D = coefficient of drag of paddle moving perpendicular to fluid
A = cross-sectional area of paddles, m^2
ρ = mass density of fluid, kg/m^3
v_p = relative velocity of paddles with respect to the fluid, m/s, usually assumed to be 0.6 to 0.75 times the paddle-tip speed
P = power requirement, W ($kg \cdot m^2/s^3$)

The application of Eq. (5–13) is illustrated in Example 5–4.

EXAMPLE 5–4 Power Requirements and Paddle Area for a Wastewater Flocculator Determine the theoretical power requirement and the paddle area required to achieve a G value of 50/s in a tank with a volume of 3000 m^3. Assume that the water temperature is 15°C, the coefficient of drag C_D for rectangular paddles is 1.8, the paddle-tip velocity v is 0.6 m/s, and the relative velocity of the paddles v_p is 0.75 v.

Solution

1. Determine the theoretical power requirement using Eq. (5–3), rearranged as shown below.

   μ at 15°C = 1.139×10^{-3} $N \cdot s/m^2$ (see Appendix C)

   $$P = G^2 \mu V$$
   $$= (50/s)^2 (1.139 \times 10^{-3}\ N \cdot s/m^2)\ (3000\ m^3)$$
   $$= 8543\ kg \cdot m^2/s^3 = 8543\ W$$
   $$= 8543\ kW$$

2. Determine the required paddle area using Eq. (5–13).
   ρ = 999.1 kg/m^3 (see Appendix C)

   $$A = \frac{2P}{C_D \rho v_p^3}$$
   $$= \frac{2(8543\ kg/m^2 \cdot s^3)}{1.8\ (999.1\ kg/m^3)(0.75 \times 0.6\ m/s)^3}$$
   $$= 104.3\ m^2$$

Turbine- and Propeller-Type Flocculators. The rotating element of turbine- and propeller-type flocculators consists of three or four blades attached to a vertical shaft (see Fig. 5–18c). The flocculator is driven with an external gear reduction system powered by a variable-speed drive. The blades of the propeller may be rectangular in shape or have the shape of a hydrofoil. Blades shaped as hydrofoils are used to limit the amount of floc shearing while at the same time providing the velocity gradients and pumping capacity needed for mixing. Typical design requirements for flocculation are presented in Table 5–14. In sizing turbine- or propeller-type flocculators, both the

Table 5–14
Typical design parameters for flocculation facilities[a]

Parameter	Symbol	Unit	Value
Velocity gradient	G	1/s	100–500
Rotational speed	n	r/min	10–30
Ratio length to width	L/W	unitless	$1 \leq L/W \leq 1.25$
Ratio impeller diameter to equivalent tank diameter[b]	D/T_e	unitless	0.35–0.45
Ratio height to equivalent tank diameter[b]	H/T_e	unitless	0.9–1.1
Tip speed			
Flat-blade turbine	TS	m/s	0.6–1.5
Pitch-blade turbine (45 or 32°)	TS	m/s	1.8–2.4
Low-shear propeller (3 or 4 blade)	TS	m/s	2–2.7
Superficial velocity[c]	SV	m/min	1–2

[a] Adapted from Philadelphia Mixer Catalog.
[b] $T_e = 1.13\sqrt{L \times W}$ where L = length and W = width in m.
[c] $SV = Q/A$ where Q is the pumping rate and A is the basin cross-sectional area.

power and the pumping requirements must be considered. In addition, the tip speed and the superficial velocity must also be considered. The required power and the pumping capacity can be estimated using Eqs. (5–9) and (5–10), presented previously. In wastewater flocculation, if variable-speed drives are provided for the flocculators (considering the minimum G required to keep particles in suspension), the mixer speed can be adjusted to optimize flocculation and energy use.

Types of Mixers Used for Continuous Mixing in Wastewater Treatment

Continuous mixing operations are used in biological treatment processes such as the activated-sludge process to maintain the mixed liquor suspended solids uniformly mixed state. In biological treatment systems the mixing device is also used to provide the oxygen needed for the process. Thus, the aeration equipment must be able to provide the oxygen needed for the process and the energy needed to maintain mixed conditions within the reactor. Both mechanical aerators and dissolved aeration devices are used. Diffused air is often used to fulfill both the mixing and oxygen requirements. Alternatively, mechanical turbine-aerator mixers may be used. Horizontal, submersible propeller mixers are often used to maintain channel velocities in oxidation ditches, mix the contents of anoxic reactors (see Fig. 5–19), and aid in the destratification of reclaimed water storage reservoirs.

Pneumatic Mixing. In pneumatic mixing, a gas (usually air or oxygen) is injected into the bottom of mixing or activated-sludge tanks, and the turbulence caused by the rising gas bubbles serves to mix the fluid contents of the tank. In aeration, soft

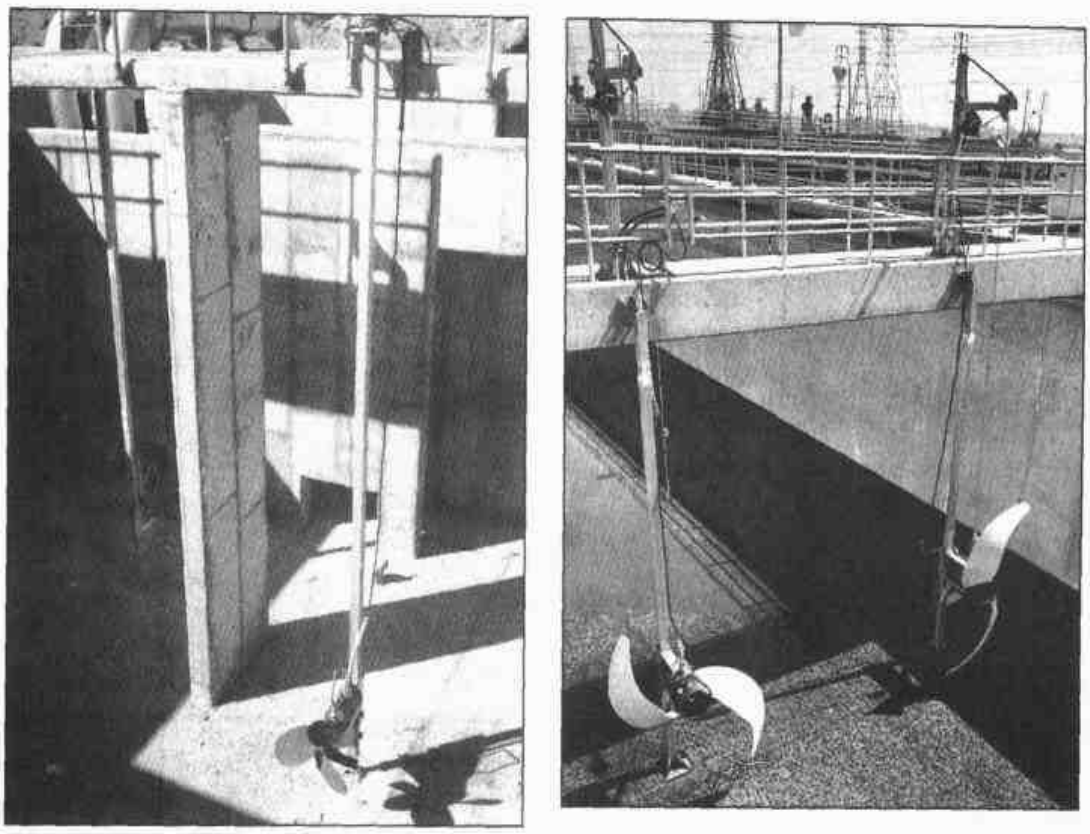


Figure 5–19
Submerged propeller mixers used to mix the contents of an anoxic reactor.

bubbles are formed with an average diameter of 5 mm while the air flow is about 10 percent of the liquid flow. The velocity gradients due to bubble formation range from a $G_{avg} < 200\ s^{-1}$ to $G_{max} = 8200\ s^{-1}$ (Masschelein, 1992).

Where air flocculation is employed, the air supply system should be adjustable so that the flocculation energy level can be varied throughout the tank. When air is injected in mixing or flocculation tanks or channels, the power dissipated by the rising air bubbles can be estimated with the following equation:

$$P = p_a V_a \ln \frac{p_c}{p_a} \qquad (5\text{–}14)$$

where P = power dissipated, kW
p_a = atmospheric pressure, kN/m^2
V_a = volume of air at atmospheric pressure, m^3/s
p_c = air pressure at the point of discharge, kN/m^2

Equation (5–14) is derived from a consideration of the work done when the volume of air released under compressed conditions expands isothermally. If the flow of air at atmospheric pressure is expressed in terms of m^3/min (ft^3/min) and the pressure is expressed in term of meters (feet) of water, Eq. (5–14) can be written as follows:

$$P = KQ_a \ln \left(\frac{h + 10.33}{10.33} \right) \qquad \text{S.I. units} \qquad (5\text{–}15a)$$

$$P = KQ_a \ln \left(\frac{h + 33.9}{33.9} \right) \qquad \text{U.S. customary units} \qquad (5\text{–}15b)$$

where K = constant = 1.689 (35.28 in U.S. customary units)
Q_a = air flow rate at atmospheric pressure, m^3/min (ft^3/min)
h = air pressure at the point of discharge expressed in meters of water, m (ft)

The velocity gradient G achieved in pneumatic mixing is obtained by substituting P from Eq. (5–15) into Eq. (5-3).

Mechanical Aerators and Mixers. The principal types of mechanical aerators used for continuous mixing are high-speed surface aerators and slow-speed surface aerators. These devices are discussed in Sec. 5–13, which deals with aeration, and in Chap. 8. Typical power requirements for mixing with mechanical aerators range from 20 to 40 $kW/10^3\ m^3$ (0.75 to 1.50 $hp/10^3\ ft^3$), depending on the type of mixer and the geometry of the tank, lagoon, or basin.

New Developments in Mixing Technology

New analytical tools that are now being applied to the analysis of and design of mixing devices include (1) computational fluid dynamics (CFD), (2) digital particle image velocimetry (DPIV), (3) laser doppler anemometry (LDA), and (4) laser-induced fluorescence (LIF). Computational fluid dynamics is used to model the fluid flow patterns in mixing devices and for scale-up analysis. In respect to fluid flow, both two- and three-dimensional models are now available. Digital particle image velocimetry is used to understand fluid movement in mixing devices. The movement of neutrally buoyant fluorescent particles is photographed using laser beam illumination. Laser doppler anemometry is used to study turbulence and to obtain data on the mean velocity at a given location in the mixing chamber. To evaluate the mean velocity, two laser beams are focused so that the beams intersect. As a particle passes through the intersection of the beams, light is reflected. The wavelength of the reflected light is a function of the particle velocity. Laser-induced fluorescence is used to measure the mixedness of solutions. Dyes such as rhodimine and other materials will fluoresce when struck by laser light of a given wavelength. The scattering of light is measured to assess the degree of mixedness. This technique is being used to study the diffusion and mixing of a substance by assessing the coefficient of variation of the mixed solution and to evaluate blending times (Chemineer, Inc., 2000).

5–5 GRAVITY SEPARATION THEORY

The removal of suspended and colloidal materials from wastewater by gravity separation is one of the most widely used unit operations in wastewater treatment. A summary of gravitational phenomena is presented in Table 5–15. Sedimentation is the term applied to the separation of suspended particles that are heavier than water, by gravitational settling. The terms *sedimentation* and *settling* are used interchangeably. A sedimentation basin may also be referred to as a sedimentation tank, clarifier, settling basin, or settling tank. Accelerated gravity settling involves the removal of particles in suspension by gravity settling in an accelerated flow field. The fundamentals of gravity separation are introduced in this section. The design of facilities for the removal of grit and TSS are considered in Secs. 5–6 and 5–7, respectively.

Table 5-15
Types of gravitational phenomena utilized in wastewater treatment

Type of separation phenomenon	Description	Application/occurrence
Discrete particle settling	Refers to the settling of particles in a suspension of low solids concentration by gravity in a constant acceleration field. Particles settle as individual entities, and there is no significant interaction with neighboring particles	Removal of grit and sand particles from wastewater
Flocculent settling	Refers to a rather dilute suspension of particles that coalesce, or flocculate, during the settling operation. By coalescing, the particles increase in mass and settle at a faster rate	Removal of a portion of the TSS in untreated wastewater in primary settling facilities, and in upper portions of secondary settling facilities. Also removes chemical floc in settling tanks
Ballasted flocculent settling	Refers to the addition of an inert ballasting agent and a polymer to a partially flocculated suspension to promote rapid settling and improved solids reduction. A portion of the recovered ballasting agent is recycled to the process	Removal of a portion of the TSS in untreated wastewater, wastewater from combined systems, and industrial wastewater. Also reduces BOD and phosphorus
Hindered settling (also called zone settling)	Refers to suspensions of intermediate concentration, in which interparticle forces are sufficient to hinder the settling of neighboring particles. The particles tend to remain in fixed positions with respect to each other, and the mass of particles settles as a unit. A solids-liquid interface develops at the top of the settling mass	Occurs in secondary settling facilities used in conjunction with biological treatment facilities
Compression settling	Refers to settling in which the particles are of such concentration that a structure is formed, and further settling can occur only by compression of the structure. Compression takes place from the weight of the particles, which are constantly being added to the structure by sedimentation from the supernatant liquid	Usually occurs in the lower layers of a deep solids or biosolids mass, such as in the bottom of deep secondary settling facilities and in solids-thickening facilities
Accelerated gravity settling	Removal of particles in suspension by gravity settling in an acceleration field	Removal of grit and sand particles from wastewater
Flotation	Removal of particles in suspension that are lighter than water by air or gas flotation	Removal of greases and oils, light material that floats, thickening of solids suspensions

Description

Sedimentation is used for the removal of grit, TSS in primary settling basins, biological floc removal in the activated-sludge settling basin, and chemical floc removal when the chemical coagulation process is used. Sedimentation is also used for solids concentration in sludge thickeners. In most cases, the primary purpose is to produce a clarified effluent, but it is also necessary to produce sludge with a solids concentration that can be handled and treated easily.

On the basis of the concentration and the tendency of particles to interact, four types of gravitational settling can occur: (1) discrete particle, (2) flocculent, (3) hindered (also called *zone*), and (4) compression. Because of the fundamental importance of the separation processes in the treatment of wastewater, the analysis of each type of separation process is discussed separately. In addition, tube settlers, used to enhance the performance of sedimentation facilities, are also described. Other gravitational separation processes include high-rate clarification, accelerated gravity settling, and flotation and are discussed in subsequent sections.

Particle Settling Theory

The settling of discrete, nonflocculating particles can be analyzed by means of the classic laws of sedimentation formed by Newton and Stokes. Newton's law yields the terminal particle velocity by equating the gravitational force of the particle to the frictional resistance, or drag. The gravitational force is given by

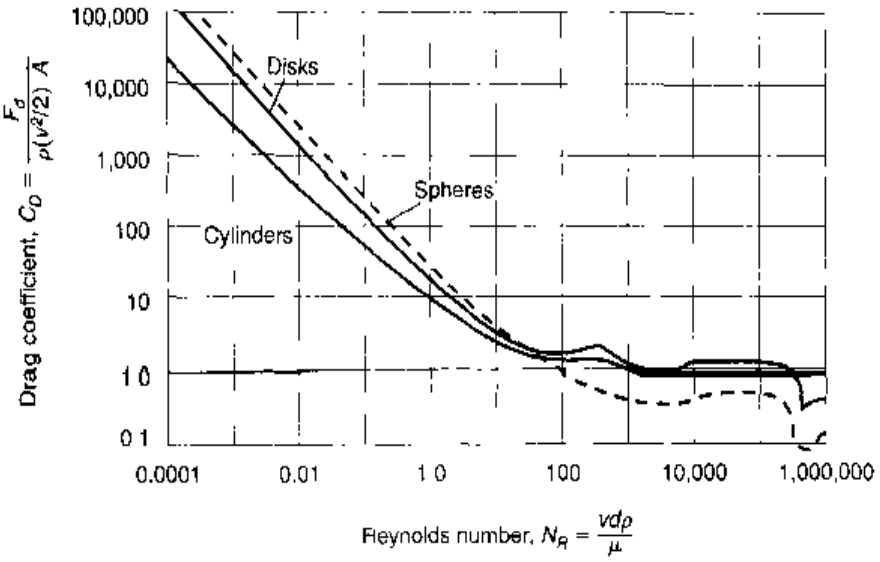
$$F_G = (\rho_p - \rho_w)gV_p \tag{5-16}$$

where F_G = gravitational force, MLT^{-2} (kg·m/s^2)
ρ_p = density of particle, ML^{-3} (kg/m^3)
ρ_w = density of water, ML^{-3} (kg/m^3)
g = acceleration due to gravity, LT^{-2} (9.81 m/s^2)
V_p = volume of particle, L^3 (m^3)

The frictional drag force depends on the particle velocity, fluid density, fluid viscosity, particle diameter, and the drag coefficient C_d (dimensionless), and is given by Eq. (5–17).

$$F_d = \frac{C_d A_p \rho_w v_p^2}{2} \tag{5-17}$$

where F_d = frictional drag force, MLT^{-2} (kg·m/s^2)
C_d = drag coefficient (unitless)
A_p = cross-sectional or projected area of particles in direction of flow, L^2 (m^2)
v_p = particle settling velocity, LT^{-1} (m/s)



Equating the gravitational force to the frictional drag force for spherical particles yields Newton's law:

$$v_{p(t)} = \sqrt{\frac{4g}{3C_d}\left(\frac{\rho_p - \rho_w}{\rho_w}\right)d_p} = \sqrt{\frac{4g}{3C_d}(sg_p - 1)d_p} \tag{5-18}$$

where $v_{p(t)}$ = terminal velocity of particle, LT^{-1} (m/s)
d_p = diameter of particle, L (m)
sg_p = specific gravity of the particle

The coefficient of drag C_d takes on different values depending on whether the flow regime surrounding the particle is laminar or turbulent. The drag coefficient for various particles is shown on Fig. 5–20 as a function of the Reynolds number. As shown on Fig. 5–20, there are three more or less distinct regions, depending on the Reynolds number: laminar ($N_R < 1$), transitional ($N_R = 1$ to 2000), and turbulent ($N_R > 2000$). Although

Figure 5–20
Coefficient of drag as a function of Reynolds number.

particle shape affects the value of the drag coefficient, for particles that are approximately spherical, the curve on Fig. 5 20 is approximated by the following equation (upper limit of $N_R = 10^4$):

$$C_d = \frac{24}{N_R} + \frac{3}{\sqrt{N_R}} + 0.34 \tag{5–19}$$

The Reynolds number N_R for settling particles is defined as

$$N_R = \frac{v_p d_p \rho_w}{\mu} = \frac{v_p d_p}{\nu} \tag{5–20}$$

where μ = dynamic viscosity, MTL^{-2} ($N \cdot s/m^2$)
ν = kinematic viscosity, L^2T^{-1} (m^2/s)

Other terms are as defined above.

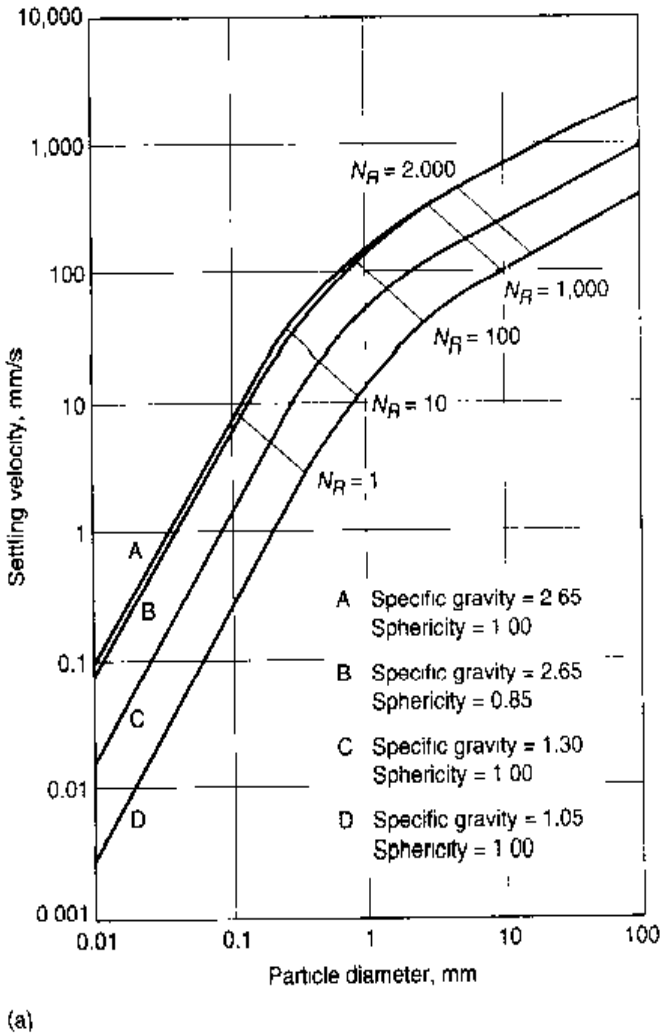
Equation (5–18) must be modified for nonspherical particles. An application that has been proposed is to rewrite Eq. (5–18) as follows (Gregory et al., 1999):

$$v_{t(t)} = \sqrt{\frac{4g}{3C_d\phi}\left(\frac{\rho_p - \rho_w}{\rho_w}\right)d_p} \approx \sqrt{\frac{4g}{3C_d\phi}(sg_p - 1)d_p} \tag{5–21}$$

where ϕ is a shape factor and the other terms are as defined previously. The value of the shape factor is 1.0 for spheres, 2.0 for sand grains, and up to and greater than 20 for fractal floc. The shape factor is especially important in wastewater treatment where few, if any, particles are spherical. The shape factor must also be accounted for in computing N_R. The application of Eq. (5–21) will be considered in subsequent discussions of flocculent and ballasted flocculent settling.

Settling in the Laminar Region. For Reynolds numbers less than about 1.0, viscosity is the predominant force governing the settling process, and the first term in Eq. (5–19) predominates. Assuming spherical particles, substitution of the first term of the drag coefficient equation [Eq. (5–19)] into Eq. (5–18) yields Stokes' law:

$$v_p = \frac{g(\rho_p - \rho_w)d_p^2}{18\mu} \approx \frac{g(sg_p - 1)d_p^2}{18\nu} \tag{5–22}$$



Terms are as defined previously.

For laminar-flow conditions, Stokes found the drag force to be

$$F_D = 3\pi\mu v_p d_p \tag{5–23}$$

Stokes' law [Eq. (5–22)] can also be derived by equating the drag force found by Stokes to the effective weight of the particle [Eq. (5–16)].

Settling in the Transition Region. In the transition region, the complete form of the drag equation [Eq. (5–16)] must be used to determine the settling velocity, as illustrated in Example 5–5. Because of the nature of the drag equation, finding the settling velocity is an iterative process. As an aid in visualizing settling in the transition region, Fig. 5–21 has been prepared, which covers the laminar and the transition region for particle sizes of interest in environmental engineering.

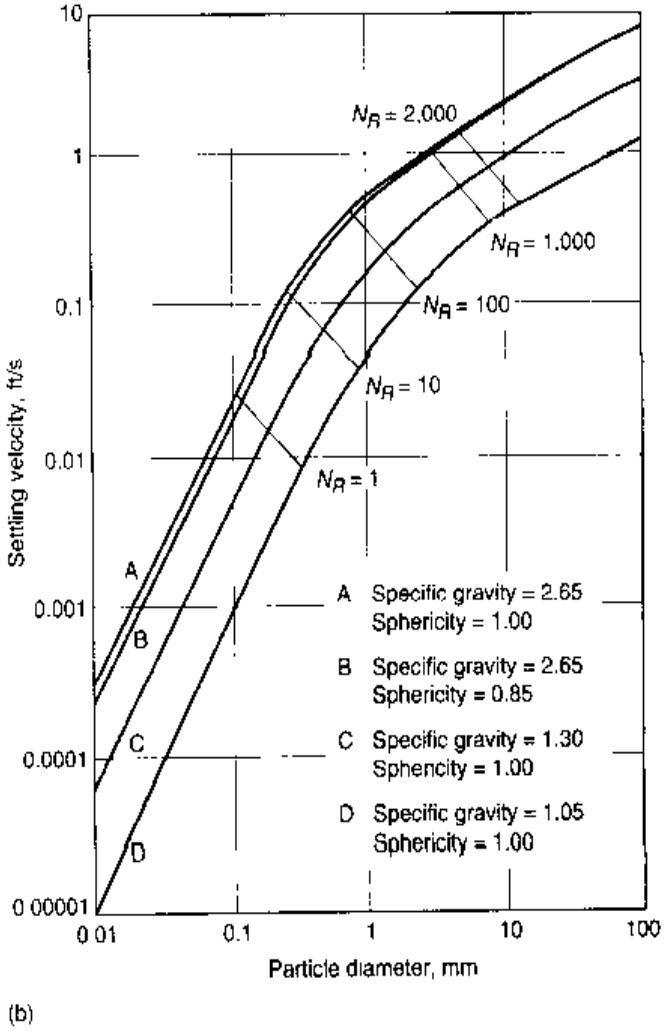


Figure 5–21

Settling velocities for various particle sizes under varying conditions at 20°C: (*a*) settling velocity in m/s versus particle size in mm, (*b*) settling velocity in ft/s versus particle size in mm. *(Crites and Tchobanoglous, 1998.)*

Settling in the Turbulent Region. In the turbulent region, inertial forces are predominant, and the effect of the first two terms in the drag coefficient equation [Eq. (5–19)] is reduced. For settling in the turbulent region, a value of 0.4 is used for the coefficient of drag. If a value of 0.4 is substituted into Eq. (5–21) for C_d, the resulting equation is

$$v_p = \sqrt{3.33g\left(\frac{\rho_p - \rho_w}{\rho_w}\right)d_p} = \sqrt{3.33g(sg_p - 1)d_p} \tag{5–24}$$

The use of Eqs. (5–18) through (5–22) is illustrated in Example 5–5.

EXAMPLE 5–5 Determination of Particle Terminal Settling Velocity Determine the terminal settling velocity for a sand particle with an average diameter of 0.5 mm (0.00164 ft), a shape factor of 0.85, and a specific gravity of 2.65, settling in water at 20°C (68°F). At this temperature, the kinematic viscosity value given in Appendix C is 1.003×10^{-6} m^2/s (1.091×10^{-5} ft^2/s).

Solution

1. Determine the terminal settling velocity for the particle using Stokes' law [(Eq. (5–22)].

$$v_p = \frac{g(sg_p - 1)d_p^2}{18\nu}$$

$$= \frac{(9.81\ m/s^2)(2.65 - 1)(0.5 \times 10^{-3}\ m)^2}{18(1.003 \times 10^{-6}\ m^2/s)} = 0.224\ m/s$$

2. Check the Reynolds number [Eq. (5–20)] (include the shape factor ϕ).

$$N_R = \frac{\phi v_p d_p}{\nu} = \frac{0.85(0.224\ m/s)(0.5 \times 10^{-3}\ m)}{(1.003 \times 10^{-6}\ m^2/s)} = 94.9$$

The use of Stokes' law is not appropriate for Reynolds number > 1.0. Therefore, Newton's law [Eq. (5–18)] must be used to determine the settling velocity in the transition region (see Fig. 5–21). The drag coefficient term in Newton's equation is dependent on the Reynolds number, which is a function of the settling velocity. Because the settling velocity is not known, an initial settling velocity must be assumed. The assumed velocity is used to compute the Reynolds number, which is used to determine the drag coefficient, which is used in the Newton equation to calculate the settling velocity. A solution is achieved when the initial assumed settling velocity is approximately equal to the settling velocity resulting from Newton's equation. The solution process is iterative, as illustrated below.

3. For the first assumed settling velocity, use the Stokes' law settling velocity calculated above. Using the resulting Reynolds number, also determined previously, compute the drag coefficient.

$$C_d = \frac{24}{N_R} + \frac{3}{\sqrt{N_R}} + 0.34 = \frac{24}{94.9} + \frac{3}{\sqrt{94.9}} + 0.34 = 0.901$$

4. Use the drag coefficient in Newton's equation to determine the particle settling velocity.

$$V_p = \sqrt{\frac{4g(sg-1)d}{3C_d}} = \sqrt{\frac{4(9.81\ \text{m/s}^2)(2.65-1)(0.5\times10^{-3}\ \text{m})}{3\times0.901}} = 0.109\ \text{m/s}$$

Because the initial assumed settling velocity (0.224 m/s) does not equal the settling velocity calculated by Newton's equation (0.109 m/s), a second iteration is necessary.

5. For the second iteration, assume a settling velocity value of 0.09 m/s, and calculate the Reynolds number. Use the Reynolds number to determine the drag coefficient, and use the drag coefficient in Newton's equation to find the settling velocity.

$$N_R = \frac{0.85(0.09\ \text{m/s})(0.5\times10^{-3}\ \text{m})}{(1.003\times10^{-6}\ \text{m}^2/\text{s})} = 38.1$$

$$C_d = \frac{24}{38.1} + \frac{3}{\sqrt{38.1}} + 0.34 = 1.456$$

$$v_p = \sqrt{\frac{4(9.81\ \text{m/s}^2)(2.65-1)(0.5\times10^{-3}\ \text{m})}{3\times1.456}} = 0.086\ \text{m/s}$$

Although the assumed settling velocity (0.09 m/s) and the calculated settling velocity (0.086 m/s) still do not agree, they are approaching closure. Successive iterations to calculate the actual settling velocity will be done as a homework problem.

Because the settling velocity used to compute the Reynolds number agrees with the settling velocity value from Newton's equation, the solution approach has been confirmed.

Discrete Particle Settling

In the design of sedimentation basins, the usual procedure is to select a particle with a terminal velocity v_c and to design the basin so that all particles that have a terminal velocity equal to or greater than v_c will be removed. The rate at which clarified water is produced is equal to

$$Q = Av_c \tag{5–25}$$

where Q = flowrate, L^3T^{-1} (m^3/s)
A = surface of the sedimentation basin, L^2 (m^2)
v_c = particle settling velocity, LT^{-1} (m/s)

Rearranging Eq. (5–25) yields

$$v_c = \frac{Q}{A} = \text{overflow rate, } LT^{-1}\ (m^3/m^2\cdot d)$$

Thus, the critical velocity is equivalent to the overflow rate or surface loading rate. A common basis of design for discrete particle settling recognizes that the flow capacity is independent of the depth.

For continuous-flow sedimentation, the length of the basin and the time a unit volume of water is in the basin (detention time) should be such that all particles with the design velocity v_c will settle to the bottom of the tank. The design velocity, detention time, and basin depth are related as follows:

$$v_c = \frac{\text{depth}}{\text{detention time}} \tag{5–26}$$

In actual practice, design factors must be adjusted to allow for the effects of inlet and outlet turbulence, short circuiting, sludge storage, and velocity gradients due to the operation of sludge-removal equipment. These design factors are discussed in Sec. 5–7. In the above discussion ideal settling conditions have been assumed.

Idealized discrete particle settling in three different types of settling basins is illustrated on Fig. 5–22. Particles that have a velocity of fall less than v_t will not all be removed during the time provided for settling. Assuming that the particles of various sizes are uniformly distributed over the entire depth of the basin at the inlet, it can be seen from an analysis of the particle trajectory on Fig. 5–23 that particles with a settling velocity less than v_t will be removed in the ratio

$$X_r = \frac{v_p}{v_t} \tag{5–27}$$

where X_r is the fraction of the particles with settling velocity v_p that are removed.

In most suspensions encountered in wastewater treatment, a large gradation of particle sizes will be found. To determine the efficiency of removal for a given settling time, it is necessary to consider the entire range of settling velocities present in the system. The settling velocities of the particles can be obtained by use of a settling column test. The particle settling data are used to construct a velocity settling curve as shown on Fig. 5–24.

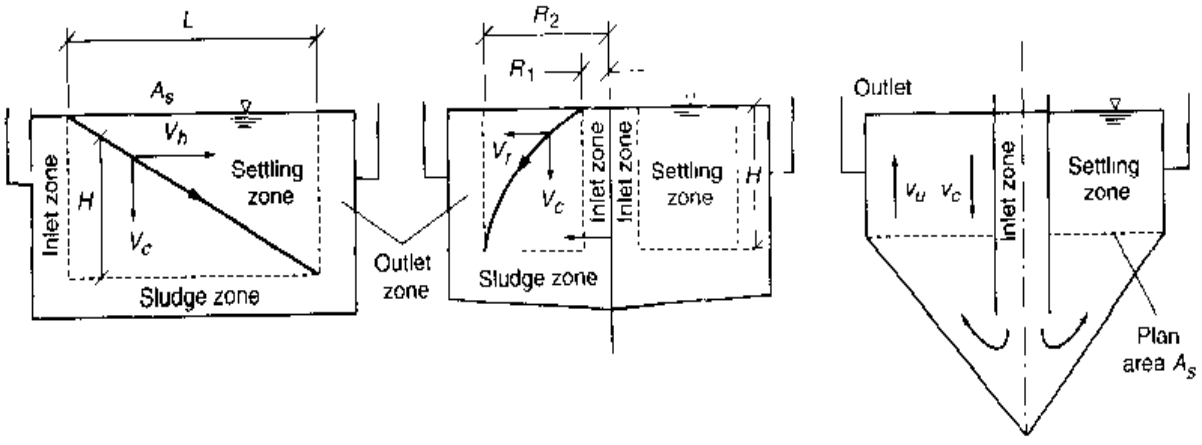

Figure 5–22

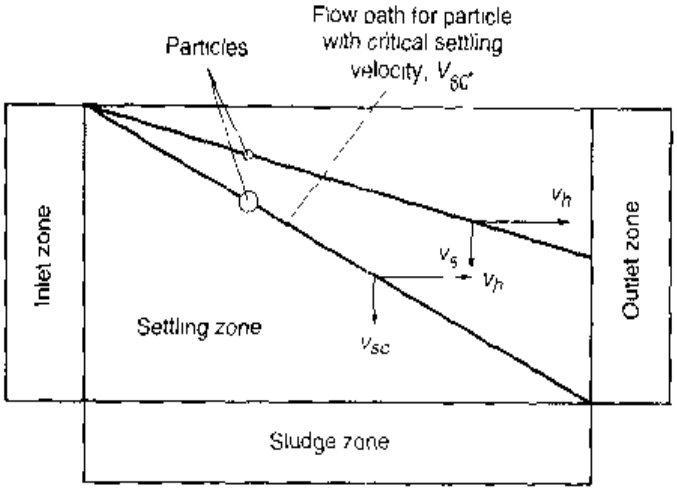
Definition sketch for the idealized settling of discrete particles in three different types of settling basins: (a) rectangular, (b) circular, and (c) upflow. *(Crites and Tchobanoglous, 1998.)*

Figure 5-23

Definition sketch for the analysis of ideal discrete particle settling.



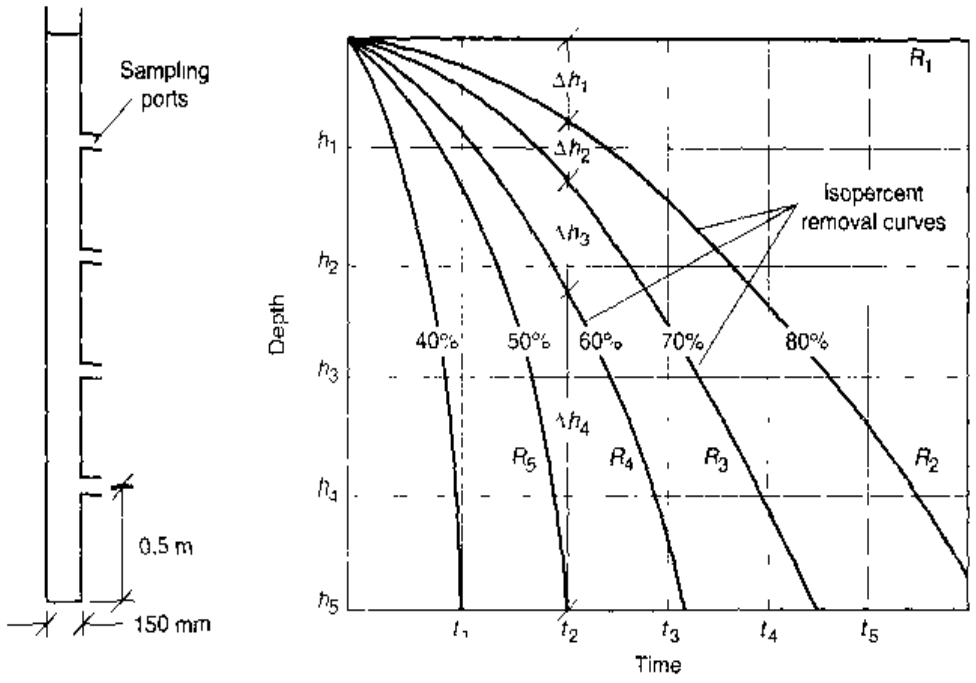


Figure 5-24

Definition sketch for the analysis of flocculent settling.

For a given clarification rate Q where

$$Q = v_c A \tag{5-28}$$

only those particles with a velocity greater than v_c will be completely removed. The remaining particles will be removed in the ratio v_p/v_c. The total fraction of particles removed for a continuous distribution is given by Eq. (5-29).

$$\text{Fraction removed} = (1 - X_c) + \int_0^{X_c} \frac{v_p}{v_c}\, dx \tag{5-29}$$

where $1 - X_c$ = fraction of particles with velocity v_p greater than v_c

$\int_0^{X_c} \frac{v_p}{v_c}\, dx$ = fraction of particles removed with v_p less than v_c

For discrete particles within a given settling velocity range, the following expression may be used

$$\text{Total fraction removed} = \frac{\sum_{i=1}^{n} \frac{v_{n_i}}{v_s}(n_i)}{\sum_{i=1}^{n} n_i} \tag{5-30}$$

where v_{n_i} = average velocity of particles in the ith velocity range
n_i = number of particles in the ith velocity range

The use of Eq. (5–30) is illustrated in Example 5–6.

EXAMPLE 5–6 Calculation of Removal Efficiency for a Primary Sedimentation Basin Determine the removal efficiency for a sedimentation basin with a critical overflow velocity of 2 $m^3/m^2 \cdot h$ in treating a wastewater containing particles whose settling velocities are distributed as given in the table below. Plot the particle histogram for the influent and effluent wastewater.

Settling velocity, m/h	Number of particles per liter × 10^{-5}
0.0–0.5	30
0.5–1.0	50
1.0–1.5	90
1.5–2.0	110
2.0–2.5	100
2.5–3.0	70
3.0–3.5	30
3.5–4.0	20
Total	500

Solution

1. Create a table for calculating the percentage removal for each particle size. Enter the particle settling velocity ranges in column (1).

Settling velocity range, m/h (1)	Average settling velocity, m/h (2)	Number of particles in influent, × 10^{-5} (3)	Fraction of particles removed (4)	Number of particles removed, × 10^{-5} (5)	Particles remaining in effluent, × 10^{-5} (6)
0.0–0.5	0.25	30	0.125	3.75	26.25
0.5–1.0	0.75	50	0.375	18.75	31.25

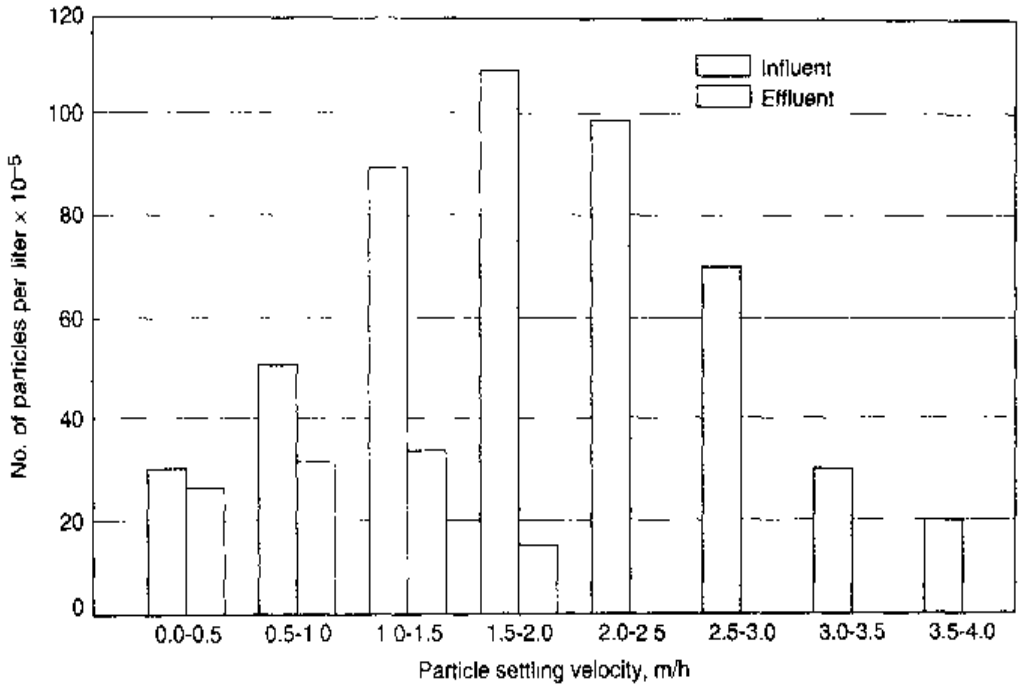
(continued)

(*Continued*)

Settling velocity range, m/h (1)	Average settling velocity, m/h (2)	Number of particles in influent, $\times 10^{-5}$ (3)	Fraction of particles removed (4)	Number of particles removed, $\times 10^{-5}$ (5)	Particles remaining in effluent, $\times 10^{-5}$ (6)
1.0–1.5	1.25	90	0.625	56.25	33.75
1.5–2.0	1.75	110	0.875	96.0	14.0
2.0–2.5	2.25	100	1.000	100.0	0.0
2.5–3.0	2.75	70	1.000	70.0	0.0
3.0–3.5	3.25	30	1.000	30.0	0.0
3.5–4.0	3.75	20	1.000	20.0	0.0
Total		500		394.75	105.25

2. Calculate the average particle settling velocity for each velocity range by taking the average of the range limits, and enter the values in column (2). For the first velocity range, the average settling velocity is (0.0 + 0.5)/2 = 0.25 m/h.
3. Enter the number of influent particles for each velocity range in column (3).
4. Calculate the removal fraction for each velocity range by dividing the average settling velocity by the critical overflow velocity (2.0 m/h), and enter the result in column (4). For the first velocity range

$$\text{Fraction removed} = \frac{v_{n_i}}{v_c} = \frac{0.25}{2.0} = 0.125$$



Where the result is greater than 1.0, enter a value of 1.0, because all of the particles are removed.

5. Determine the number of particles removed by multiplying the number of influent particles by the percent removal [column (3) × column (4)]. Enter the values in column (5).
6. Calculate the particles remaining by subtracting the particles removed from the number of influent particles [column (3) − column (5)]. Enter the result in column (6).
7. Compute the removal efficiency by calculating the sum of particles removed and dividing the sum by the total number of particles in the influent.

$$\text{Total percent removed} = \frac{\sum_{i=1}^{n} \frac{v_{n_i}}{v_c}(n_i)}{\sum_{i=1}^{n} n_i} \times 100$$

$$= \frac{394.75 \times 10^{-5}}{500 \times 10^{-5}} \times 100 = 78.95\%$$

8. Plot the particle histogram for the influent and effluent wastewater.

Flocculent Particle Settling

Particles in relatively dilute solutions will not act as discrete particles but will coalesce during sedimentation. As coalescence or flocculation occurs, the mass of the particle increases, and it settles faster. The extent to which flocculation occurs is dependent on the opportunity for contact, which varies with overflow rate, depth of the basin, velocity gradients in the system, concentration of particles, and range of particle sizes. The effects of these variables can be determined only by sedimentation tests.

The settling characteristics of a suspension of flocculent particles can be obtained by using a settling column test. Such a column can be of any diameter but should be equal in height to the depth of the proposed tank. The solution containing the suspended matter should be introduced into the column in such a way that a uniform distribution of particle sizes occurs from top to bottom. Care should be taken to ensure that a uniform temperature is maintained throughout the test to eliminate convection currents. Settling should take place under quiescent conditions. The duration of the test should be equivalent to the settling time in the proposed tank.

At the conclusion of the settling time, the settled matter that has accumulated at the bottom of the column is drawn off, the remaining liquid is mixed, and the TSS of the liquid is measured. The TSS of the liquid is then compared to the sample TSS before settling to obtain the percent removal.

The more traditional method of determining settling characteristics of a suspension is to use a column similar to the one described above but with sampling ports inserted

at approximately 0.5 m (1.5 ft) intervals. At various time intervals, samples are withdrawn from the ports and analyzed for suspended solids. The percent removal is computed for each sample analyzed and is plotted as a number against time and depth, as elevations are plotted on a survey grid. Curves of equal percent removal are drawn as shown on Fig. 5–24. From the curves shown on Fig. 5–24, the overflow rate for various settling is determined by noting the value where the curve intersects the x axis. The settling velocity v_t is

$$v_t = \frac{H}{t_t} \tag{5–31}$$

where H = height of the settling column, L (m)
t_t = time required for a given degree of removal to be achieved, T (min)

The fraction of particles removed is given by

$$R, \% = \sum_{n=1}^{n} \left(\frac{\Delta h_n}{H}\right)\left(\frac{R_n + R_{n+1}}{2}\right) \tag{5–32}$$

where R = TSS removal, %
n = number of equal percent removal curve
Δh_n = distance between curves of equal percent removal, L (m)
H = total height of settling column, L (m)
R_n = equal percent removal curve number n
R_{n+1} = equal percent removal curve number $n + 1$

The advantage of the more traditional method is that it is possible to obtain removal data at various depths of settling. The removal percentage obtained using the curve given on Fig. 5–24 is illustrated in Example 5–7.

EXAMPLE 5–7 Removal of Flocculent Suspended Solids Using the results of the settling test shown on Fig. 5–24, determine the overall removal of solids if the detention time is t_2 and the depth is h_5. Also demonstrate that the same result is obtained when the solids are measured after settling has occurred.

Solution

1. Determine the percent removal.

   Percent removal

   $$= \frac{\Delta h_1}{h_5} \times \frac{R_1 + R_2}{2} + \frac{\Delta h_2}{h_5} \times \frac{R_2 + R_3}{2} + \frac{\Delta h_3}{h_5} \times \frac{R_3 + R_4}{2} + \frac{\Delta h_4}{h_5} \times \frac{R_4 + R_5}{2}$$

2. For the curves shown on Fig. 5–24, a total removal for quiescent settling is 65.7 percent. The computations follow.

$\frac{\Delta h_n}{h_5} \times \frac{R_n + R_{n+1}}{2}$ =	percent removal
$0.20 \times \frac{100 + 80}{2}$ =	18.00
$0.11 \times \frac{80 + 70}{2}$ =	8.25
$0.15 \times \frac{70 + 60}{2}$ =	9.75
$0.54 \times \frac{60 + 50}{2}$ =	29.70
1.00	65.70

3. Determine the percent removal if the liquid had been mixed and the solids were measured.
   a. Assume the initial solids concentration is equal to 100 and that at the end of the settling period the concentration of the solids at the top of the column is equal to zero.
   b. Set up a computation table and determine the remaining solids after settling.

$\Delta h \times \frac{TSS_n \times TSS_{n+1}}{2}$ =	average TSS
$0.20 \times \frac{0 + 20}{2}$ =	2.00
$0.11 \times \frac{20 + 20}{2}$ =	2.75
$0.15 \times \frac{30 + 40}{2}$ =	5.25
$0.54 \times \frac{40 + 50}{2}$ =	24.30
	34.30

The percent removal is $R_t = 100 - 34.30 = 65.70$

Comment To account for the less than optimum conditions encountered in the field, the design settling velocity or overflow rate obtained from column studies often is multiplied by a factor of 0.65 to 0.85, and the detention times are multiplied by a factor of 1.25 to 1.5.

Inclined Plate and Tube Settling

Inclined plate and tube settlers are shallow settling devices consisting of stacked offset trays or bundles of small plastic tubes of various geometries (see Fig. 5–25*a*) that are used to enhance the settling characteristics of sedimentation basins. They are based on

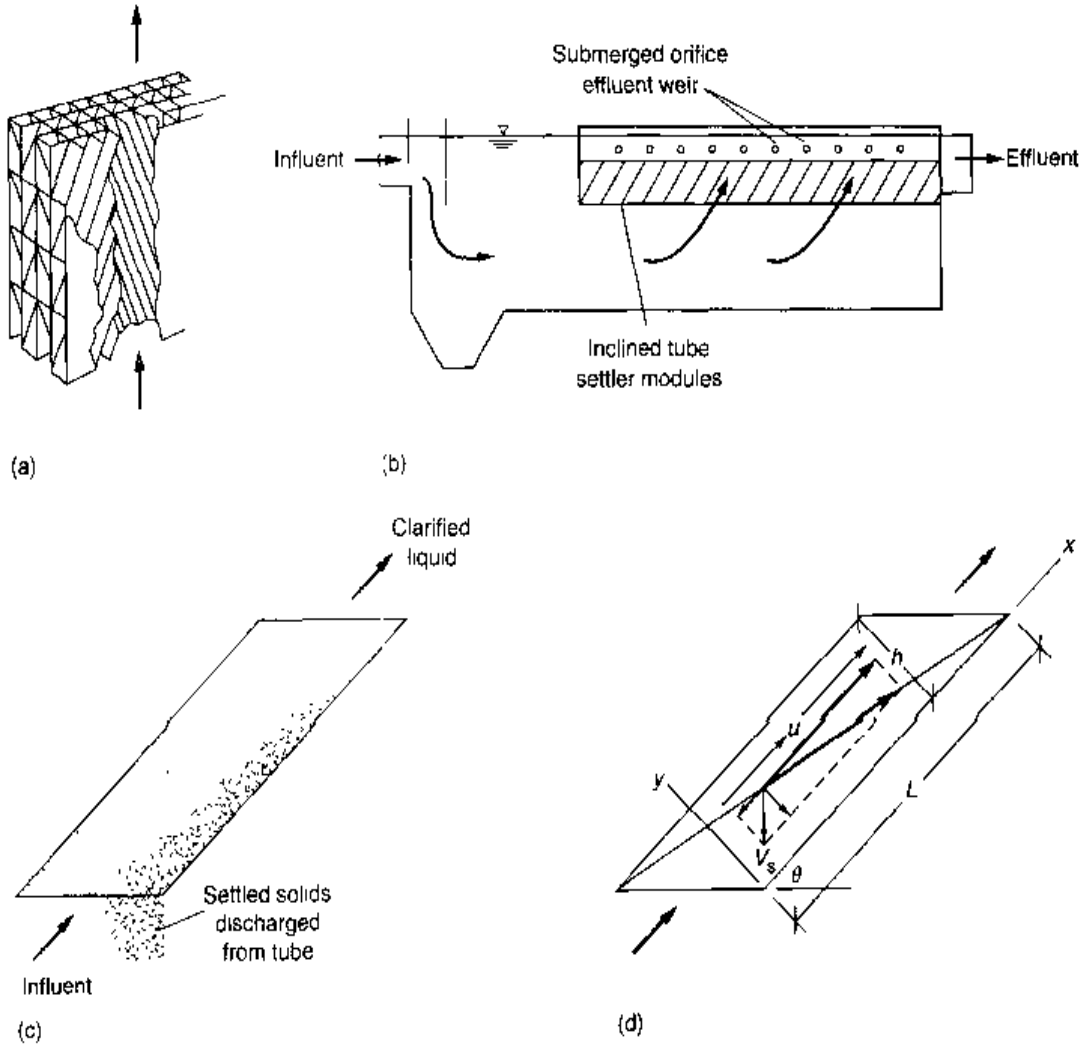


Figure 5–25

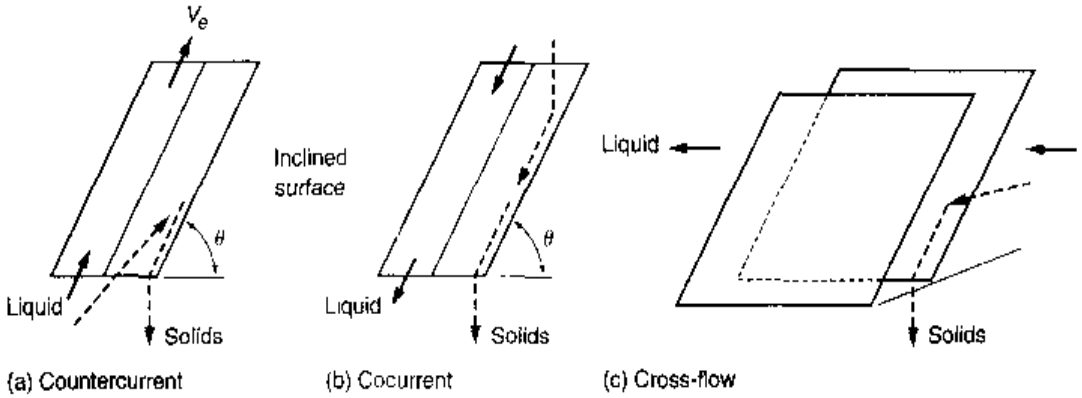
Plate and tube settlers: (*a*) module of inclined tubes, (*b*) tubes installed in a rectangular sedimentation tank, (*c*) operation, and (*d*) definition sketch for the analysis of settling in a tube settler.



the theory that settling depends on the settling area rather than detention time. Although they are used predominantly in water-treatment applications, plate and tube settlers are used in wastewater-treatment for primary, secondary, and tertiary sedimentation. In primary sedimentation applications, however, fine screening should be provided ahead of the settling operation to prevent plugging of the plates or tubes.

To be self-cleaning, plate or tube settlers are usually set at an angle between 45 and 60° above the horizontal. When the angle is increased above 60°, the efficiency decreases. If the plates and tubes are inclined at angles less than 45°, solids will tend to accumulate within the plates or tubes. Nominal spacing between plates is 50 mm (2 in), with an inclined length of 1 to 2 m (3 to 6 ft). To control biological growths and the production of odors (the principal problems encountered with their use), the accumulated solids must be flushed out periodically (usually with a high-pressure water). The need for flushing poses a problem with the use of plate and tube settlers when the characteristics of the solids to be removed vary from day to day.

The main objective in inclined settler development has been to obtain settling efficiencies close to theoretical limits. Attention must be given to providing equal flow distribution to each settler, producing good flow distribution within each settler, and collecting settled solids while preventing resuspension.

Figure 5-26

Alternative flow patterns through tube settlers: (a) countercurrent with respect to the movement of solids, (b) cocurrent with the respect to the movement of solids, and (c) cross-flow. *(AWWA, 1999.)*

Inclined settling systems are generally constructed for use in one of three ways with respect to the direction of liquid flow relative to the direction of particle settlement: (1) countercurrent, (2) cocurrent, and (3) cross-flow. The flow patterns are shown schematically on Fig. 5–26.

Countercurrent Settling. With countercurrent flow, wastewater suspension in the basin passes upward through the plate or tube modules and exits from the basin above the modules (see Fig. 5–25*a*). The solids that settle out within the plates or tubes move by gravity countercurrently downward and out of the modules to the basin bottom (see Fig. 5–25*c*). Tube settlers are mostly used in the countercurrent mode.

In countercurrent settling, the time t for a particle to settle the vertical distance between two parallel inclined surfaces is (AWWA, 1999):

$$t = \frac{w}{v \cos \theta} \tag{5-33}$$

where w = perpendicular distance between surfaces, L (m)
v = settling velocity, LT^{-1} (m/s)
θ = angle of the surface inclination from the horizontal

The length of surface L_p needed to provide this time, if the liquid velocity between the surfaces is v_θ, is

$$L_p = \frac{w(v_\theta - v \sin \theta)}{v \cos \theta} \tag{5-34}$$

By rearranging this equation, all particles with a settling velocity v and greater are removed if

$$v \geq \frac{v_\theta w}{L_p \cos \theta + w \sin \theta} \tag{5-35}$$

When many plates or tubes are used

$$v_\theta = \frac{Q}{Nwb} \tag{5-36}$$

where Q = flowrate, L^3T^{-1} (m^3/s)
N = number of channels made by $N+1$ plates or tubes

b = dimension of the surface at right angles to w and Q, L (m)
w = perpendicular distance between surfaces, L (m)
v_θ = settling velocity, LT^{-1} (m/s)

A proprietary settler, the Lamella® Gravity Settler, manufactured by the Parkson Corporation, is based on countercurrent settling with modifications (see Fig. 5–27). The feed stream is introduced into the settler by means of a feed duct to the feed box, which is a bottomless channel between plate sections. The flow is directed downward toward individual side-entry plate slots. The feed is distributed across the width of the plates and flows upward under laminar flow conditions. The plates are inclined 55° from the horizontal. The solids settle on the plates and the clean supernatant exits the plates through orifice holes. The orifice holes are placed immediately above each plate and are sized to induce a calculated pressure drop to ensure the feed is hydraulically distributed

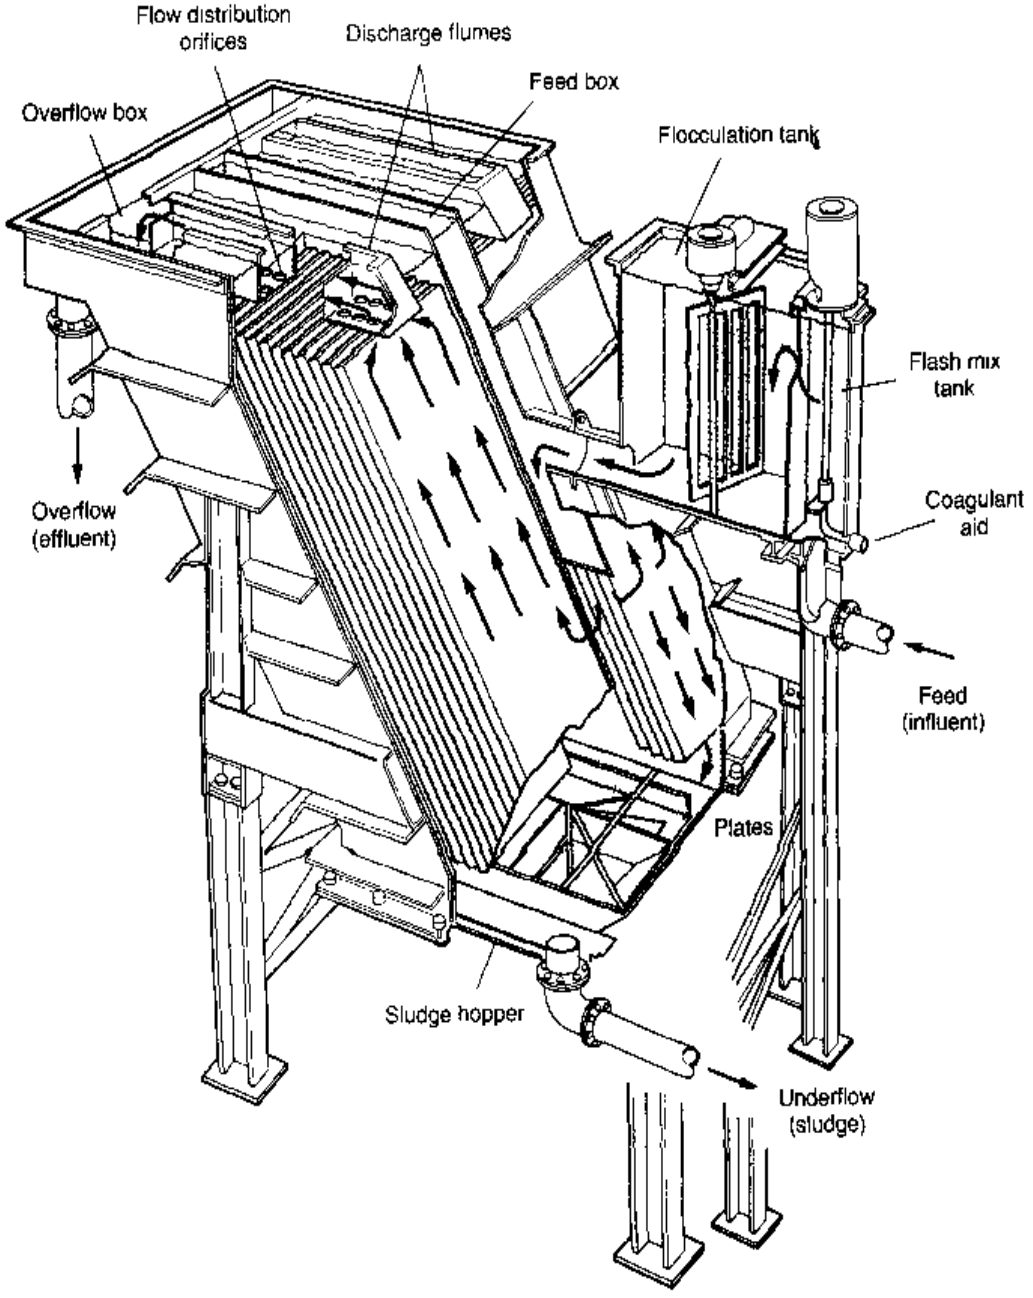


Figure 5–27
Example of a Lamella plate settler. *(Courtesy Parkson Corporation.)*

equally among the plates. The solids slide down the plates into a collection hopper. Further thickening of the solids occurs in the hopper due to compression in the quiescent zone made possible by feeding the plates from the side rather than from the bottom. Plate packs can also be retrofitted into existing clarifiers to improve performance.

Cocurrent Settling. In cocurrent settling, the solids suspension is introduced above the inclined surfaces and the flow is down through the tubes or plates (see Fig. 5–26*b*). The time for a particle to settle the vertical distance between two surfaces is the same as for countercurrent settling. The length of surface needed, L_p, however, has to be based on downward and not upward liquid flow, as follows:

$$L_p = w\frac{(v_\theta - v\sin\theta)}{v\cos\theta} \tag{5–37}$$

Consequently, the condition for removal of particles is given by

$$v \geq \frac{v_\theta w}{L_p\cos\theta - w\sin\theta} \tag{5–38}$$

Cross-Flow Settling. In cross-flow settling, the liquid flow is horizontal and does not interact with the vertical settling velocity (see Fig. 5–26*c*). The length of the surface L_p is determined by

$$L_p = \frac{wv_\theta}{v\cos\theta} \tag{5–39}$$

and

$$v \geq \frac{v_\theta w}{L_p\cos\theta} \tag{5–40}$$

Hindered (Zone) Settling

In systems that contain a high concentration of suspended solids, both hindered or zone settling and compression settling usually occur in addition to discrete (free) and flocculent settling. The settling phenomenon that occurs when a concentrated suspension, initially of uniform concentration throughout, is placed in a graduated cylinder, is illustrated on Fig. 5–28. Because of the high concentration of particles, the liquid tends to move up through the interstices of the contacting particles. As a result, the contacting particles tend to settle as a zone or "blanket," maintaining the same relative position with respect to each other. The phenomenon is known as hindered settling. As the particles settle, a relatively clear layer of water is produced above the particles in the settling region. The scattered, relatively light particles remaining usually settle as discrete or flocculent particles, as discussed previously. In most cases, an identifiable interface develops between the upper region and the hindered settling region on Fig. 5–28. The rate of settling in the hindered settling region is a function of the concentration of solids and their characteristics.

As settling continues, a compressed layer of particles begins to form on the bottom of the cylinder in the compression settling region. The particles apparently form a struc-

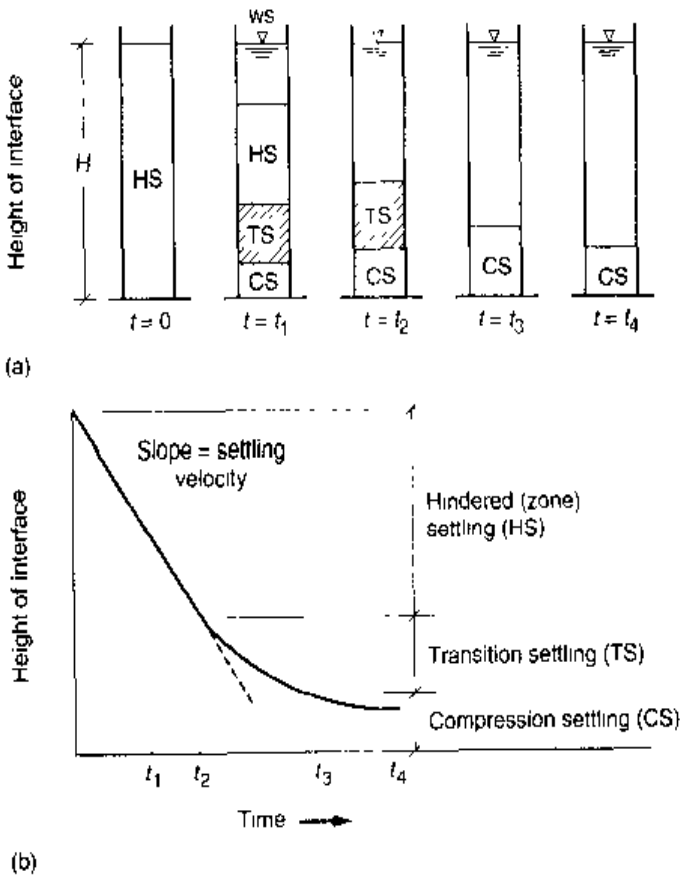

Figure 5–28

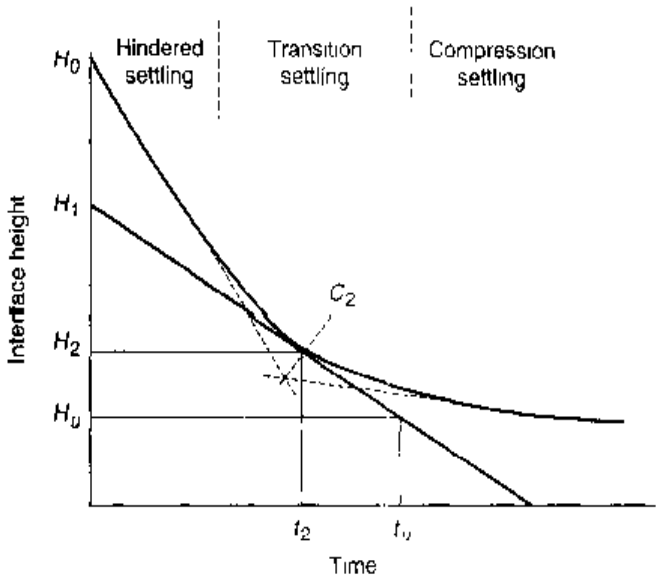
Definition sketch for hindered (zone) settling: (*a*) settling column in which the suspension is transitioning through various phases of settling and (*b*) the corresponding interface settling curve.



ture in which there is close physical contact between the particles. As the compression layer forms, regions containing successively lower concentrations of solids than those in the compression region extend upward in the cylinder. Thus, in actuality the hindered settling region contains a gradation in solids concentration from that found at the interface of the settling region to that found in the compression settling region.

Because of the variability encountered, settling tests are usually required to determine the settling characteristics of suspensions where hindered and compression settling are important considerations. On the basis of data derived from column settling tests, two different design approaches can be used to obtain the required area for the settling/thickening facilities. In the first approach, the data derived from one or more batch settling tests are used. In the second approach, known as the solids flux method, data from a series of settling tests conducted at different solids concentrations are used. Both methods are described in the following discussion. The solids flux method is considered further in Sec. 8–8 in Chap. 8. It should be noted that both methods have been used where existing plants are to be expanded or modified. These methods are, however, seldom used in the design of small treatment plants.

Area Requirement Based on Single-Batch Test Results. For purposes of design, the final overflow rate selected should be based on a consideration of the following factors: (1) the area needed for clarification, (2) the area needed for thickening, and (3) the rate of sludge withdrawal. Column settling tests, as previously described, can be used to determine the area needed for the free settling region directly. However, because the area required for thickening is usually greater than the area required for the settling, the rate of free settling rarely is the controlling factor. In the case of the activated-sludge

Figure 5–29

Graphical analysis of hindered (zone) interface settling curves.

process where stray, light fluffy floc particles may be present, it is conceivable that the free flocculent settling velocity of these particles could control the design.

The area requirement for thickening is determined according to a method developed by Talmadge and Fitch (1955). A column of height H_0 is filled with a suspension of solids of uniform concentration C_0. The position of the interface as time elapses and the suspension settles is given on Fig. 5–29. The rate at which the interface subsides is then equal to the slope of the curve at that point in time. According to the procedure, the area required for thickening is given by Eq. (5–41):

$$A = \frac{Qt_u}{H_0} \tag{5–41}$$

where A = area required for sludge thickening, L^2 (m^2)
Q = flowrate into tank, L^3T^{-1} (m^3/s)
H_0 = initial height of interface in column, L (m)
t_u = time to reach desired underflow concentration, T (s)

The critical concentration controlling the solids handling capability of the tank occurs at a height H_2 where the concentration is C_2. This point is determined by extending the tangents to the hindered settling and compression regions of the subsidence curve to the point of intersection and bisecting the angle thus formed, as shown on Fig. 5–29. The time t_u can be determined as follows:

1. Construct a horizontal line at the depth H_u that corresponds to the depth at which the solids are at the desired underflow concentration C_u. The value of H_u is determined using the following expression:

$$H_u = \frac{C_0 H_0}{C_u} \tag{5–42}$$

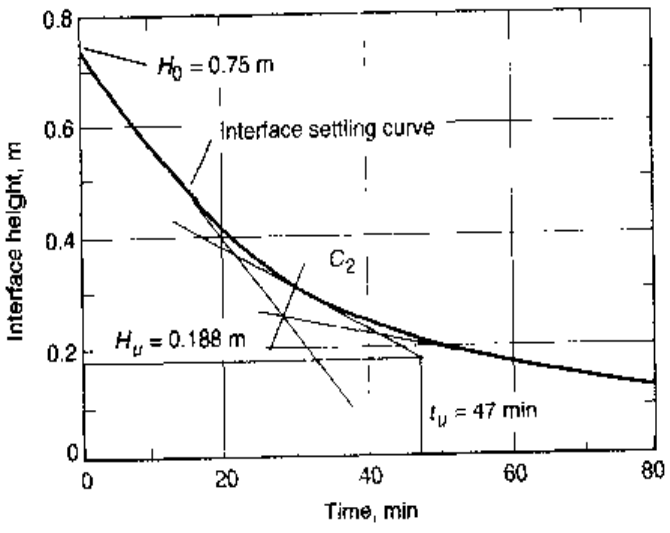
2. Construct a tangent to the settling curve at the point indicated by C_2.
3. Construct a vertical line from the point of intersection of the two lines drawn in steps 1 and 2 to the time axis to determine the value of t_u.

With this value of t_u, the area required for the thickening is computed using Eq. (5–41). The area required for clarification is then determined. The larger of the two areas is the controlling value. Application of this procedure is illustrated in Example 5–8.

EXAMPLE 5–8 Sizing an Activated-Sludge Settling Tank The settling curve shown in the following diagram was obtained for an activated sludge with an initial solids concentration C_0 of 3000 mg/L. The initial height of the interface in the settling column was at 0.75 m (2.5 ft). Determine the area required to yield a thickened solids concentration, C_u of 12,000 mg/L with a total flow of 3800 m^3/d (1 Mgal/d). Determine also the solids loading ($kg/m^2 \cdot d$) and the overflow rate ($m^3/m^2 \cdot d$).

Solution

1. Determine the area required for thickening using Eq. (5–41).
   a. Determine the value of H_u



$$H_u = \frac{C_0 H_0}{C_u}$$

$$= \frac{(3000 \text{ mg/L})(0.75 \text{ m})}{(12{,}000 \text{ mg/L})} = 0.188 \text{ m}$$

On the following settling curve, a horizontal line is constructed at $H_u = 0.188$ m. A tangent is constructed to the settling curve at C_2, the midpoint of the region between hindered and compression settling. Bisecting the angle formed where the two tangents meet determines point C_2. The intersection of the tangent at C_2 and the line $H_u = 0.188$ m determines t_u. Thus $t_u = 47$ min, and the required area is

$$A = \frac{Qt_u}{H_0} = \left[\frac{(3800 \text{ m}^3/\text{d})}{(24 \text{ h/d})(60 \text{ min/h})}\right]\left(\frac{47 \text{ min}}{0.75 \text{ m}}\right) = 165 \text{ m}^2$$

2. Determine the area required for clarification.

a. Determine the interface subsidence velocity v. The subsidence velocity is determined by computing the slope of the tangent drawn from the initial portion of the interface settling curve. The computed velocity represents the unhindered settling rate of the sludge.

$$v = \left(\frac{0.75\text{ m} - 0.3\text{ m}}{29.5\text{ m}}\right)\left(\frac{60\text{ min}}{\text{h}}\right) = 0.92\text{ m/h}$$

b. Determine the clarification rate. Because the clarification rate is proportional to the liquid volume above the critical sludge zone, it may be computed as follows:

$$Q = 3800\text{ m}^3\text{/d}\left(\frac{0.75\text{ m} - 0.188\text{ m}}{0.75\text{ m}}\right) = 2847\text{ m}^3\text{/d}$$

c. Determine the area required for clarification. The required area is obtained by dividing the clarification rate by the settling velocity.

$$A = \frac{Q_c}{v} = \frac{(2847\text{ m}^3\text{/d})}{(24\text{ h/d})(0.91\text{ m/h})} = 129\text{ m}^2$$

3. The controlling area is the thickening area (165 m^2) because it exceeds the area required for clarification (129 m^2).
4. Determine the solids loading. The solids loading is computed as follows:

$$\text{Solids, kg/d} = \frac{(3800\text{ m}^3\text{/d})(3000\text{ g/m}^3)}{(10^3\text{ g/kg})} = 11{,}400\text{ kg/d}$$

$$\text{Solids loading} = \frac{(11{,}400\text{ kg/d})}{165\text{ m}^2} = 69.1\text{ kg/m}^2\text{·d}$$

5. Determine the hydraulic loading rate.

$$\text{Hydraulic loading rate} = \frac{(3800\text{ m}^3\text{/d})}{165\text{ m}^2} = 23.0\text{ m}^3\text{/m}^2\text{·d}$$

Comment An alternative approach for sizing the secondary clarifiers using the initial settling velocity of the sludge is given in Sec. 8–8 in Chap. 8.

Area Requirements Based on Solids Flux Analysis. An alternative method of determining the area required for hindered settling is based on an analysis of the solids (mass) flux (Coe and Clevenger, 1916). In the solids flux method of analysis it is assumed that a settling basin is operating at steady state. Within the tank, the downward flux of solids is brought about by gravity (hindered) settling and by bulk transport due to the underflow that is being pumped out and recycled. The solids flux method of analysis is used to assess the performance of existing facilities and to obtain information for the design of new facilities to treat the same wastewater. Application of the solids flux

method of analysis is illustrated in Sec. 8–7 in Chap. 8, and additional information may be found in the following references: Dick and Ewing (1967); Dick and Young (1972); Keinath (1989); Wahlberg and Keinath (1988); and Yoshika et al. (1957).

Compression Settling

The volume required for the sludge in the compression region can also be determined by settling tests. The rate of consolidation has been found to be proportional to the difference in the depth at time t and the depth to which the sludge will settle after a long period of time. The long-term consolidation can be modeled as a first-order decay function, as given by Eq. (5–43).

$$H_t - H_\infty = (H_2 - H_\infty)e^{-it} \tag{5–43}$$

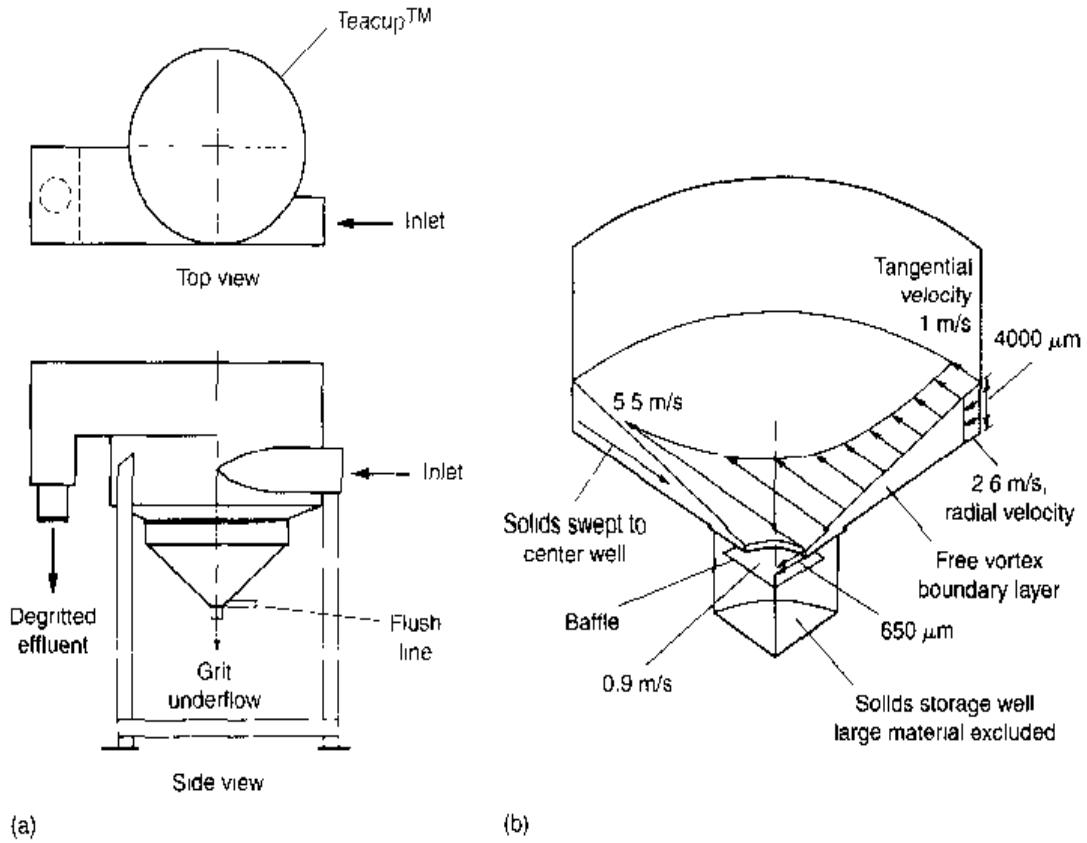
where H_t = sludge height at time t, L
H_∞ = sludge depth after long settling period, on the order of 24 h, L
H_2 = sludge height at time t_2, L
i = constant for a given suspension

Stirring serves to compact solids in the compression region by breaking up the floc and permitting water to escape. Rakes are often used on sedimentation equipment to manipulate the solids and thus produce better compaction.

Gravity Separation in an Accelerated Flow Field

Sedimentation, as described previously, occurs under the force of gravity in a constant acceleration field. The removal of settleable particles can also be accomplished by taking advantage of a changing acceleration field. A number of devices that take advantage of both gravitational and centrifugal forces and induced velocities have been developed for the removal of grit from wastewater. The principles involved are illustrated on Fig. 5–30. In appearance, the separator looks like a large diameter cylinder with a conical bottom. Wastewater, from which grit is to be separated, is introduced tangentially near the top and exits through the opening in the top of the unit. The liquid is removed at the top. Grit is removed through an opening in the bottom of the unit.

Because the top of the separator is enclosed, the rotating flow creates a free vortex within the separator. The most important characteristic of a free vortex is that the product of the tangential velocity times the radius is a constant:



$$Vr = \text{constant} \tag{5–44}$$

where V = tangential velocity, LT^{-1} (m/s)
r = radius, L (m)

The significance of Eq. (5–44) can be illustrated by the following example. Assume the tangential velocity in a separator with a 1.5 m (5 ft) radius is 0.9 m/s (3 ft/s). The product of the velocity times the radius at the outer edge of the separator is equal to 1.35 m^2/s (15 ft^2/s). If the discharge port has a radius of 0.9 m (1 ft), then the tangential velocity at the entrance to the discharge port is 4.5 m/s (15 ft/s). The centrifugal force experienced by a particle within this flow field is equal to the square of the velocity divided by the radius. Because the centrifugal force is also proportional to the inverse of the radius, a fivefold decrease in the radius results in a 125-fold increase in the centrifugal force.

Figure 5–30

Accelerated gravity separator: (*a*) outline sketch and (*b*) definition sketch. *(From Eutek.)*

Because of the high centrifugal forces near the discharge port, some of the particles, depending on their size, density, and drag, are retained within the body of the free vortex near the center of the separator, while other particles are swept out of the unit. Grit and sand particles will be retained while organic particles are discharged from the unit. Organic particles having the same settling velocity as sand will typically be from four to eight times as large. The corresponding drag forces for these organic particles will be from 16 to 64 times as great. As a result, the organic particles tend to move with the fluid and are transported out of the separator. The particles held in the free vortex ultimately settle to the bottom of the unit under the force of gravity. Organic particles that sometimes settle usually consist of oil and grease attached to grit or sand particles.

5–6 GRIT REMOVAL

Removal of grit from wastewater may be accomplished in grit chambers or by the centrifugal separation of solids. Grit chambers are designed to remove grit, consisting of sand, gravel, cinders, or other heavy solid materials that have subsiding velocities or specific gravities substantially greater than those of the organic putrescible solids in wastewater. Grit chambers are most commonly located after the bar screens and before the primary sedimentation tanks. Primary sedimentation tanks function for the removal of the heavy organic solids. In some installations, grit chambers precede the screening facilities. Generally, the installation of screening facilities ahead of the grit chambers makes the operation and maintenance of the grit removal facilities easier.

Locating grit chambers ahead of wastewater pumps, when it is desirable to do so, would normally involve placing them at considerable depth at added expense. It is therefore usually deemed more economical to pump the wastewater, including the grit,

to grit chambers located at a convenient position ahead of the treatment plant units, recognizing that the pumps may require greater maintenance.

Types of Grit Chambers

Grit chambers are provided to (1) protect moving mechanical equipment from abrasion and accompanying abnormal wear; (2) reduce formation of heavy deposits in pipelines, channels, and conduits; and (3) reduce the frequency of digester cleaning caused by excessive accumulations of grit. The removal of grit is essential ahead of centrifuges, heat exchangers, and high-pressure diaphragm pumps.

There are three general types of grit chambers: horizontal-flow, of either a rectangular or a square configuration; aerated; or vortex type. In the horizontal-flow type, the flow passes through the chamber in a horizontal direction and the straight-line velocity of flow is controlled by the dimensions of the unit, an influent distribution gate, and a weir at the effluent end. The aerated type consists of a spiral-flow aeration tank where the spiral velocity is induced and controlled by the tank dimensions and quantity of air supplied to the unit. The vortex type consists of a cylindrical tank in which the flow enters tangentially creating a vortex flow pattern; centrifugal and gravitational forces cause the grit to separate. Design of grit chambers is commonly based on the removal of grit particles having a specific gravity of 2.65 and a wastewater temperature of 15.5°C (60°F). However, analysis of grit-removal data indicates the specific gravity ranges from 1.3 to 2.7 (WPCF, 1985).

Horizontal-Flow Grit Chambers

Rectangular and square horizontal-flow grit chambers have been used for many years. Their use, however, in new installations has been limited in favor of aerated and vortex-type grit chambers. Representative design data for horizontal-flow grit chambers are presented in Table 5–16.

Table 5–16
Typical design information for horizontal-flow grit chambers

	U.S. customary units			SI units		
	Unit	Range	Typical	Unit	Range	Typical
Detention time	s	45–90	60	s	45–90	60
Horizontal velocity	ft/s	0.8–1.3	1.0	m/s	0.25–0.4	0.3
Settling velocity for removal of:						
0.21 mm (65-mesh) material	ft/min[a]	3.2–4.2	3.8	m/min[a]	1.0–1.3	1.15
0.15 mm (65-mesh) material	ft/min[a]	2.0–3.0	2.5	m/min[a]	0.6–0.9	0.75
Headloss in a control section as percent of depth in channel	%	30–40	36[b]	%	30–40	36[b]
Added length allowance for inlet and outlet turbulence	%	25–50	30	%	25–50	30

[a] If the specific gravity of the grit is significantly less than 2.65, lower velocities should be used.

[b] For Parshall flume control.

Rectangular Horizontal-Flow Grit Chambers. The oldest type of grit chamber used is the rectangular horizontal-flow, velocity-controlled type. These units were designed to maintain a velocity as close to 0.3 m/s (1.0 ft/s) as practical and to provide sufficient time for grit particles to settle to the bottom of the channel. The design velocity will carry most organic particles through the chamber and will tend to resuspend any organic particles that settle but will permit the heavier grit to settle out.

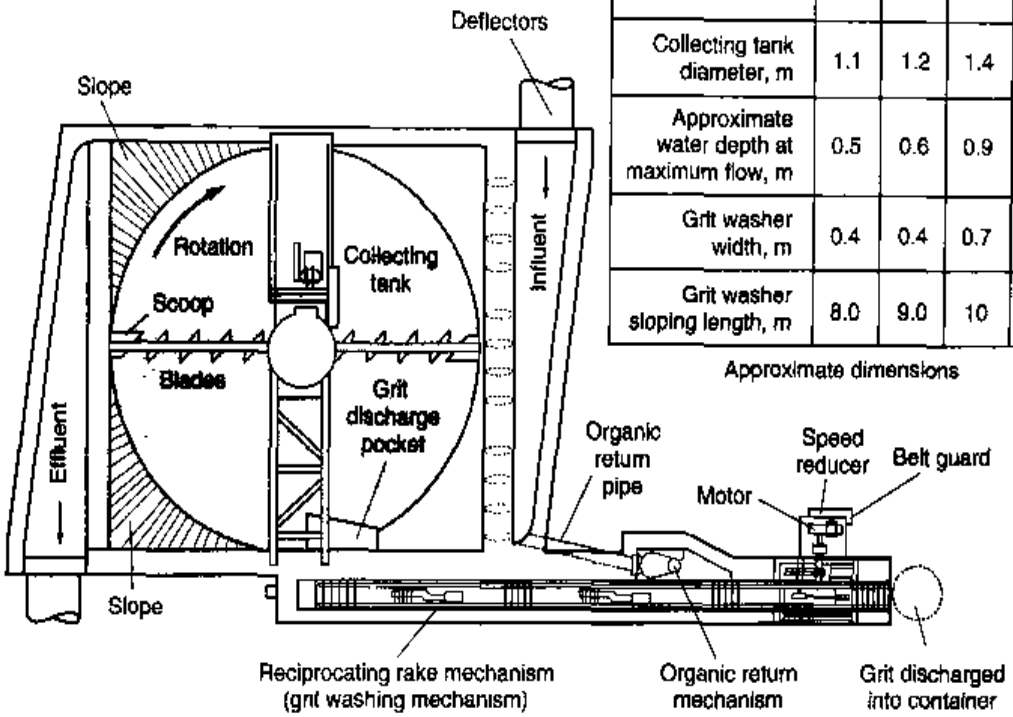
The basis of design of rectangular horizontal-flow grit chambers is that, under the most adverse conditions, the lightest particle of grit will reach the bed of the channel prior to its outlet end. Normally, grit chambers are designed to remove all grit particles that will be retained on a 0.21-mm-diameter (65-mesh) screen, although many chambers have been designed to remove grit particles retained on a 0.15-mm-diameter (100-mesh) screen. The length of channel will be governed by the depth required by the settling velocity and the control section, and the cross-sectional area will be governed by the rate of flow and by the number of channels. Allowance should be made for inlet and outlet turbulence.

Grit removal from horizontal-flow grit chambers is accomplished usually by a conveyor with scrapers, buckets, or plows. Screw conveyors or bucket elevators are used to elevate the removed grit for washing or disposal. In small plants, grit chambers are sometimes cleaned manually.

Square Horizontal-Flow Grit Chambers. Square horizontal-flow grit chambers, such as those shown on Fig. 5–31, have been in use for over 60 years. Influent to the units is distributed over the cross section of the tank by a series of vanes or gates, and the distributed wastewater flows in straight lines across the tank and overflows a weir in a free discharge. Where square grit chambers are used, it is generally advisable to use at least two units. These types of grit chambers are designed on the basis of overflow rates that are dependent on particle size and the temperature of the wastewater. They are nominally designed to remove 95 percent of the 0.15-mm-diameter (100-mesh) particles at peak flow. A typical set of design curves is shown on Fig. 5–32.

In square grit chambers, the solids are removed by a rotating raking mechanism to a sump at the side of the tank. Settled grit may be moved up an incline by a reciprocating rake mechanism (see Fig. 5–31) or grit may be pumped from the tank through a cyclone degritter to separate the remaining organic material and concentrate grit. The concentrated grit then may be washed again in a classifier using a submerged reciprocating rake or an inclined-screw conveyor. By either method, organic solids are separated from the grit and flow back into the basin, resulting in a cleaner, dryer grit.

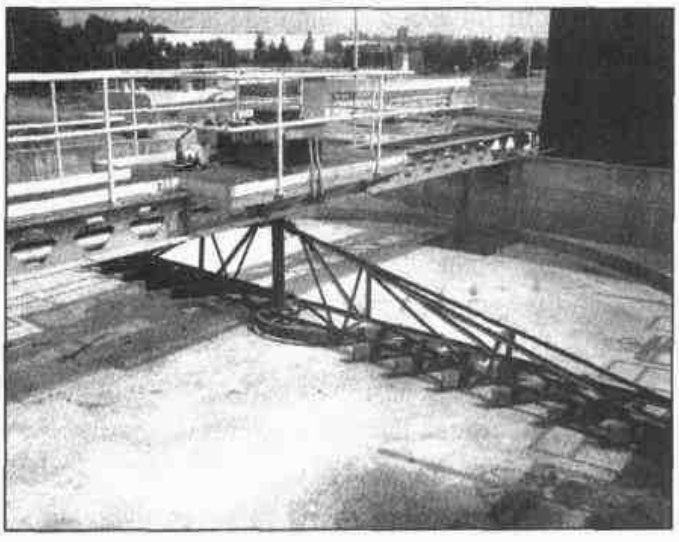
Aerated Grit Chambers



In aerated grit chambers, air is introduced along one side of a rectangular tank to create a spiral flow pattern perpendicular to the flow through the tank. The heavier grit particles that have higher settling velocities settle to the bottom of the tank. Lighter, principally organic, particles remain in suspension and pass through the tank. The velocity of roll or agitation governs the size of particles of a given specific gravity that will be removed. If the velocity is too great, grit will be carried out of the chamber; if it is too small, organic material will be removed with the grit. Fortunately, the quantity of air is easily adjusted. With proper adjustment, almost 100 percent removal will be obtained,

Figure 5–31

Typical square horizontal-flow grit chamber: (*a*) schematic, and (*b*) photo of empty basin. The two rakes are used to move settled grit to the periphery for removal.



Collecting tank diameter, m	3.0	6.0	9.0	12.0

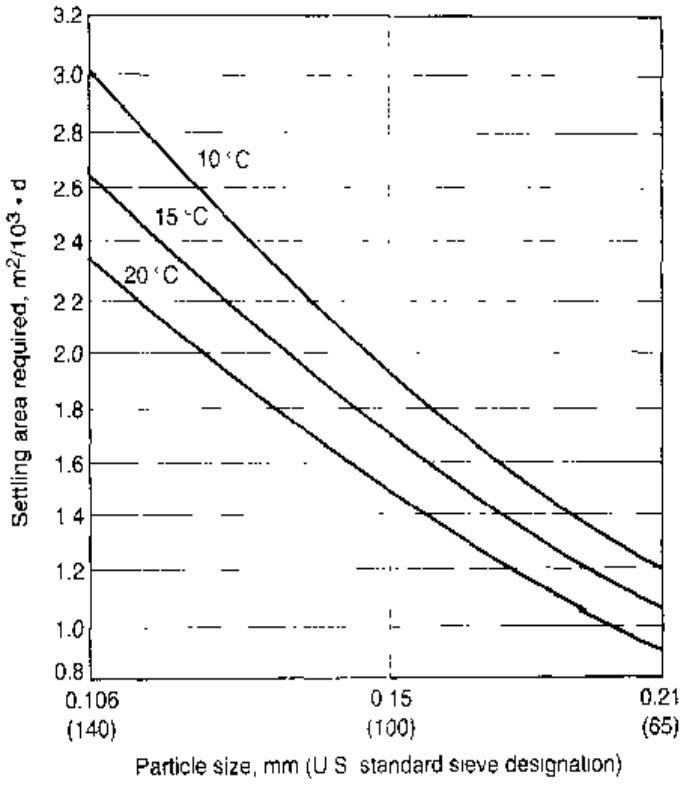
(a)



(b)

and the grit will be well washed. (Grit that is not well washed and contains organic matter is an odor nuisance and attracts insects.)

Aerated grit chambers are nominally designed to remove 0.21-mm-diameter (65-mesh) or larger, with 2- to 5-minute detention periods at the peak hourly rate of flow. The cross section of the tank is similar to that provided for spiral circulation in activated-sludge aeration tanks, except that a grit hopper about 0.9 m (3 ft) deep with steeply

Figure 5–32

Area required for settling grit particles with a specific gravity of 2.65 in wastewater at indicated temperatures.

sloping sides is located along one side of the tank under the air diffusers (see Fig. 5–33). The air diffusers are located about 0.45 to 0.6 m (1.5 to 2 ft) above the normal plane of the bottom. Influent and effluent baffles are used frequently for hydraulic control and improved grit-removal effectiveness. Basic design data for aerated grit chambers are presented in Table 5–17. The design of aerated grit chambers is illustrated in Example 5–9.

Wastewater will move through the tank in a spiral path (see Fig. 5–34) and will make two to three passes across the bottom of the tank at maximum flow and more passes at lesser flows. Wastewater should be introduced in the direction of the roll. To determine the required headloss through the chamber, the expansion in volume caused by the air must be considered.

For grit removal, aerated grit chambers are often provided with grab buckets traveling on monorails and centered over the grit collection and storage trough (see Fig. 5–35). An added advantage of a grab bucket grit-removal system is that dropping the grit from the bucket through the tank contents can further wash grit. Other installations are equipped with chain-and-bucket conveyors, running the full length of the storage troughs, which move the grit to one end of the trough and elevate it above the wastewater level in a continuous operation. Screw conveyors, tubular conveyors, jet pumps, and airlifts have also been used. Grit-removal equipment for aerated grit chambers is subject to the same wear as experienced in the horizontal-flow units. For large installations, traveling-bridge grit collectors, as shown on Fig. 5–36, can be used. Grit pumps are immersed in the grit chambers and travel the entire length, pumping grit into a stationary grit trough collection system. The pumps can operate continuously or they can be programmed to run on cycles based on time or flow.

Figure 5–33
Typical section through an aerated grit chamber.

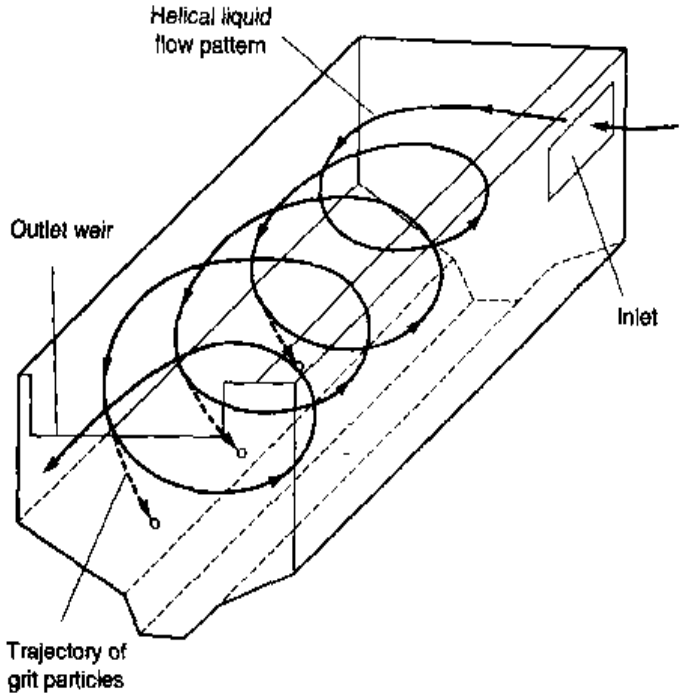
In areas where industrial wastewater is discharged to the collection system, the release of volatile organic compounds (VOCs) by the air agitation in aerated grit chambers needs to be considered. The release of significant amounts of VOCs can be a health risk to the treatment plant operators. Where release of VOCs is an important consideration, covers may be required or nonaerated-type grit chambers used.

Figure 5–34

Helical flow pattern in an aerated grit chamber.



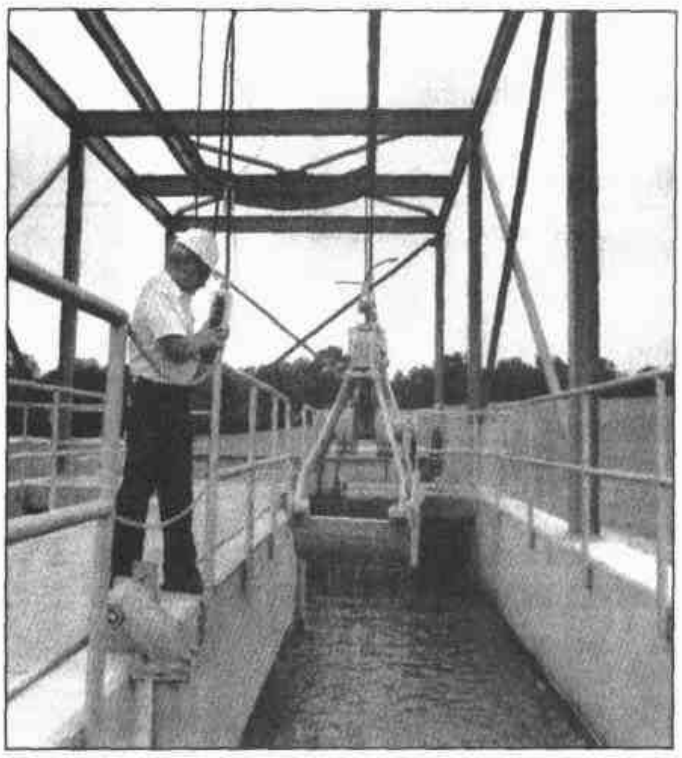


Figure 5–35

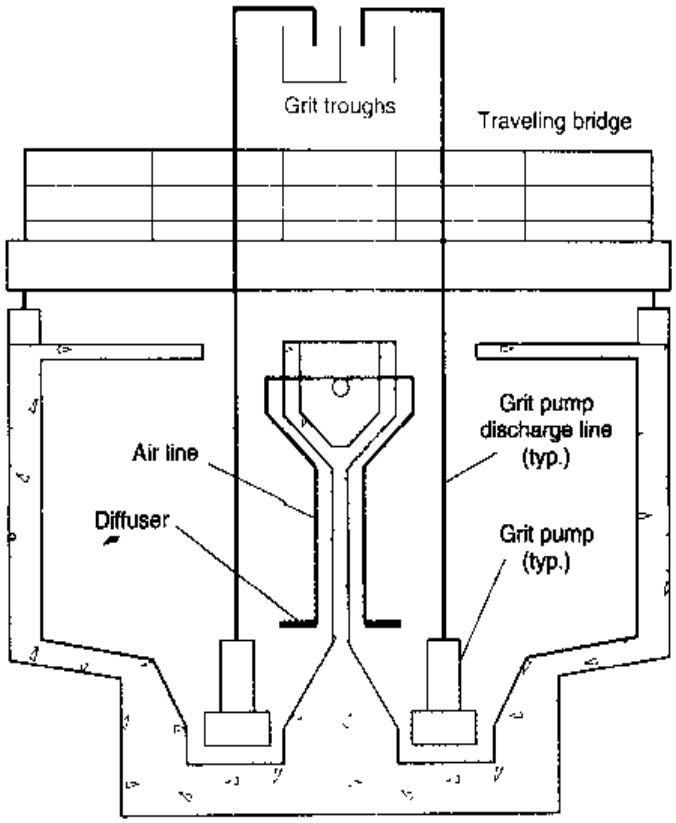


Grab bucket used to remove grit from aerated grit chamber.

EXAMPLE 5–9 Design of Aerated Grit Chamber Design an aerated grit chamber for the treatment of municipal wastewater. The average flowrate is 0.5 m^3/s, and the peaking factor curve given on Fig. 3–13 is applicable.

Figure 5–36

Aerated grit chamber with traveling-bridge-type grit removal system Pumps are mounted on the traveling bridge for removal of grit from the grit hopper. The diffusers create the helical flow pattern as shown in Fig. 5–34.

Solution:

1. Establish the peak flowrate for design. Assume that the aerated grit chamber will be designed for the 1-day sustained peak flowrate. From Fig. 3–11, the peaking factor is found to be 2.75, and the peak design flowrate is

   Peak flowrate = 0.5 $m^3/s \times 2.75 = 1.38\ m^3/s$

2. Determine the grit chamber volume. Because it will be necessary to drain the chamber periodically for routine maintenance, use two chambers. Assume the average detention time at the peak flowrate is 3 min.

   Grit chamber volume, m^3 (each) = (1/2)(1.38 m^3/s) × 3 min × 60 s/min

   $= 124.2\ m^3$

3. Determine the dimensions of each grit chamber. Use a width-to-depth ratio of 1.2:1 and assume that the depth is 3 m.

   a. Width = 1.2 (3 m) = 3.6 m

   b. $$\text{Length} = \frac{\text{volume}}{\text{width} \times \text{depth}} = \frac{124.2\ m^3}{3\ m \times 3.6\ m} = 11.5\ m$$

4. Determine the detention time in each grit chamber at average flow.

   $$\text{Detention time} = \frac{124.2\ m^3}{(0.25\ m^3/s)} = 496.8\ s \left(\frac{1\ min}{60\ s}\right) = 8.28\ min$$

5. Determine the air supply requirement. Assume that 0.3 m^3/min·m of length will be adequate.

   Air required (length basis) = 11.5 m × 0.3 m^3/min·m
   = 3.45 m^3/min for each grit chamber

   Total air supply required = 3.45 × 2 = 6.9 m^3/min

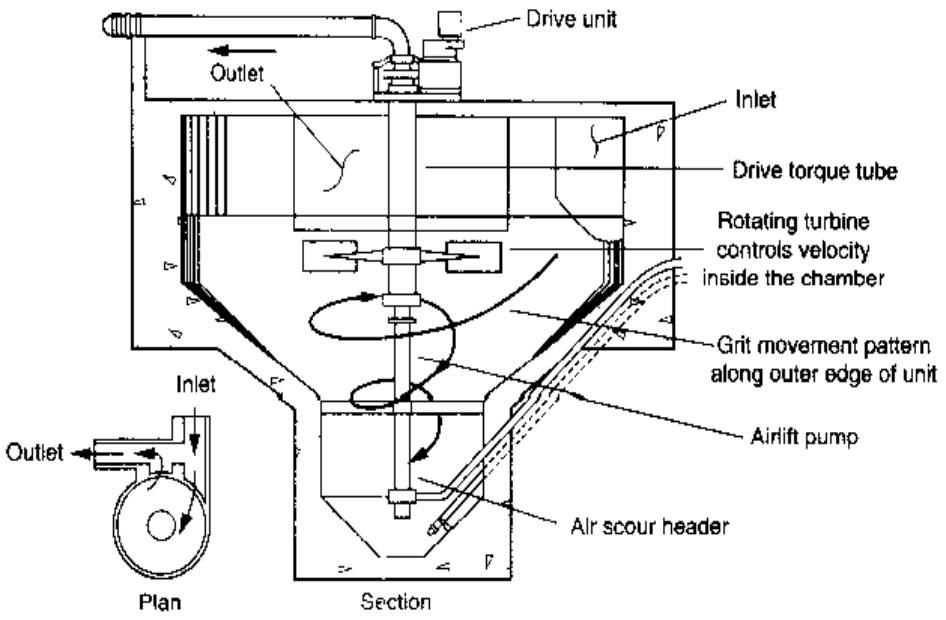
6. Estimate the quantity of grit at peak flow. Assume a value of 0.05 $m^3/10^3$ m^3 at peak flow.

   Volume grit = [(1.38 m^3/s)(86,400 s/d)(0.05 $m^3/10^3$ m^3)]
   = 5.96 m^3/d

Comment In designing aerated grit chambers, methods of regulating the air flow rate should be provided to control grit-removal rates and improve the cleanliness of the grit.

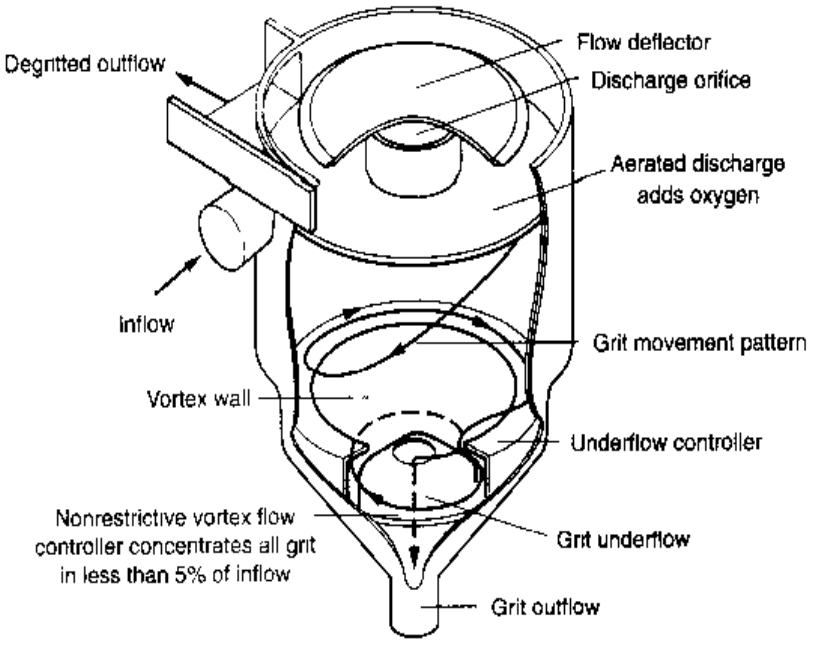
Vortex-Type Grit Chambers

Grit is also removed in devices that use a vortex flow pattern. Two types of devices are shown on Fig. 5–37. In one type, illustrated on Fig. 5–37*a*, wastewater enters and exits tangentially. The rotating turbine maintains constant flow velocity, and its adjustable-pitch blades promote separation of organics from the grit. The action of the propeller produces a toroidal flow path for grit particles. The grit settles by gravity into the hopper in one revolution of the basin's contents. Solids are removed from the hopper by a grit pump or an airlift pump. Grit removed by a grit pump can be discharged to a hydroclone for removal of the remaining organic material. Grit removed by an airlift may be dewatered on a wedgewire screen (see Screening, Sec. 5–1, for description). Typical design data are presented in Table 5–18. If more than two units are installed, special arrangements for flow splitting are required.



In the second type, illustrated on Fig. 5–37*b*, a vortex is generated by the flow entering tangentially at the top of the unit. Effluent exits the center of the top of the unit from a rotating cylinder, or "eye" of the fluid. Centrifugal and gravitational forces within this cylinder minimize the release of particles with densities greater than water. Grit settles by gravity to the bottom of the unit, while organics, including those separated from grit particles by centrifugal forces, exit principally with the effluent. Organics remaining with the settled grit are separated as the grit particles move along the unit floor. Headloss in the unit is a function of the size particle to be removed and increases significantly for very fine particles. Vortex grit-removal units are sized to handle peak flowrates up to 0.3 m^3/s (7 Mgal/d) per unit. Grit is removed from the unit by a cleated belt conveyor. Because of its overall height, this type of grit system requires a deep basement, or a lift station if it is installed above grade.

Solids (Sludge) Degritting



Where grit chambers are not used and the grit is allowed to settle in the primary settling tanks, grit removal is accomplished by pumping dilute quantities of primary

Figure 5-37

Vortex-type grit chambers: (a) Pista *(Courtesy Smith & Loveless)* and (b) Teacup. *(Courtesy Eutek.)*

(a)

(b)

sludge to a cyclone degritter. The cyclone degritter acts as a centrifugal separator in which the heavy particles of grit and solids are separated by the action of a vortex and discharged separately from the lighter particles and the bulk of the liquid. The principal advantage of cyclone degritting is the elimination of the cost of building, operating, and maintaining grit chambers. The disadvantages are (1) pumping of dilute quantities of solids usually requires solids thickeners, and (2) pumping of grit with the liquid primary solids increases the cost of operating and maintaining solids collectors and the primary sludge pumps.

Table 5-18
Typical design information for vortex-type grit chambers

Item	U.S. customary units			SI units

Grit Characteristics, Quantities, Processing, and Disposal

Grit consists of sand, gravel, cinders, or other heavy materials that have specific gravities or settling velocities considerably greater than those of organic particles. In addition to these materials, grit includes eggshells, bone chips, seeds, coffee grounds, and large organic particles. The characteristics, quantities, processing, and disposal of grit are discussed below.

Characteristics of Grit. Generally, what is removed as grit is predominantly inert and relatively dry material. However, grit composition can be highly variable, with moisture content ranging from 13 to 65 percent, and volatile content from 1 to 56 percent. The specific gravity of clean grit particles reaches 2.7 for inerts but can be as low as 1.3 when substantial organic material is agglomerated with inerts. A bulk density of 1600 kg/m^3 (100 lb/ft^3) is commonly used for grit. Often, enough organics are present in the grit so that it quickly putrefies if not properly handled after removal from the wastewater. Grit particles 0.2 mm and larger have been cited as the cause of most downstream problems.

The actual size distribution of retained grit exhibits variation due to differences in collection system characteristics, as well as variations in grit-removal efficiency. Generally, most grit particles are retained on a 0.15-mm (100-mesh) sieve, reaching nearly 100 percent retention in some instances; however, grit can be much finer. In the southeastern United States, where fine sand known as "sugar sand" constitutes a portion of the grit, less than 60 percent of the grit was retained on a 0.15-mm (100-mesh) screen in some cases.

The character of grit normally collected in grit chambers and from cyclone degritters varies widely from what might be normally considered as clean grit, to grit that includes a large proportion of putrescible organic material. Unwashed grit may contain

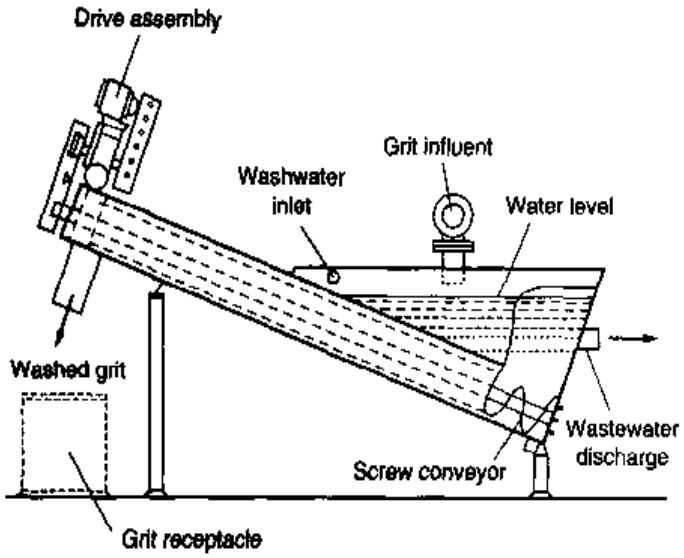
Table 5–19
Comparison of quantities of grit removed from wastewater from separate and combined collection systems[a]

Type of system	Ratio of maximum day to average day	Average grit quantity	
		ft³/Mgal	m³/1000 m³
Separate	1.5 to 3:1	0.53–5	0.004–0.037
Combined	3 to 15:1	0.53–24	0.004–0.18

[a]WEF (1998b).

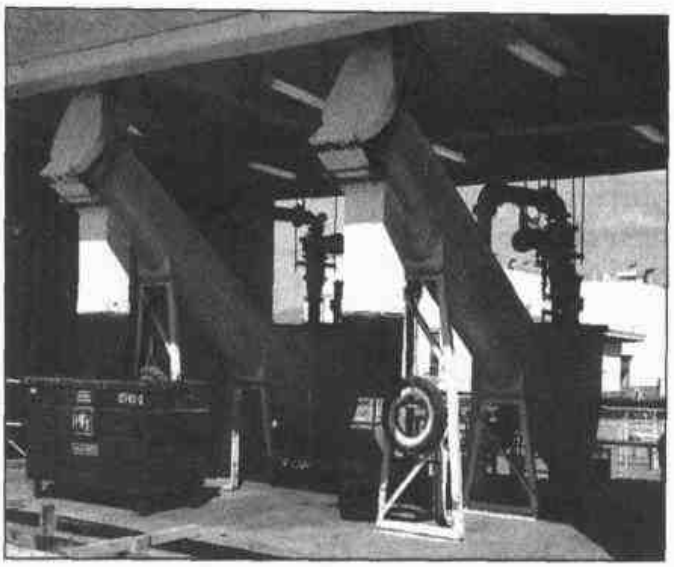
50 percent or more of organic material, has a distinctly disagreeable odor, and, unless promptly disposed of, may attract insects and rodents.

Quantities of Grit. The quantities of grit will vary greatly from one location to another, depending on the type of sewer system, the characteristics of the drainage area, the condition of the sewers, the frequency of street sanding to counteract icing conditions, the types of industrial wastes, the number of household garbage grinders served, and in areas with sandy soils. Typical values for aerated grit chambers are reported in Table 5–17. A comparison of the quantities of grit removed from separate and combined sewer systems is shown in Table 5–19.



It is difficult to interpret grit-removal data because grit itself is poorly characterized and almost no data exist on relative removal efficiencies. The information on grit characteristics derives from what has been removed as grit. Sieve analyses are not normally performed on grit chamber influents and effluents. For these reasons, the efficiencies of grit-removal systems cannot be compared.

Grit Separation and Washing. Grit separators and grit washers may accomplish removal of a major part of the organic material contained in grit. When some of the heavier organic matter remains with the grit, grit washers are commonly used to provide a second stage of volatile solids separation. Examples of grit separation and washing units are shown on Fig. 5–38.



Two principal types of grit washers are available. One type relies on an inclined submerged rake that provides the necessary agitation for separation of the grit from the organic materials and, at the same time, raises the washed grit to a point of discharge above water level (similar to the inclined ramp shown on Fig. 5–31). Another type of grit washer (see Fig. 5–38) uses an inclined screw and moves the grit up the ramp. Both types can be equipped with water sprays to assist in the cleansing action. Hydroclone separators are often installed at the inlet to the grit washer to improve grit separation and organics removal.

Disposal of Grit. The most common method of grit disposal is transport to a landfill. In some large plants, grit is incinerated with solids. As with screenings, some states require grit to be lime stabilized before disposal in a landfill. Disposal in all cases should be done in conformance with the appropriate environmental regulations.

In larger plants where trucks are used to transfer grit, elevated grit storage facilities may be provided with bottom-loading gates. Difficulties experienced in getting the grit to flow freely from the storage hoppers have been minimized by using steep slopes on

(a)

(b)

Figure 5-38

Example of grit separation and washing unit: (a) schematic and (b) view of typical installation.

the storage hoppers, by applying air beneath the grit, and by the use of hopper vibrators. Drainage facilities for collection and disposal of drippings from the bottom-loading gates are desirable. Grab buckets operating on a monorail system may also be used to load trucks directly from the grit chambers.

Pneumatic conveyors are sometimes used to convey grit short distances. Advantages of pneumatic conveying include (1) no elevated storage hoppers are required, and (2) attendant odor problems associated with storage are eliminated. The principal disadvantage is the considerable wear on piping, especially at bends.

5–7 PRIMARY SEDIMENTATION

The objective of treatment by sedimentation is to remove readily settleable solids and floating material and thus reduce the suspended solids content. Primary sedimentation is used as a preliminary step in the further processing of the wastewater. Efficiently designed and operated primary sedimentation tanks should remove from 50 to 70 percent of the suspended solids and from 25 to 40 percent of the BOD.

Sedimentation tanks have also been used as stormwater retention tanks, which are designed to provide a moderate detention period (10 to 30 min) for overflows from either combined sewers or storm sewers. The purpose of sedimentation is to remove a substantial portion of the organic solids that otherwise would be discharged directly to the receiving waters. Sedimentation tanks have also been used to provide detention periods sufficient for effective disinfection of such overflows.

The purpose of this section is to describe the various types of sedimentation facilities, to consider their performance, and to review important design considerations. Sedimentation tanks used for secondary treatment are considered in Chap. 8.

Description

Almost all treatment plants use mechanically cleaned sedimentation tanks of standardized circular or rectangular design (see Fig. 5–39). The selection of the type of sedimentation unit for a given application is governed by the size of the installation, by rules and regulations of local control authorities, by local site conditions, and by the experience and judgment of the engineer. Two or more tanks should be provided so that the process may remain in operation while one tank is out of service for maintenance and repair work. At large plants, the number of tanks is determined largely by size limitations. Typical design information and dimensions for rectangular and circular sedimentation tanks used for primary treatment are presented in Tables 5–20 and 5–21.

Rectangular Tanks. Rectangular sedimentation tanks may use either chain-and-flight solids collectors or traveling-bridge-type collectors. A rectangular tank that uses a chain-and-flight-type collector is shown on Fig. 5–40. Equipment for settled solids removal generally consists of a pair of endless conveyor chains, manufactured of alloy steel, cast iron, or thermoplastic. Attached to the chains at approximately 3-m (10-ft) intervals are scraper flights made of wood or fiberglass, extending the full width of the tank or bay. The solids settling in the tank are scraped to solids hoppers in small tanks and to transverse troughs in large tanks. The transverse troughs are equipped with collecting mechanisms (cross collectors), usually either chain-and-flight or screw-type collectors, which convey solids to one or more collection hoppers. In very long units (over 50 m), two collection mechanisms can be used to scrape solids to collection points near the middle of the tank length. Where possible, it is desirable to locate solids pumping facilities close to the collection hoppers.

Rectangular tanks may also be cleaned by a bridge-type mechanism that travels up and down the tank on rubber wheels or on rails supported on the sidewalls. One or more scraper blades are suspended from the bridge. Some of the bridge mechanisms are designed so that the scraper blades can be lifted clear of the solids blanket on the return travel.

[a]If widths of rectangular mechanically cleaned tanks are greater than 6 m (20 ft), multiple bays with individual cleaning equipment may be used, thus permitting tank widths up to 24 m (80 ft) or more.

Figure 5–40

Typical rectangular primary sedimentation tank: (*a*) plan and (*b*) section.

Where cross collectors are not provided, multiple solids hoppers must be installed. Solids hoppers have operating difficulties, notably solids accumulation on the slopes and in the corners and arching over the solids drawoff piping. Wastewater may also be drawn through the solids hopper, bypassing some of the accumulated solids, resulting in a "rathole" effect. A cross collector is more advisable, except possibly in small plants, because a more uniform and concentrated solids can be withdrawn and many of the problems associated with solids hoppers can be eliminated.

Because flow distribution in rectangular tanks is critical, one of the following inlet designs is used: (1) full-width inlet channels with inlet weirs, (2) inlet channels with submerged ports or orifices, (3) or inlet channels with wide gates and slotted baffles. Inlet weirs, while effective in spreading flow across the tank width, introduce a vertical

velocity component into the solids hopper that may resuspend the solids particles. Inlet ports can provide good distribution across the tank width if the velocities are maintained in the 3 to 9 m/min (10 to 30 ft/min) range. Inlet baffles are effective in reducing the high initial velocities and distribute flow over the widest possible cross-sectional area. Where full-width baffles are used, they should extend from 150 mm (6 in) below the surface to 300 mm (12 in) below the entrance opening.

For installations of multiple rectangular tanks, below-grade pipe and equipment galleries can be constructed integrally with the tank structure and along the influent end. The galleries are used to house the sludge pumps and sludge drawoff piping. The galleries also provide access to the equipment for operation and maintenance. Galleries can also be connected to service tunnels for access to other plant units.

Scum is usually collected at the effluent end of rectangular tanks with the flights returning at the liquid surface. The scum is moved by the flights to a point where it is trapped by baffles before removal. Water sprays can also move the scum. The scum can be scraped manually up an inclined apron, or it can be removed hydraulically or mechanically, and for scum removal a number of means have been developed. For small installations, the most common scum drawoff facility consists of a horizontal, slotted pipe that can be rotated by a lever or a screw. Except when drawing scum, the open slot is above the normal tank water level. When drawing scum, the pipe is rotated so that the open slot is submerged just below the water level, permitting the scum accumulation to flow into the pipe. Use of this equipment results in a relatively large volume of scum liquor.

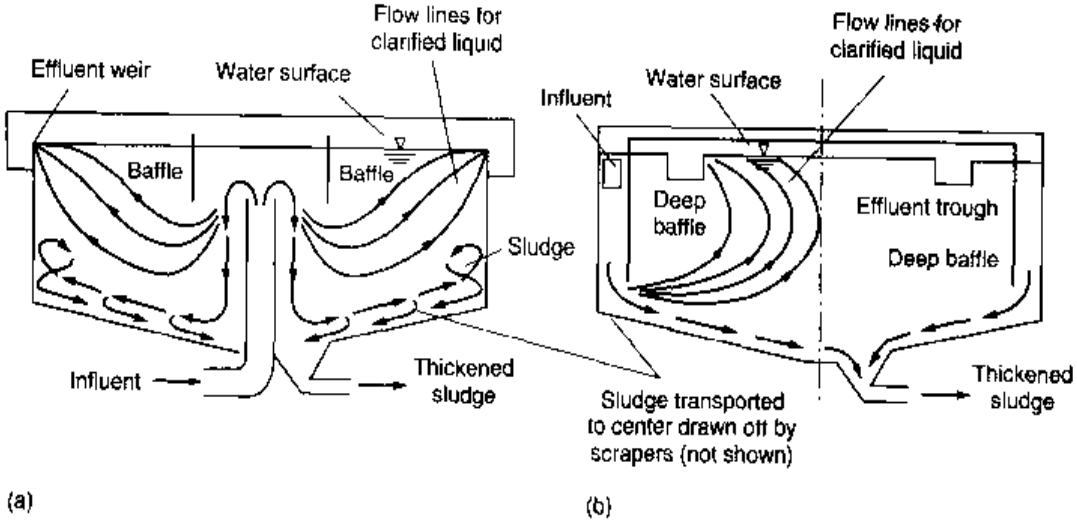
Another method for removing scum is by a transverse rotating helical wiper attached to a shaft. Scum is removed from the water surface and moved over a short inclined apron for discharge to a cross-collecting scum trough. The scum may then be flushed to a scum ejector or hopper ahead of a scum pump. Another method of scum removal consists of a chain-and-flight type of collector that collects the scum at one side of the tank and scrapes it up a short incline for deposit in scum hoppers, whence it can be pumped to disposal units. Scum is also collected by special scum rakes in rectangular tanks that are equipped with the carriage or bridge type of sedimentation tank equipment. In installations where appreciable amounts of scum are collected, the scum hoppers are usually equipped with mixers to provide a homogeneous mixture prior to pumping. Scum is usually disposed of with the solids and biosolids produced at the plant; however, separate scum disposal is used at many plants.

Multiple rectangular tanks require less land area than multiple circular tanks and find application where site space is at a premium. Rectangular tanks also lend themselves to nesting with preaeration tanks and aeration tanks in activated-sludge plants, thus permitting common wall construction and reducing construction costs. They are also used generally where tank roofs or covers are required.

Circular Tanks. In circular tanks the flow pattern is radial (as opposed to horizontal in rectangular tanks). To achieve a radial flow pattern, the wastewater to be settled can be introduced in the center or around the periphery of the tank, as shown on Fig. 5–41. Both flow configurations have proved to be satisfactory generally, although the center-feed type is more commonly used, especially for primary treatment. In the center-feed design (see Fig. 5–41*a*), the wastewater is transported to the center of the tank in a pipe suspended from the bridge, or encased in concrete beneath the tank floor.

Figure 5–41

Typical circular primary sedimentation tanks: (*a*) center feed and (*b*) peripheral feed. (*Crites and Tchobanoglous, 1998.*)



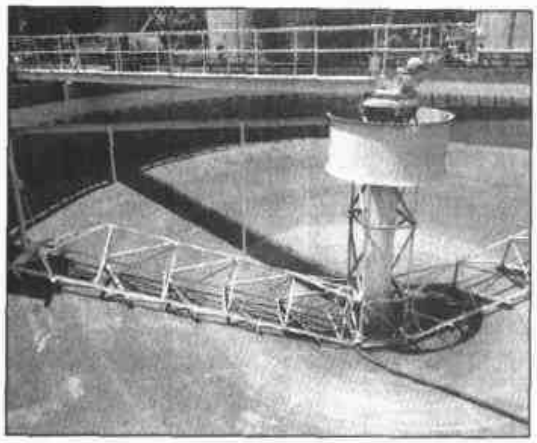


Figure 5–42

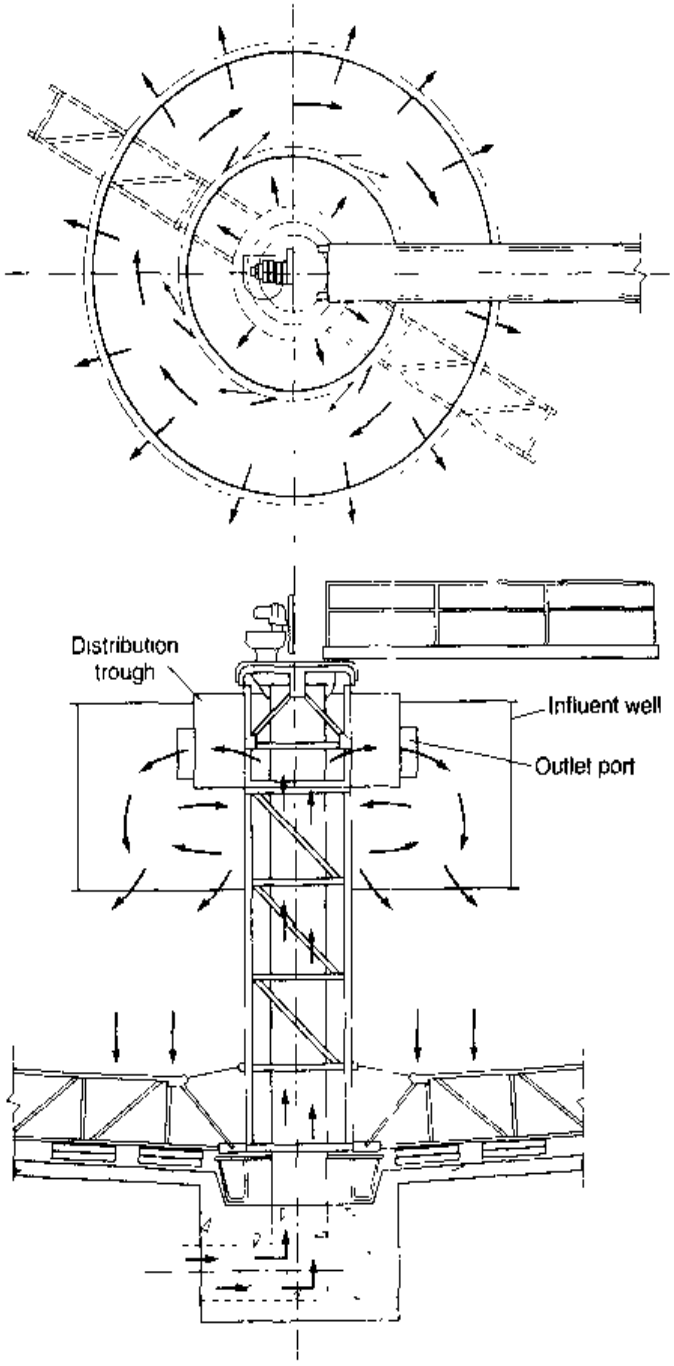
Typical circular primary sedimentation tank.

At the center of the tank, the wastewater enters a circular well designed to distribute the flow equally in all directions (see Fig. 5–42). The center well has a diameter typically between 15 and 20 percent of the total tank diameter and ranges from 1 to 2.5 m (3 to 8 ft) in depth and should have a tangential energy-dissipating inlet within the feedwell.

The energy-dissipating device (see Fig. 5–43) functions to collect influent from the center column and discharge it tangentially into the upper 0.5 to 0.7 m of the feedwell. The discharge ports are sized to produce a velocity of ≤ 0.75 m/s at maximum flow and 0.30 to 0.45 m/s at average flow. The feedwell should be sized so that the maximum downward velocity does not exceed 0.75 m/s. The depth of the feedwell should extend about 1 meter below the energy-dissipating inlet ports (Randall et al., 1992).

In the peripheral-feed design (see Fig. 5–41*b*), a suspended circular baffle forms an annular space into which the inlet wastewater is discharged in a tangential direction. The wastewater flows spirally around the tank and underneath the baffle, and the clarified liquid is skimmed off over weirs on both sides of a centrally located weir trough. Grease and scum are confined to the surface of the annular space. Peripheral feed tanks are used generally for secondary clarification.

Circular tanks 3.6 to 9 m (12 to 30 ft) in diameter have the solids-removal equipment supported on beams spanning the tank. Tanks 10.5 m (35 ft) in diameter and larger have a central pier that supports the mechanism and is reached by a walkway or bridge.



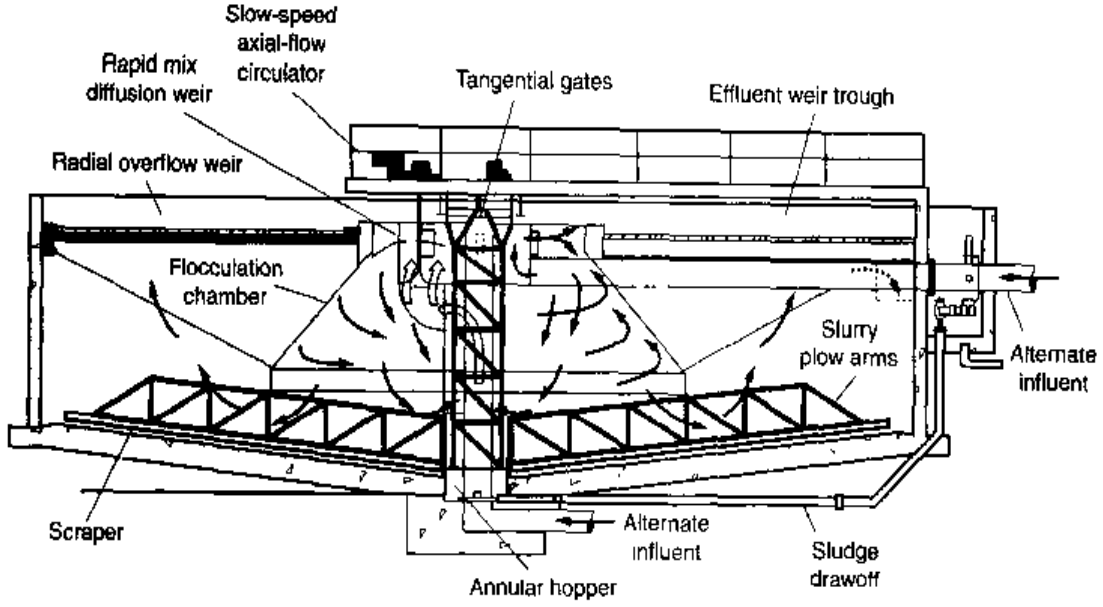


Figure 5-43
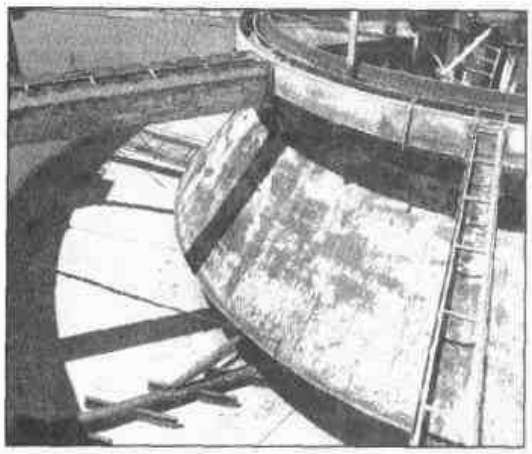
Typical energy-dissipating and flow distribution inlet for a center-feed sedimentation tank. The inner ring is used to create a tangential flow pattern. *(Randall, et al., 1992.)*



The bottom of the tank is sloped at about 1 in 12 (vertical:horizontal) to form an inverted cone, and the solids are scraped to a relatively small hopper located near the center of the tank.

Multiple tanks are customarily arranged in groups of two or four. The flow is divided among the tanks by a flow-split structure, commonly located between the tanks. Solids are usually withdrawn by sludge pumps for discharge to the solids processing and disposal units.

Combination Flocculator-Clarifier. Combination flocculator-clarifiers are often used in water treatment and sometimes used for wastewater treatment, especially in cases where enhanced settling, such as for industrial wastewater treatment or for

(a)

(b)

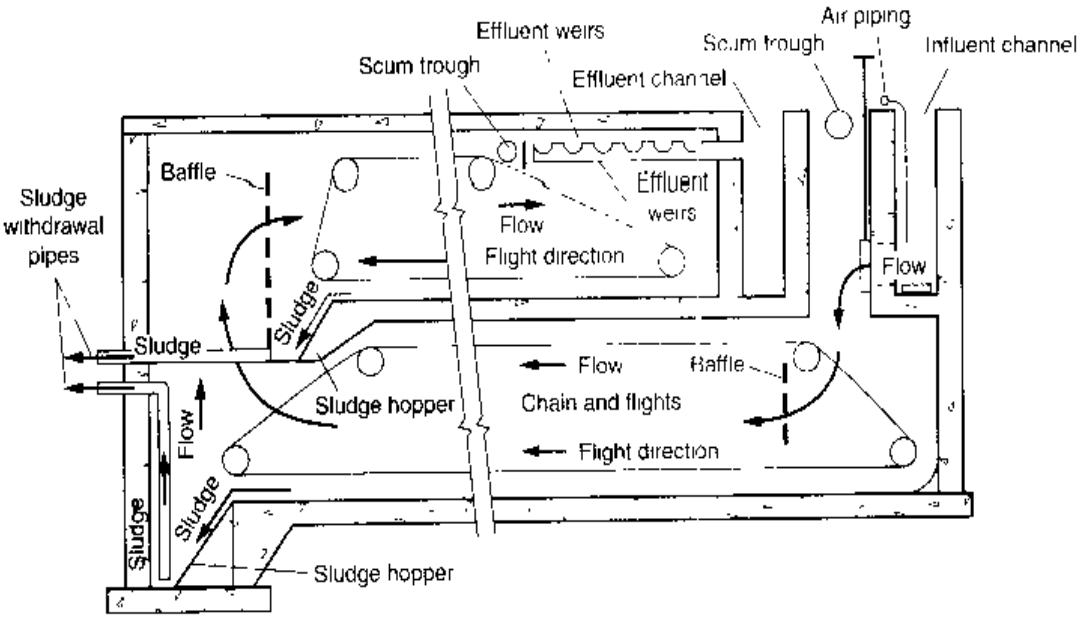


Figure 5–44

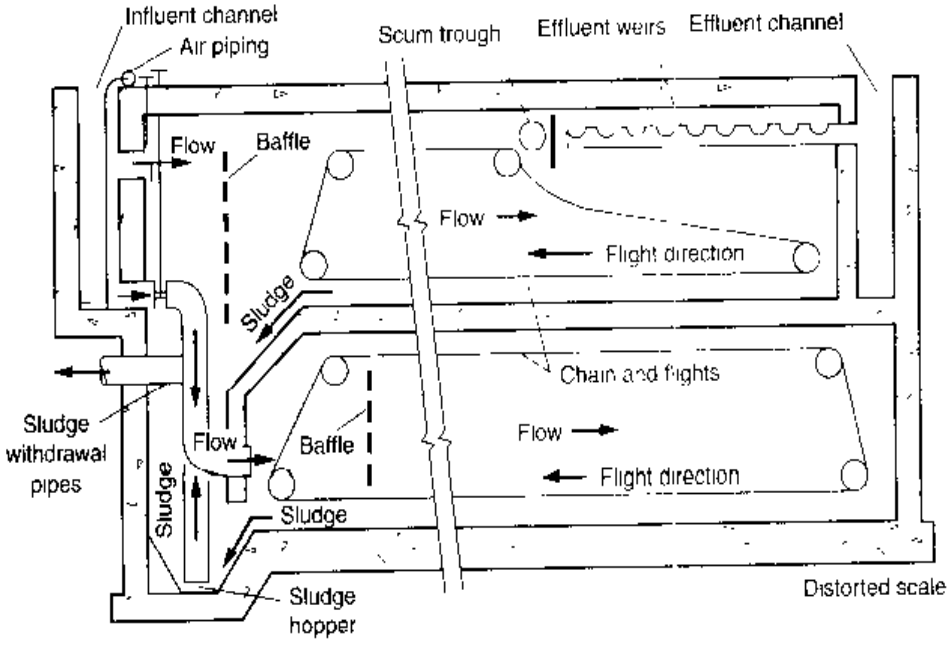
Typical flocculator-clarifier: (a) schematic and (b) view of empty tank. In some designs, turbine or propeller mixers are included in the flocculation chamber.



biosolids concentration, is required. Inorganic chemicals or polymers can be added to improve flocculation. Circular clarifiers are ideally suited for incorporation of an inner, cylindrical flocculation compartment (see Fig. 5–44). Wastewater enters through a center shaft or well and flows into the flocculation compartment, which is generally equipped with a paddle-type or low-speed mixer. The gentle stirring causes flocculent particles to form. From the flocculation compartment, flow then enters the clarification zone by passing down and radially outward. Settled solids and scum are collected in the same way as in a conventional clarifier.

Stacked (Multilevel) Clarifiers. Stacked clarifiers originated in Japan in the 1960s where limited land area is available for the construction of wastewater-treatment facilities. Since that time, stacked clarifiers have been used in the United States, the most notable installation of which is at the Deer Island Wastewater Treatment Plant constructed in Boston harbor. Design of these types of clarifiers recognizes the importance of settling area to settling efficiency. Operation of stacked rectangular clarifiers is similar to conventional rectangular clarifiers in terms of influent and effluent flow patterns and solids collection and removal. The stacked clarifiers are actually two (or

more) tanks, one located above the other, operating on a common water surface (see Fig. 5–45). Each clarifier is fed independently, resulting in parallel flow through the lower and upper tanks. Settled solids are collected from each tank with chain and flight solids collectors, discharging to a common hopper. In addition to saving space, advantages claimed for stacked clarifiers include less piping and pumping requirements.

(a)

(b)

Figure 5–45

Typical section through a stacked clarifier: (a) series flow and (b) parallel flow type used at the Deer Island Wastewater Treatment Plant, Boston, MA. Note: In the parallel flow type, the upper effluent weirs serve both the upper and lower clarifiers. Channels for the discharge of effluent from the lower to the upper clarifier are located on either side of the sludge collection mechanism in the upper clarifier.

Because the facilities are more compact and have less exposed surface area, better control of odors and volatile organic compound emissions is possible. Disadvantages include higher construction cost than conventional clarifiers and more complex structural design. Design criteria for stacked clarifiers, as regards overflow and weir rates, are similar to conventional primary and secondary clarifiers.

Sedimentation Tank Performance

The efficiency of sedimentation basins with respect to the removal of BOD and TSS is reduced by (1) eddy currents formed by the inertia of the incoming fluid, (2) wind-induced circulation cells formed in uncovered tanks, (3) thermal convection currents, (4) cold or warm water causing the formation of density currents that move along the bottom of the basin and warm water rising and flowing across the top of the tank, and (5) thermal stratification in hot arid climates (Fair and Geyer, 1954). Factors that affect performance are considered in the following discussion.

BOD and TSS Removal. Typical performance data for the removal of BOD and TSS in primary sedimentation tanks, as a function of the detention time and constituent concentration, are presented on Fig. 5–46. The curves shown on Fig. 5–46 are derived from observations of the performance of actual sedimentation tanks. The curvilinear relationships in the figure can be modeled as rectangular hyperbolas using the following relationship (Crites and Tchobanoglous, 1998).

$$R = \frac{t}{a + bt} \tag{5-45}$$

where R = expected removal efficiency
t = nominal detention time T
a, b = empirical constants

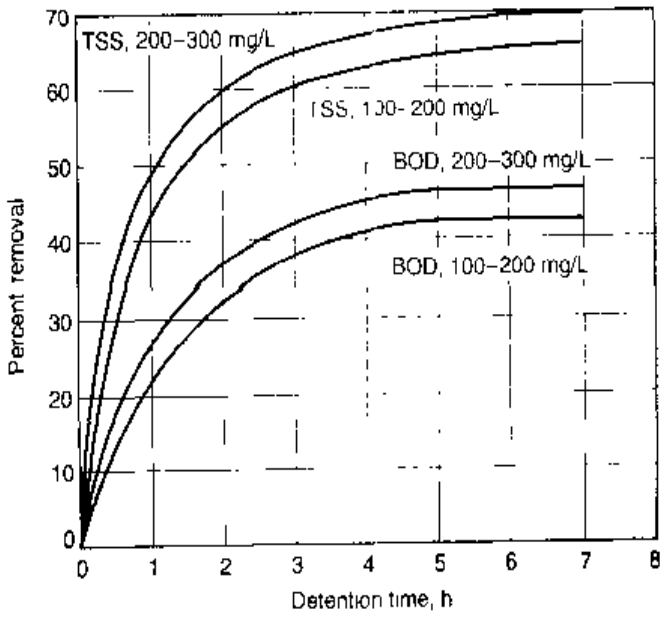


Figure 5–46
Typical BOD and TSS removal in primary sedimentation tanks. *(Greeley, 1938.)*

Typical values for the empirical constants in Eq. (5–45) at 20°C are as follows:

Item	a	b
BOD	0.018	0.020
TSS	0.0075	0.014

A fact that is often overlooked in sedimentation tank performance is the change in the wastewater characteristics that occurs through the sedimentation process. Larger, more slowly biodegradable suspended solids settle first, leaving a more volatile fraction in suspension that remains in the primary tank effluent. The strict use of removal curves, such as those given on Fig. 5–46, does not account for the transformation in wastewater characteristics that actually occurs. Where possible for domestic wastewater, primary tank influent and effluent should be characterized to determine concentration and composition of the constituents. Such characterization is important when determining the organic loading required to be treated by the succeeding biological treatment units. Further discussion on the effects of wastewater characterization on biological processes is contained in Chaps. 7 and 8.

Short Circuiting and Hydraulic Stability. In an ideal sedimentation basin (see Fig. 5–47*a*), a given block of entering water should remain in the basin for the full detention time. Unfortunately, in practice sedimentation basins are seldom ideal and considerable short circuiting will be observed for one or more of the reasons cited above. To determine if short circuiting exists and to what extent, tracer studies, as discussed in Sec. 4–4 in Chap. 4, should be performed. Time-concentration curves should be developed for analysis. If in the repeated tests the time-concentration curves are similar, then the basin is stable. If the time-concentration curves (also known as residence time distribution (RTD) curves and discussed in Sec. 4–4) are not repeatable, the basin is unstable and the performance of the basin will be erratic (Fair and Geyer, 1954). The method of influent flow distribution, as discussed above, will also affect short circuiting.

Temperature Effects. Temperature effects can be significant in sedimentation basins. It has been shown that a 1° Celsius temperature differential between the incoming wastewater and the wastewater in the sedimentation tank will cause a density current to form (see Figs. 5–47*b* and *c*). The impact of the temperature effects on performance will depend on the material being removed and its characteristics.

Wind Effects. Wind blowing across the top of open sedimentation basins can cause circulation cells to form (see Fig. 5–47*d*). When circulation cells form, the effective volumetric capacity of the basin is reduced. As with temperature effects, the impact of the reduced volume on performance will depend on the material being removed and its characteristics.

Design Considerations

If all solids in wastewater were discrete particles of uniform size, uniform density, uniform specific gravity, and uniform shape, the removal efficiency of these solids would be dependent on the surface area of the tank and time of detention. The depth of the tank would have little influence, provided that horizontal velocities would be maintained

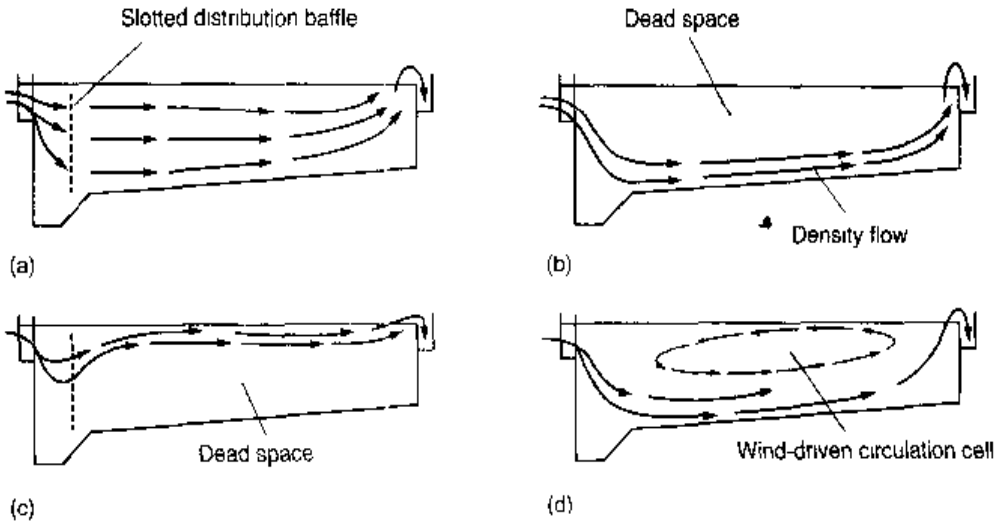

Figure 5–47

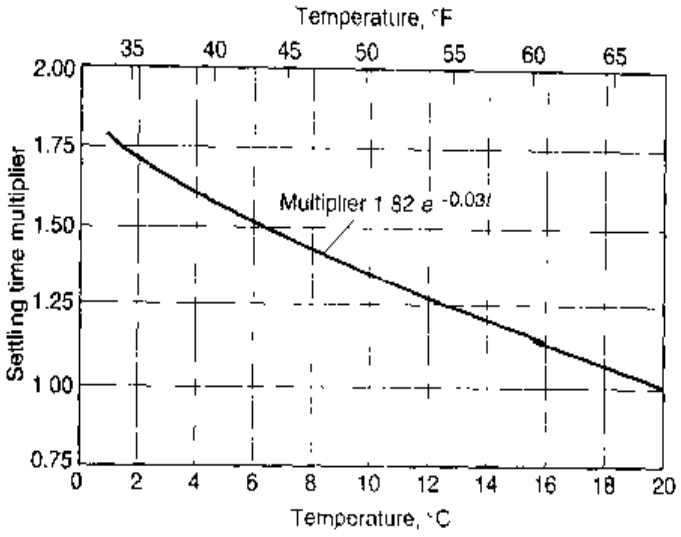
Typical flow patterns observed in rectangular sedimentation tanks: (*a*) ideal flow, (*b*) effect of density flow or thermal stratification (water in tank is warmer than influent), (*c*) effect of thermal stratification (water in tank is colder than influent), and (*d*) formation of wind-driven circulation cell. *(Crites and Tchobanoglous, 1998.)*

below the scouring velocity. However, the solids in most wastewaters are not of such regular character but are heterogeneous in nature, and the conditions under which they are present range from total dispersion to complete flocculation. Design parameters for sedimentation are considered below. Typical design data for sedimentation tanks are presented in Tables 5–17 and 5 -18. Additional details on the analysis and design of sedimentation tanks may be found in WPCF, 1985. A design procedure is illustrated in Example 5–10.



Detention Time. The bulk of the finely divided solids reaching primary sedimentation tanks is incompletely flocculated but is susceptible to flocculation. Flocculation is aided by eddying motion of the fluid within the tanks and proceeds through the coalescence of fine particles, at a rate that is a function of their concentration and of the natural ability of the particles to coalesce upon collision. As a general rule, coalescence of a suspension of solids becomes more complete as time elapses, thus, detention time is a consideration in the design of sedimentation tanks. The mechanics of flocculation are such, however, that as the time of sedimentation increases, less and less coalescence of remaining particles occurs.

Normally, primary sedimentation tanks are designed to provide 1.5 to 2.5 h of detention based on the average rate of wastewater flow. Tanks that provide shorter detention periods (0.5 to 1 h), with less removal of suspended solids, are sometimes used for preliminary treatment ahead of biological treatment units. In cold climates, increases in water viscosity at lower temperatures retard particle settling in clarifiers and reduce performance at wastewater temperatures below 20°C (68°F). A curve showing the increase in detention time necessary to equal the detention time at 20°C is presented on Fig. 5–48 (WPCF, 1985). For wastewater having a temperature of 10°C, for example, the detention period is 1.38 times that required at 20°C to achieve the same efficiency. Thus, in cold climates, safety factors should be considered in clarifier design to ensure adequate performance.

Surface Loading Rates. Sedimentation tanks are normally designed on the basis of a surface loading rate (commonly termed "overflow rate") expressed as cubic

Figure 5–48

Curve of the increase in detention time required at cooler temperatures to achieve the same sedimentation performance as achieved at 20°C.

meters per square meter of surface area per day, $m^3/m^2 \cdot d$ (gallons per square foot of surface area per day, $gal/ft^2 \cdot d$). The selection of a suitable loading rate depends on the type of suspension to be separated. Typical values for various suspensions are reported in Table 5–20. Designs for municipal plants must also meet the approval of state regulatory agencies, many of which have adopted standards for surface loading rates that must be followed. When the area of the tank has been established, the detention period in the tank is governed by water depth. Overflow rates in current use result in nominal detention periods of 2.0 to 2.5 h, based on average design flow.

The effect of the surface loading rate and detention time on suspended solids removal varies widely depending on the character of the wastewater, proportion of settleable solids, concentration of solids, and other factors. It should be emphasized that overflow rates must be set low enough to ensure satisfactory performance at peak rates of flow, which may vary from over 3 times the average flow in small plants to 2 times the average flow in large plants (see discussion of peak flowrates in Chap. 3).

Weir Loading Rates. In general, weir loading rates have little effect on the efficiency of primary sedimentation tanks and should not be considered when reviewing the appropriateness of clarifier design. For general information purposes only, typical weir loading rates are given in Table 5–20. The placement of weirs and baffles in secondary sedimentation applications is discussed in Sec. 8–8 of Chap. 8.

Scour Velocity. To avoid the resuspension (scouring) of settled particles, horizontal velocities through the tank should be kept sufficiently low. Using the results from studies by Shields (1936), Camp (1946) developed the following equation for the critical velocity.

$$V_H = \left(\frac{8k(s-1)gd}{f}\right)^{1/2} \tag{5–46}$$

where V_H = horizontal velocity that will just produce scour, LT^{-1} (m/s)

k = constant that depends on type of material being scoured (unitless)

s = specific gravity of particles
g = acceleration due to gravity, LT^{-2} (9.81 m/s^2)
d = diameter of particles, L
f = Darcy-Weisbach friction factor (unitless)

Typical values of k are 0.04 for unigranular sand and 0.06 for more sticky, interlocking matter. The term f (the Darcy-Weisbach friction factor) depends on the characteristics of the surface over which flow is taking place and the Reynolds number. Typical values of f are 0.02 to 0.03. Either SI or U.S. customary units may be used in Eq. (5–46), so long as they are consistent, because k and f are dimensionless.

EXAMPLE 5–10 Design of a Primary Sedimentation Basin The average flowrate at a small municipal wastewater-treatment plant is 20,000 m^3/d. The highest observed peak daily flowrate is 50,000 m^3/d. Design rectangular primary clarifiers with a channel width of 6 m (20 ft). Use a minimum of two clarifiers. Calculate the scour velocity, to determine if settled material will become resuspended. Estimate the BOD and TSS removal at average and peak flow. Use an overflow rate of 40 m^3/m^2·d at average flow (see Table 5–20) and a side water depth of 4 m (13.1 ft).

Solution

1. Calculate the required surface area. For average flow conditions, the required area is

$$A = \frac{Q}{OR} = \frac{(20{,}000\ \text{m}^3/\text{d})}{(40\ \text{m}^3/\text{m}^2\cdot\text{d})} = 500\ \text{m}^2$$

2. Determine the tank length.

$$L = \frac{A}{W} = \frac{500\ \text{m}^2}{2 \times 6\ \text{m}} = 41.7\ \text{m}$$

However, for the sake of convenience, the surface dimensions will be rounded to 6 m by 42 m.

3. Compute the detention time and overflow rate at average flow.
Using the assumed sidewater depth of 4 m,

$$\text{Tank volume} = 4\ \text{m} \times 2(42\ \text{m} \times 6\ \text{m}) = 2016\ \text{m}^2$$

$$\text{Overflow rate} = \frac{Q}{A} = \frac{(20{,}000\ \text{m}^3/\text{d})}{2(6\ \text{m} \times 42\ \text{m})} = 39.7\ \text{m}^3/\text{m}^2 \cdot \text{d}$$

$$\text{Detention time} = \frac{\text{Vol.}}{Q} = \frac{(2016\ \text{m}^3)(24\ \text{h/d})}{(20{,}000\ \text{m}^3/\text{d})} = 2.42\ \text{h}$$

4. Determine the detention time and overflow rate at peak flow.

$$\text{Overflow rate} = \frac{Q}{A} = \frac{(50{,}000\ \text{m}^3/\text{d})}{2(6\ \text{m} \times 42\ \text{m})} = 99.2\ \text{m}^3/\text{m}^2 \cdot \text{d}$$

$$\text{Detention time} = \frac{\text{Vol.}}{Q} = \frac{(2016\ \text{m}^3)(24\ \text{h/d})}{(50{,}000\ \text{m}^3/\text{d})} = 0.97\ \text{h}$$

5. Calculate the scour velocity [Eq. (5–46)], using the following values:

Cohesion constant	$k = 0.05$
Specific gravity	$s = 1.25$
Acceleration due to gravity	$g = 9.81\ \text{m/s}^2$
Diameter of particles	$d = 100\ \mu\text{m} = 100 \times 10^{-6}\ \text{m}$
Darcy-Weisbach friction factor	$f = 0.025$

$$V_H = \left[\frac{8k(s-1)gd}{f}\right] = \left[\frac{(8)(0.05)(0.25)(9.81)(100 \times 10^{-6})}{0.025}\right]^{1/2} = 0.063\ \text{m/s}$$

6. Compare the scour velocity calculated in the previous step to the peak flow horizontal velocity (the peak flow divided by the cross-sectional area through which the flow passes).

   The peak flow horizontal velocity through the settling tank is

$$V = \frac{Q}{A_x} = \left[\frac{(50{,}000\ \text{m}^3/\text{d})}{2(6\ \text{m} \times 4\ \text{m})}\right]\left[\frac{1}{(24\ \text{h/d})(3600\ \text{s/h})}\right] = 0.012\ \text{m/s}$$

   The horizontal velocity value, even at peak flow, is substantially less than the scour velocity. Therefore, settled matter should not be resuspended.

7. Use Eq. (5–45) and the accompanying coefficients to estimate the removal rates for BOD and TSS at average and peak flow.

   a. At average flow:

$$\text{BOD removal} = \frac{t}{a + bt} = \frac{2.42}{0.018 + (0.020)(2.42)} = 36\%$$

$$\text{TSS removal} = \frac{t}{a + bt} = \frac{2.42}{0.0075 + (0.014)(2.42)} = 58\%$$

   b. At peak flow:

$$\text{BOD removal} = \frac{t}{a + bt} = \frac{0.97}{0.018 + (0.020)(0.97)} = 26\%$$

$$\text{TSS removal} = \frac{t}{a + bt} = \frac{0.97}{0.0075 + (0.014)(0.97)} = 46\%$$

Table 5–22
Typical values of specific gravity and solids concentration of solids and scum removed from primary sedimentation tanks

Type of solids (sludge)	Specific gravity	Solids concentration, %[a]	
		Range	Typical
Primary only:			
Medium-strength wastewater	1.03	4–12	6
From combined sewer system	1.05	4–12	6.5
Primary and waste-activated sludge	1.03	2–6	3
Primary and trickling filter humus sludge	1.03	4–10	5

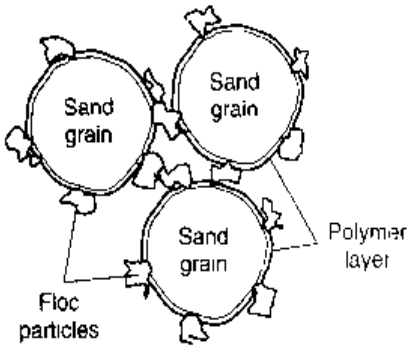
Characteristics and Quantities of Solids (Sludge) and Scum

Typical values of specific gravity and solids concentration of solids (sludge) and scum removed from primary sedimentation tanks are presented in Table 5–22. Scum consists of a variety of floatable materials, and solids concentrations vary widely.

In primary sedimentation tanks used in activated-sludge plants, provision may be required for handling the excess activated sludge that may be discharged into the influent of the primary tanks for settlement and consolidation with the primary sludge. For treatment plants where waste-activated sludge is returned to the primary sedimentation tanks, the primary sedimentation tanks should include provisions for light flocculent solids of 98 to 99.5 percent moisture and for concentrations ranging from 1500 to 10,000 mg/L in the influent mixed liquor.



The volume of solids produced in primary settling tanks must be known or estimated so that these tanks and subsequent solids pumping, processing, and disposal facilities can be properly designed. The solids volume will depend on (1) the characteristics of the untreated wastewater, including strength and freshness; (2) the period of sedimentation and the degree of purification to be effected in the tanks; (3) the condition of the deposited solids, including specific gravity, water content, and changes in volume under the influence of tank depth or mechanical solids-removal devices; and (4) the period between solids-removal operations. Additional information on the characteristics and quantities of solids produced during primary sedimentation and other treatment operations and processes is provided in Chap. 14.

5–8 HIGH-RATE CLARIFICATION

High-rate clarification employs physical/chemical treatment and utilizes special flocculation and sedimentation systems to achieve rapid settling. The essential elements of high-rate clarification are enhanced particle settling and the use of inclined plate or tube settlers. Advantages of high-rate clarification are (1) units are compact and thus reduce space requirements, (2) start-up times are rapid (usually less than 30 min) to achieve

Figure 5–49

Schematic of microsand ballasted floc particles. Polymer layer is used to absorb chemical flocs onto sand grains. *(Adapted from Kr ger Catalog.)*

peak efficiency, and (3) a highly clarified effluent is produced. Enhanced particle flocculation and high-rate clarification applications are discussed in this section. Inclined plate and tube settlers were discussed previously in Sec. 5–5.

Enhanced Particle Flocculation

Enhanced particle flocculation has been used in Europe for more than 15 years but has only been introduced relatively recently in the United States. In its most basic form, enhanced particle flocculation involves the addition of an inert ballasting agent (usually silica sand or recycled chemically conditioned sludge) and a polymer to a coagulated and partially flocculated suspension. The polymer appears to coat the ballasting particles and forms the "glue" that binds the chemical floc to the ballasted particles (see Fig. 5–49). After contact with the ballasting agent, the mixture is stirred gently in a maturation tank that allows the floc particles to grow. The particles grow as the larger, faster-settling particles overtake and collide with slower-settling particles (see Fig. 5–13*b*). The velocity gradient G for flocculation is important as a high gradient will cause a breakdown in the floc particles, and insufficient agitation will inhibit floc formation. Velocity gradients for enhanced particle settling of wastewater generally range from 200 to 400 s^{-1}.

Analysis of Ballasted Particle Flocculation and Settling

The settling velocity of the ballasted particle is increased, when compared to an unballasted floc particle, by (1) increasing the density of the particle, (2) decreasing the coefficient of drag and increasing the Reynolds number, and (3) decreasing the shape factor through the formation of more dense spherical-shaped particles [see (Eq. 5–18)]. The ballasted floc particles appear to be more spherical than the floc particles alone. In effect, ballasted flocculent particles settle with a velocity closer to that of a discrete particle than that of flocculent particles that have very high shape factors. The comparative settling velocities of ballasted particles compared to other particles are illustrated in Example 5–11.

EXAMPLE 5–11 Calculation of Settling Velocities of Ballasted Floc and Other Particles Determine the settling velocities for ballasted floc, spherical, and wastewater particles having the characteristics tabulated below.

Parameter	Particle type		
	Ballasted floc	Spherical	Wastewater particle
Average diameter, μm	200	150	500
Particle specific gravity	2.6	2.65	1.0035
Shape factor	2.5	1	18
Wastewater specific gravity	1.003	1.003	1.003

Solution Using Eq. (5–22) and the same computation procedure as Example 5–5, calculate the particle settling velocity for a ballasted floc particle and compare to spherical and wastewater floc particles.

1. Determine the terminal settling velocity for the ballasted floc particle.

$$v_p = \frac{g(sg_p - 1)d_p^2}{18\nu}$$

$$= \frac{(9.81\ \text{m/s}^2)(2.6 - 1)(200 \times 10^{-6}\ \text{m})}{18(1.003 \times 10^{-6}\ \text{m}^2/\text{s})}$$

$$= 0.0348\ \text{m/s}$$

$(d_p = 200\ \mu\text{m} = 200 \times 10^{-6}\ \text{m})$

2. Check the Reynolds number [Eq. (5–20)] (include the shape factor ϕ).

$$N_R = \frac{\phi v_p d_p}{\nu} = \frac{(2.5)(0.0348\ \text{m/s})(200 \times 10^{-6}\ \text{m})}{(1.003 \times 10^{-6}\ \text{m}^2\text{s})} = 17.3$$

Because the Reynolds number > 1.0, Newton's law [Eq. (5–18)] must be used to determine the settling velocity in the transition region (see Fig. 5–21). Follow the iterative procedure described in Example 5–5.

3. For the first assumed settling velocity, use the Stokes' law settling velocity calculated above. Using the resulting Reynolds number, also determined previously, compute the drag coefficient.

$$C_d = \frac{24}{N_R} + \frac{3}{\sqrt{N_R}} + 0.34 = \frac{24}{17.3} + \frac{3}{\sqrt{17.3}} + 0.34 = 2.445$$

4. Use the drag coefficient in Newton's equation to determine the particle settling velocity in Eq. (5–21), which incorporates the shape factor.

$$v_p = \sqrt{\frac{4g(sg - 1)d}{3C_d\phi}} = \sqrt{\frac{4(9.81\ \text{m/s}^2)(2.6 - 1)(200 \times 10^{-6}\ \text{m})}{3 \times 2.445 \times 2.5}}$$

$$= 0.026\ \text{m/s}$$

Because the initial assumed settling velocity (0.345 m/s) does not equal the Newton's equation settling velocity (0.026 m/s), additional iterations are necessary.

5. For a following iteration, assume a settling velocity value of 0.022 m/s, and calculate the Reynolds number (the assumed value is based on several trial iterations for various velocities). Use the Reynolds number to determine the drag coefficient, and use the drag coefficient in Newton's equation to find the settling velocity.

$$N_R = \frac{(2.5)(0.022\ \text{m/s})(200 \times 10^{-6}\ \text{m})}{(1.003 \times 10^{-6}\ \text{m}^2/\text{s})} = 10.97$$

$$C_d = \frac{24}{10.97} + \frac{3}{\sqrt{10.97}} + 0.34 = 3.43$$

$$v_p = \sqrt{\frac{4(9.81\ \text{m/s}^2)(2.6 - 1)(200 \times 10^{-6}\ \text{m})}{3 \times 3.43 \times 1}} = 0.022\ \text{m/s}$$

The assumed and calculated settling velocities (0.022 m/s) are in agreement.

6. Using the same computational procedure, calculate the settling velocities for the spherical and wastewater particles. The results of the calculations for the three particle settling velocities are summarized below:

Ballasted floc particle = 0.022 m/s = 79 m/h

Spherical particle = 0.0164 m/s = 59 m/h

Wastewater particle = 0.00038 m/s = 1.4 m/h

Comment Although the particle settling velocities vary widely because of the particle characteristics (specific gravity, shape, and size), as illustrated in this example, by forming a ballasted floc particle the settling velocity can be enhanced significantly. Increasing the size and density of the wastewater particles by various means of ballasting is one of the premises of high-rate clarification. Because an iterative process is needed to calculate settling velocities in the transition zone, a spreadsheet program can expedite the computation process by allowing several assumed velocities to be tried to effect closure with the computed velocity.

Process Application

Three basic types of process are used for high-rate clarification: (1) ballasted flocculation with lamella plate clarification, (2) three-stage flocculation with lamella plate clarification, and (3) dense-solids flocculation/clarification with lamella plate clarification. Each of these processes can operate at high overflow rates that allow significant reduction in the physical size of the sedimentation units. A summary of the principal features of each process is presented in Table 5–23. Applications for high-rate clarification include (1) providing advanced primary treatment, (2) treating wet-weather flows and combined sewer overflows, (3) treating waste filter backwash water, and (4) treating return flows from solids-processing facilities. Ranges of overflow rates and BOD and TSS removals for treating wet-weather flows (domestic wastewater plus infiltration/

inflow) are reported in Table 5–24 (Sawey, 1998). The processes are illustrated on Fig. 5–50 and are discussed below.

Ballasted Flocculation. Ballasted flocculation employs a proprietary process, shown on Fig. 5–50*a*, in which a flocculation aid and a ballasting agent (typically a silica microsand) are used to form dense microfloc particles. The resulting floc particles are thus "ballasted" and settle rapidly. The treatment system consists of three compartments

Table 5–23
Summary of features of high-rate clarification processes

Process	Features
Microsand ballasted flocculation and clarification	• Microsand provides nuclei for floc formation • Floc is dense and settles rapidly • Lamella clarification, when used, provides high-rate settling in a small tank volume
Chemical addition, multistage flocculation, and lamella clarification	• Three-stage flocculation enhances floc formation • Lamella clarification provides high-rate settling in a small tank volume
Two-stage flocculation with chemically conditioned recycled sludge followed by lamella clarification	• Settled sludge solids are recycled to accelerate floc formation • Dense floc is formed that settles rapidly • Lamella clarification provides high-rate settling in a small tank volume

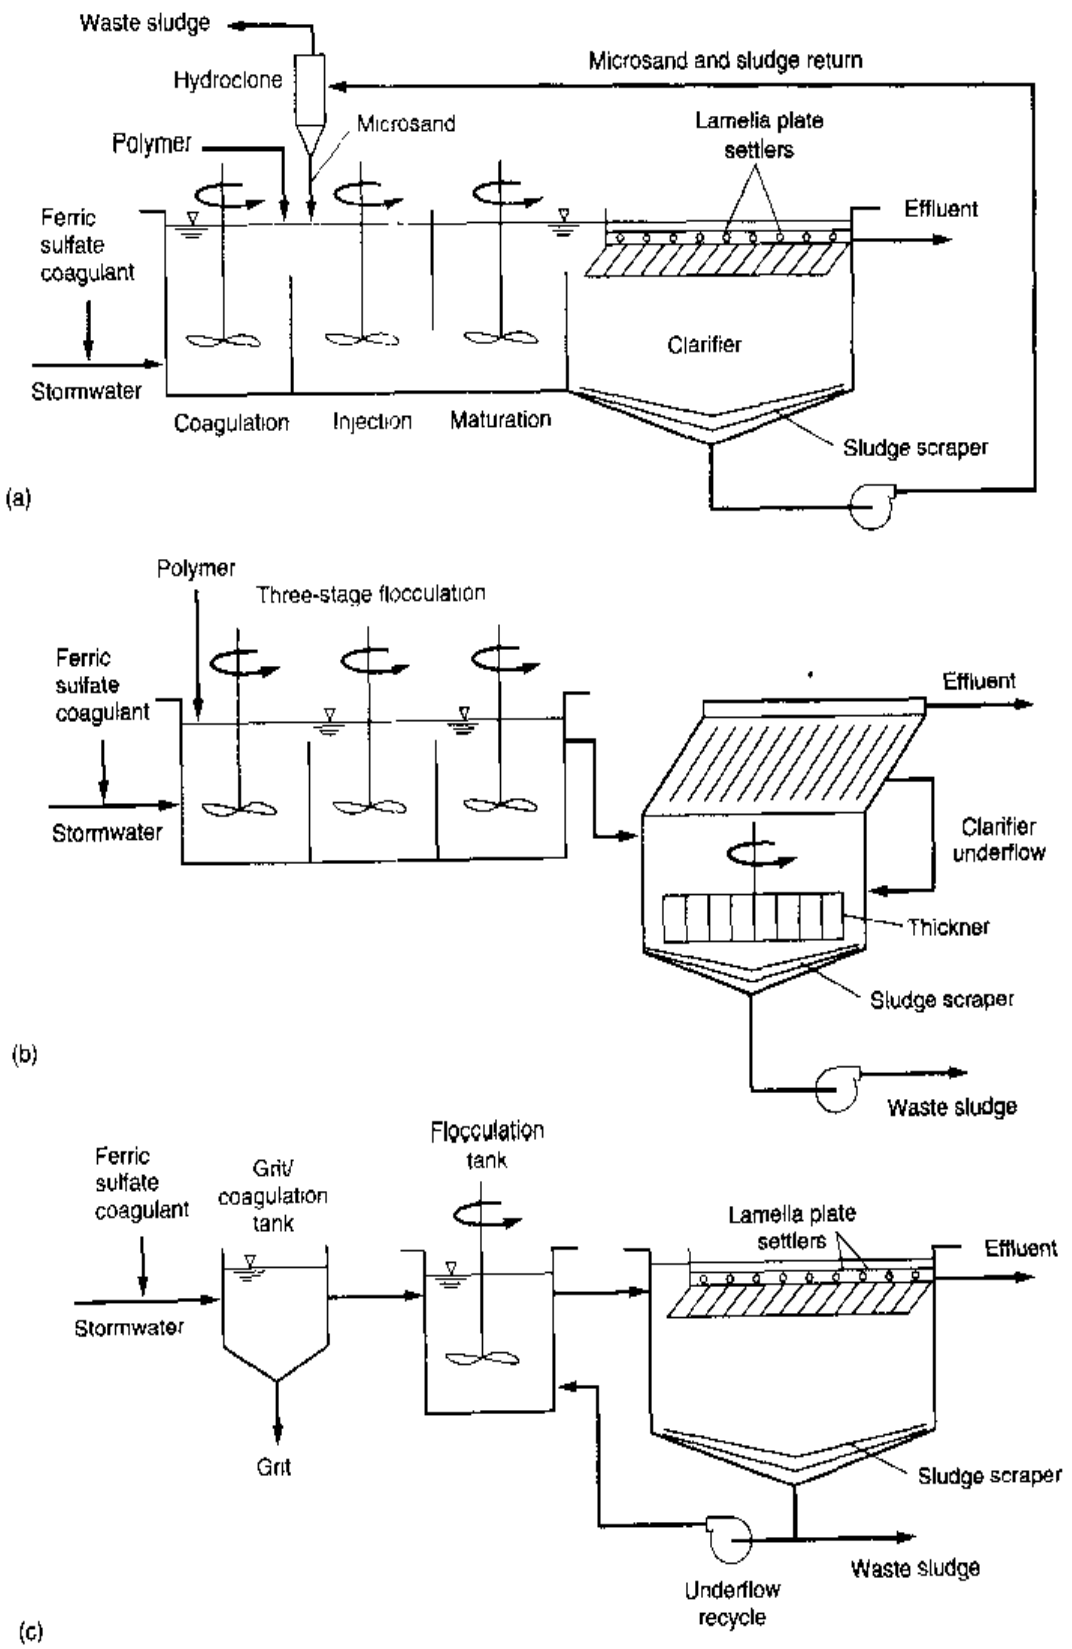


Table 5–24
Ranges of overflow rates and BOD and TSS removals from high-rate clarification processes treating wet-weather flows[a]

Parameter/Process	Ballasted flocculation	Lamella plate clarification	Dense sludge
Overflow rates			
Low, $m^3/m^2 \cdot d$ ($gal/ft^2 \cdot min$)	1200–2900 (20–50)	880 (15)	2300 (40)
Medium, $m^3/m^2 \cdot d$ ($gal/ft^2 \cdot min$)	1800–3500 (30–60)	1200 (20)	2900 (50)
High, $m^3/m^2 \cdot d$ ($gal/ft^2 \cdot min$)	2300–4100 (40–70)	1800 (30)	3500 (60)
BOD removals, %			
At low overflow rates	35–50	45–55	25–35
At medium overflow rates	40–60	35–40	40–50
At high overflow rates	30–60	35–40	50–60
TSS removals, %			
At low overflow rates	70–90	60–70	80–90
At medium overflow rates	40–80	65–75	70–80
At high overflow rates	30–80	40–50	70–80

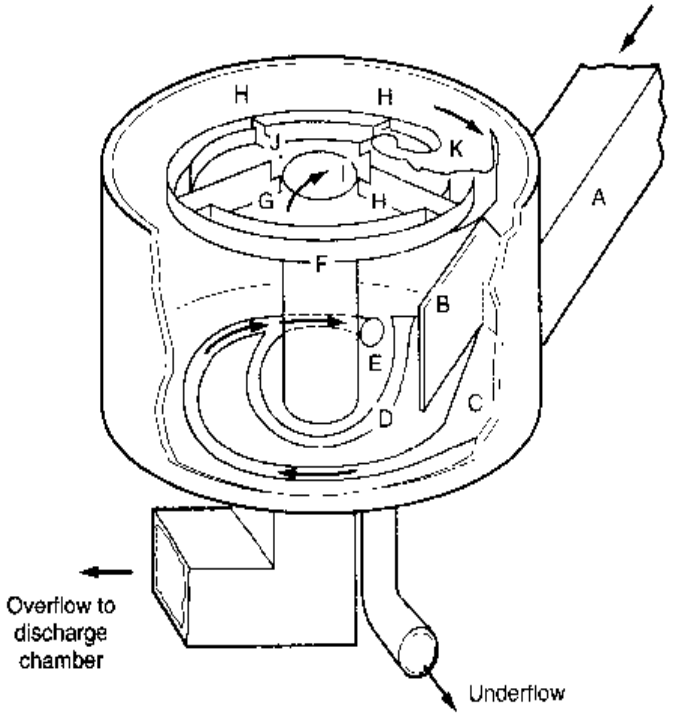
Figure 5–50

High-rate clarification processes: (*a*) ballasted flocculation, (*b*) lamella plate clarification, and (*c*) dense-sludge.

or zones: a mixing zone, maturation zone, and settling zone. Depending on the manufacturer of the process equipment, separate, serial compartments can be used to perform the process functions, or the functions can be combined in a single vessel. Either lamella plate settling or conventional gravity clarification can be used.

Typically, screened wastewater is introduced to the ballasted flocculation reactor where a chemical coagulant (typically an iron salt) is injected to destabilize the solids. The wastewater then enters a mixing zone where microsand and polymer are injected to maximize the efficiency of flocculation and enhance settling of suspended solids. In the mixing zone, the polymer acts as a bonding agent for adhering the destabilized solids to the microsand. The maturation zone follows and is used to keep the solids in suspension while floc particles continue to develop and grow. Once developed, the ballasted floc particles settle rapidly to the bottom of the clarifier. Sand and floc particles removed from the clarified water are pumped to a cyclone separator (hydroclone) for separation of the sand. The separated sand is returned to the injection tank, and solids from the hydroclone are sent to the biosolids-processing facilities. The microsand usually ranges in size from 100 to 150 μm for treating wastewater and combined wastewater flows and has a specific gravity greater than 2.6 to enhance settling.

Lamella Plate Clarification. Lamella plate clarification uses chemical addition followed by three-stage flocculation and a lamella plate clarifier (see Fig. 5–50*b*). Coagulant and polymer are injected into the influent wastewater prior to entrance into the flocculation zone. When chemically conditioned wastewater passes through each of the three flocculation zones, the mixing energy gradient is decreased as the wastewater proceeds from one stage to the next. The chemically conditioned/flocculated wastewater then passes to the lamella clarifier for solids separation. A portion of the clarifier underflow can be recycled to the influent of the process to enhance settling, or the entire underflow can be sent to a thickening tank and the solids-processing facilities.



Dense-Sludge Process. The dense-sludge system is a proprietary process and differs from ballasted flocculation in that recycled chemically conditioned solids are used to form microfloc particles with the incoming wastewater instead of microsand. As shown on Fig. 5–50*c*, the influent wastewater enters an air-mixing zone where grit separation occurs and coagulant (usually ferric sulfate) is injected. After mixing, the wastewater flows into the first stage of a two-stage flocculation tank where polymer is added together with chemically conditioned, recirculated solids. Recirculated solids accelerate the flocculation process and ensure the formation of dense, homogeneous floc particles. In the second stage of flocculation, grease and scum begin separating and are removed. Flow from the flocculation tank enters a presettling zone and then passes into a lamella plate settler. Most of the suspended flocculated solids are separated directly in the presettling zone; the residual flocculated particles are removed in the lamella settler. A portion of the settled solids is recirculated, and the remainder is sent to the solids processing and disposal system.

5–9 LARGE-SCALE SWIRL AND VORTEX SEPARATORS FOR COMBINED WASTEWATER AND STORMWATER

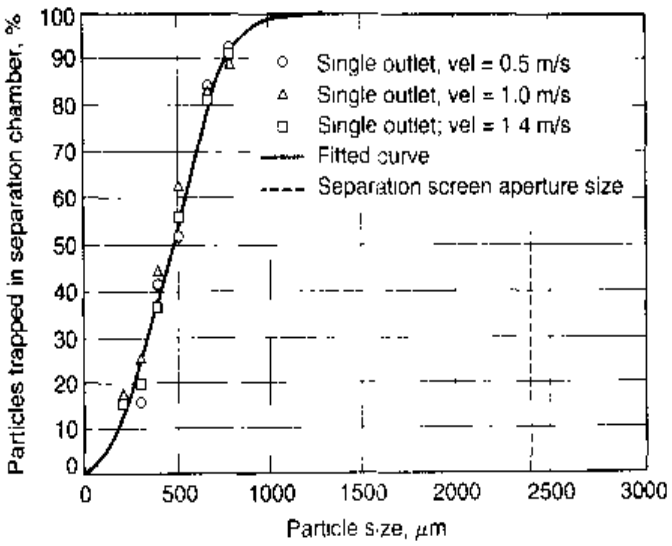
Solids-separation devices such as swirl concentrators and vortex separators have been used in Europe and, to a lesser extent, in the United States for the treatment of combined sewer overflows (CSOs) and stormwater. These devices are compact solids-separation units with no moving parts. A typical vortex-type CSO solids-separation unit is illustrated on Fig. 5–51. Operation of vortex separators is based on the movement of

Figure 5–51

Typical vortex separator used for solids removal from combined sewer overflows. *(Pisano, et al., 1990.)*

Legend

A	Influent channel	F	Scum baffle
B	Flow deflector	G	Overflow weir
C	Solids underflow channel	H	Baffle
D	Solids collector channel	I	Overflow discharge pipe
E	Underflow discharge pipe	J	Scum trap plate
		K	Scum trap



particles within the unit. Water velocity moves the particles in a swirling action around the separator, additional flow currents move the particles toward the vortex, gravity pulls particles down, and a sweeping action moves heavier particles across the sloping floor toward the central drain.

During wet weather, the outflow from the unit is throttled, causing the unit to fill and to self-induce a swirling vortexlike flow regime. In the device shown on Fig. 5–51, secondary flow currents rapidly separate settleable grit and floatable matter. Concentrated foul matter is intercepted for treatment while the cleaner, treated flow discharges to receiving waters. The device is intended to operate under extremely high flow regimes.

A device more recently developed and termed the continuous deflection separator (CDS) differs from the more traditional vortex separator in that it utilizes a filtration mechanism for solids separation and does not rely on secondary flow currents induced by the vortex action. The CDS system (pictured previously on Fig. 5–5*b*) involves a single flow path and has one outlet point while other types of vortex separators discharge flows at the top and bottom of the units. The flow conditions within the CDS separation chamber have a different velocity profile. The surface velocity increases with increasing distance from the center of the separation chamber of the CDS unit, the reverse of that normally observed in conventional vortex separators. Solids separation is enhanced by a large expanded stainless-steel plate that acts as a filter screen with an outer volute outlet passage. The perforations in the separation screen are typically elongated in shape and are aligned with the longer axis in the vertical direction. The separation

Figure 5-52

Particle capture from a Continuous Deflection Separator (CDS) vortex separator. *(Wong, et al., 1997.)*

screen is installed so that the leading edge of each perforation extends into the flow stream of the containment chamber. Perforations in the screen can range from 1200 to 4700 μm (0.0475 to 0.185 in).

The CDS device is most appropriately used to capture the "first flush" and set up to divert all flows up to a threshold discharge. In tests conducted by Wong (1997), greater than 90 percent capture was reported for solids as small as 900 microns (see Fig. 5–52). Headloss through the separation unit varies depending on flowrate and screen openings.

5–10 FLOTATION

Flotation is a unit operation used to separate solid or liquid particles from a liquid phase. Separation is brought about by introducing fine gas (usually air) bubbles into the liquid phase. The bubbles attach to the particulate matter, and the buoyant force of the combined particle and gas bubbles is great enough to cause the particle to rise to the surface. Particles that have a higher density than the liquid can thus be made to rise. The rising of particles with lower density than the liquid can also be facilitated (e.g., oil suspension in water).

In wastewater treatment, flotation is used principally to remove suspended matter and to concentrate biosolids (see Chap. 14). The principal advantages of flotation over sedimentation are that very small or light particles that settle slowly can be removed more completely and in a shorter time. Once the particles have been floated to the surface, they can be collected by a skimming operation.

Description

The present practice of flotation as applied to wastewater treatment is confined to the use of air as the flotation agent. Air bubbles are added or caused to form by (1) injection of air while the liquid is under pressure, followed by release of the pressure (dissolved-air flotation), and (2) aeration at atmospheric pressure (dispersed-air flotation). In these systems, the degree of removal can be enhanced through the use of various chemical additives. In municipal wastewater treatment, dissolved-air flotation is frequently used, especially for thickening of waste biosolids.

Dissolved-Air Flotation. In dissolved-air flotation (DAF) systems, air is dissolved in the wastewater under a pressure of several atmospheres, followed by release of the pressure to the atmospheric level (see Fig. 5–53). In small pressure systems, the entire flow may be pressurized by means of a pump to 275 to 350 kPa (40 to 50 lb/in^2 gage) with compressed air added at the pump suction (see Fig. 5–53*a*). The entire flow is held in a retention tank under pressure for several minutes to allow time for the air to dissolve. It is then admitted through a pressure-reducing valve to the flotation tank where the air comes out of solution in very fine bubbles.

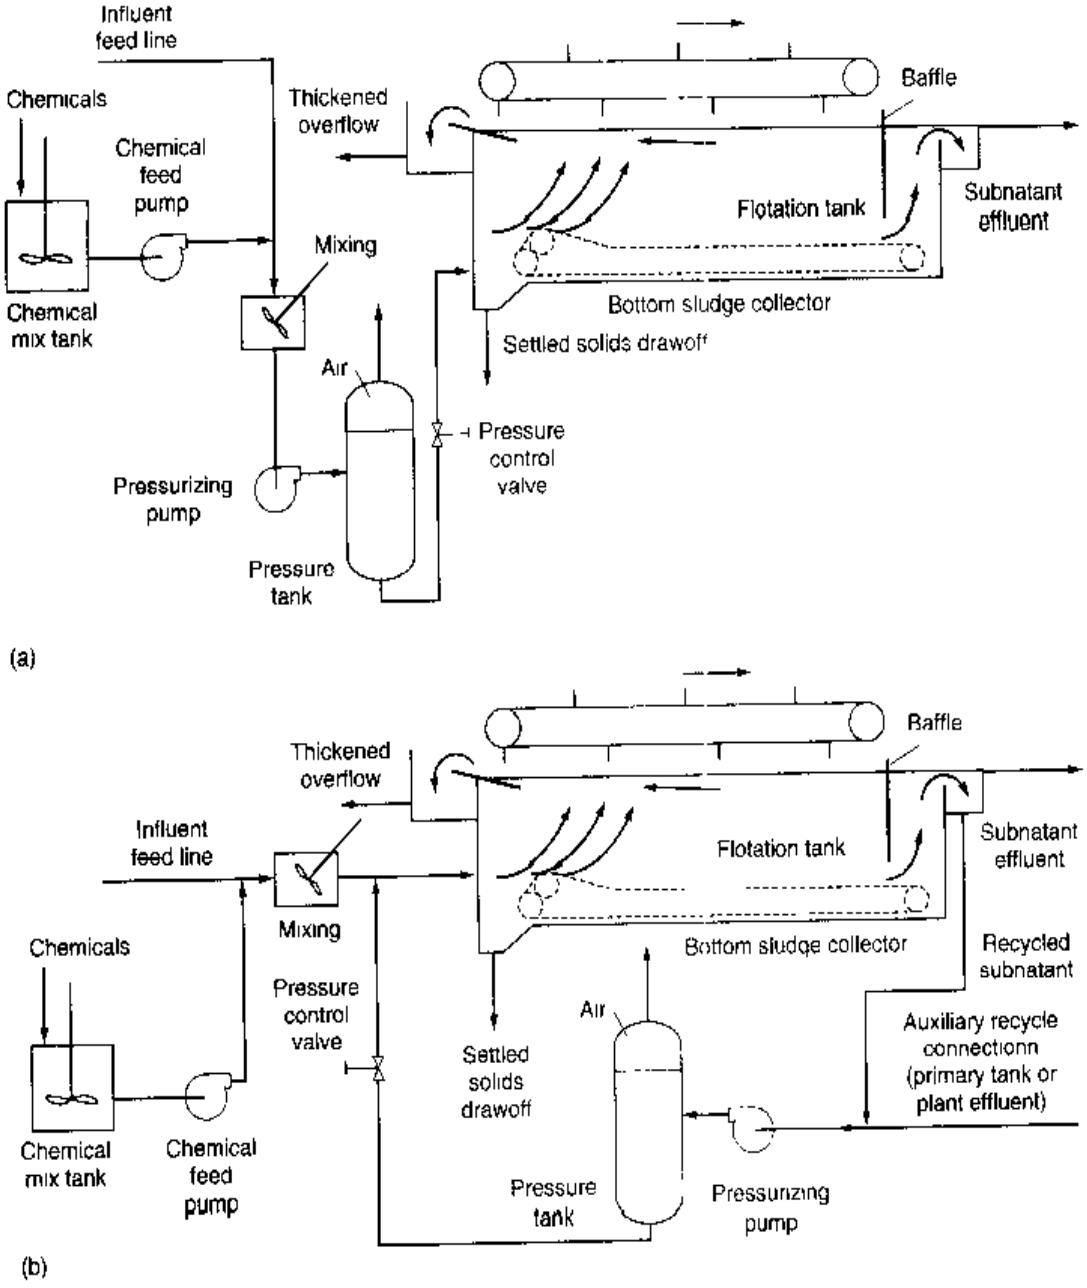


Figure 5–53

Schematic of dissolved-air flotation systems: (*a*) without recycle in which the entire flow is passed through the pressurizing tank and (*b*) with recycle in which only the recycle flow is pressurized. The pressurized flow is mixed with the influent before being released into the flotation tank.

In the larger units, a portion of the DAF effluent (15 to 120 percent) is recycled, pressurized, and semisaturated with air (Fig. 5–53*b*). The recycled flow is mixed with the unpressurized main stream just before admission to the flotation tank, with the result that the air comes out of solution in contact with particulate matter at the entrance to the tank. Pressure types of units have been used mainly for the treatment of industrial wastes and for the concentration of solids.

Dispersed-Air Flotation. Dispersed-air (sometimes referred to as induced-air) flotation is seldom used in municipal wastewater treatment, but it is used in industrial applications for the removal of emulsified oil and suspended solids from high-volume waste or process waters. In dispersed-air flotation systems, air bubbles are formed by introducing the gas phase directly into the liquid phase through a revolving impeller. The spinning impeller acts as a pump, forcing fluid through disperser openings and creating a vacuum in the standpipe (see Fig. 5–54). The vacuum pulls air (or gas) into the standpipe and thoroughly mixes it with the liquid. As the gas/liquid mixture travels through the disperser, a mixing force is created that causes the gas to form very fine bubbles. The liquid moves through a series of cells before leaving the unit. Oil particles and suspended solids attach to the bubbles as they rise to the surface. The oil and suspended solids gather in dense froth at the surface and are removed by skimming paddles. The advantages of a dispersed-air flotation system are (1) compact size, (2) lower capital cost, and (3) capacity to remove relatively free oil and suspended solids. The disadvantages of induced-air flotation include higher connected power requirements than the pressurized system, performance is dependent on strict hydraulic control, and less flocculation flexibility. The quantities of float skimmings are significantly higher

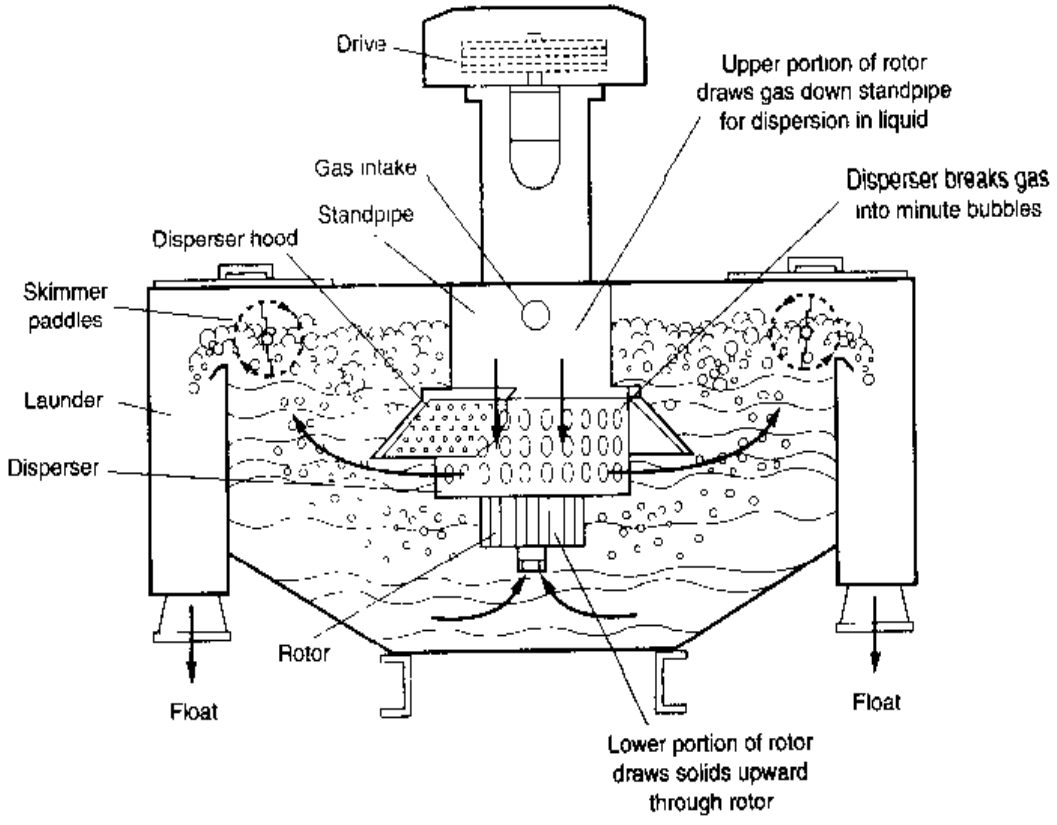

Figure 5–54

Dispersed-air flotation unit. Air is induced and dispersed into the liquid by pumping action of the inductors. *(Courtesy Eimco.)*

than the pressurized unit: 3 to 7 percent of the incoming flow as compared to less than 1 percent for dissolved-air systems (Eckenfelder, 2000).

Chemical Additives. Chemicals are commonly used to aid the flotation process. These chemicals, for the most part, function to create a surface or a structure that can easily absorb or entrap air bubbles. Inorganic chemicals, such as the aluminum and ferric salts and activated silica, can be used to bind the particulate matter together and, in so doing, create a structure that can easily entrap air bubbles. Various organic polymers can be used to change the nature of either the air-liquid interface or the solid-liquid interface, or both. These compounds usually collect on the interface to bring about the desired changes.

Design Considerations for Dissolved-Air Flotation Systems

Because flotation is very dependent on the type of surface of the particulate matter, laboratory and pilot-plant tests should be performed to yield the necessary design criteria. Factors that must be considered in the design of flotation units include the concentration of particulate matter, quantity of air used, the particle-rise velocity, and the solids loading rate. In the following analysis, dissolved-air flotation is discussed because it is the method most commonly used.

The performance of a dissolved-air flotation system depends primarily on the ratio of the volume of air to the mass of solids (A/S) required to achieve a given degree of clarification. The ratio will vary with each type of suspension and must be determined experimentally using a laboratory flotation cell. A typical laboratory flotation cell is shown on Fig. 5–55. Procedures for conducting the necessary tests may be found in Higbie (1935) and WEF (1998*c*). Typical A/S ratios encountered in the thickening of solids and biosolids in wastewater-treatment plants vary from about 0.005 to 0.060.

The relationship between the A/S ratio and the solubility of air, the operating pressure, and the concentration of solids for a system in which all the flow is pressurized is given in Eq. (5–47).

$$\frac{A}{S} = \frac{1.3\, s_a (fP - 1)}{S_a} \qquad [5\text{–}47]$$

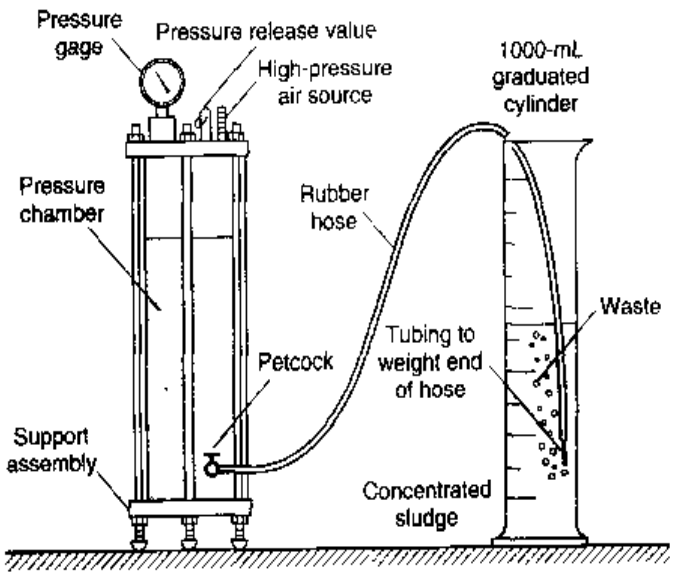

Figure 5–55
Schematic of dissolved-air flotation test apparatus.

where A/S = air to solids ratio, mL (air)/mg(solids)
s_a = air solubility, mL/L
f = fraction of air dissolved at pressure P, usually 0.5
P = pressure, atm

$$= \frac{p + 101.35}{101.35} \text{ (SI units)}$$

$$= \frac{p + 14.7}{14.7} \text{ (U.S. customary units)}$$

p = gage pressure, kPa (lb/in^2 gage)
S_a = influent suspended solids, g/m^3 (mg/L)

Temp., °C	0	10	20	30
s_a, mL/L	29.2	22.8	18.7	15.7

The corresponding equation for a system with only pressurized recycle is

$$\frac{A}{S} = \frac{1.3\, s_a(fP - 1)R}{S_a Q} \quad \{5\text{–}48\}$$

where R = pressurized recycle, m^3/d (Mgal/d)
Q = mixed-liquor flow, m^3/d (Mgal/d)

In both of the foregoing equations, the numerator represents the weight of air and the denominator the weight of the solids. The factor 1.3 is the weight in milligrams of 1 mL of air and the term (-1) within the brackets accounts for the fact that the system is to be operated at atmospheric conditions. The use of these equations is illustrated in Example 5–12. Additional information about the use of flotation for treating oily wastewaters can be found in Eckenfelder (2000).

The required area of the thickener is determined from a consideration of the rise velocity of the solids, 8 to 160 L/m^2·min (0.2 to 4.0 gal/min·ft^2), depending on the solids concentration, degree of thickening to be achieved, and the solids loading rate (see Table 14–20).

EXAMPLE 5–12 Flotation Thickening of Activated-Sludge Mixed Liquor Design a flotation thickener without and with pressurized recycle to thicken the solids in activated-sludge mixed liquor from 0.3 to about 4 percent. Assume that the following conditions apply:

1. Optimum A/S ratio = 0.008 mL/mg
2. Temperature = 20°C
3. Air solubility = 18.7 mL/L
4. Recycle-system pressure = 275 kPa
5. Fraction of saturation = 0.5
6. Surface-loading rate = 8 L/m^2·min
7. Sludge flowrate = 400 m^3/d

Solution (without Recycle)

1. Compute the required pressure using Eq. (5–47).

$$\frac{A}{S} = \frac{1.3\, s_a (fP - 1)}{S_a}$$

$$0.008 \text{ mL/mg} = \frac{1.3\ (18.7 \text{ mL/L})(0.5P - 1)}{(3000 \text{ mg/L})}$$

$$0.5\, P = 0.99 + 1$$

$$P = 3.98 \text{ atm} = \frac{p + 101.35}{101.35}$$

$p = 302$ kPa (43.8 lb_f/in^2gage)

2. Determine the required surface area.

$$A = \frac{(400 \text{ m}^3/\text{d})(10^3 \text{ L/m}^3)}{(8 \text{ L/m}^2\cdot\text{min})(1440 \text{ min/d})} = 34.7 \text{ m}^2$$

3. Check the solids loading rate.

$$\text{kg/m}^2\cdot\text{d} = \frac{(400 \text{ m}^3/\text{d})(3000 \text{ g/m}^3)}{(34.7 \text{ m}^2)(10^3 \text{ g/kg})} = 34.6 \text{ kg/m}^2$$

Solution (with Recycle)

1. Determine pressure in atmospheres.

$$p = \frac{275 + 101.35}{101.35} = 3.73 \text{ atm}$$

2. Determine the required recycle rate using Eq. (5–48).

$$\frac{A}{S} = \frac{1.3 s_a (fP - 1)R}{S_a Q}$$

$$0.008 \text{ mL/mg} = \frac{1.3\ (18.7 \text{ mL/L})[0.5\ (3.73) - 1]R}{(3000 \text{ mg/L})(400 \text{ m}^3/\text{d})}$$

$$R = 461.9 \text{ m}^3/\text{d}$$

3. Determine the required surface area.

$$A = \frac{(461.9 \text{ m}^3/\text{d})(10^3 \text{ L/m}^3)}{(8 \text{ L/m}^2\cdot\text{min})(1440 \text{ min/d})} = 40.1 \text{ m}^2$$

Comment Alternatively, the recycle flowrate could have been set and the pressure determined. In an actual design, the costs associated with the recycle pumping, pressurizing systems, and tank construction can be evaluated to find the most economical combination.

5–11 OXYGEN TRANSFER

Oxygen transfer, the process by which oxygen is transferred from the gaseous to the liquid phase, is a vital part of a number of wastewater-treatment processes. The functioning of aerobic processes, such as activated sludge, biological filtration, and aerobic digestion, depends on the availability of sufficient quantities of oxygen. The application of oxygen transfer is covered in this section, and the types of aeration systems are presented in Sec. 5–12. The fundamental theory of liquid-gas mass transfer is discussed in Chap. 4, Sec. 4–8.

Description

The most common application of oxygen transfer is in the biological treatment of wastewater. Because of the low solubility of oxygen and the consequent low rate of oxygen transfer, sufficient oxygen to meet the requirements of aerobic waste treatment does not enter water through normal surface air-water interfaces. To transfer the large quantities of oxygen that are needed, additional interfaces must be formed. Either air or oxygen can be introduced into the liquid, or the liquid in the form of droplets can be exposed to the atmosphere.

Oxygen can be supplied by means of air or pure-oxygen bubbles introduced to the water to create additional gas-water interfaces. In wastewater-treatment plants, submerged-bubble aeration is most frequently accomplished by dispersing air bubbles in the liquid at depths up to 10 m (~30 ft); depths up to 30 m (~100 ft) have been used in some European designs. Hydraulic shear devices may also be used to create small bubbles by impinging a flow of liquid at an orifice to break up the air bubbles into smaller sizes. Turbine mixers may be used to disperse air bubbles introduced below the center of the turbine; they are designed both to mix the liquid in the basin and to expose it to the atmosphere in the form of small liquid droplets.

Evaluation of Oxygen Transfer Coefficient

For a given volume of water being aerated, aeration devices are evaluated on the basis of the quantity of oxygen transferred per unit of air introduced to the water for equivalent conditions (temperature and chemical composition of the water, depth at which the air is introduced, etc.). The evaluation of the oxygen transfer coefficient in clean water and wastewater is considered in the following discussion.

Oxygen Transfer in Clean Water. The accepted procedure for determining the overall oxygen transfer coefficient in clean water, as detailed in ASCE (1992), may be outlined as follows. The accepted test method involves the removal of dissolved oxygen (DO) from a known volume of water by the addition of sodium sulfite followed by reoxygenation to near the saturation level. The DO of the water volume is monitored during the reaeration period by measuring DO concentrations at several different points selected to best represent the contents of the tank. The minimum number of points, their distribution, and range of DO measurements made at each determination point are specified in the procedure (ASCE, 1992).

The data obtained at each determination point are then analyzed by a simplified mass transfer model (see Sec. 4-8 in Chap. 4):

$$\frac{C_s - C_t}{C_s - C_o} = e^{-(K_L a)t} \tag{4-136}$$

where $K_L a$ = overall liquid film coefficient
C_t = concentration in liquid bulk phase at time t, mg/L
C_s = concentration in equilibrium with gas as given by Henry's law
C_o = initial concentration

Equation (4–136) is used to estimate the apparent volumetric mass transfer coefficient $K_L a$ and the equilibrium concentration C_s^*, obtained as the aeration period approaches infinity. The term C_s^* is substituted for the term C_s in Eq. (4–136). A nonlinear regression analysis is employed to fit Eq. (4–136) to the DO profile measured at each determination point during reoxygenation test period. In this way, estimates of $K_L a$ and C_s^* are obtained at each determination point. These estimates are adjusted to standard conditions and the standard oxygen transfer rate (mass of oxygen dissolved per unit time at a hypothetical concentration of zero DO) is obtained as the average of the products of the adjusted point $K_L a$ values, the corresponding adjusted point C_s^* values, and the tank volume (ASCE, 1992).

Oxygen Transfer in Wastewater. In an activated-sludge system, the $K_L a$ value can be determined by considering the uptake of oxygen by microorganisms. Typically, oxygen is maintained at a level of 1 to 3 mg/L and the microorganisms use the oxygen as rapidly as it is supplied. In equation form,

$$\frac{dC}{dt} = K_L a(C_s - C) - r_M \tag{5–49}$$

where C = concentration of oxygen in solution
r_M = rate of oxygen used by the microorganisms

Typical values of r_M vary from 2 to 7 g/d per gram of mixed-liquor volatile suspended solids (MLVSS). If the oxygen level is maintained at a constant level, dC/dt is zero and

$$r_M = K_L a\,(C_s - C) \tag{5–50}$$

C in this case is constant also.

Values of r_M can he determined in a laboratory by using a respirometer. In this case, $K_L a$ can easily be determined as follows:

$$K_L a = \left(\frac{r_M}{C_s - C}\right) \tag{5–51}$$

Prediction of oxygen transfer rates in aeration systems is nearly always based on an oxygen rate model. The overall oxygen mass transfer coefficient $K_L a$ is usually determined in test or full-scale facilities. If pilot-scale facilities are used to determine $K_L a$ values, scale-up must be considered. The mass transfer coefficient $K_L a$ is also a function of tem-

perature, intensity of mixing (and hence of the type of aeration device used and the geometry of the mixing chamber), and constituents in the water (Tchobanoglous and Schroeder, 1985). The effects of temperature, mixing intensity, tank geometry, and wastewater characteristics and the application of correction factors are discussed below. Determination of K_La is illustrated in Example 5–13.

Effect of Temperature on Oxygen Transfer. Temperature effects are treated in the same manner as they were treated in establishing the BOD rate coefficient (i.e., by using an exponential function to approximate the van't Hoff–Arrhenius relationship):

$$K_La_{(T)} = K_La_{(20^\circ C)}\,\theta^{T-20} \tag{5–52}$$

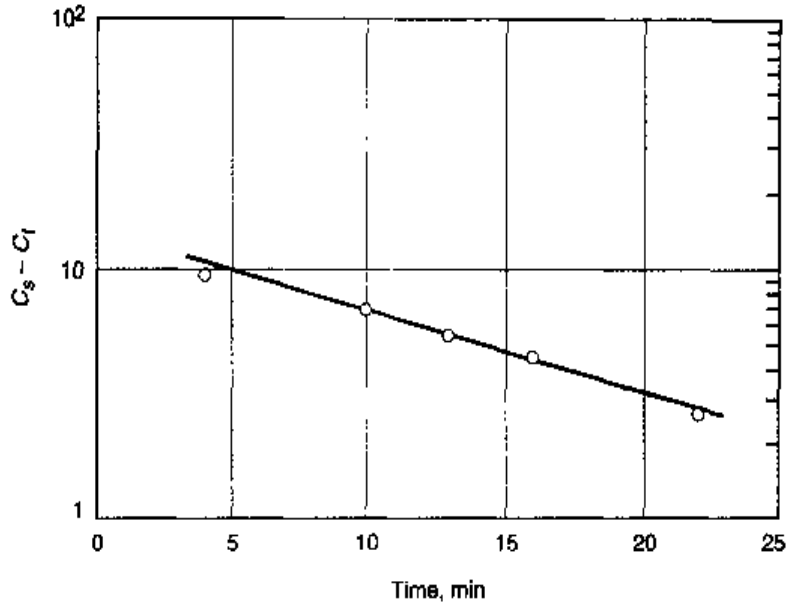
where $K_La_{(T)}$ = oxygen mass transfer coefficient at temperature T, s^{-1}
$K_La_{(20^\circ C)}$ = oxygen mass transfer coefficient at 20°C, s^{-1}

Reported values for θ vary with the test conditions. Typical θ values are in the range of 1.015 to 1.040. The θ value of 1.024 is typical for both diffused and mechanical aeration devices.

EXAMPLE 5–13 Determination of K_La Value The following data have been obtained from a surface aeration test. Using the data, determine the K_La value at 20°C using a linear regression analysis. The temperature of the water was 15°C.

Time, min	DO conc., mg/L
4	0.8
7	1.8
10	3.3
13	4.5
16	5.5
19	5.2
22	7.3

Solution



1. To analyze the field data, rewrite Eq. (4–136) in a linear form.

$$\log (C_s - C_t) = \log (C_s - C_o) - \frac{K_La}{2.303}t$$

2. Determine $C_s - C_t$, and plot $C_s - C_t$ versus t on semilog paper.
   a. $C_{s(15^\circ C)} = 10.17$ (see Appendix E)

Time, min	$C_s - C_t$, mg/L
4	9.35
7	8.35
10	6.85
13	5.65
16	4.65
19	4.95
22	2.85

b. Plot $C_s - C_t$ versus t. See the following plot:

3. Determine the value of $K_L a$ at 20°C.
   a. From the plot, the value of $K_L a$ at 15°C is

$$K_L a = 2.303 \frac{\log C_{t_1} - \log C_{t_2}}{t_2 - t_1} (60)$$

$$K_L a = 2.303 \left(\frac{\log 8.35 - \log 2.85}{22 - 7} \right) (60)$$

$$K_L a = 4.39 \text{ h}^{-1}$$

   b. The approximate value of $K_L a$ at 20°C is

$$K_L a_{20} = (1.91)\ 1.024^{20-15}$$

$$= 4.94 \text{ h}^{-1}$$

Comment The value of $K_L a$ determined in this example is approximate because a linear regression analysis was used. To obtain a more accurate value of $K_L a$, the nonlinear method outlined in ASCE (1992) should be used.

Effects of Mixing Intensity and Tank Geometry. Effects of mixing intensity and tank geometry are difficult to deal with on a theoretical basis but must be considered in the design process because aeration devices are often chosen on the basis of efficiency. Efficiency is strongly related to the K_La value associated with a given aeration unit. In most cases an aeration device is rated for a range of operating conditions using tap water having a low TDS concentration. A correction factor α is used to estimate the K_La value in the actual system:

$$\alpha = \frac{K_La \text{ (wastewater)}}{K_La \text{ (tap water)}} \tag{5–53}$$

where α is the correction factor. Values of α vary with the type of aeration device, the basin geometry, the degree of mixing, and the wastewater characteristics. Values of α vary from about 0.3 to 1.2. Typical values for diffused and mechanical aeration equipment, discussed in the following section, are in the range of 0.4 to 0.8 and 0.6 to 1.2, respectively. If the basin geometry in which the aeration device is to be used is significantly different from that used to test the device, great care must be exercised in selecting an appropriate α value.

Effects of Wastewater Characteristics. The correction factor β is used to correct the test system oxygen transfer rate for differences in oxygen solubility due to constituents in the water such as salts, particulates, and surface-active substances:

$$\beta = \frac{C_s \text{ (wastewater)}}{C_s \text{ (clean water)}} \tag{5–54}$$

Values of β vary from about 0.7 to 0.98. A β value of 0.95 is commonly used for wastewater. Because the determination of β is within the capability of most wastewater-treatment plant laboratories, experimental verification of assumed values is recommended.

Application of Correction Factors. The actual amount of oxygen required must be obtained by applying factors to a standard oxygen requirement that reflect the effects of salinity-surface tension (beta factor), temperature, elevation, diffused depth (for diffused aeration systems), the desired oxygen operating level, and the effects of mixing intensity and basin configuration. The interrelationship of these factors is given by the following expression:

$$\text{AOTR} = \text{SOTR}\left(\frac{\beta C_{s,T,H} - C_L}{C_{s,20}}\right)(1.024^{T-20})(\alpha)(F) \tag{5–55}$$

where AOTR = actual oxygen transfer rate under field conditions, kg O_2/h
SOTR = standard oxygen transfer rate in tap water at 20°C, and zero dissolved oxygen, kg O_2/h
β = salinity–surface tension correction factor, typically 0.95 to 0.98, see Eq. (5–54)
$C_{s,T,H}$ = average dissolved oxygen saturation concentration in clean water in aeration tank at temperature T and altitude H, mg/L

$$= (C_{s,T,H})\frac{1}{2}\left(\frac{P_d}{P_{\text{atm},H}} + \frac{O_t}{21}\right)$$ (Note: For surface aerators, $C_{\bar{s},T,H} = C_{s,T,H}$)

The term in the brackets when multiplied by one-half represents the average pressure at mid depth and accounts for the loss of oxygen to biological uptake. If the biological uptake is not considered, then the following expression can be used:

$$= (C_{s,T,H})\left(\frac{P_{atm,H} + P_{w,\text{ mid depth}}}{P_{atm,H}}\right),$$

$C_{s,T,H}$ = oxygen saturation concentration in clean water at temperature T and altitude H (see Appendix D), mg/L
P_d = pressure at the depth of air release, kPa
$P_{atm,H}$ = atmospheric pressure at altitude H (see Appendix B), kPa
$P_{w,\text{ mid depth}}$ = pressure at mid depth, above point of air release, due to water column
O_t = percent oxygen concentration leaving tank, usually 18 to 20 percent
C_L = operating oxygen concentration, mg/L
$C_{s,20}$ = dissolved oxygen saturation concentration in clean water at 20°C and 1 atm, mg/L
T = operating temperature, °C
α = oxygen transfer correction factor for waste [(Eq. 5–53)]
F = fouling factor, typically 0.65 to 0.9

Note that the AOTR and SOTR values given above can also be expressed as transfer efficiencies. The fouling factor F is used to account for both internal and external fouling of air diffusers (see Sec. 5–12). Internal fouling is caused by impurities in the compressed air, whereas external fouling is caused by the formation of biological slimes and inorganic precipitants. The oxygen necessary for the biological process can be supplied by using air or pure oxygen. Three methods of introducing oxygen to the contents of the aeration tank used commonly are (1) mechanical aeration, (2) injection of diffused air, and (3) injection of high-purity oxygen.

5–12 AERATION SYSTEMS

There are several types of aeration systems used for wastewater treatment. The systems used depend on the function to be performed, type and geometry of the reactor, and cost to install and operate the system. In this section, the commonly used types of aeration systems and devices are described.

Types of Aeration Systems

The various types of aeration systems used and their applications are described in Table 5–25. The principal types, diffused-air systems, mechanical aeration, and high-purity oxygen systems, are discussed in the following paragraphs. Postaeration, which is a special application for aeration, is also discussed in the latter part of this section.

Diffused-Air Aeration

The two basic methods of aerating wastewater are (1) to introduce air or pure oxygen into the wastewater with submerged diffusers or other aeration devices or (2) to agitate the wastewater mechanically so as to promote solution of air from the atmosphere. A diffused-air system consists of diffusers that are submerged in the wastewater, header

Table 5–25
Description of commonly used devices for wastewater aeration

Classification	Description	Use or application
Submerged:		
Diffused air		
Fine-bubble (fine-pore) system	Bubbles generated with ceramic, plastic, or flexible membranes (domes, tubes, disks, plates, or panel configurations)	All types of activated-sludge processes
Coarse-bubble (nonporous) system	Bubbles generated with orifices, injectors and nozzles, or shear plates	All types of activated-sludge processes, channel and grit chamber aeration, and aerobic digestion
Sparger turbine	Low-speed turbine and compressed-air injection	All types of activated-sludge processes and aerobic digestion
Static tube mixer	Short tubes with internal baffles designed to retain air injected at bottom of tube in contact with liquid	Aerated lagoons and activated-sludge processes
Jet	Compressed air injected into mixed liquor as it is pumped under pressure through jet device	All types of activated-sludge processes, equalization tank mixing and aeration, and deep tank aeration
Surface:		
Low-speed turbine aerator	Large-diameter turbine used to expose liquid droplets to the atmosphere	Conventional activated-sludge processes, aerated lagoons, and aerobic digestion
High-speed floating aerator	Small-diameter propeller used to expose liquid droplets to the atmosphere	Aerated lagoons and aerobic digestion
Aspirating	Inclined propeller assembly	Aerated lagoons
Rotor-brush or rotating-disk assembly	Blades or disks mounted on a horizontal central shaft are rotated through the liquid. Oxygen is induced into the liquid by the splashing action of the rotor and by exposure of liquid droplets to the atmosphere	Oxidation ditch, channel aeration, and aerated lagoons
Cascade	Wastewater flows over a series of steps in sheet flow	Postaeration

pipes, air mains, and the blowers and appurtenances through which the air passes. The following discussion covers the selection of diffusers, the design of blowers, and air piping design.

Diffusers. In the past, the various diffusion devices have been classified as either fine bubble or coarse bubble, with the connotation that fine bubbles were more efficient in transferring oxygen. The definition of terms and the demarcation between fine and coarse bubbles, however, have not been clear, but they continue to be used. The current preference is to categorize the diffused aeration systems by the physical characteristics of the equipment. Three categories are defined: (1) porous or fine-pore diffusers, (2) nonporous diffusers, and (3) other diffusion devices such as jet aerators, aspirating aerators, and U-tube aerators. The various types of diffused-air devices are described in Table 5–26.

Table 5–26 Description of commonly used air diffusion devices[a]

Type of diffuser or device	Transfer efficiency	Description	See fig. no.
Porous			
Disk	High	Rigid ceramic disks mounted on air-distribution pipes near the tank floor	5–56*a, c*
Dome	High	Dome-shaped ceramic diffusers mounted on air-distribution pipes near the tank floor	5–56*b*
Membrane	High	Flexible porous membrane supported on disk mounted on an air-distribution grid	5–56*d*
Panel	Very high	Rectangular panel with a flexible plastic perforated membrane	5–58
Nonporous			
Fixed orifice			
Orifice	Low	Devices usually constructed of molded plastic and mounted on air-distribution pipes	5–59*a*
Slotted tube	Low	Stainless-steel tubing containing perforations and slots to provide a wide band of diffused air	5–59*b*
Static tube	Low	Stationary vertical tube mounted on basin bottom and functions like an air-lift pump	5–60*a*

[a] Adapted in part from WEF (1998*b*).

Porous Diffusers Porous diffusers are made in many shapes, the most common being domes, disks, and membranes (see Fig. 5–56*a*, *b*, *c*, and *d*). Tubes are also used. Plates were once the most popular but are costly to install and difficult to maintain. Porous domes, disks, and membranes have largely supplanted plates in newer installations. Domes, disks, or tube diffusers are mounted on or screwed into air manifolds, which may run the length of the tank close to the bottom and along one or two sides, or short manifold headers may be mounted on movable drop pipes on one side of the tank. Dome and disk diffusers may also be installed in a grid pattern on the bottom of the aeration tank to provide uniform aeration throughout the tank (see Fig. 5–57).

Numerous materials have been used in the manufacture of porous diffusers. These materials generally fall into the categories of rigid ceramic and plastic materials and flexible plastic, rubber, or cloth sheaths. The ceramic materials consist of rounded or irregular-shaped mineral particles bonded together to produce a network of interconnecting passageways through which compressed air flows. As the air emerges from the surface pores, pore size, surface tension, and air flowrate interact to produce the bubble size. Porous plastic materials are newer developments. Similar to the ceramic materials, the plastics contain a number of interconnecting channels or pores through which the compressed air can pass. Thin, flexible sheaths made from soft plastic or synthetic rub-

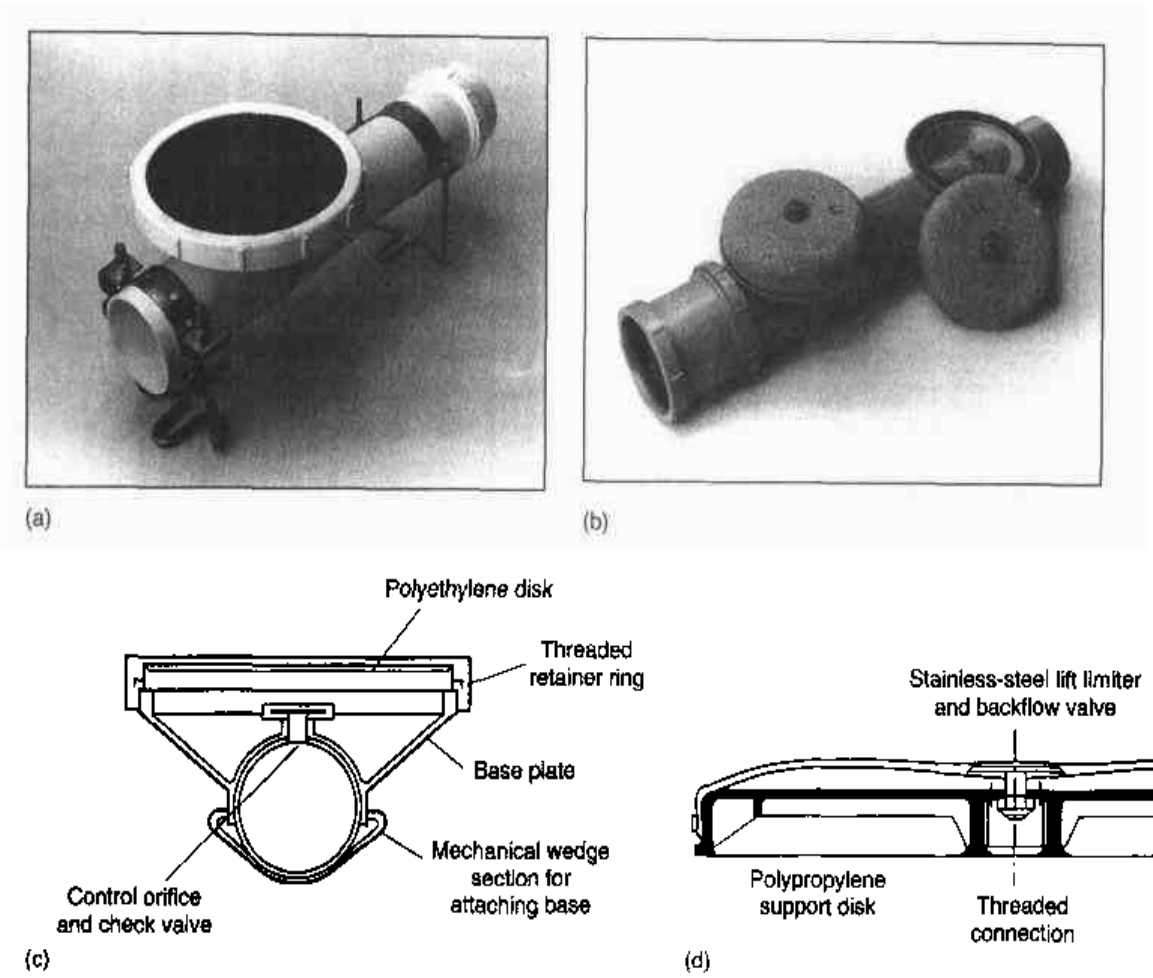


Figure 5–56

Typical porous air diffusers: (a) aluminum oxide disk, (b) ceramic dome, (c) polyethylene disk, and (d) perforated membrane.

ber have also been developed and adapted to disks and tubes. Air passages are created by punching minute holes in the sheath material. When the air is turned on, the sheath expands and each slot acts as a variable aperture opening; the higher the air flowrate, the greater the opening.

Rectangular panels that use a flexible polyurethane sheet (see Fig. 5–58) are also used in activated-sludge aeration. The panels are constructed with a stainless-steel frame and are placed on or close to the bottom of the tank and anchored. Advantages cited for aeration panels are (1) ultra-fine bubbles are produced that significantly improve oxygen transfer and system energy efficiency, (2) large areas of the tank floor can be covered, which facilitates mixing and oxygen transfer, and (3) foulants can be dislodged by "bumping," i.e., increasing the airflow to flex the membrane. Disadvantages are (1) the panel is a proprietary design and thus lacks competitive bidding, (2) the membrane has a higher headloss, which may affect blower performance in retrofit applications, and (3) increased blower air filtration is required to prevent internal fouling.

With all porous diffusers, it is essential that the air supplied be clean and free of dust particles that might clog the diffusers. Air filters, often consisting of viscous-impingement and dry-barrier types, are commonly used. Precoated bag filters and electrostatic filters have also been used. The filters should be installed on the blower inlet.

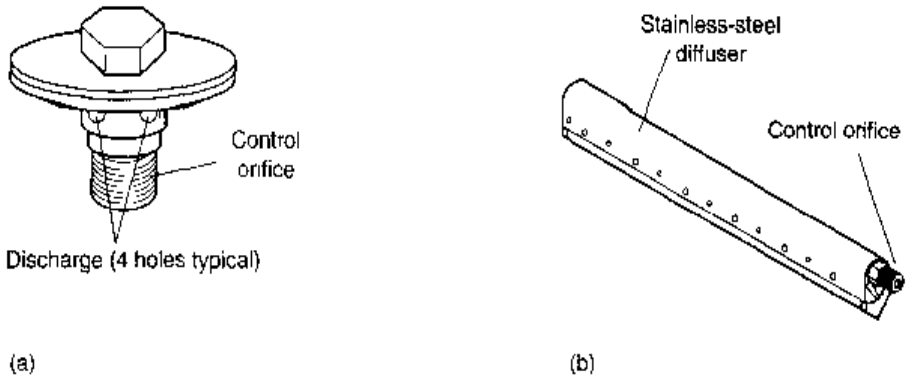
(a)

(b)

Nonporous Diffusers Several types of nonporous diffusers are available (see Fig. 5–59*a* and *b*). Nonporous diffusers produce larger bubbles than porous diffusers and consequently have lower aeration efficiency; but the advantages of lower cost, less maintenance, and the absence of stringent air-purity requirements may offset the lower oxygen transfer efficiency and energy cost. Typical system layouts for orifice diffusers closely parallel the layouts for porous dome and disk diffusers; however, single- and dual-roll spiral patterns using narrow- or wide-band diffuser placement are the most common. Applications for orifice and tube diffusers include aerated grit chambers, channel aeration, flocculation basin mixing, aerobic digestion, and industrial waste treatment (WEF, 1998*b*).

Figure 5–59

Nonporous diffusers used for the transfer of oxygen: (*a*) orifice and (*b*) tube.



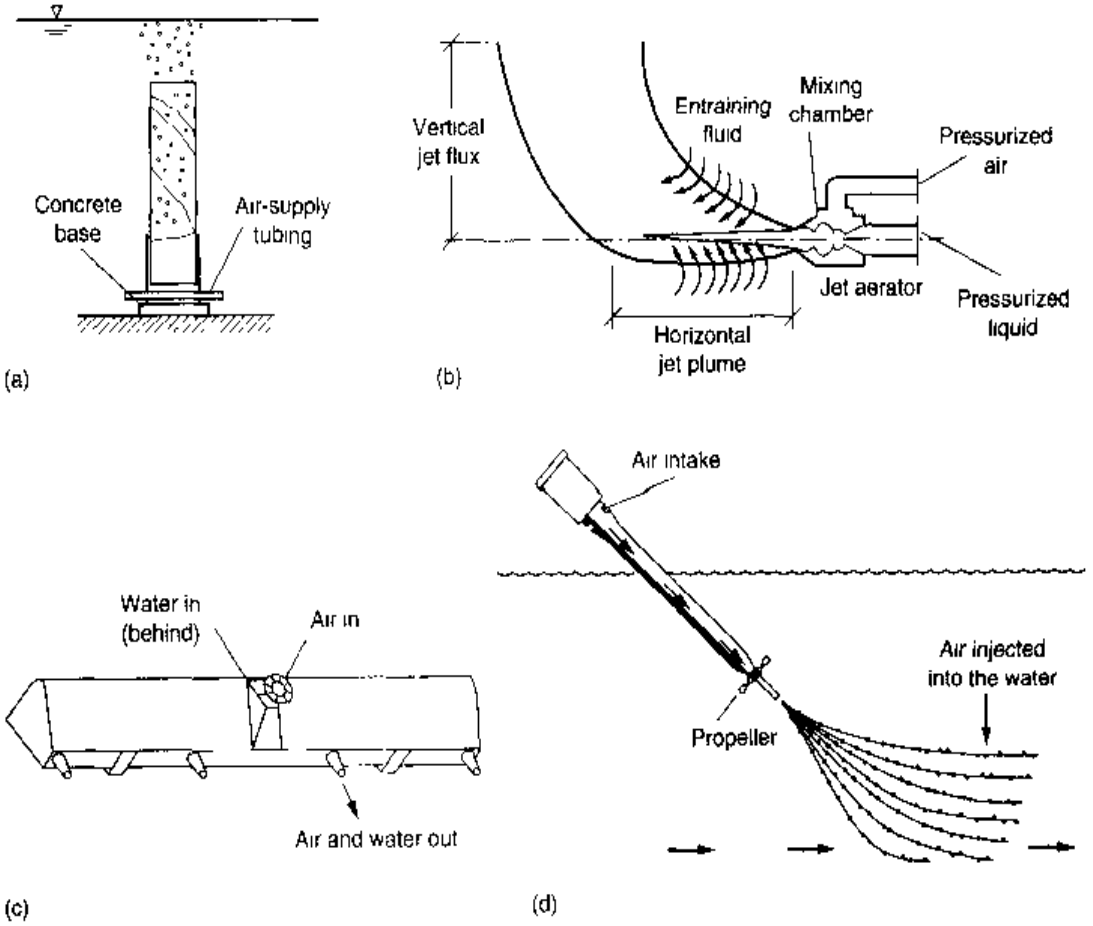


Figure 5–60

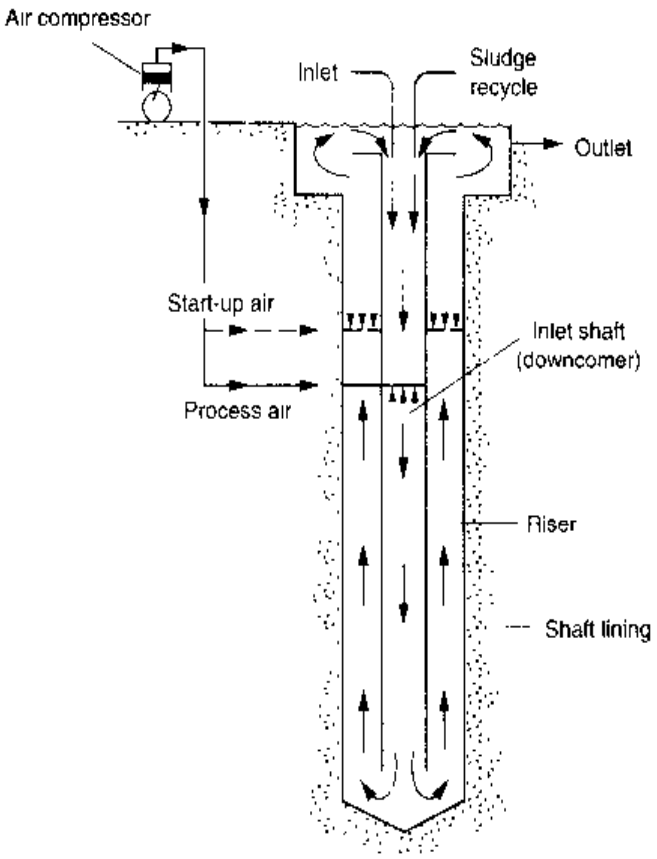

Other devices used for the transfer of oxygen: (*a*) static tube mixer where air is introduced at the base of the aerator that contains mixing elements, (*b*) jet reactor in which pressurized air and liquid are combined in a mixing chamber (As the jet is emitted, the surrounding liquid is entrained to enhance oxygen transfer.), (*c*) jet aerator in a manifold arrangement, and (*d*) aspirating aerator.

In the static tube aerator (see Fig. 5–60*a*), air is introduced at the bottom of a circular tube that can vary in height from 0.5 to 1.25 m (1.5 to 4.0 ft). Internally, the tubes are fitted with alternately placed deflection plates to increase the contact of the air with the wastewater. Mixing is accomplished because the tube aerator acts as an airlift pump. Static tubes are normally installed in a grid-type floor coverage pattern.

Other Air-Diffusion Devices Jet aeration (see Fig. 5–60*b* and *c*) combines liquid pumping with air diffusion. The pumping system recirculates liquid in the aeration basin, ejecting it with compressed air through a nozzle assembly. This system is particularly suited for deep (>8 m) tanks. Aspirating aeration (Fig. 5–60*d*) consists of a

Figure 5–61
U-tube aerator.

motor-driven aspirator pump. The pump draws air in through a hollow tube and injects it underwater where both high velocity and propeller action create turbulence and diffuse the air bubbles. The aspirating device can be mounted on a fixed structure or on pontoons. U-tube aeration consists of a deep shaft that is divided into two zones (see Fig. 5–61). Air is added to the influent wastewater in the downcomer under high pressure; the mixture travels to the bottom of the tube and then back to the surface. The great depth to which the air-water mixture is subjected results in high oxygen transfer efficiencies because the high pressure forces all the oxygen into solution. U-tube aeration has particular application for high-strength wastes.

Diffuser Performance. The efficiency of oxygen transfer depends on many factors, including the type, size, and shape of the diffuser; the air flowrate; the depth of submersion; tank geometry including the header and diffuser location; and wastewater characteristics. Aeration devices are conventionally evaluated in clean water and the results adjusted to process operating conditions through widely used conversion factors. Typical clean water transfer efficiencies and air flowrates for various diffused-air devices are reported in Table 5–27. Typically, the standard oxygen transfer efficiency (SOTE) increases with depth; the transfer efficiencies in Table 5–27 are shown for the 4.5-m (15-ft) depth, the most common depth of submergence. Data on the variation of SOTE with water depth for various diffuser types can be found in WPCF (1988). The variation of oxygen transfer efficiencies with the type of diffuser and diffuser arrangement are also illustrated in Table 5–27. Additional data on the effects of diffuser arrangement on transfer efficiency are reported in U.S. EPA (1989).

Table 5-27
Typical information on the clean water oxygen transfer efficiency of various air diffuser systems[a]

Diffuser type and placement	Air flowrate/diffuser		SOTE (%) at 4.5 m (15 ft) submergence[b]
	ft³/min	m³/min	
Ceramic disks—grid	0.4–3.4	0.01–0.1	25–35
Ceramic domes—grid	0.5–2.5	0.015–0.07	27–37
Ceramic plates—grid	2.0–5.0[c]	0.6–1.5[d]	26–33
Rigid porous plastic tubes			
Grid	2.4–4.0	0.07–0.11	28–32

N/A – not applicable.

Oxygen transfer efficiency (OTE) of porous diffusers may also decrease with use due to internal clogging or exterior fouling. Internal clogging may be due to impurities in the compressed air that have not been removed by the air filters. External fouling may be due to the formation of biological slimes or inorganic precipitants. The effect of fouling on OTE is described by the term F. The rate at which F decreases with time is designated f_F, which is expressed as the decimal fraction of OTE lost per unit time. The rate of fouling

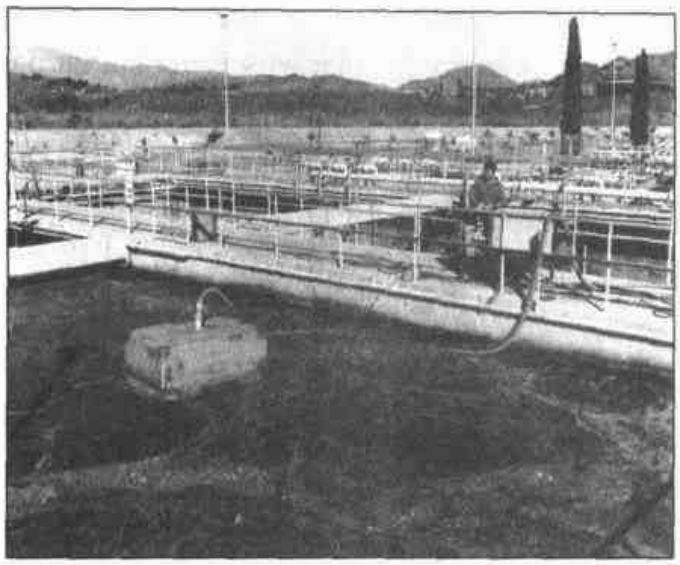

Figure 5–62
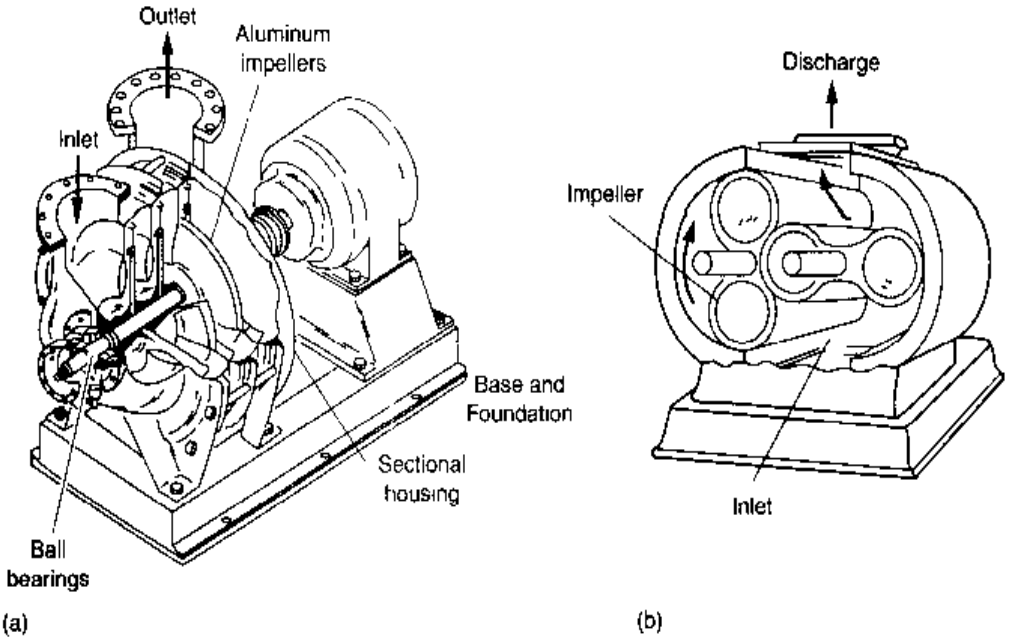
Aeration hood used to measure oxygen transfer rates in a biological wastewater treatment reactor.

will depend on the operating conditions, changes in wastewater characteristics, and the time in service. The fouling rates are important in determining the loss of OTE and the expected frequency of diffuser cleaning. Fouling and the rate of fouling can be estimated by (1) conducting full-scale OTE tests over a period of time, (2) monitoring aeration system efficiency (see Fig. 5–62), and (3) conducting OTE tests of fouled and new diffusers.



Factors commonly used to convert the oxygen transfer required for clean water to wastewater are the alpha, beta, and theta factors as described in Sec. 5–11. The alpha factor, the ratio of the K_La of wastewater to the K_La of clean water, is especially important because alpha factor varies with the physical features of the diffuser system, the geometry of the reactor, and the characteristics of the wastewater. Wastewater constituents may affect porous diffuser oxygen transfer efficiencies to a greater extent than other aeration devices, resulting in lower alpha factors. The presence of constituents such as detergents, dissolved solids, and suspended solids can affect the bubble shape and size and result in diminished oxygen transfer capability. Values of alpha varying from 0.4 to 0.9 have been reported for fine-bubble diffuser systems (Hwang and Stenstrom, 1985). Therefore, considerable care must be exercised in the selection of the appropriate alpha factors.

Another measure of the performance of porous diffusers is the combination of the alpha and fouling factors, designated by the term αF. In a number of in-process studies, the values of αF have ranged widely, from 0.11 to 0.79 with a mean of < 0.5, and were significantly lower than anticipated (U.S. EPA, 1989). The variability of αF was found to be site-specific, and demonstrated the need for the designer to investigate and evaluate carefully the environmental factors that may affect porous diffuser performance in selecting an appropriate α or αF factor.

Because the amount of air used per kilogram (pound) of BOD removed varies greatly from one plant to another, and there is risk in comparing the air use at different plants, not only because of the factors mentioned above but also because of different loading rates, control criteria, and operating procedures. Extra-high air flowrates applied along one side of a tank reduce the efficiency of oxygen transfer and may even reduce the net oxygen transfer by increasing circulating velocities. The result is a shorter residence time of air bubbles as well as larger bubbles with less transfer surface.

Figure 5–63

Typical blowers used for diffused-air aeration: (a) centrifugal and (b) rotary-lobe positive displacement.

Methods of cleaning porous diffusers may consist of refiring of ceramic plates, high-pressure water sprays, brushing, or chemical treatment with acid or caustic baths. Additional details on cleaning methods may be found in U.S. EPA (1989).

Blowers. There are three types of blowers commonly used for aeration: centrifugal, rotary lobe positive displacement, and inlet guide vane-variable diffuser. Centrifugal blowers (see Fig. 5–63*a*) are almost universally used where the unit capacity is greater than 425 m^3/min (15,000 ft^3/min) of free air. Rated discharge pressures range normally from 48 to 62 kN/m^2 (7 to 9 lb_f/in^2). Centrifugal blowers have operating characteristics similar to a low-specific-speed centrifugal pump. The discharge pressure rises from shutoff to a maximum at about 50 percent of capacity and then drops off. The operating point of the blower is determined, similar to a centrifugal pump, by the intersection of the head-capacity curve and the system curve.

In wastewater-treatment plants, the blowers must supply a wide range of airflows with a relatively narrow pressure range under varied environmental conditions. A blower usually can only meet one particular set of operating conditions efficiently. Because it is necessary to meet a wide range of airflows and pressures at a wastewater-treatment plant, provisions have to be included in the blower system design to regulate or turn down the blowers. Methods to achieve regulation or turndown are (1) flow blowoff or bypassing, (2) inlet throttling, (3) adjustable discharge diffuser, (4) variable-speed driver, and (5) parallel operation of multiple units. Inlet throttling and an adjustable discharge diffuser are applicable only to centrifugal blowers; variable-speed drivers are more commonly used on positive-displacement blowers. Flow blowoff and bypassing is also an effective method of controlling surging of a centrifugal blower, a phenomenon that occurs when the blower operates alternately at zero capacity and full capacity, resulting in vibration and overheating. Surging occurs when the blower operates in a low volumetric range.

For higher discharge pressure applications [> 55 kN/m^2 (8 lb_f/in^2)] and for capacities smaller than 425 m^3/min (15,000 ft^3/min) of free air per unit, rotary-lobe positive-displacement blowers are commonly used (see Fig. 5–63*b*). The positive-displacement

blower is a machine of constant capacity with variable pressure. The units cannot be throttled, but capacity control can be obtained by the use of multiple units or a variable-speed drive. Rugged inlet and discharge silencers are essential.

A relatively new blower design, the inlet guide vane-variable diffuser that was developed in Europe, mitigates some of the problems and considerations associated with standard centrifugal and positive-displacement aeration blowers. The design is based on a single-stage centrifugal operation that incorporates actuators to position the inlet guide vane and variable diffusers to vary blower flowrate and optimize efficiency. The blowers are especially well suited to applications with medium to high fluctuations in inlet temperature, discharge pressure, and flowrate. Blower capacities range from 85 to 1700 m^3/min (3000 to 60,000 ft^3/min) at pressures up to 170 kN/m^2 (25 lb_f/in^2). Turndown rates of up to 40 percent of maximum capacity are possible without significant reduction in operating efficiency over the range of operation. Principal disadvantages are high initial cost and a sophisticated computer control system to ensure efficient operation.

The performance curve for a centrifugal blower is a plot of pressure versus inlet air volume and resembles the performance curve for a centrifugal pump. The performance curve typically is a falling-head curve where the pressure decreases as the inlet volume increases. Blowers are rated at standard air conditions, defined as a temperature of 20°C (68°F), a pressure of 760 mm Hg (14.7 lb_f/in^2), and a relative humidity of 36 percent. Standard air has a specific weight of 1.20 kg/m^3 (0.0750 lb/ft^3). The air density affects the performance of a centrifugal blower; any change in the inlet air temperature and barometric pressure will change the density of the compressed air. The greater the gas density, the higher the pressure will rise. As a result, greater power is needed for the compression process (see Fig. 5–64). (Typical values for the specific weight of ambient air are presented in Appendix B). Blowers must be selected to have adequate capacity for a hot summer day, and be provided with a driver with adequate power for the coldest winter weather. The power requirement for adiabatic compression is given in Eq. (5–56).

$$P_w = \frac{wRT_1}{29.7\,n\,e}\left[\left(\frac{p_2}{p_1}\right)^{0.283} - 1\right] \quad \text{SI units} \qquad (5\text{–}56a)$$

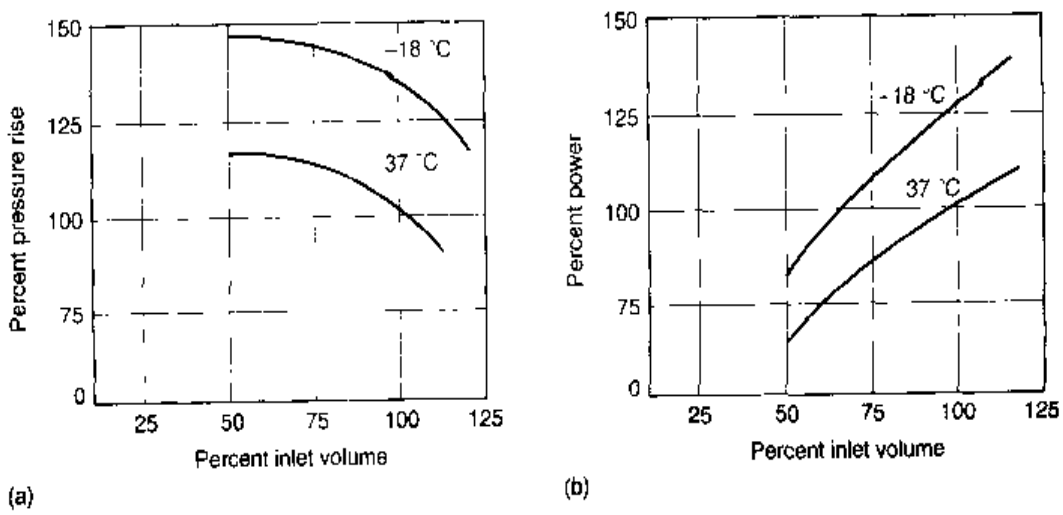


Figure 5–64

Characteristic curves for centrifugal blower at various inlet air temperatures.

$$P_w = \frac{wRT_1}{550\,n\,e}\left[\left(\frac{p_2}{p_1}\right)^{0.283} - 1\right] \text{ (U.S. customary units)} \qquad (5\text{–}56b)$$

where P_w = power requirement of each blower, kW (hp)
w = weight of flow of air, kg/s (lb/s)
R = engineering gas constant for air, 8.314 kJ/k mol K (SI units)
53.3 ft·lb/(lb air)·°R (U.S. customary units)
T_1 = absolute inlet temperature, K (°R)
p_1 = absolute inlet pressure, atm (lb_f/in^2)
p_2 = absolute outlet pressure, atm (lb_f/in^2)
n = $(k - 1)/k = 0.283$ for air
k = 1.395 for air
29.7 = constant for SI units conversion
550 = ft·lb/s·hp
e = efficiency (usual range for compressors is 0.70 to 0.90)

Air Piping. Air piping consists of mains, valves, meters, and other fittings that transport compressed air from the blowers to the air diffusers. Because the pressures are low [less than 70 kN/m^2 (10 lb_f/in^2)], lightweight piping can be used.

The piping should be sized so that losses in air headers and diffuser manifolds are small in comparison to the losses in the diffusers. Typically, if headlosses in the air piping between the last flow-split device and the farthest diffuser are less than 10 percent of the headloss across the diffusers, good air distribution through the aeration basin can be maintained. Valves and control orifices are an important consideration in piping design (WEF, 1998*b*). Typical velocities in air piping are given in Table 5–28.

Friction losses in air piping can be calculated using the Darcy-Weisbach equation written in the following form:

$$h_L = f\,\frac{L}{D}\,h_i \qquad (5\text{–}57)$$

where h_L = friction loss, mm (in) of water
f = dimensionless friction factor obtained from Moody diagram (see Appendix G) based on relative roughness. It is recommended that f be increased by at least 10 percent to allow for an increase in friction factor as the pipe ages.

Table 5–28
Typical air velocities in aeration header pipes

Pipe diameter		Velocity[a]	
in	mm	ft/min	m/min
1–3	75–225	1200–1800	360–540
4–10	100–250	1800–3000	540–900
12–24	300–600	2700–4000	800–1200
30–60	750–1500	3800–6500	1100–2000

[a] At standard conditions.

L = equivalent length of pipe, m (ft)
D = pipe diameter, m (ft)
h_i = velocity head of air, mm (in) of water

The friction factor for steel pipes carrying air can be approximated by Eq. (5–58) (McGhee, 1991).

$$f = \frac{0.029\ (D)^{0.027}}{Q^{0.148}} \qquad (5\text{–}58)$$

where Q = airflow, m³/min (ft³/min) under prevailing pressure and temperature conditions
D = pipe diameter, m (ft)

Headloss in a straight pipe can be computed by substituting Eq. (5–58) in Eq. (5–57), which yields

$$h_L = 9.82 \times 10^{-8}\left(\frac{fLTQ^2}{PD}\right) \qquad (5\text{–}59)$$

where P = air supply pressure, atm
T = temperature in pipe, K [from Eq. (5–60)]

$$T = T_o\ (P/P_o)^{0.283} \qquad (5\text{–}60)$$

where T_o = ambient air temperature, K (maximum summer air temperature)
P_o = ambient barometric temperature, atm

Losses in elbows, tees, valves, etc., can be computed as a fraction of velocity head using headloss coefficient K values given in the companion volume to this text (Metcalf & Eddy, 1981) or in standard hydraulic texts. Minor losses can also be computed as equivalent lengths of straight pipe, as follows:

$$L = 55.4\ CD^{1.2} \qquad (5\text{–}61)$$

where L = equivalent length of pipe, L (m)
D = pipe diameter, L (m)
C = resistance factor (see Table 5–29)

Table 5–29
Resistance factors for fittings in aeration piping systems

Fitting	C factor
Long-radius ell or run of standard tee	0.33
Medium-radius ell or run of tee reduced by 25 percent	0.42
Standard ell or run of tee reduced 50 percent	0.67
Tee through side outlet	1.33
Gate valves	0.25
Globe valve	2.00
Angle valve	0.90

Table 5–30
Typical headlosses through air filters, blower silences, and check valves[a]

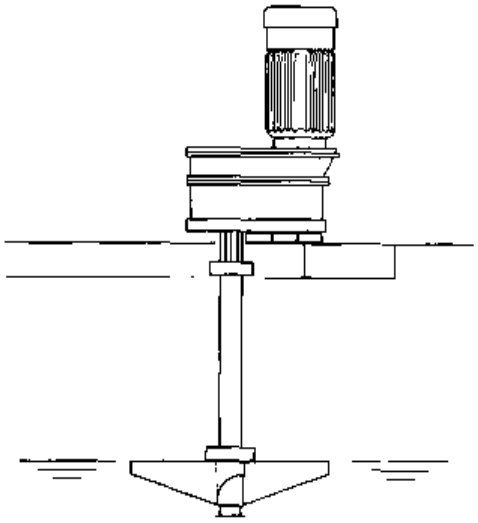
Device	Headloss	
	mm	in
Air filter	13–76	0.5–3
Silencer		
Centrifugal blower	13–38	0.5–1.5
Positive-displacement blower	152–216	6–8.5
Check valve	20–203	0.8–8

[a] Adapted from Qasim (1999)

Meter losses can be estimated as a fraction of the differential velocity head across the meter, depending on the type of meter. Losses in air filters, blower silencers, and check valves should be obtained from equipment manufacturers, but approximate values given in Table 5–30 can be used as a guide (Qasim, 1999).

The discharge pressure at the blowers will be the sum of the above losses, the depth of water over the air diffusers, and the loss through the diffusers.

Because of the high temperature of the air discharged by blowers [60 to 80°C (140 to 180°F)], condensation in the air piping is not a problem, except where piping is submerged in the wastewater. It is essential, however, that provisions be made for pipe expansion and contraction. Where porous diffusers are used, pipes must be made of nonscaling materials or must be lined with material that will not corrode. Pipe materials are often stainless steel, fiberglass, or plastics suitable for higher temperatures. Other materials used include mild steel or cast iron with external coatings (e.g., coal-tar epoxy or vinyl). Interior surfaces include cement lining or coal tar or vinyl coatings.



Mechanical Aerators

Mechanical aerators are commonly divided into two groups based on major design and operating features: aerators with vertical axis and aerators with horizontal axis. Both groups are further subdivided into surface and submerged aerators. In surface aerators, oxygen is entrained from the atmosphere; in submerged aerators, oxygen is entrained from the atmosphere and, for some types, from air or pure oxygen introduced in the tank bottom. In either case, the pumping or agitating action of the aerators helps to keep the contents of the aeration tank or basin mixed. In the following discussion, the various types of aerators will be described, along with aerator performance and the energy requirement for mixing.

Surface Mechanical Aerators with Vertical Axis. Surface mechanical aerators with a vertical axis are designed to induce either updraft or downdraft flows through a pumping action (see Fig. 5–65). Surface aerators consist of submerged or partially submerged impellers that are attached to motors mounted on floats or on fixed structures. The impellers are fabricated from steel, cast iron, noncorrosive alloys, and fiberglass-reinforced plastic and are used to agitate the wastewater vigorously, entraining air in the wastewater and causing a rapid change in the air-water interface to facilitate solution of the air. Surface aerators may be classified according to the type of

Figure 5–65

(d)

impeller used: centrifugal, radial-axial, or axial; or the speed of rotation of the impeller: low and high speed. Centrifugal impellers belong to the low-speed category; the axial-flow impeller type aerators operate at high speed. In low-speed aerators, the impeller is driven through a reduction gear by an electric motor (see Fig. 5–65*a*). The motor and gearbox are usually mounted on a platform that is supported either by piers extending to the bottom of the tank or by beams that span the tank. Low-speed aerators may also be mounted on floats. In high-speed aerators, the impeller is coupled directly to the rotating element of the electric motor (see Fig. 5–65*c*). High-speed aerators are almost always mounted on floats. These units were originally developed for use in ponds or lagoons where the water surface elevation fluctuates, or where a rigid support would be impractical. Surface aerators may be obtained in sizes from 0.75 to 100 kW (1 to150 hp).

Submerged Mechanical Aerators with Vertical Axis. Most surface mechanical aerators are upflow types that rely on violent agitation of the surface and air entrainment for their efficiency. With submerged mechanical aerators, however, air or

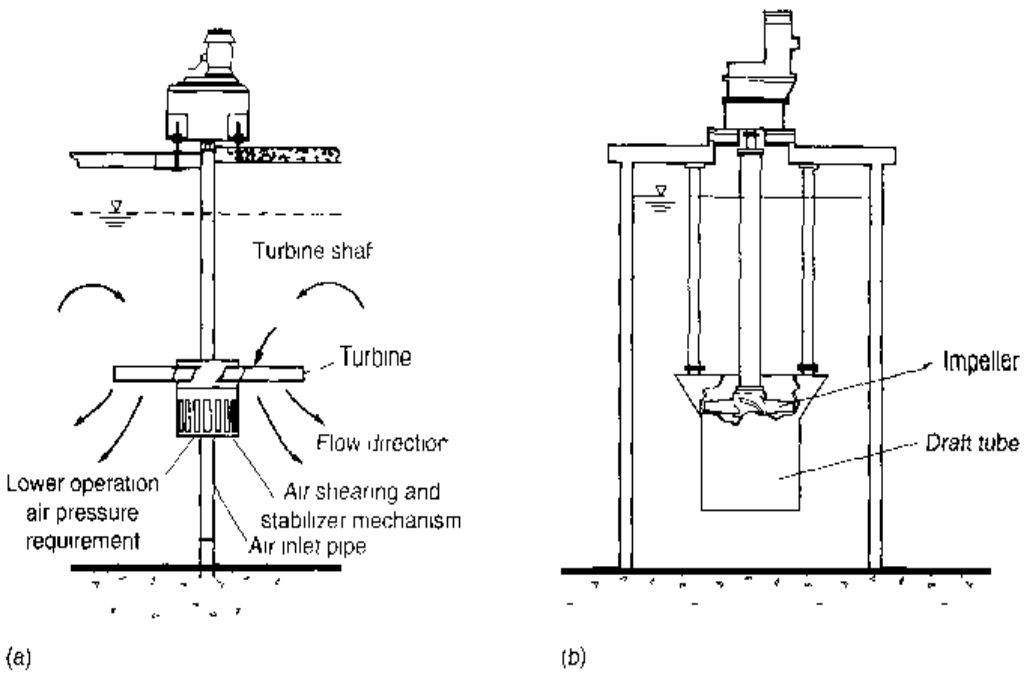

Figure 5-66

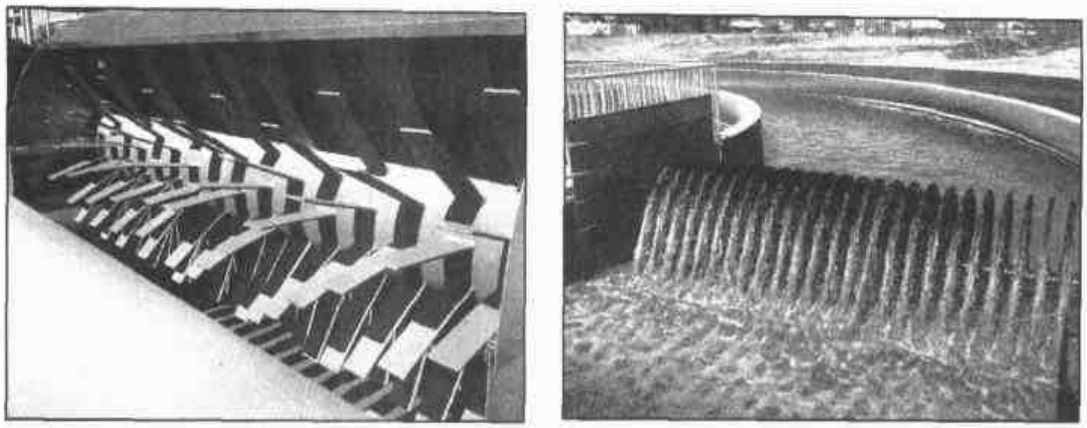
Typical submerged mechanical aerators: (*a*) turbine type with supplementary air or oxygen feed introduced below the turbine, and (*b*) draft tube turbine aerator equipped with an air sparger. *(Adapted from Philadelphia Mixer Catalog.)*



pure oxygen may also be introduced by diffusion into the wastewater beneath the impeller or downflow of radial aerators (see Fig. 5–66*a*). The impeller is used to disperse the air bubbles and mix the tank contents. A draft tube may be used with either upflow or downflow models to control the flow pattern of the circulating liquid within the aeration tank (see Fig. 5–66*b*). The draft tube is a cylinder, usually with flared ends, mounted concentrically with the impeller. The length of the draft tube depends upon the aerator manufacturer. Submerged mechanical aerators may be obtained in sizes from 0.75 to 100 kW (1 to 150 hp).

Mechanical Aerators with Horizontal Axis. Mechanical aerators with horizontal axis are divided into two groups: surface and submerged aerators. The surface aerator is patterned after the original Kessener brush aerator, a device used to provide both aeration and circulation in oxidation ditches. The brush-type aerator had a horizontal cylinder with bristles mounted just above the water surface. The bristles were submerged in the water and the cylinder was rotated rapidly by an electric motor drive, spraying wastewater across the tank, promoting circulation, and entraining air in the wastewater. Angle steel, steel of other shapes, or plastic bars or blades are now used instead of bristles. A typical horizontal-axis surface aerator is shown on Fig. 5–67.

Submerged horizontal-axis aerators are similar in principle to surface aerators except disks or paddles attached to rotating shafts are used to agitate the water. The disk aerator has been used in numerous applications for channel and oxidation ditch aeration. The disks are submerged in the wastewater for approximately one-eighth to three-eighths of the diameter and enter the water in a continuous, nonpulsating manner. Recesses in the disks introduce entrapped air beneath the surface as the disk turns. Spacing of the disks can vary depending on the oxygen and mixing requirements of the process. Typical power requirements are reported as 0.1 to 0.75 kW/disk (0.15 to 1.00 hp/disk) (WPCF, 1988).

(a) (b)

Table 5–31
Typical ranges of oxygen transfer capabilities for various types of mechanical aerators[a]

Aeration system	Transfer rate, lb O_2/hp·h		Transfer rate, kg O_2/kW·h	
	Standard[b]	Field[c]	Standard	Field
Surface low-speed	2.5–3.5	1.2–2.4	1.5–2.1	0.7–1.5
Surface low-speed with draft tube	2.0–4.6	1.2–2.1	1.2–2.8	0.7–1.3
Surface high-speed	1.8–2.3	1.2–2.0	1.1–1.4	0.7–1.2
Submerged turbine with draft tube	2.0–3.3	1.2–1.8[d]	1.2–2.0	0.6–1.1
Submerged turbine	1.8–3.5		1.1–2.1	
Submerged turbine with sparger	2.0–3.3	1.2–1.8[d]	1.2–2.0	0.7–1.0
Horizontal rotor	1.5–3.6	0.8–1.8	1.5–2.1	0.5–1.1

[a] Derived in part from WPCF (1988) and WEF (1998*b*).

[b] Standard conditions: tap water 20°C (68°F); at 100 kN/m^2 (14.7 lb$_f$/in^2); and initial dissolved oxygen = 0 mg/L

[c] Field conditions: wastewater, 15°C (59°F); altitude 150 m (500 ft), α = 0.85, β = 0.9; operating dissolved oxygen = 2 mg/L

[d] Based on research results, it appears that α values may be lower than 0.85; reported ranges vary from 0.3 to 1.1, WEF (1998*b*).

Aerator Performance. Mechanical aerators are rated in terms of their oxygen transfer rate expressed as kilograms of oxygen per kilowatt-hour (pounds of oxygen per horsepower-hour) at standard conditions. Standard conditions exist when the temperature is 20°C, the dissolved oxygen is 0.0 mg/L, and the test liquid is tap water. Testing and rating are normally done under non-steady-state conditions using fresh water, deaerated with sodium sulfite. Commercial-size surface aerators range in efficiency from 1.20 to 2.4 kg O_2/kW·h (2 to 4 lb O_2/hp·h). Oxygen transfer data for various types of mechanical aerators are reported in Table 5–31. Efficiency claims for aerator performance should be accepted by the design engineer only when they are supported by actual test data for the actual model and size of aerator under consideration. For design purposes, the standard performance data must be adjusted to reflect anticipated field

conditions by using the following equation. The term within the brackets represents the correction factor.

$$N = N_o\left(\frac{\beta C_{walt} - C_L}{9.17}\right)1.024^{T-20}\,\alpha \qquad (5\text{–}62)$$

where N = kg O_2/kW·h (lb O_2/hp·h) transferred under field conditions
N_o = kg O_2/kW·h (lb O_2/hp·h) transferred in water at 20°C, and zero dissolved oxygen
β = salinity–surface tension correction factor, usually 1
C_{walt} = oxygen saturation concentration for tap water at given temperature and altitude (see Appendix C), mg/L and Fig. 5–68
C_L = operating oxygen concentration, mg/L
T = temperature, °C
α = oxygen transfer correction factor for waste (see Table 5–32)

The application of this equation is illustrated in Chap. 8, Sec. 8–7, which deals with the design of aerated lagoons.

Figure 5–68
Oxygen solubility correction factor versus elevation.

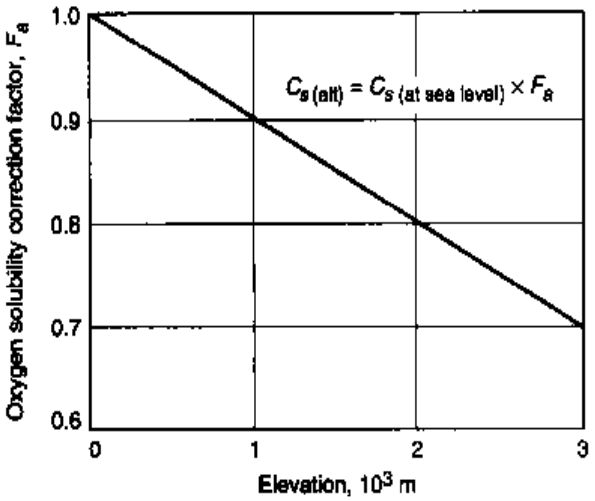

Table 5–32
Typical values of alpha factors for low-speed surface aerators and selected wastewater types[a]

Wastewater type	BOD_5, mg/L		α factor[b]	
	Influent	Effluent	Influent	Effluent
Municipal wastewater	180	3	0.82	0.98
Pulp and paper	187	50	0.68	0.77
Kraft paper	150–300	37–48	0.48–0.68	0.7–1.1
Bleached paper	250	30	0.83–1.98	0.86–1.0
Pharmaceutical plant	4500	380	1.65–2.15	0.75–0.83
Synthetic fiber plant	5400	585	1.88–3.25	1.04–2.65

[a] WPCF (1988).
[b] Research suggests that α values may be lower and more variable than values listed in table.

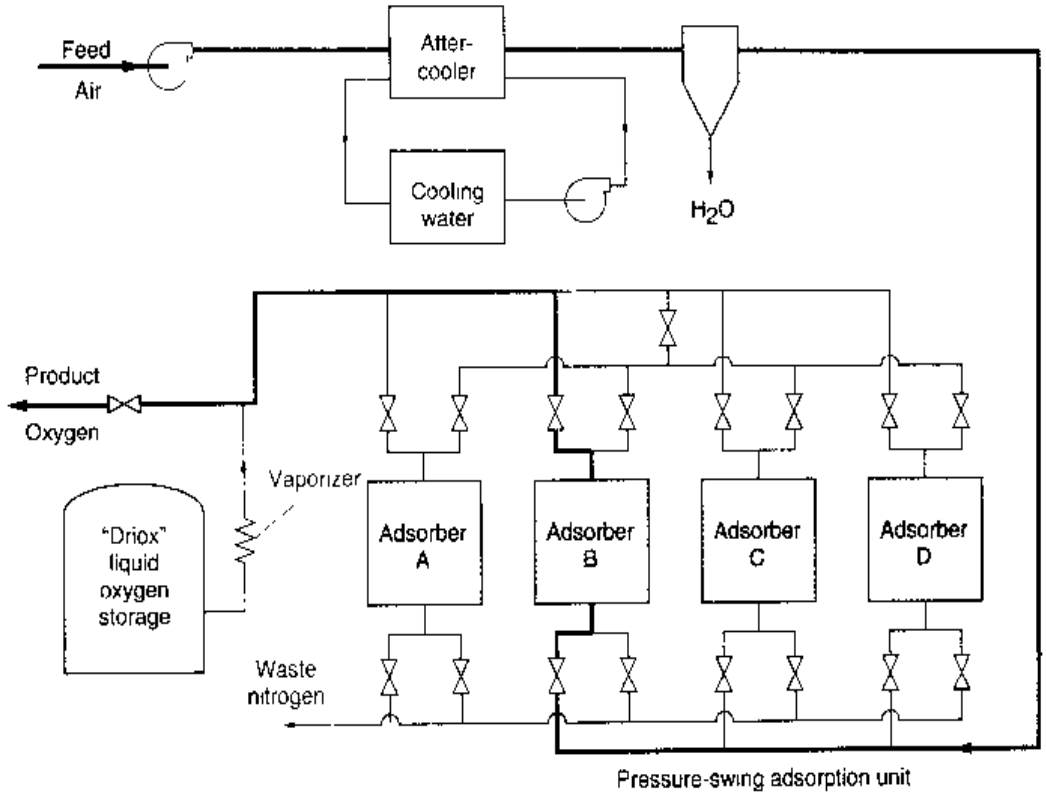
Energy Requirement for Mixing in Aeration Systems

As with diffused-air systems, the size and shape of the aeration tank are very important if good mixing is to be achieved. Aeration tanks may be square or rectangular and may contain one or more aerators. The depth and width of the aeration tanks for mechanical surface aerators are dependent on aerator size, and typical values are given in Table 5–33. Depths up to 11 m (35 ft) have been used with submerged-draft tube mixers.

In diffused-air systems, the air requirement to ensure good mixing varies from 20 to 30 $m^3/10^3$ m^3·min (20 to 30 $ft^3/10^3$ ft^3·min) of tank volume, for a spiral-roll aeration pattern. For a grid system of aeration in which the diffusers are installed uniformly along the aeration basin bottom, mixing rates of 10 to 15 $m^3/10^3$ m^3·min (10 to 15 $ft^3/10^3$ ft^3·min) have been suggested (WPCF, 1988). Typical power requirements for maintaining a completely mixed flow regime with mechanical aerators vary from 20 to 40 $kW/10^3$ m^3 (0.75 to 1.50 $hp/10^3$ ft^3), depending on the type and design of the aerator, the nature and concentration of the suspended solids, the temperature, and the geometry of the aeration tank, lagoon, or basin. In the design of aerated lagoons for the treatment of domestic wastewater, it is extremely important that the mixing power requirement be checked because, in most instances, it will be the controlling factor.

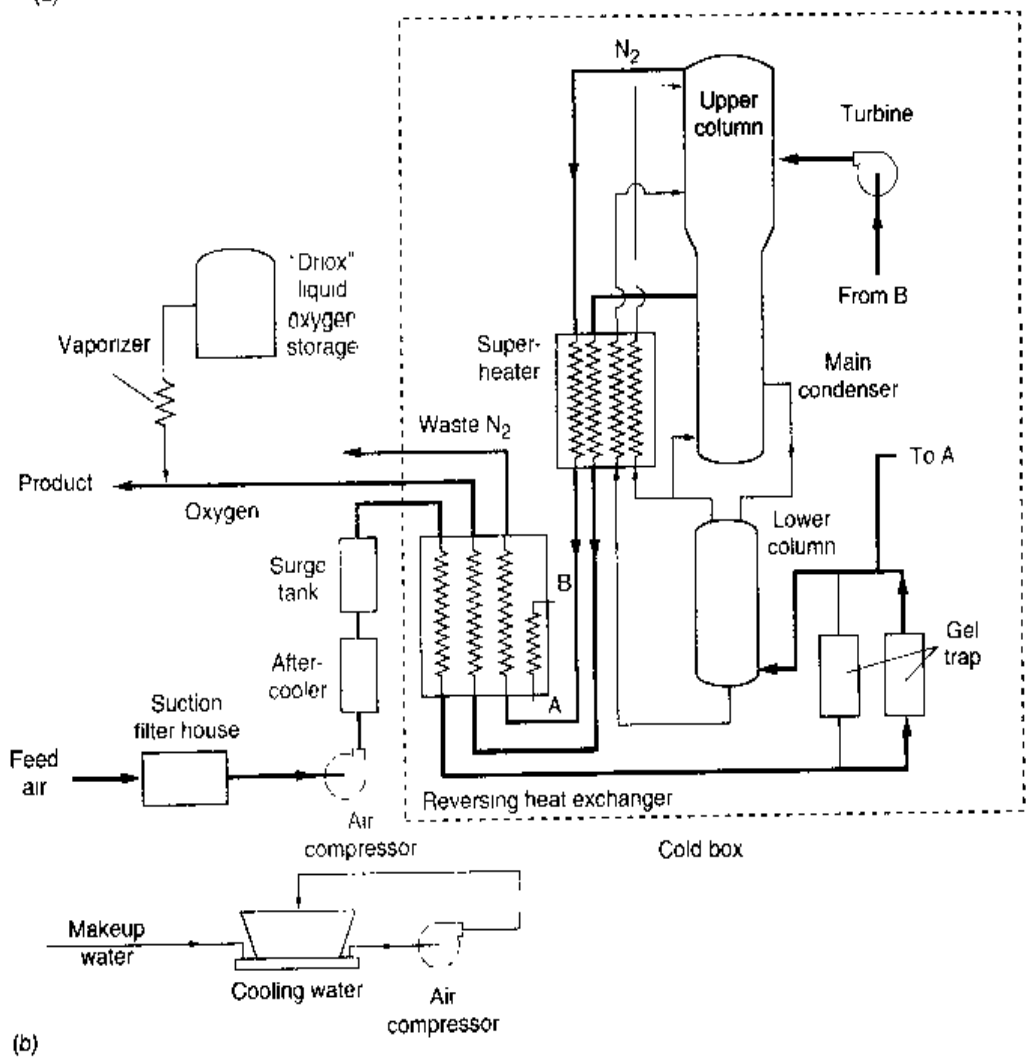
Generation and Dissolution of High-Purity Oxygen

After the quantity of oxygen required is determined, it is necessary, where high-purity oxygen is to be used, to specify the type of oxygen generator that will best serve the needs of the plant. There are two basic oxygen generator designs: (1) a pressure swing adsorption (PSA) system for smaller and more common plant sizes [less than 150,000 m^3/d (40 Mgal/d)], and (2) the traditional cryogenic air-separation process for large applications. Liquid oxygen can also be trucked in and stored onsite in a liquid form.



Pressure-Swing Adsorption. The pressure-swing adsorption system uses a multibed adsorption process to provide a continuous flow of oxygen gas (U.S. EPA, 1974). A schematic diagram of the four-bed system is shown on Fig. 5–69*a*. The operating principle of the pressure-swing adsorption generator is that the oxygen is separated from the feed air by adsorption at high pressure, and the adsorbent is regenerated by "blowdown" to low pressure. The process operates on a repeated cycle having two

Table 5–33
Typical aeration tank dimensions for mechanical surface aerators



Aerator size		Tank dimensions			
		U.S. customary units		SI units	
hp	kW	Depth, ft	Width, ft	Depth, m	Width, m
10	7.5	10–12	30–40	3–3.5	9–12
20	15	12–14	35–50	3.5–4	10–15
30	22.5	13–15	40–60	4–4.5	12–18
40	30	12–17	45–65	3.5–5	14–20

Figure 5–69

Schematic diagrams for the generation of oxygen used in the high-purity oxygen-activated sludge process: (a) pressure-swing adsorption and (b) cryogenic air separation.

(a)

(b)

basic steps, adsorption and regeneration. During the adsorption step, feed air flows through one of the adsorber vessels until the adsorbent is partially loaded with impurity. At that time the feed-air flow is switched to another adsorber, and the first adsorber is regenerated. During regeneration, the impurities are cleaned from the adsorbent so that the bed will be available again for the adsorption step. Regeneration is carried out by depressurizing to atmospheric pressure, purging with some of the oxygen, and repressurizing back to the pressure of the feed air.

Cryogenic Air Separation. The cryogenic air separation process involves the liquefaction of air, followed by fractional distillation to separate it into its components (mainly nitrogen and oxygen). A schematic diagram of this process is shown on Fig. 5–69*b*. First, the entering air is filtered and compressed, and then it is fed to the reversing heat exchangers, which perform the dual function of cooling and removing the water vapor and carbon dioxide by freezing these mixtures out into the exchanger surfaces. Periodically switching or reversing the feed air and the waste nitrogen streams through identical passes of the exchangers to regenerate their water vapor and carbon dioxide removal capacity accomplishes this process.

Next, the air is processed through "cold and gel traps," which are adsorbent beds that remove the final traces of carbon dioxide as well as most hydrocarbons from the feed air. The processed air is then divided into two streams. The first stream is fed directly to the lower column of the distillation unit. The second stream is returned to the reversing heat exchangers and partially warmed to provide the required temperature difference across the exchanger. This stream is then passed through an expansion turbine and fed into the upper column of the distillation unit. An oxygen-rich liquid exits from the bottom of the lower column and the liquid nitrogen exits from the top. Both streams are then subcooled and transferred to the upper column. In this column, the descending liquid phase becomes progressively richer in oxygen, and the liquid that subsequently collects in the condenser reboiler is the oxygen product stream. This oxygen is recirculated continually through an adsorption trap to remove all possible residual traces of hydrocarbons. The waste nitrogen exits from the top portion of the upper column and is heat exchanged along with the oxygen product to recover all available refrigeration and to regenerate the reversing heat exchangers.

Dissolution of Commercial Oxygen. Oxygen is very insoluble in water—even pure oxygen—and requires special considerations to ensure high absorption efficiency. Oxygen dissolution equipment designed for air only optimizes energy consumption because the air is free and efficient oxygen absorption is not relevant. However, because of the cost of commercial oxygen, the facilities used for its dissolution must be designed to both efficiently absorb the commercial oxygen as well as minimize the unit energy consumption. These requirements rule out the more common aeration equipment alternatives.

Dissolution Time. A key feature that must be incorporated into a commercial oxygen dissolution system is oxygen retention time. To optimize the absorption of pure oxygen it has been found that a detention time of about 100 s is required. Further, two-phase flow must be maintained to avoid the coalescence of the oxygen bubbles to maintain absorption efficiency. Unfortunately, some pure oxygen dissolution systems con-

sume as much energy to dissolve a ton of pure oxygen as standard surface aerators consume in dissolving a ton of oxygen from air.

Speece Cone (Downflow Bubble Contactor). A system that incorporates prolonged oxygen bubble contact time and high rates of oxygen transfer is a cone-shaped chamber, downflow bubble contact aerator termed the Speece cone (see Fig. 5–70*a*). Water enters the chamber at the apex with a velocity of approximately 3 m/s (10 ft/s). This inlet velocity provides the energy to maintain a two-phase bubble swarm in the cone, ensuring a very high bubble/water interface, resulting in a proportionately high gas transfer rate. The expanding horizontal cross section of the cone reduces the downward flow velocity of the water to less than 0.3 m/s (1 ft/s). Because the bubbles have a nominal buoyant velocity of about 0.3 m/s, if the downflow velocity of the water is reduced below the buoyant velocity of the bubbles, they will remain indefinitely in the cone, thus satisfying the required bubble residence time. The water, however, has a residence time of about 10 s, reflecting a relatively small volume of reactor cone. This system incorporates the desired features of relatively small size, high rate of oxygen transfer, and more than adequate bubble residence time (Speece and Tchobanoglous, 1990).

U-Tube Contactor. Another oxygen transfer system that incorporates desirable features for efficient dissolution of commercial oxygen with low unit energy consumption is the U-tube (see Fig. 5–70*b*). At a depth of 30 m (100 ft) and a throughput velocity of 2.5 m/s (8 ft/s), the residence time is 25 s. Because a contact time of 25 s is low, off-gas recycle back through the system can be used to increase the contact time to about 100 s where efficient absorption occurs. The energy requirements are low because the bubble/water mixture is pumped through a filled U-tube pipe that is hydrostatically pressurized by its vertical configuration. Use of the U-tube enhances gas transfer significantly.

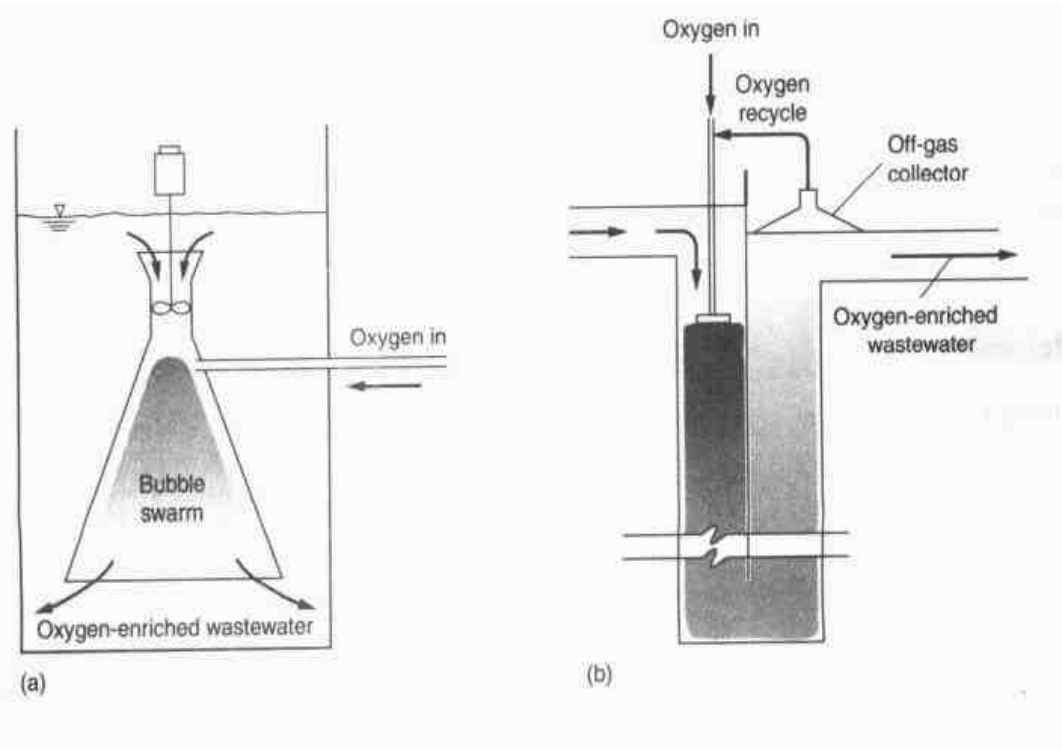

Figure 5–70

Pure oxygen dissolution systems: (*a*) Speece cone (downflow bubble contactor) and (*b*) U-tube contactor. *(Speece and Tchobanoglous, 1990.)*

Energy consumption is about 54 kWh/Mg O_2 (60 kWh/ton) while producing an effluent dissolved oxygen of 60 mg/L (Speece and Tchobanoglous, 1990).

Conventional Diffused Aeration. Conventional diffused aeration or surface aerators must operate in a closed headspace to absorb commercial oxygen efficiently. A concrete cover usually is placed over the aeration tank to enclose the headspace.

Postaeration

The requirement for postaeration systems has developed in recent years with the introduction of effluent standards and permits that include high dissolved oxygen levels (5 to 8 mg/L). Dissolved oxygen levels have become standard for discharge to water-quality-limited stream sections and to effluent dominated waters. The regulatory intent is to ensure that low dissolved oxygen levels in the treated effluent do not cause immediate depression after mixture with the waters of the receiving stream. To meet postaeration requirements, three methods are most commonly used: (1) cascade aeration, (2) mechanical aeration, and (3) diffused air. The Speece cone, described above, can also be used for postaeration and for reaerating reclaimed water-storage reservoirs.

Cascade Aeration. If site constraints and hydraulic conditions permit gravity flow, the least costly method to raise dissolved oxygen levels is with the use of cascade aeration. Cascade aeration consists of using the available discharge head to create turbulence as the wastewater falls in a thin film over a series of concrete steps. Performance depends on the initial dissolved oxygen level, required discharge dissolved oxygen, and wastewater temperature. Typical design information is given in Table 5–34. Where the cascade aeration facility joins the chlorine contact basin, the postaeration structure may be made equal to the chlorine contact basin width for ease of construction.

The most commonly used method for determining required cascade height is based on the following equations developed by Barrett (1960).

$$H = \frac{R - 1}{0.361\,ab\,(1 + 0.046 \times t)} \qquad \text{SI units} \qquad (5\text{–}63a)$$

Table 5–34
Typical design information for a cascade-type postaeration system

	U.S. customary units			SI units		
Parameter	**Units**	**Range**	**Typical**	**Units**	**Range**	**Typical**
Hydraulic loading rate at average design flow	gal/ft of width·d	100,000–500,000	240,000	m^3/m of width·d	1240–6200	3000
Step dimensions						
Height	in	6–12	8	mm	150–300	200
Length	in	12–24	18	mm	300–600	450
Cascade height	ft	6–16		m	2–5	

$$H = \frac{R - 1}{0.11\,ab\,(1 + 0.046 \times T)} \qquad \text{U.S. customary units} \qquad (5\text{–}63b)$$

where R = deficit ratio = $\dfrac{C_s - C_o}{C_s - C}$

C_s = dissolved oxygen saturation concentration of the wastewater at temperature T, mg/L

C_o = dissolved oxygen concentration of the postaeration influent, mg/L

C = required final dissolved oxygen level after postaeration, mg/L

a = water-quality parameter equal to 0.8 for a wastewater-treatment plant effluent

b = weir geometry parameter for a weir, $b = 1.0$; for steps, $b = 1.1$; for step weir, $b = 1.3$)

T = water temperature, °C

H = height through which water falls, m (ft)

A key element is the proper selection of the critical wastewater temperature, which affects the dissolved oxygen saturation concentration C_s. The effect of temperature is illustrated in Example 5–14.

EXAMPLE 5–14 Calculation of Cascade Aeration Height Calculate the height of a cascade aeration system for a wastewater-treatment plant in a warm climate where the wastewater temperature averages 20°C in the winter and 25°C in the summer. The dissolved oxygen in the influent to the postaeration system C_o is 1.0 mg/L and the required final dissolved oxygen concentration C is 6.0 mg/L.

Solution

1. Determine the dissolved oxygen saturation concentration C_s at the wastewater temperatures.
   a. From Appendix D, the dissolved oxygen solubilities are:

      for 20°C = 9.08 mg/L; for 25°C = 8.24 mg/L.

2. Calculate the cascade height for $T = 20$°C using Eq. (5–63*a*).
   a. Calculate the deficit ratio

$$R = \text{deficit ratio} = \frac{C_s - C_o}{C_s - C} = \frac{9.08 - 1.0}{9.08 - 6.0} = 2.62$$

   b. Calculate the cascade height, assuming steps.

$$H = \frac{R - 1}{0.361\,ab\,(1 + 0.046T)}$$

$$H = \frac{2.62 - 1}{0.361\,(0.8)(1.1)(1 + 0.046 \times 20)}$$

$$H = 2.66 \text{ m } (8.73 \text{ ft})$$

3. Calculate the cascade height for $T = 25°C$.
   a. Calculate the deficit ratio

$$R = \frac{8.24 - 1.0}{8.24 - 6.0} = 3.23$$

   b. Calculate the cascade height, assuming steps and using the same computation procedure as in 2*b* above.

$H = 3.12$ m (9.99 ft)

Comment The increased wastewater temperature increases the dissolved oxygen deficit ratio and therefore affects the height of the cascade. The maximum wastewater temperatures should be checked to ensure the cascade height is not underdesigned.

Mechanical Aeration. Two major types of mechanical aeration equipment are commonly used for postaeration systems: low-speed surface aerators and submerged turbine aerators. Low-speed surface aerators are preferred because they are usually the most economical, except where high oxygen transfer rates are required. For high oxygen transfer rates, submerged turbine units are preferred. Most installations consist of two or more aerators in rectangular basins. Detention times for postaeration using either mechanical or diffused-air aeration are usually 10 to 20 min at peak flowrates.

Diffused-Air Aeration. In larger treatment plants, diffused aeration systems may be more appropriate. Coarse- or fine-bubble diffusers may be used. Depending on the depth of submergence, transfer efficiencies of 5 to 8 percent may be attained with nonporous diffusers, and 15 to 25 percent with fine-pore diffusers. After secondary treatment, the alpha factors should range from 0.85 to 0.95 for nonporous systems, and from 0.70 to 0.85 for fine-pore systems.

EXAMPLE 5–15 Derivation of Equation for Estimating Diffused-Air Requirements for Postaeration Develop an expression that can be used to estimate the diffused-air requirement for the postaeration of effluent following chlorination. Assume that aeration will be accomplished in a plug-flow reactor.

Solution

1. Write an equation for the oxygen-solution rate. The appropriate expression, similar to Eq. (5–50), is

$$r_m = \frac{dm}{dt} = K'_T (C_s - C)$$

where K'_T = overall mass transfer coefficient for the given conditions

$$K'_T = K'_{20} \times (1.024)^{T-20}$$

2. Write an expression for the oxygen-transfer efficiency. The efficiency may be defined as

$$E = \frac{(dm/dt)_{20°C,C=0}}{M}$$

where E = oxygen transfer efficiency
$(dm/dt)_{20°C,C=0}$ = oxygen-solution rate at 20°C and zero dissolved oxygen
M = mass rate at which oxygen is introduced

3. Develop a differential expression for the mass rate at which oxygen is introduced. The mass rate at which oxygen is introduced is given by

$$M = \frac{1}{E}\left(\frac{dm}{dt}\right)_{20°C,C=0}$$

$$= \frac{1}{E}\left(\frac{dm}{dt}\right)_T \frac{(dm/dt)_{20°C,C=0}}{(dm/dt)_T}$$

Substituting for $(dm/dt)_{20,\,C=0}$ and $(dm/dt)_T$ yields

$$M = \frac{1}{E}\left(\frac{dm}{dt}\right)_T \frac{(C_s)_{20°C}}{(C_s - C)_T(1.024)^{T-20}}$$

If the expression is applied to an infinitesimal transverse segment of the tank and $Q\,dC$ is substituted for dm/dt [note that $V(dC/dt) = dm/dt$ and $Q = V/dt$], then the differential form of the above expression can be rewritten as

$$dm = \frac{Q(C_s)_{20°C}}{E(1.024)^{T-2}}\left(\frac{dC}{C_s - C}\right)_T$$

4. Derive the integrated form of the differential expression that was derived in step 3. The integrated form of the equation can be obtained by integrating the expression from the inlet of the tank where $C = C_i$ to the outlet of the tank where $C = C_o$:

$$\int_0^M dM = \frac{Q(C_s)_{20°C}}{E(1.024)^{T-20}} \int_{C_i}^{C_o} \frac{dc}{C_s - C}$$

$$M = \frac{Q(C_s)_{20°C}}{E(1.024)^{T-20}}\left(\ln \frac{C_s - C_i}{C_s - C_o}\right)_T$$

5. Rewrite the equation derived in step 4 in a more practical format. Note that the density of air is 1.23 kg/m^3 and air contains about 23 percent oxygen by weight. Using these values, the rate of oxygen input, in terms of the equivalent air flowrate expressed in m^3/s, is equal to

$$Q_a = 3.53 \times 10^{-3} \frac{Q(C_s)_{20°C}}{E(1.024)^{T-20}}\left(\ln \frac{C_s - C}{C_s - C_o}\right)$$

where Q_a = required air flowrate, m^3/s
Q = wastewater flowrate, m^3/s
C_s = saturation concentration of oxygen at 20°C, g/m^3

Comment The value of Q_a is usually multiplied by a factor of 1.1 to account for the fact that the saturation value of oxygen in wastewater is about 95 percent of that in distilled water, and to account for the difference in the transfer rates.

Aeration Using the Speece Cone. In postaeration with a Speece cone, a sidestream of the main flow is oxygenated and then reblended with the main flow before discharge. In open reservoirs used for storing reclaimed water, problems occur due to temperature stratification, low dissolved oxygen, and release of odors, principally hydrogen sulfide (see Sec. 13–4). The Speece cone, which has a very high oxygen transfer rate and is shown on Fig. 5–70*a*, is ideally suited for reservoir aeration and temperature destratification. For reservoir aeration applications, compressed air can be used instead of high-purity oxygen.

5–13 REMOVAL OF VOLATILE ORGANIC COMPOUNDS (VOCs) BY AERATION

At some wastewater-treatment facilities, volatile organic compounds (VOCs) such as trichloroethylene (TCE) and 1,2-dibromo-3-chloropropane (DBCP) have been detected in wastewater. The uncontrolled release of such compounds that now occurs in wastewater-collection systems and wastewater-treatment plants is an area of concern. The mechanisms governing the release of these compounds, the locations where the release of these compounds is most prevalent, and the methods of controlling the discharge of these compounds to the atmosphere are discussed in this section.

Emission of VOCs

The principal mechanisms governing the release of VOCs in wastewater collection and treatment facilities are (1) volatilization and (2) gas stripping. These mechanisms and the principal locations where VOCs are released are considered in the following discussion.

Volatilization. The release of VOCs from wastewater surfaces to the atmosphere is termed volatilization. Volatile organic compounds are released because they partition between the gas and water phase until equilibrium concentrations are reached (Roberts et al., 1984). The mass transfer (movement) of a constituent between these two phases is a function of the constituent concentration in each phase relative to the equilibrium concentration. Thus, the transfer of a constituent between phases is greatest when the concentration in one of the phases is far from equilibrium. Because the concentration of VOCs in the atmosphere is extremely low, the transfer of VOCs usually occurs from wastewater to the atmosphere.

Gas Stripping. Gas stripping of VOCs occurs when a gas (usually air) is temporarily entrained in wastewater or is introduced purposefully to achieve a treatment

objective. When gas is introduced into a wastewater, VOCs are transferred from the wastewater to the gas. The forces governing the transfer between phases are the same as described above. For this reason, gas (air) stripping is most effective when contaminated wastewater is exposed to contaminant-free air. In wastewater treatment, air stripping occurs most commonly in aerated grit chambers, aerated biological treatment processes, and aerated transfer channels. Specially designed facilities (e.g., stripping towers) for gas stripping are considered in Sec. 11–8 in Chap 11.

Locations Where VOCs Are Emitted. The principal locations where VOCs are emitted from wastewater collection and treatment facilities are summarized in Table 5–35. The degree of VOC removal at a given location will depend on local conditions. Mass transfer is considered in the following section.

Mass Transfer Rates for VOCs

The mass transfer of VOCs can, for practical purposes, be modeled using the following equation (Roberts et al., 1984, and Thibodeaux, 1979):

$$r_{VOC} = -K_L a_{VOC}(C - C_s) \tag{5–64}$$

Where r_{VOC} = rate of VOC mass transfer, $\mu g/m^3 \cdot h$
$(K_L a)_{VOC}$ = overall VOC mass transfer coefficient, 1/h
C = concentration of VOC in liquid, $\mu g/m^3$
C_s = saturation concentration of VOC in liquid, $\mu g/m^3$

Due to chemical handling and analytical requirements, measuring $K_L a_{VOC}$ is much more difficult than measuring $K_L a_{O_2}$. Therefore, a practical approach is to relate the $K_L a_{VOC}$ to the $K_L a_{O_2}$. The following equation relates the mass transfer coefficients as a function of the VOC and O_2 diffusion coefficients in water:

$$K_L a_{VOC} = K_L a_{O_2}\left(\frac{D_{VOC}}{D_{O_2}}\right)^n \tag{5–65}$$

where $K_L a_{VOC}$ = system mass transfer coefficient, T^{-1} (1/h)
$K_L a_{O_2}$ = system oxygen mass transfer coefficient, T^{-1} (1/h)
D_{VOC} = diffusion coefficient of VOC in water, L^2T^{-1} (cm^2/s)
D_{O_2} = diffusion coefficient of oxygen in water, L^2T^{-1} cm^2/s
n = coefficient

Diffusion coefficient values for different compounds can be obtained from Schwarzenbach et al. (1993) or in other handbooks, and some variation in literature values will be found. Experimental investigations of $K_L a_{VOC}$ versus $K_L a_{O_2}$ have shown that Eq. (5–65) can be generally applicable, and that the value for n varies depending on whether the gas/liquid transfer is accomplished by surface aeration, diffused aeration, or a packed column air stripper, and the power intensity of the gas transfer device (Roberts and Dandliker, 1983; Matter-Muller et al.; 1981, Hsieh et al., 1993; Libra, 1993; and Bielefeldt and Stensel, 1999). For practical power intensities of less than 100 W/m^3 a reasonable value of n is 0.50 for packed columns and mechanical aeration and 1.0 for diffused aeration. For higher power intensities the work of Hsieh et al. (1993) should be consulted. The $K_L a_{VOC}$ was also found to be essentially the same in wastewater as in tap water (Bielefeldt and Stensel, 1999).

Table 5–35
Sources, methods of release, and control of VOCs from wastewater facilities

Source	Method of release	Suggested control strategies
Domestic, commercial, and industrial discharges	Discharge of small amounts of VOCs in liquid wastes	Institute active source control program to limit the discharge of VOCs to municipal sewers
Wastewater sewers	Volatilization from the surface enhanced by flow-induced turbulence	Seal existing manholes. Eliminate the use of structures that create turbulence and enhance volatilization
Sewer appurtenances	Volatilization due to turbulence at junctions, etc. Volatilization and air stripping at drop manholes and junction chambers	Isolate and cover existing appurtenances
Pump stations	Volatilization and air stripping at influent wetwell inlets	Vent gases from wetwell to VOC treatment unit. Use variable-speed pumps to reduce size of wetwell
Bar racks	Volatilization due to turbulence	Cover units. Reduce headloss through bar racks
Comminutors	Volatilization due to turbulence	Cover units. Use in-line enclosed comminutors
Parshall flume	Volatilization due to turbulence	Cover units. Use alternative measuring device
Grit chamber	Volatilization due to turbulence in horizontal-flow grit chambers. Volatilization and air stripping in aerated grit chambers. Volatilization in vortex-type grip chambers	Cover aerated and vortex-type grit chambers. Reduce turbulence in horizontal-flow grit chambers; cover if necessary
Equalization basins	Volatilization from surface enhanced by local turbulence. Air stripping where diffused air is used	Cover units. Use submerged mixers. Reduce air flow
Primary and secondary sedimentation tanks	Volatilization from surface. Volatilization and air stripping at overflow weirs, in effluent channel, and at other discharge points	Cover tanks. Replace overflow weirs with drops with submerged launders
Biological treatment	Air stripping in diffused-air activated sludge. Volatilization in activated-sludge processes with surface aeratars. Volatilization from surface enhanced by local turbulence. Volatilization from trickling filters	Cover units. In activated-sludge systems, use submerged mixers and reduce aeration rate
Transfer channels	Volatilization from surface enhanced by local turbulence. Volatilization and air stripping in aerated transfer channels	Use enclosed transfer channels
Digester gas	Uncontrolled release of digester gas. Discharge of incompletely combusted or incinerated digester gas	Controlled thermal incineration, combustion, or flaring of digester gas

Mass Transfer of VOCs from Surface and Diffused-Air Aeration Processes

The amount of VOCs released from a complete-mix reactor used for the activated-sludge process will depend on the method of aeration (e.g., surface aeration or diffused aeration).

Complete-Mix Reactor with Surface Aeration. A materials balance for the stripping of a VOC written around a complete-mix reactor is as follows, assuming no other removal mechanisms for the VOC compound such as biodegradation or solids sorption are applicable.

1. General word statement:

Rate of accumulation of VOC within the system boundary	=	Rate of flow of VOC into the system boundary	−	Rate of flow of VOC out of the system boundary	+	Amount of VOC removed through system boundary by stripping	(5–66)

2. Simplified word statement:

Accumulation = inflow − outflow + decrease due to stripping (5–67)

3. Symbolic representation

$$\frac{dC}{dt}V = QC_i - QC_e + r_{VOC}V \tag{5–68}$$

where dC/dt = rate of change in VOC concentration in reactor
V = volume of complete mix reactor, L^3 (m^3)
Q = liquid flowrate, L^3T^{-1} (m^3/s)
C_i = concentration of VOC in influent to reactor, ML^{-3} ($\mu g/m^3$)
C_e = concentration of VOC in effluent from reactor, ML^{-3} ($\mu g/m^3$)
r_{VOC} = rate of VOC mass transfer, $ML^{-3}T^{-1}$ ($\mu g/m^3 \cdot h$)

Substituting for r_{VOC} from Eq. (5–68) and τ for V/Q yields

$$\frac{dC}{dt} = \frac{C_i - C_e}{\tau} + [-(K_L a)_{VOC}(C_e - C_s)] \tag{5–69}$$

If steady-state conditions are assumed and it is further assumed that C_i is equal to zero, then the amount of VOC that can be removed by surface aeration is given by the following expression:

$$1 - \frac{C_e}{C_i} = 1 - [1 + (K_L a)\tau]^{-1} \tag{5–70}$$

If a significant amount of the VOC is adsorbed or biodegraded, the results obtained with the above equation will be overestimated. The above analysis can also be used to estimate the release of VOCs at weirs and drops by assuming the time period is about 30 s.

Complete Mix Reactor with Diffused-Air Aeration. The corresponding expression to Eq. (5–67) for a complete-mix reactor with diffused-air aeration is developed

by a mass balance on the VOC compound. At steady state the VOC in equals the VOC out, and the corresponding mass balance is

$$\underset{\text{liquid stream}}{\text{Inflow in}} = \underset{\text{liquid stream}}{\text{outflow}} + \underset{\text{in exit gas}}{\text{outflow}}$$

$$QC_i = QC_e + Q_g C_{g,e} \tag{5–71}$$

where Q = liquid flowrate, $L^3 T^{-1}$ (m^3/s)
C_i = VOC concentration in influent, ML^{-3} ($\mu g/m^3$)
C_e = VOC concentration in effluent, ML^{-3} ($\mu g/m^3$)
Q_g = gas flowrate, $L^3 T^{-1}$ (m^3/s)
$C_{g,e}$ = VOC concentration in exit gas, ML^{-3} ($\mu g/m^3$)

The general expression for the removal of VOC by gas sparging through a liquid is (Bielefeldt and Stensel, 1999)

$$Q_g C_{g,e} = Q_g H_u C_e (1 - e^{-\phi}) \tag{5–72}$$

where ϕ = VOC saturation parameter defined as

$$\phi = \frac{(K_l a)_{VOC} V}{H_u Q_g} \tag{5–73}$$

Eq. (5–72) can be rearranged as follows:

$$Q(C_i - C_e) = H_u C_e (1 - e^{-\phi}) \tag{5–74}$$

Solving Eq. (5–74) for C_e/C_i yields

$$\frac{C_e}{C_i} = \left[1 + \frac{Q_g}{Q} H_u (1 - e^{-\phi})\right]^{-1} \tag{5–75}$$

and the fraction removed is given by

$$1 - \frac{C_e}{C_i} = 1 - \left[1 + \frac{Q_g}{Q} H_u (1 - e^{-\phi})\right]^{-1} \tag{5–76}$$

The application of the above equations is illustrated in Example 5–16.

EXAMPLE 5–16 Stripping of Benzene in the Activated-Sludge Process Determine the amount of benzene that can be stripped in a complete-mix activated-sludge reactor equipped with a diffused-air aeration system. Assume the following conditions apply:

1. Wastewater flowrate = 4000 m^3/d
2. Aeration tank volume = 1000 m^3
3. Depth of aeration tank = 6 m
4. Air flowrate = 50 m^3/min at standard conditions
5. Oxygen mass transfer rate = 6.2/h
6. Influent concentration of benzene = 100 $\mu g/m^3$
7. $H = 5.49 \times 10^{-3}$ m^3-atm/mol (see Table 5–36)

Table 5–36
Physical properties of selected volatile and semivolatile organic compounds[a,b]

Compounds	mw	mp, °C	bp, °C	vp, mmHg	vd	sg	Sol., mg/L	C_s, g/m³	H, m³-atm/mole	log K_{ow}

[a]Data were adapted from Lang et al., 1987.

[b]All values are reported at 20°C.

Note: mw = molecular weight, mp = melting point, bp = boiling point, vd = vapor density, sg = specific gravity, Sol = solubility, C_s = saturation concentration in air, H = Henry's law constant, log K_{ow} = logarithm of the octanol-water partition coefficient.

8. $n = 1.0$
9. Temperature = 20°C
10. Oxygen diffusivity = 2.11×10^{-5} cm²/s
11. Benzene diffusivity = 0.96×10^{-5} cm²/s

Solution

1. Determine the quantity of air referenced to the middepth of the aeration tank, which represents the depth for an average bubble size

$$Q_g = (50 \text{ m}^3/\text{min}) \times \frac{10.33}{10.33 + 3} = 38.7 \text{ m}^3/\text{min}$$

2. Determine the air/liquid ratio

$$Q = \frac{(4000 \text{ m}^3/\text{d})}{(1440 \text{ min/d})} = 2.78 \text{ m}^3/\text{min}$$

$$\frac{Q_g}{Q} = \frac{(38.7 \text{ m}^3/\text{min})}{(2.78 \text{ m}^3/\text{min})} = 13.9$$

3. Estimate the mass transfer coefficient for benzene using Eq. (5–65).

$$K_L a_{\text{VOC}} = K_L a_{O_2} \left(\frac{D_{\text{VOC}}}{D_{O_2}} \right)^n = (6.2/\text{h}) \left[\frac{(0.96 \times 10^{-5} \text{ cm}^2/\text{s})}{(2.11 \times 10^{-5} \text{ cm}^2/\text{s})} \right]^{1.0}$$

$$K_L a_{\text{VOC}} = 2.82/\text{h} = 0.047/\text{min}$$

4. Determine the dimensionless value of Henry's constant using Eq. (2–51).

$$H_u = \frac{H}{RT}$$

$$H_u = \frac{(0.00549 \text{ m}^3\cdot\text{atm/mole})}{(0.000082057 \text{ atm}\cdot\text{m}^3/\text{mole}\cdot\text{K})[(273.15 + 20)\text{K}]} = 0.228$$

5. Determine the saturation parameter ϕ using Eq. (5–73).

$$\phi = \frac{(K_L a)_{\text{VOC}} V}{H_u Q_g}$$

$$\phi = \frac{(0.047/\text{min} \times 1000 \text{ m}^3)}{(0.228 \times 38.7 \text{ m}^3/\text{min})} = 5.33$$

6. Determine the fraction of benzene removed from the liquid phase using Eq. (5–76).

$$1 - \frac{C_e}{C_i} = 1 - \left[1 + \frac{Q_g}{Q} (H_u)(1 - e^{-\phi}) \right]^{-1}$$

$$1 - \frac{C_e}{C_i} = 1 - [1 + 13.9\,(0.228)(1 - e^{-5.33})]^{-1}$$

$$1 - \frac{C_e}{C_i} = 1 - 0.32 = 0.68$$

Comment The computations presented in this example problem are based on the assumption that the concentration of benzene in the influent is not being reduced by adsorption or biological degradation.

Control Strategies for VOCs

Volatilization and gas stripping are, as noted previously, the principal means by which VOCs are released from wastewater-treatment facilities. In general, it can be shown that the release of VOCs from open surfaces is quite low compared to the release of VOCs at points of liquid turbulence and by gas stripping. Thus, the principal strategies for controlling the release of VOCs, as reported in Table 5–35, are (1) source control, (2) elimination of points of turbulence, and (3) the covering of various treatment facilities. Three serious problems associated with the covering of treatment facilities are (1) treatment of the off-gases containing VOCs, (2) corrosion of mechanical parts, and (3) provision for confined space entry for personnel for equipment maintenance. The treatment of off-gases is considered here.

Treatment of Off-Gases. The off-gases containing VOCs from covered treatment facilities will have to be treated before they can be discharged to the atmosphere. Options for the off-gas treatment include (see Fig. 5–71): (1) vapor-phase adsorption on granular activated carbon or other VOC selective resins, (2) thermal incineration, (3) catalytic incineration, (4) combustion in a flare, (5) biofiltration, and (6) combustion in a boiler or process heater (U.S. EPA, 1986; WEF, 1997). The application of these processes will depend primarily on the volume of air to be treated and the types and concentrations of the VOCs contained in the airstream. The first four of these off-gas treatment processes are considered in greater detail in the following discussion. Biofiltration is discussed in Chap. 15 under Sec. 15–3, Odor Management. Use of a boiler or heater is done only where a combustion process is included as part of the plant facilities.

Vapor-Phase Adsorption Adsorption is the process whereby hydrocarbons and other compounds are adsorbed selectively on the surface of such materials as activated carbon, silica gel, or alumina. Of the available adsorbents, activated carbon is used most

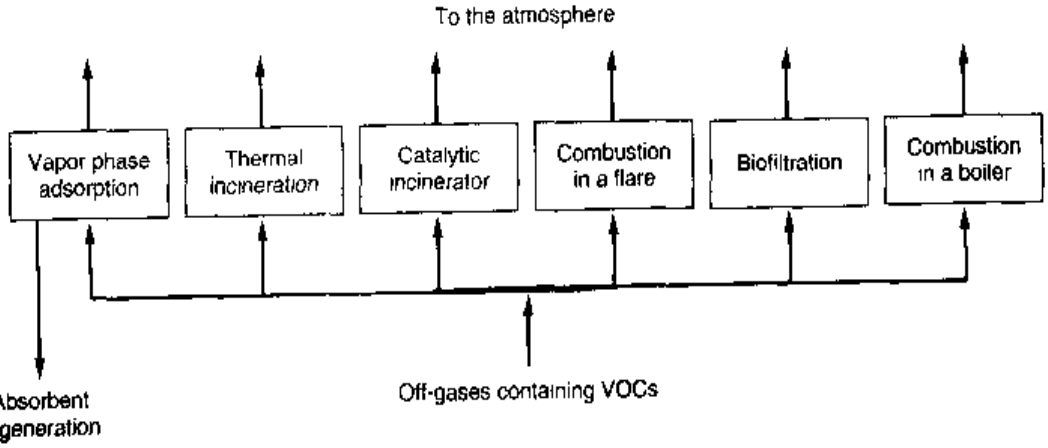

Figure 5–71
Options for treating off-gases containing VOCs. *(Adapted from Eckenfelder, 2000.)*

widely. The adsorption capacity of an adsorbent for a given VOC is often represented by adsorption isotherms that relate the amount of VOC adsorbed (adsorbate) to the equilibrium pressure (or concentration) at constant temperature. Typically, the adsorption capacity increases with the molecular weight of the VOC being adsorbed. In addition, unsaturated compounds are generally more completely adsorbed than saturated compounds, and cyclical compounds are more easily adsorbed than linearly structured materials. Also, the adsorption capacity is enhanced by lower operating temperatures and higher concentrations. VOCs characterized by low vapor pressures are more easily adsorbed than those with high vapor pressures (U.S. EPA, 1986).

Carbon adsorption is usually carried out as a batch operation, involving multiple beds (see Fig. 5–72). The two main steps in the adsorption operation include adsorption and regeneration, usually performed in sequence. For control of continuous emission streams, at least one bed remains on-line in the adsorption mode while the other is being regenerated. In a typical batch operation, the off-gas containing VOCs is passed through the carbon bed where the VOC's are adsorbed on the bed surface. As the adsorption capacity of the bed is approached, traces of VOCs appear in the exit stream, indicating that the breakthrough point of the bed has been attained. The off-gas is then directed to a parallel bed containing regenerated adsorbent, and the process continued. Concurrently, the saturated bed is regenerated by the passage of hot air (see Fig. 5–72, Mode A), hot inert gases (see Fig. 5–72, Mode B), low-pressure steam, or a combination of vacuum and hot gas. Because adsorption is a reversible process, the VOCs adsorbed on the bed can be desorbed by supplying heat (equivalent to the amount of heat released during adsorption). Small residual amounts of VOCs are always left on the carbon bed, because complete desorption is technically difficult to achieve and economically

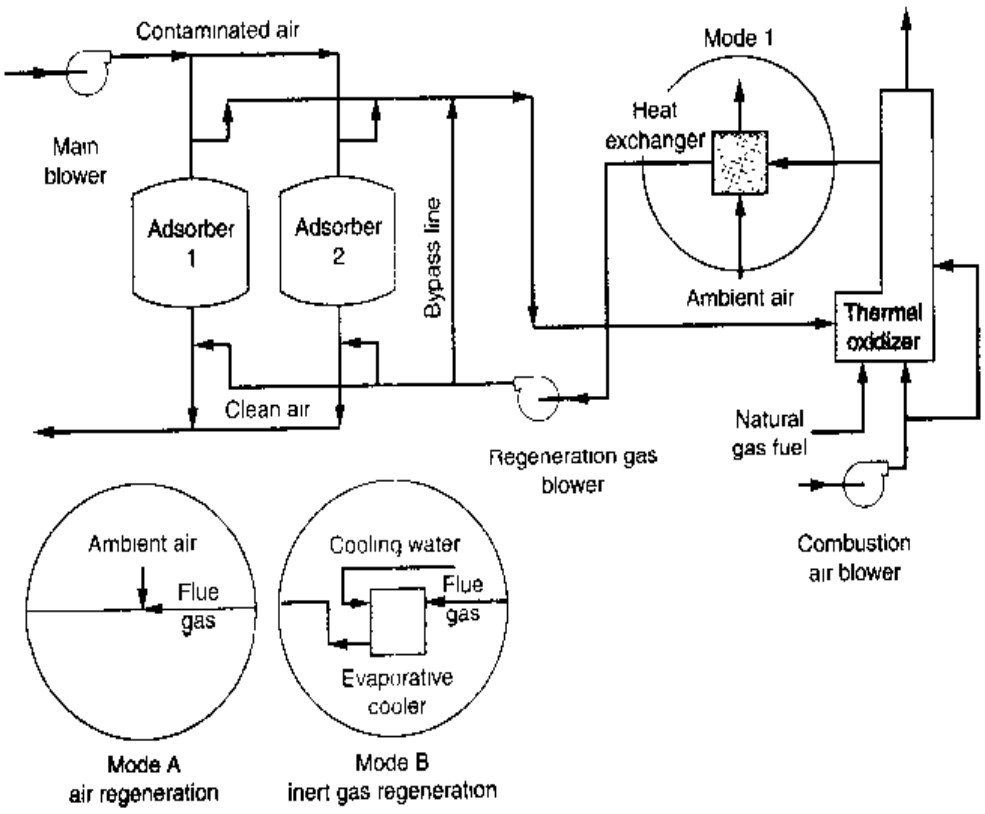

Figure 5–72

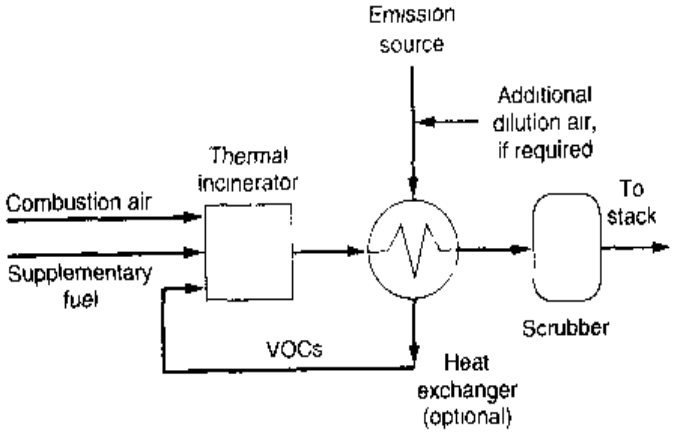
Gas phase carbon adsorption and regeneration system for the treatment of VOCs in off-gas.

impractical. Regeneration with hot air and a hot inert gas is considered in the following discussion.

Hot air regeneration is used when the VOCs are either nonflammable or have a high ignition temperature and thus do not pose a risk of carbon fires. A portion of the hot flue gas in the oxidizer is mixed with ambient air to cool the gas to below 180°C (350°F). The regeneration gas is driven upflow (or countercurrent to adsorption flow) through the GAC adsorber. As the temperature of the carbon bed rises, the desorbed organics are transferred to the regeneration gas stream. The regeneration gas containing the desorbed VOCs is sent directly to the thermal oxidizer where the VOCs are destroyed. After the bed has been maintained at the desired regeneration temperature for a sufficient period of time, regeneration is ended. The bed is then cooled to approximately ambient temperature by shutting off the hot regeneration gas and continuing to pass ambient air through the carbon bed. The regeneration and cooling times are predetermined based on the amount of carbon in the adsorber and the expected loading on the carbon (U.S. EPA, 1986).

Where the VOCs contained in the off-gas include compounds such as ketones and aldehydes that may pose fire risks at elevated temperatures in the presence of oxygen, inert gas regeneration is used. A relatively inert gas can be obtained by passing a portion of the hot flue gas from the thermal oxidizer through an evaporative cooler. It is possible, therefore, to keep the oxygen concentration in the regeneration gas at a low of 2 to 5 percent by volume. The desorbed VOCs are transferred along with the regeneration gas to the thermal oxidizer. A controlled amount of secondary air is added to the oxidizer. The addition of air ensures complete combustion of the VOCs but limits the excess oxygen level in the oxidizer to an acceptable range (e.g., 2 to 5 percent by volume). Regeneration is complete when the carbon bed has reached the necessary temperature for a given period of time, and VOCs are no longer being desorbed from the bed. Cooling of the bed is accomplished by increasing the water flowrate to the evaporative cooler and reducing the regeneration gas temperature to between 105 and 120°C (220 and 250°F).

Thermal Incineration Thermal incineration (see Fig. 5 73) is used to oxidize VOCs at high temperatures. The most important variables to consider in thermal incinerator design are the combustion temperature and residence time because these design variables determine the VOC destruction efficiency of the incinerator. Further, at a given



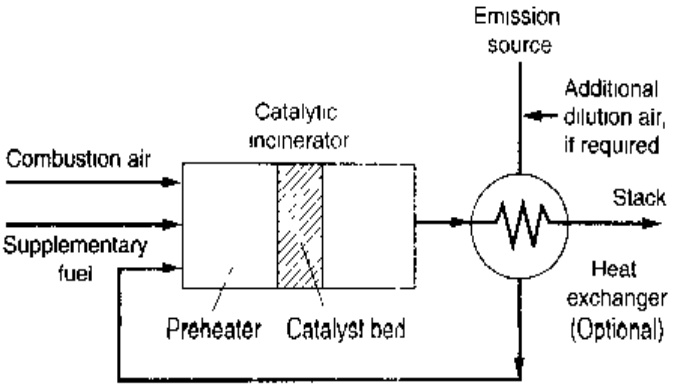


Figure 5–73
Schematic diagram of a thermal incinerator system for VOCs in off-gas released from treatment facilities.

Figure 5–74

Schematic diagram of a catalytic incinerator system for VOCs in off-gas released from treatment facilities.

combustion temperature and residence time, destruction efficiency is also affected by the degree of turbulence, or mixing of the emission stream and hot combustion gases, in the incinerator. In addition, halogenated organics are more difficult to oxidize than unsubstituted organics; hence, the presence of halogenated compounds in the emission stream requires higher temperature and longer residence times for complete oxidation. When emission streams treated by thermal incineration are dilute (i.e., low heat content), supplementary fuel is required to maintain the desired combustion temperatures. Supplementary fuel requirements may be reduced by recovering the energy contained in the hot flue gases from the incinerator.

Catalytic Incineration In catalytic incineration (see Fig. 5–74), VOCs in an emission stream are oxidized with the help of a catalyst. A catalyst is a substance that accelerates the rate of a reaction at a given temperature without being appreciably changed during the reaction. Catalysts typically used for VOC incineration include platinum and palladium; other formulations are also used, including metal oxides for emission streams containing chlorinated compounds. The catalyst bed (or matrix) in the incinerator is generally a metal mesh-mat, ceramic honeycomb, or other ceramic matrix structure designed to maximize catalyst surface area. The catalysts may also be in the form of spheres or pellets. Before passing through the catalyst bed, the emission stream is preheated, if necessary, in a natural gas-fired preheater (U.S. EPA, 1986).

The performance of a catalytic incinerator is affected by several factors including (1) operating temperature, (2) space velocity (reciprocal of residence time), (3) VOC composition and concentration, (4) catalyst properties, and (5) presence of catalyst poisons or inhibitors in the emission stream. In catalytic incinerator design, the important variables are the operating temperature at the catalyst bed inlet and the space velocity. The operating temperature for a particular destruction efficiency is dependent on the concentration and composition of the VOC in the emission stream and the type of catalyst used (U.S. EPA, 1986).

Combustion in a Flare Flares, commonly used for disposal of waste digester gas, can be used to destroy most VOCs found in off-gas streams. Flares can be designed and operated to handle fluctuations in emission VOC content, inerts content, and flowrate. Several different types of flares are available including steam-assisted, air-assisted, and pressure-head flares. Steam-assisted flares are employed in cases where large volumes

of waste gases are released. Air-assisted flares are generally used for moderate off-gas gas flows. Pressure-head flares are used for small gas flows.

Disposal of Off-Gases. Another method for the ultimate disposal of treated off-gases is to discharge them through high stacks. Stacks as high as 30 to 40 m (100 to 130 ft) have been constructed for dispersal of off-gases into the atmosphere. The dispersion lowers the concentration of any residuals left in the gas stream by dilution with the ambient air. With the passage of the Clean Air Act in 1990, discharge of untreated off-gases has been phased out.

PROBLEMS AND DISCUSSION TOPICS

5–1 A bar screen is inclined at a 60° angle from the horizontal. The rectangular bars have a diameter of 20 mm and a clear spacing of 25 mm. Determine the headloss when the bars are cleaned and the velocity approaching the screen is 1 m/s. Is this a very realistic computation in terms of what actually happens at a treatment plant?

5–2 Design an aerated grit chamber for a plant with an average flowrate of 15,000 m^3/d and a peak hourly flowrate of 40,000 m^3/d. Determine the amount of air required and the pressure at the discharge of the blowers. Allow a 250-mm loss in the diffusers, and add the submergence plus 30 percent for loss in piping and valves. Determine the power required using an appropriate blower formula. Use a blower efficiency of 70 percent. Determine the monthly power bill, assuming a motor efficiency of 90 percent and a power cost of $0.08/kWh.

5–3 Design an aerated grit chamber installation for an average wastewater flowrate of 0.3 m^3/s and a peak flowrate of 1.0 m^3/s. The average depth is 3 m, the width-to-depth ratio is 1.5:1, and the detention time at peak flow is 3.5 min. The aeration rate is 0.4 m^3/min per m of tank length. Determine the dimensions of the grit chambers and the total air required.

5–4 Discuss the advantages and disadvantages of aerated grit chambers versus vortex-type grit chambers. Cite two references.

5–5 Visit your local treatment plant and review the grit and screenings operations. What methods do they use and what problems do they have? How might their operations be improved as compared to alternative methods described in this chapter?

5–6 Using the information given in the data table presented in Example 5–1, determine (*a*) the off-line storage volume needed to equalize the flowrate and (*b*) the effect of flow equalization on the BOD mass loading rate. How does the BOD mass loading-rate curve determined in this problem compare with the curve shown in step 2d? In your estimation, does the difference in the mass loading rate justify the cost of the larger basin required for in-line storage?

5–7 Using the information given in the data table presented in Example 5–1, estimate the in-line volume required to reduce the variation in the BOD mass loading rate between the maximum and minimum from the existing ratio of 26.1:1 to a peak value of 5:1.

5–8 The contents of a tank are to be mixed with a turbine impeller that has six flat blades. The diameter of the impeller is 3 m, and the impeller is installed 1.25 m above the bottom of the 20-ft tank. If the temperature is 30°C and the impeller is rotated at 30 r/min, what will be the power consumption? Find the Reynolds number using Eq. (5–7).

5–9 It is desired to flash-mix some chemicals with incoming wastewater that is to be treated. Mixing is to be accomplished using a flat-paddle mixer 500 mm in diameter having six blades. If the temperature of the coming water is 10 C and the mixing chamber power number is 1.70, determine:
(a) The speed of rotation when the Reynolds number is approximately 100,000
(b) Why it is desirable to have a high Reynolds number in most mixing operations
(c) The required mixer motor size, assuming an efficiency factor of 20 percent.

5–10 Assuming that a given flocculation process can be defined by a first-order reaction ($r_N = -kN$), complete the following table assuming the process is occurring in a plug-flow reactor with a detention time of 10 min. What would the value be after 5 min if a batch reactor were used instead, assuming the rate constant is the same?

Time, t	0	5	10
Particles, No./unit volume	10	(?)	3

5–11 If the steady-state effluent from a continuous-flow stirred-tank reactor used as a flocculator contained 3 particles/unit volume, determine the concentration of particles in the effluent 5 min after the process started before steady-state conditions are reached. Assume that the influent contains 10 particles/unit volume, the detention time in the CFSTR is equal to 10 min, and that the first-order kinetics apply ($r_N = \quad kN$)

5–12 An air flocculation system is to be designed. If a G value of 60 s^{-1} is to be used, estimate the air flowrate that will be necessary for a 200 m^3 flocculation chamber. Assume the depth of the flocculation basin is to be 4 m.

5–13 Determine the required air flowrate to accomplish the flocculation operation in Example 5–4 pneumatically. Assume the air will be released at a depth of 3 m.

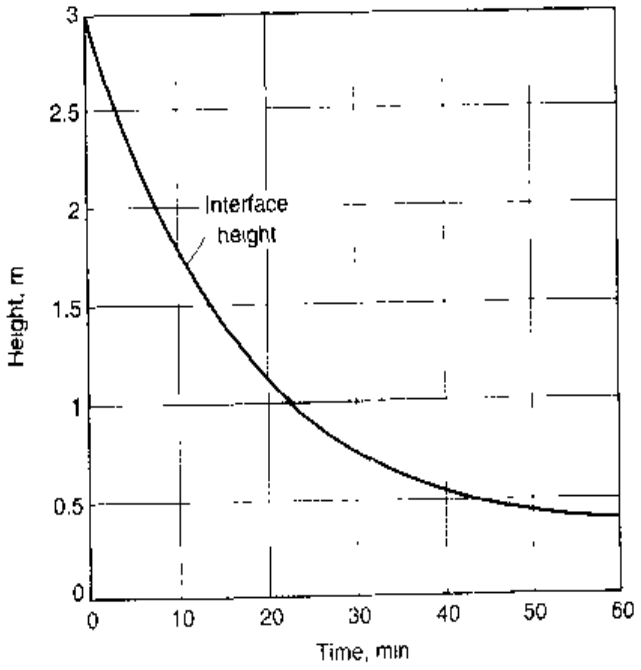
5–14 Derive Stokes' law by equating Eq. (5–19) to the effective particle mass.

5–15 Determine the settling velocity in m/s of a sand particle with a specific gravity of 2.65 and a diameter of 1 mm. Assume that the Reynolds number is 275.

5–16 Prepare a spreadsheet for computing the spherical and wastewater settling velocities for the data given in Example 5–8. What are the values of Reynolds number and coefficient of drag necessary to have the assumed velocities agree with the calculated velocities?

5–17 Determine the removal efficiency for a sedimentation basin with a critical velocity V_o of 2 m/h in treating a wastewater containing particles whose settling velocities are distributed as given in the table below. Plot the particle histogram for the influent and effluent wastewater.

Velocity, m/h	Number of particles
0.0–0.5	20
0.5–1.0	40
1.0–1.5	80
1.5–2.0	120
2.0–2.5	100
2.5–3.0	70
3.0–3.5	20
3.5–4.0	10



5–18 The rate of flow through an ideal clarifier is 8000 m^3/d, the detention time is 1 h, the depth is 3 m. If a full-length movable horizontal tray is set 1 m below the surface of the water, determine the percent removal of particles having a settling velocity of 1 m/h. Could the removal efficiency of the clarifier be improved by moving the tray? If so, where should the tray be located and what would be the maximum removal efficiency? What effect would moving the tray have if the particle settling velocity were equal to 0.3 m/h?

5–19 In Example 5–5, the assumed and calculated particle settling velocities did not reach closure. Continue the calculation iterations to find the actual settling velocity.

5–20 For a flocculent suspension, determine the removal efficiency for a basin 3 m deep with an overflow rate V_o equal to 3 m/h using the laboratory settling data presented in the following table.

	Percent suspended solids removed at indicated depth (m)				
Time, min	**0.5**	**1.0**	**1.5**	**2**	**2.5**
20	61				
30	71	63	55		
40	81	72	63	61	57
50	90	81	73	67	63
60	. . .	90	80	74	68
70	. . . .	. . . .	86	80	75
80	. . .	. . .	. . . .	86	81

5–21 The curve following was obtained from a settling test in a 3-m cylinder. The initial solids concentration was 3600 mg/L. Determine the thickener area required for a concentration C_u of 12,000 mg/L with a solids flow of 1500 m^3/d.

5–22 Design a circular radial-flow sedimentation tank for a town with a projected population of 45,000. Assume that the wastewater flow is 400 L/capita·d. Design for 2 h detention at the average flow.

Determine the tank depth and diameter to produce an overflow rate of 36 $m^3/m^2 \cdot d$ for average flow. Assume standard tank dimensions to fit mechanisms made in diameters with increments of 1.0 m and in depth increments of 0.5 m.

5–23 A rectangular settling tank has an overflow rate of 30 $m^3/m^2 \cdot d$ and dimensions of 2.75 m deep by 6 m wide by 15 m long. Determine whether or not particles with a diameter of 0.1 mm and a specific gravity of 2.5 will be scoured from the bottom. Use $f = 0.03$ and $k = 0.04$.

5–24 Determine the percentage increase in the hydraulic and solids-loading rates of the primary settling facilities of a treatment plant when 200 m^3/d of settled waste activated sludge containing 2000 mg/L of suspended solids is discharged to the existing primary facilities for thickening. The average plant flowrate is 20,000 m^3/d and the influent suspended-solids concentration is about 350 mg/L. The design overflow rate for the primary settling tanks without the waste solids is 32 $m^3/m^2 \cdot d$ and the detention time is 2.8 h. Do you believe that the added incremental loadings will affect the performance of the primary settling facilities? Document the basis for your answer.

5–25 Prepare a table and compare the data from a minimum of five references with regard to the following primary sedimentation tank design parameters: (1) detention time (with and without preaeration); (2) expected BOD removal; (3) expected suspended-solids removal; (4) mean horizontal velocity; (5) surface loading rate in $m^3/m^2 \cdot d$; (6) effluent weir overflow rate per unit length; (7) size of organic particle removed; (8) length-to-width ratio (rectangular tanks); (9) average depth. List all references.

5–26 A medium-size treatment plant is being designed, and circular and rectangular primary sedimentation tanks are being considered. What factors should be considered in the evaluation and selection of the type of tank? List the advantages and disadvantages for each type. Cite at least three recent references (since 1980).

5–27 Contrast dissolved-air flotation with sedimentation discussing the following parameters:

(a) Detention time
(b) Surface-loading rate
(c) Power input
(d) Efficiency
(e) Most favorable application for each type

5–28 The following data were obtained from a test program designed to evaluate a new diffused-air aeration system. Using these data, determine the value of $K_L a$ at 20°C and the equilibrium dissolved-oxygen concentration in the test tank. The test program was conducted using tap water at a temperature of 24°C.

C, mg/L	1.5	2.7	3.9	4.8	6.0	7.0	8.2
dC/dt, mg/L-h	8.4	7.5	5.3	4.9	4.2	2.8	2.0

5–29 If the volume of the test tank used to evaluate the aeration system in Prob. 5–28 were equal to 100 m^3 and the air flowrate were equal to 2 m^3/min, determine the maximum oxygen-transfer efficiency at 20°C and 1.0 atmosphere.

5–30 Using the equation developed in Example 5–15, estimate the air flowrate in m^3/min required to increase the oxygen content of chlorinated effluent from zero to 4 mg/L. The effluent flowrate is

equal to 20,000 m^3/d. Assume that the transfer efficiency is 6 percent and the temperature is 15°C. What is the air requirement when the temperature is 25°C?

5–31 Alternative diffused-air aeration devices are being considered for installation with a submergence of 4.5 m in an aeration tank at an activated-sludge treatment plant. The oxygen required for biological treatment is 7000 kg/d. Determine the standard oxygen transfer rate and theoretical air requirements for ceramic dome diffusers installed in a grid pattern as compared to nonporous diffusers installed for a dual-spiral roll. The wastewater temperature is 20°C and the α factors are 0.64 for ceramic domes and 0.75 for the nonporous diffusers, respectively.

5–32 Using the data in Prob. 5–31 and a wintertime wastewater temperature of 10°C, determine the theoretical air requirements for cold-weather operation. How will equipment selection be affected in meeting both summer and winter operation?

PROBLEMS AND DISCUSSION TOPICS 541

REFERENCES 543

Those processes used for the treatment of wastewater in which change is brought about by means of or through chemical reactions are known as *chemical unit processes.* In the field of wastewater treatment, chemical unit processes usually are used in conjunction with the physical unit operations discussed in Chap. 5, and the biological unit processes to be discussed in Chaps. 7 through 10, to meet specific treatment objectives.

The purpose in this chapter is to present and discuss: (1) the role of chemical unit processes in wastewater treatment; (2) some fundamentals of chemical coagulation; (3) the precipitation reactions that occur when various chemicals are added to improve the performance of wastewater-treatment facilities; (4) the chemical reactions involved in the precipitation of phosphorus from wastewater; (5) the precipitation of heavy metals and dissolved inorganic substances; (6) chemical oxidation; (7) chemical neutralization, scale control, and stabilization; and (8) chemical storage, feeding, piping, and control systems. Advanced chemical oxidation and ion exchange are considered in Chap. 11. Adsorption, sometimes classified as a chemical unit process, but which, more correctly, should be classified as a physical unit operation, is considered in Chap. 11. Chemical disinfection, an extremely important and much-used chemical unit process, is considered separately in Chap. 12.

6–1 ROLE OF CHEMICAL UNIT PROCESSES IN WASTEWATER TREATMENT

The principal chemical unit processes used for wastewater treatment include (1) chemical coagulation, (2) chemical precipitation, (3) chemical disinfection, (4) chemical oxidation, (5) advanced oxidation processes, (6) ion exchange, and (7) chemical neutralization, scale control, and stabilization. The applications and the limitations involved in the use of these processes are considered in the following discussion.

Application of Chemical Unit Processes

Applications of chemical unit processes for the management and treatment of wastewater are reported in Table 6–1. Chemical processes, in conjunction with various physical operations, have been developed for the complete secondary treatment of untreated (raw) wastewater, including the removal of either nitrogen or phosphorus or both. Chemical processes have also been developed to remove phosphorus by chemical precipitation, and are designed to be used in conjunction with biological treatment. Other

Lime storage is in the silo shown behind the building that is used to house the lime slaking facilities and the reverse osmosis units, used for advanced treatment. Granular medium-depth filters are shown to the right of the lime clarifier in the foreground.

chemical processes have been developed for the removal of heavy metals and for specific organic compounds and for the advanced treatment of wastewater. Currently the most important applications of chemical unit processes in wastewater treatment are for (1) the disinfection of wastewater, (2) the precipitation of phosphorus, and (3) the coagulation of particulate matter found in wastewater at various stages in the treatment process (see Fig. 6–1).

Considerations in the Use of Chemical Unit Processes

In considering the application of the chemical unit processes to be discussed in this chapter, it is important to remember that one of the inherent disadvantages associated with most chemical unit processes, as compared with the physical unit operations, is that they are additive processes (i.e., something is added to the wastewater to achieve the removal of something else). As a result, there is usually a net increase in the dissolved constituents in the wastewater. For example, where chemicals are added to enhance the removal efficiency of particulate sedimentation, the total dissolved solids (TDS) concentration of the wastewater is always increased. Similarly, when chlorine is added to wastewater, the TDS of the effluent is increased. If the treated wastewater is to be reused, the increase in dissolved constituents can be a significant factor. This additive aspect is in contrast to the physical unit operations and the biological unit processes, which may be described as being subtractive, in that wastewater constituents are removed from the wastewater. A significant disadvantage of chemical precipitation processes is the handling, treatment, and disposal of the large volumes of sludge that is produced. Another disadvantage of chemical unit processes is that the cost of most chemicals is related to the cost of energy. As a result, the end user has little control over chemical costs.

6–2 FUNDAMENTALS OF CHEMICAL COAGULATION

Colloidal particles found in wastewater typically have a net negative surface charge. The size of colloids (about 0.01 to 1 μm) is such that the attractive body forces between

particles are considerably less than the repelling forces of the electrical charge. Under these stable conditions, Brownian motion keeps the particles in suspension. Brownian motion (i.e., random movement) is brought about by the constant thermal bombardment of the colloidal particles by the relatively small water molecules that surround them. Coagulation is the process of destabilizing colloidal particles so that particle growth can occur as a result of particle collisions. The theory of chemical coagulation reactions is very complex. The simplified reactions used in this and other textbooks to describe coagulation and chemical precipitation processes can only be considered approximations as the reactions may not necessarily proceed as indicated.

Coagulation reactions are often incomplete, and numerous side reactions with other substances in wastewater may take place depending on the characteristics of the wastewater which will vary throughout the day as well as seasonally. To introduce the subject of chemical coagulation the following topics are discussed in this section: (1) basic definitions for coagulation and flocculation, (2) the nature of particles in wastewater, (3) the development and measurement of surface charge, (4) consideration of particle-particle interaction, (5) particle destabilization with potential determining ions and electrolytes, (6) particle destabilization and aggregation with polyelectrolytes, and (7) particle destabilization and removal with hydrolyzed metal ions. The following discussion is meant to serve as an introduction to the nature of the phenomena and processes involved in the coagulation process.

Basic Definitions

The term "chemical coagulation" as used in this text includes all of the reactions and mechanisms involved in the chemical destabilization of particles and in the formation of larger particles through perikinetic flocculation (aggregation of particles in the size range from 0.01 to 1 μm). *Coagulant* and *flocculent* are terms that will also be encountered in the literature on coagulation. In general, a *coagulant* is the chemical that is added to destabilize the colloidal particles in wastewater so that floc formation can result. A *flocculent* is a chemical, typically organic, added to enhance the flocculation process. Typical coagulants and flocculants include natural and synthetic organic polymers, metal salts such as alum or ferric sulfate, and prehydrolized metal salts such as polyaluminum chloride (PACl) and polyiron chloride (PICl). Flocculants, especially organic polymers, are also used to enhance the performance of granular medium filters and in the dewatering of digested biosolids. In these applications, the flocculant chemicals are often identified as filter aids.

The term "flocculation" is used to describe the process whereby the size of particles increases as a result of particle collisions. As noted in Chap. 5, there are two types of flocculation: (1) *microflocculation* (also known as *perikinetic flocculation*), in which particle aggregation is brought about by the random thermal motion of fluid molecules known as Brownian motion or movement and (2) *macroflocculation* (also known as *orthokinetic flocculation*), in which particle aggregation is brought about by inducing velocity gradients and mixing in the fluid containing the particles to be flocculated. Another form of macroflocculation is brought about by differential settling in which large particles overtake small particles to form larger particles. The purpose of flocculation is to produce particles, by means of aggregation, that can be removed by inexpensive particle-separation procedures such as gravity sedimentation and filtration. Again as noted in Chap. 5, macroflocculation is ineffectual until the colloidal particles

reach a size of 1 to 10 μm through contacts produced by Brownian motion and gentle mixing.

Nature of Particles in Wastewater

The particles in wastewater may, for practical purposes, be classified as suspended and colloidal. Suspended particles are generally larger than 1.0 μm and can be removed by gravity sedimentation. In practice, the distinction between colloidal and suspended particles is blurred because the particles removed by gravity settling will depend on the design of the sedimentation facilities. Because colloidal particles cannot be removed by sedimentation in a reasonable period of time, chemical methods (i.e., the use of chemical coagulants and flocculant aids) must be used to help bring about the removal of these particles.

To understand the role that chemical coagulants and flocculant aids play in bringing about the removal of colloidal particles, it is important to understand the characteristics of the colloidal particles found in wastewater. Important factors that contribute to the characteristics of colloidal particles in wastewater include (1) particle size and number, (2) particle shape and flexibility, (3) surface properties including electrical characteristics, (4) particle-particle interactions, and (5) particle-solvent interactions (Shaw, 1966). Particle size, particle shape and flexibility, and particle-solvent interactions are considered below. Because of their importance, the development and measurement of surface charge and particle-particle interactions are considered separately.

Particle Size and Number. The size of colloidal particles in wastewater considered in this text is typically in the range from 0.01 to 1.0 μm. As noted in Chap. 2, some researchers have classified the size range for colloidal particles as varying from 0.001 to 1 μm. The number of colloidal particles in untreated wastewater and after primary sedimentation is typically in the range from 10^6 to 10^{12}/mL. It is important to note that the number of colloidal particles will vary depending on the location where the sample is taken within a treatment plant. The number of particles, as will be discussed later, is of importance with respect to the method to be used for their removal.

Particle Shape and Flexibility. Particle shapes found in wastewater can be described as spherical, semispherical, ellipsoids of various shapes (e.g., prolate and oblate), rods of various length and diameter (e.g., *E. coli*), disk and disklike, strings of various lengths, and random coils. Large organic molecules are often found in the form of coils which may be compressed, uncoiled, or almost linear. The shape of some larger floc particles is often described as fractal. The particle shape will vary depending on the location within the treatment process that is being evaluated. The shape of the particles will affect the electrical properties, the particle-particle interactions, and particle-solvent interactions. Because of the many shapes of particles encountered in wastewater, the theoretical treatment of particle-particle interactions is an approximation at best.

Particle-Solvent Interactions. There are three general types of colloidal particles in liquids: hydrophobic or "water-hating," hydrophilic or "water-loving," and association colloids. The first two types are based on the attraction of the particle surface for water. Hydrophobic particles have relatively little attraction for water; while hydrophilic particles have a great attraction for water. It should be noted, however, that

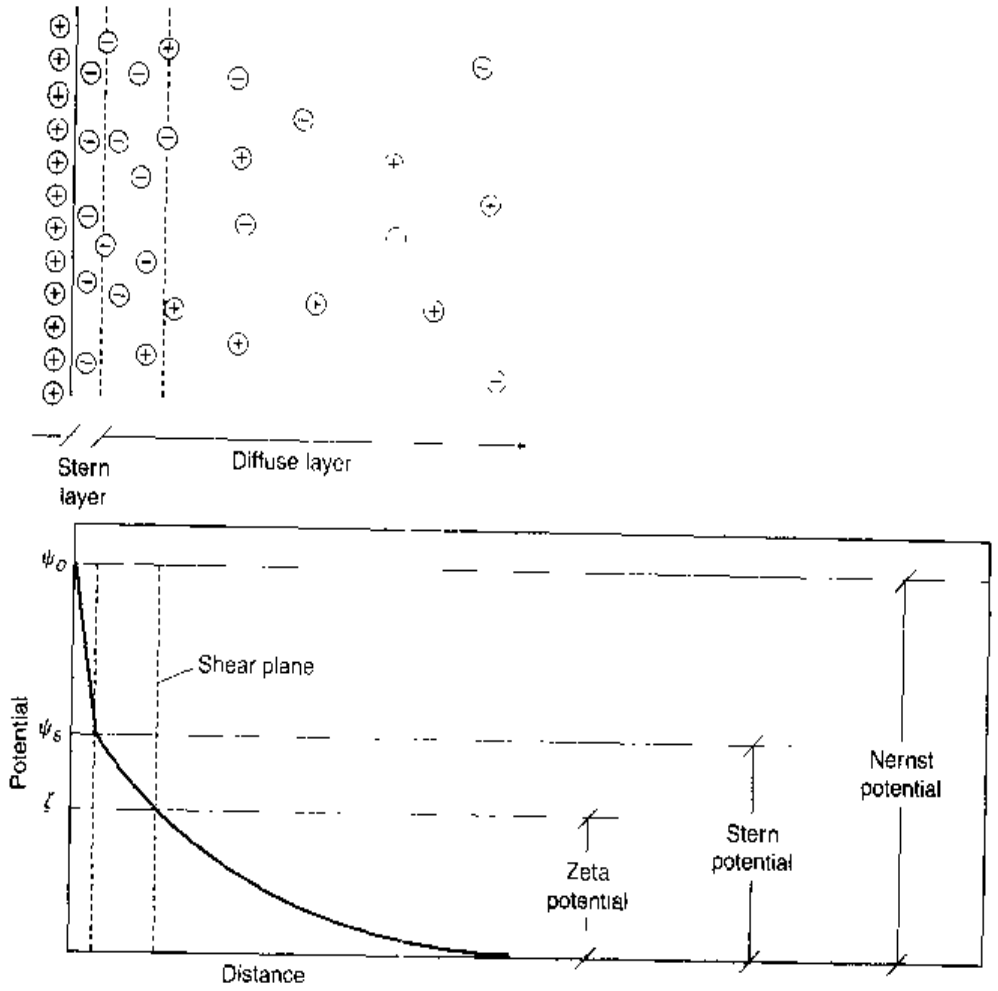
water can interact to some extent even with hydrophobic particles. Some water molecules will generally adsorb on the typical hydrophobic surface, but the reaction between water and hydrophilic colloids occurs to a much greater extent. The third type of colloid is known as an association colloidal, typically made up of surface-active agents such as soaps, synthetic detergents, and dyestuffs which form organized aggregates known as micelles.

Development and Measurement of Surface Charge

An important factor in the stability of colloids is the presence of a surface charge. It develops in a number of different ways, depending on the chemical composition of the medium (wastewater in this case) and the nature of the colloid. Surface charge develops most commonly through (1) isomorphous replacement, (2) structural imperfections, (3) preferential adsorption, and (4) ionization, as defined below. Regardless of how it develops, the surface charge, which promotes stability, must be overcome if these particles are to be aggregated (flocculated) into larger particles with enough mass to settle easily.

Isomorphous Replacement. Charge development through isomorphous replacement occurs in clay and other soil particles, in which ions in the lattice structure are replaced with ions from solution (e.g., the replacement of Si^{4+} with Al^{3+}).

Structural Imperfections. In clay and similar particles, charge development can occur because of broken bonds on the crystal edge and imperfections in the formation of the crystal.



Preferential Adsorption. When oil droplets, gas bubbles, or other chemically inert substances are dispersed in water, they will acquire a negative charge through the preferential adsorption of anions (particularly hydroxyl ions).

Ionization. In the case of substances such as proteins or microorganisms, surface charge is acquired through the ionization of carboxyl and amino groups (Shaw, 1966). This ionization can be represented as follows, where R represents the bulk of the solid (Fair et al., 1968):

$$\underset{\text{at high pH}}{R_{NH_2}^{COO^-}} \qquad \underset{\text{at low pH}}{R_{NH_3}^{COOH}} \qquad \underset{\text{at isoelectric point}}{R_{NH}^{COO}} \tag{6-1}$$

The Electrical Double Layer. When the colloid or particle surface becomes charged, some ions of the opposite charge (known as counterions) become attached to the surface (see Fig. 6–2). They are held there through electrostatic and van der Waals forces of attraction strongly enough to overcome thermal agitation. Surrounding this fixed layer of ions is a diffuse layer of ions, which is prevented from forming a compact double layer by thermal agitation, as illustrated schematically on Fig. 6–2. The electrical double layer consists of a compact layer (Stern) in which the potential drops from ψ_o to ψ_s, and a diffuse layer in which the potential drops from ψ_s to 0 in the bulk solution.

Figure 6–2
Stern model of electrical double layer. *(Shaw, 1966.)*

Measurement of Surface Potential. If a particle is placed in an electrolyte solution, and an electric current is passed through the solution, the particle, depending on its surface charge, will be attracted to one or the other of the electrodes, dragging with it a cloud of ions. The potential at the surface of the cloud (called the surface of shear) is sometimes measured in wastewater-treatment operations. The measured value is often called the zeta potential. Theoretically, however, the zeta potential should correspond to the potential measured at the surface enclosing the fixed layer of ions attached to the particle, as shown on Fig. 6–2. The use of the measured zeta potential value is limited because it will vary with the nature of the solution components.

Particle-Particle Interactions

Particle-particle interactions are extremely important in bringing about aggregation by means of Brownian motion. The theory that has been developed to describe particle-particle interactions is based on the consideration of interaction between two charged flat plates and between two charged spheres (Deryagin and Landau, 1941; Verwey and Overbeek, 1948). As neither of these developments is directly applicable to the particles found in wastewater, as described above, the analysis for two charged flat plates will be used for illustrative purposes. The interaction between two plates is illustrated on Fig. 6–3. As shown on Fig. 6–3, the two principal forces involved are the forces of repulsion, due to the electrical properties of the charged plates, and the van der Waals

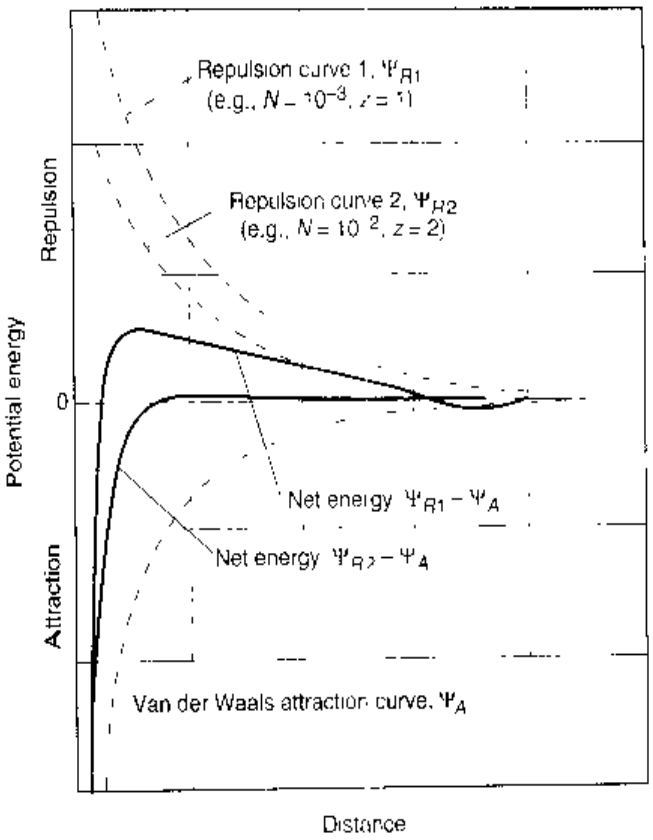


Figure 6–3

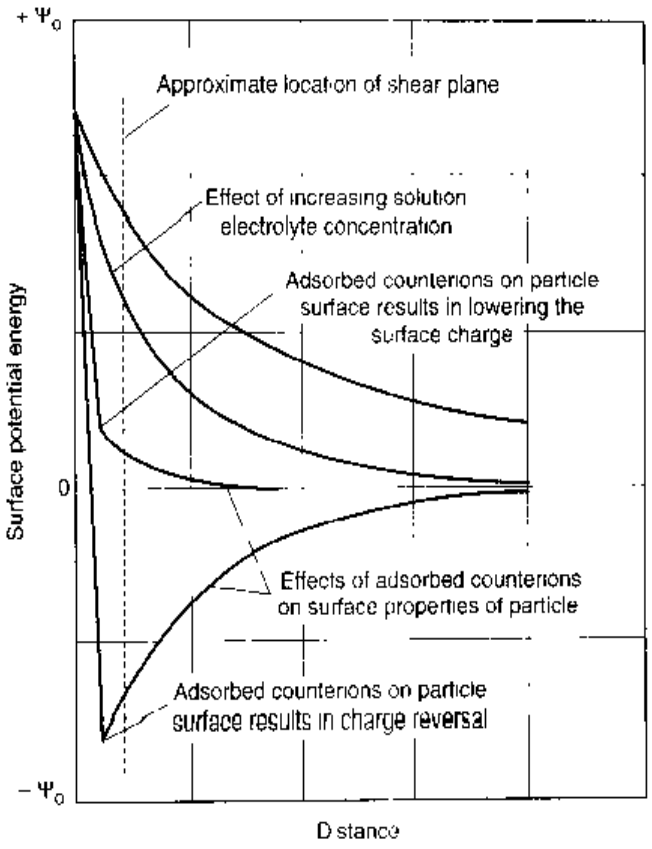
Definition sketch for particle-particle interactions based on the repulsion due to particle surface charge and van der Waals forces of attraction

forces of attraction. It should be noted that the van der Waals forces of attraction do not come into play until the two plates are brought together in close proximity to each other.

The net total energy shown by the solid lines on Fig. 6–3 is the difference between the forces of repulsion and attraction. The two conditions, with respect to the forces of repulsion, are illustrated on Fig. 6–3. As shown for condition 1, the forces of attraction will predominate at short and long distances. The net energy curve for condition 1 contains a repulsive maximum that must be overcome if the particles, represented as the two plates, are to be held together by the van der Waals force of attraction. In condition 2, there is no energy barrier to overcome. Clearly, if colloidal particles are to be removed by microflocculation, the repulsive force must be reduced. Although floc particles can form at long distances as shown by the net energy curve for condition 1, the net force holding these particles together is weak and the floc particles that are formed can be ruptured easily.



Particle Destabilization with Potential-Determining Ions and Electrolytes

To bring about particle aggregation through microflocculation, steps must be taken to reduce particle charge or to overcome the effect of this charge. The effect of the charge can be overcome by (1) the addition of potential-determining ions, which will be taken up by or will react with the colloid surface to lessen the surface charge and (2) the addition of electrolytes, which have the effect of reducing the thickness of the diffuse electric layer and, thereby, reduce the zeta potential.

Use of Potential-Determining Ions. The addition of potential-determining ions to promote coagulation can be illustrated by the addition of strong acids or bases

Figure 6–4

Definition sketch for the effects of the addition of counterions and electrolytes to solutions containing charged colloidal particles.

to reduce the charge of metal oxides or hydroxides to near zero so that coagulation can occur. The effect of adding potential-determining ions in a solution containing charged particles is illustrated on Fig. 6–4. The magnitude of the effect will depend on the concentration of potential-determining ions added. The following ratios, known as the Shultz-Hardy rule, can be used to assess the effectiveness of potential-determining or counterions:

$$1:\frac{1}{2^6}:\frac{1}{3^6} \quad \text{or} \quad 100:1.6:0.13 \tag{6–2}$$

It is interesting to note that depending on the concentration and nature of the counterions added, it is possible to reverse the charge of the double layer and develop a new stable particle.

The effect of adding counterions to a solution containing charged particles is illustrated on Fig. 6–5. The upper curve on Fig. 6–5 represents the surface charge of the particle as a function of the concentration of counterions added. The lines designated kT represent the thermal kinetic energy of the particle. The lower diagram is a plot of the turbidity that would result if the particles that have been destabilized and have undergone microflocculation were removed by settling. As shown, when the surface charge (either positive or negative) is greater than the thermal kinetic energy of the particles, the particles will not flocculate and the original turbidity is observed.

Additional details on the use of counterions may be found in Shaw (1966). The use of potential determining ions is not feasible in either water or wastewater treatment because of the massive concentration of ions that must be added to bring about sufficient compression of the electrical double layer to effect perikinetic flocculation.

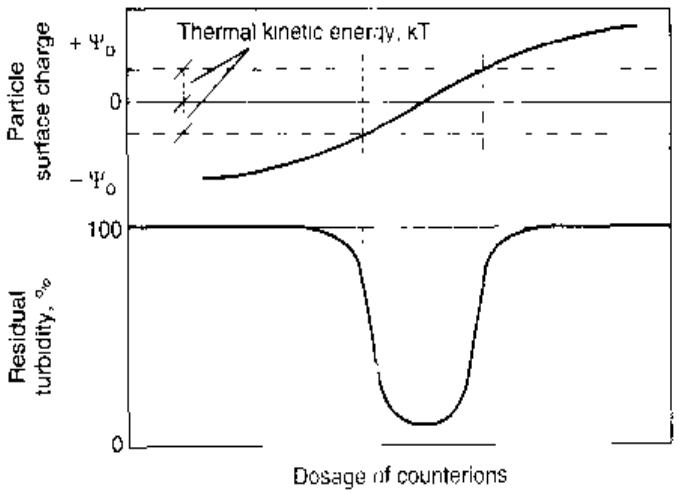


Figure 6–5
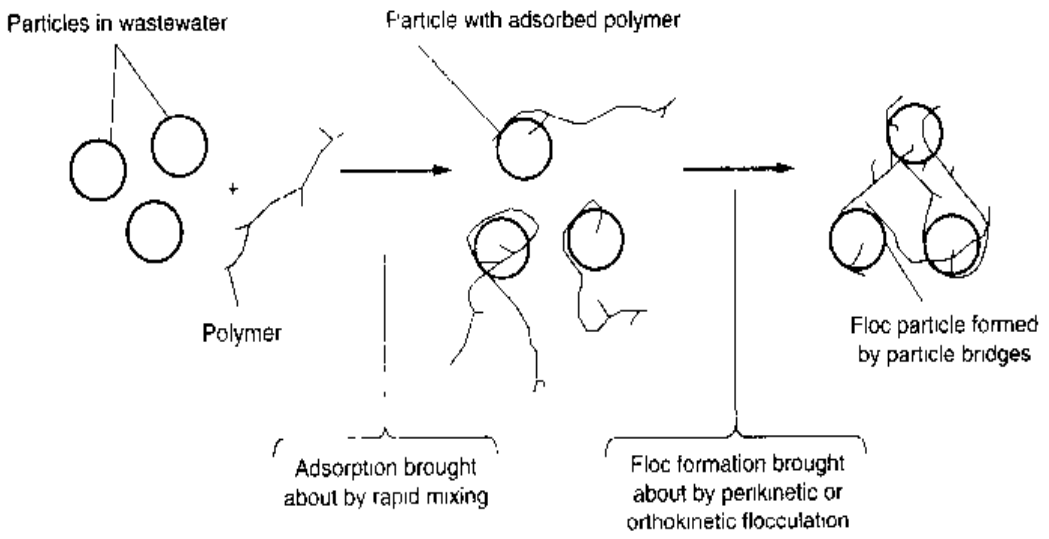
Definition sketch for the reversal of particle surface charge due to the addition of counterions.



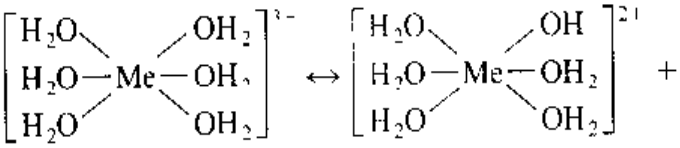
Use of Electrolytes. Electrolytes can also be added to coagulate colloidal suspensions. Increased concentration of a given electrolyte will cause a decrease in zeta potential and a corresponding decrease in repulsive forces as illustrated in condition 2 on Fig. 6–3 and on Fig. 6–4. The concentration of an electrolyte that is needed to destabilize a colloidal suspension is known as the *critical coagulation concentration* (CCC). Increasing the concentration of an indifferent electrolyte will not result in the restabilization of the colloidal particles. As with the addition of potential-determining ions, the use of electrolytes is also not feasible in wastewater treatment. As discussed subsequently, a change in the particle charge will occur when chemicals are added to adjust the pH of the wastewater to optimize the performance of hydrolyzed metal ions used as coagulants.

Particle Destabilization and Aggregation with Polyelectrolytes

Polyelectrolytes may be divided into two categories: natural and synthetic. Important natural polyelectrolytes include polymers of biological origin and those derived from starch products such as cellulose derivatives and alginates. Synthetic polyelectrolytes consist of simple monomers that are polymerized into high-molecular-weight substances. Depending on whether their charge, when placed in water, is negative, positive, or neutral, these polyelectrolytes are classified as anionic, cationic, and nonionic, respectively. The action of polyelectrolytes may be divided into the following three general categories.

Charge Neutralization. In the first category, polyelectrolytes act as coagulants that neutralize or lower the charge of the wastewater particles. Because wastewater particles normally are charged negatively, cationic polyelectrolytes are used for this purpose. In this application, the cationic polyelectrolytes are considered to be primary coagulants. To effect charge neutralization, the polyelectrolyte must be adsorbed to the particle. Because of the large number of particles found in wastewater, the mixing intensity must be sufficient to bring about the adsorption of the polymer onto the colloidal particles. With inadequate mixing, the polymer will eventually fold back on itself and its effectiveness in reducing the surface charge will be diminished. Further, if the number of colloidal particles is limited, it will be difficult to remove them with low polyelectrolyte dosages.

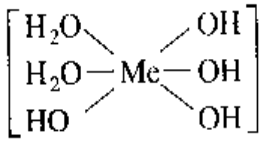
Figure 6–6
Definition sketch for interparticle bridging with organic polymers.



Polymer Bridge Formation. The second mode of action of polyelectrolytes is interparticle bridging (see Fig. 6–6). In this case, polymers that are anionic and nonionic (usually anionic to a slight extent when placed in water) become attached at a number of adsorption sites to the surface of the particles found in the wastewater. A bridge is formed when two or more particles become adsorbed along the length of the polymer. Bridged particles become intertwined with other bridged particles during the flocculation process. The size of the resulting three-dimensional particles grows until they can be removed easily by sedimentation. Where particle removal is to be achieved by the formation of particle-polymer bridges, the initial mixing of the polymer and the wastewater containing the particles to be removed must be accomplished in a matter of seconds. Instantaneous initial mixing is usually not required as the polymers are already formed, which is not the case with the polymers formed by metal salts (see discussion of hydrolyzed metal ions given below). As noted above, the mixing intensity must be sufficient to bring about the adsorption of the polymer onto the colloidal particles. If inadequate mixing is provided, the polymer will eventually fold back on itself, in which case it is not possible to form polymer bridges.

Charge Neutralization and Polymer Bridge Formation. The third type of polyelectrolyte action may be classified as a charge neutralization and bridging phenomenon, which results from using cationic polyelectrolytes of extremely high molecular weight. Besides lowering the surface charge on the particle, these polyelectrolytes also form particle bridges as described above.

Particle Destabilization and Removal with Hydrolyzed Metal Ions



In contrast with the aggregation brought about by the addition of chemicals that act as counterions, electrolytes, and polymers, aggregation brought about by the addition of alum or ferric sulfate is a more complex process. To understand particle destabilization and the removals achieved with hydrolyzed metal ions, it will be instructive to consider first the formation of metal ion hydrolysis products. Operating ranges for action of metal salts and the importance of initial mixing are also considered in light of the formation of these particles.

Formation of Hydrolysis Products. In the past, it was thought that free Al^{3+} and Fe^{3+} were responsible for the effects observed during particle aggregation; it is now known, however, that their hydrolysis products are responsible (Stumm and Morgan, 1962; Stumm and O'Melia, 1968). Although the effect of these hydrolysis products is only now appreciated, it is interesting to note that their chemistry was first elucidated in the early 1900s by Pfeiffer (1902–1907), Bjerrum (1906–1920), and Werner (1907) (Thomas, 1934). In the early 1900s, Pfeiffer proposed that the hydrolysis of trivalent metal salts, such as chromium, aluminum, and iron, could be represented as

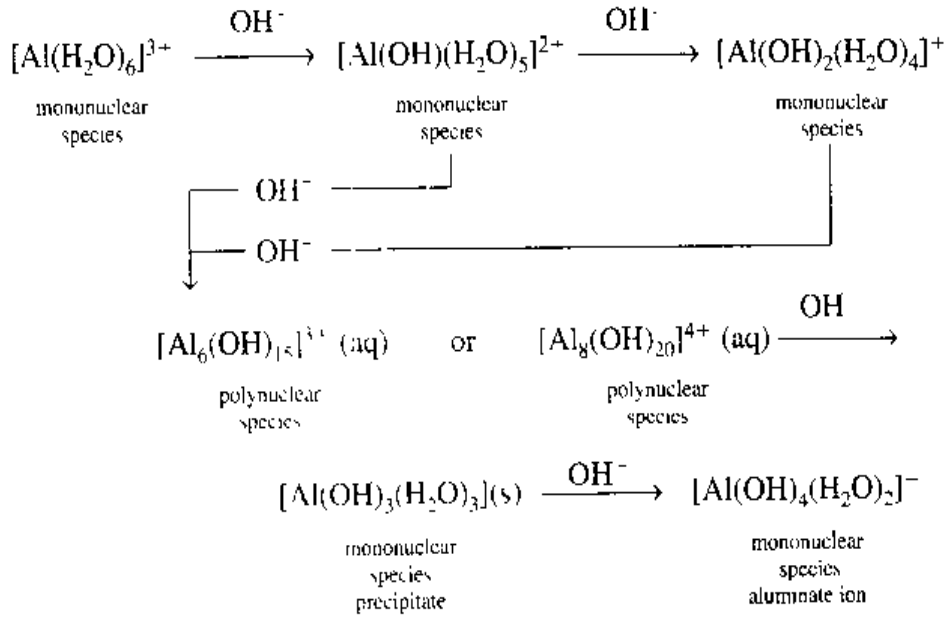
(6–3)

with the extent of the dissociation depending on the anion associated with the metal and on the physical and chemical characteristics of the solution. Further, it was proposed that, upon the addition of sufficient base, the dissociation can proceed to produce a negative ion (Thomas, 1934), such as

(6–4)

It should be noted that the complex compounds given in Eqs. (6–3) and (6–4) are known as *coordination compounds*, which are defined as a central metal ion (or atom) attached to a group of surrounding molecules or ions by coordinate covalent bonds. The surrounding molecules or ions are known as *ligands*, and the atoms attached directly to the metal ion are called ligand donor atoms (McMurry and Fay, 1998). Ligand compounds of interest in wastewater treatment include carbonate (CO_3^{2-}), chloride (Cl^-), hydroxide (OH^-), ammonia (NH_3), and water (H_2O).

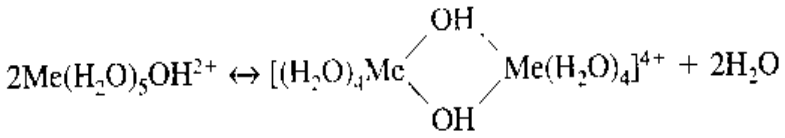
In addition, a number of the coordination compounds are also *amphoteric* in that they can exist both in strong acids and in strong bases (McMurry and Fay, 1998). For example, aluminum hydroxide behaves as follows in acidic and basic solutions:



$$\text{In acid: } Al(OH)_3(s) + 6H_3O^+(aq) \leftrightarrow Al^{3+}(aq) + 6H_2O \quad (6\text{–}5)$$

$$\text{In base: } Al(OH)_3(s) + OH^-(aq) \leftrightarrow Al(OH)_4^-(aq) \quad (6\text{–}6)$$

As shown in Eq. (6–5), $Al(OH)_3$ will dissolve in the presence of excess acid to form aqueous Al^{3+}. In the presence of excess hydroxide, $Al(OH)_3$ will dissolve to form the aluminate ion, $Al(OH)_4^-$. The acid and base properties of the hydroxides and the nature of the covalent bonds will depend on the position of the element on the periodic table. Further, it should be noted some basic hydroxides will dissolve in strong acid, but not in a strong base (McMurry and Fay, 1998).



Over the past 50 years, it has been observed that the intermediate hydrolysis reactions of Al(III) are much more complex than would be predicted on the basis of a model in which a base is added to the solution. At the present time the complete chemistry for the formation of hydrolysis reactions and products is not well understood (Letterman et al., 1999). A hypothetical model [see Eq. (6–7)], proposed by Stumm (Fair et al., 1968)

for Al(III), is useful for the purpose of illustrating the complex reactions involved. A number of alternative formation sequences have also been proposed (Letterman, 1991).

(6–7)

Before the reaction proceeds to the point where a negative aluminate ion is produced, polymerization as depicted in the following formula will usually take place (Thomas, 1934).

(6–8)

As illustrated by Eqs. (6–7) and (6–8), the possible combinations of the various hydrolysis products are endless, and their enumeration is not the purpose here. What is important, however, is the realization that one or more of the hydrolysis products and/or polymers may be responsible for the observed action of aluminum or iron.

Further, because the hydrolysis reactions follow a stepwise process, the effectiveness of aluminum and iron will vary with time. For example, an alum slurry that has been prepared and stored will behave differently from a freshly prepared solution when it is added to a wastewater. For a more detailed review of the chemistry involved, the excellent articles on this subject by Stumm and Morgan (1962) and Stumm and O'Melia (1968) are recommended. Additional details on the chemistry of aluminum and iron may be found in Benefield et al. (1982), Morel and Hering (1993), Pankow (1991), Snoeyink and Jenkins (1980), Sawyer et al. (1994), and Stumm and Morgan (1981).

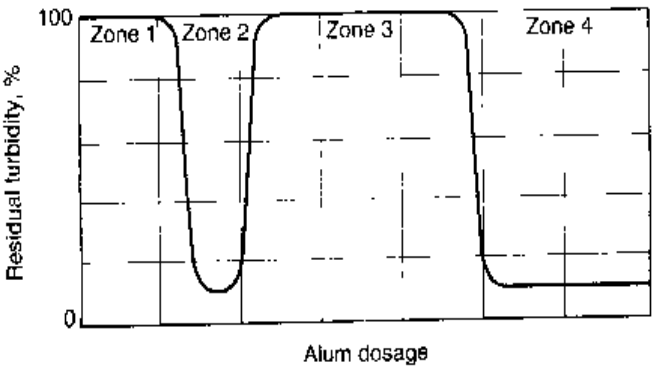
Action of Hydrolyzed Metal Ions. The action of hydrolyzed metal ions in bringing about the destabilization and removal of colloidal particles may be divided into the following three categories:

1. Adsorption and charge neutralization
2. Adsorption and interparticle bridging
3. Enmeshment in sweep floc

Adsorption and charge neutralization involves the adsorption of mononuclear and polynuclear metal hydrolysis species [see Eq. (6–5)] on the colloidal particles found in wastewater. It should be noted that it is also possible to get charge reversal with metal salts, as described previously with the addition of counterions (see Fig. 6–5). Adsorption and interparticle bridging involves the adsorption of polynuclear metal hydrolysis species and polymer species [see Eqs. (6–5) and (6–6)] which, in turn, will ultimately form particle-polymer bridges, as described previously. As the coagulant requirement for adsorption and charge neutralization is satisfied, metal hydroxide precipitates and soluble metal hydrolysis products will form as defined by Eq. (6–5). If a sufficient concentration of metal salt is added, large amounts of metal hydroxide floc will form. Following macroflocculation, large floc particles will be formed that will settle readily. In turn, as these floc particles settle, they sweep through the water containing colloidal particles. The colloidal particles that become enmeshed in the floc will thus be removed from the wastewater. In most wastewater applications, the sweep floc mode of operation is used most commonly where particles are to be removed by sedimentation.

The sequence of reactions and events that occur in the coagulation and removal of particles can be illustrated pictorially as shown on Fig. 6–7. In zone 1, sufficient coagulant has not been added to destabilize the colloidal particles, even though some reduction in surface charge may occur due to the presence of Fe^{3+} and some mononuclear hydrolysis species. In zone 2, the colloidal particles have been destabilized by the adsorption of mono- and polynuclear hydrolysis species, and, if allowed to flocculate and settle, the residual turbidity would be lowered as shown. In zone 3, as more coagulant is added, the surface charge of the particles has reversed due to the continued adsorption of mono- and polynuclear hydrolysis species (see Fig. 6–5). As the colloidal particles are now positively charged, they cannot be removed by perikinetic flocculation. As more coagulant is added, zone 4 is reached, where large amounts of hydroxide floc will form. As the floc particles settle, the colloidal particles will be removed by the sweep action of the settling floc particles, and the residual turbidity will be lowered as shown. The coagulant dosage required to reach any of the zones will depend on the nature of the colloidal particles and the pH and temperature of the wastewater. Specific constituents (e.g., organic matter) will also have an effect on the coagulant dose.

It is also very important to note that the example reaction sequence given by Eq. (6–5) and the coagulation process illustrated on Fig. 6–7 are time-dependent. For example, if it is desired to destabilize the colloidal particles in wastewater with mono- and polynuclear species, then *rapid* and *intense* initial mixing of the metal salt and the



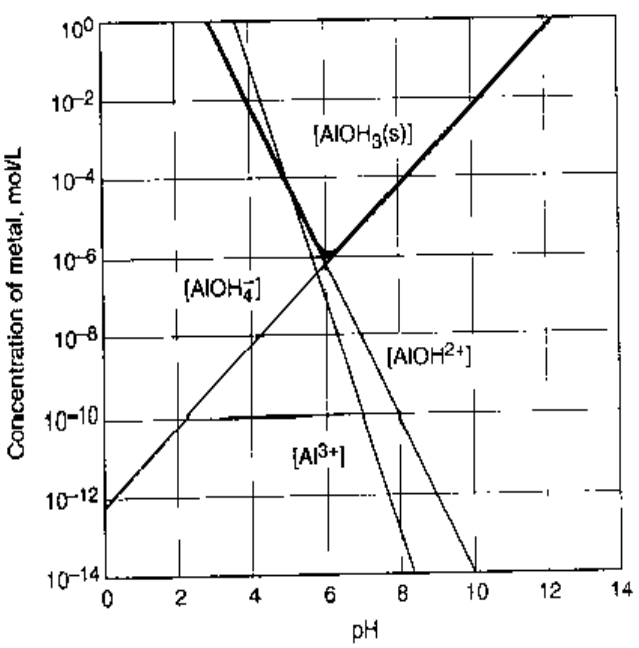


Figure 6–7

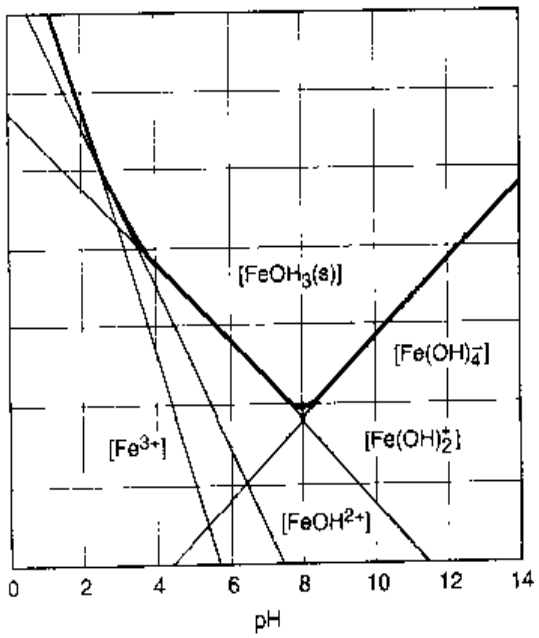
Definition sketch for the effects of the continued addition of a coagulant (e.g., alum) on the destabilization and flocculation of colloidal particles.

wastewater containing the particles to be destabilized is of critical importance. If the reaction is allowed to proceed to the formation of metal hydroxide floc, it will be difficult to contact the chemical and the particles. As discussed below, it has been estimated that the formation of the mono- and polynuclear and polymer hydroxide species occurs in a fraction of a second.

Solubility of Metal Salts. To further appreciate the action of the hydrolyzed metal ions, it will be useful to consider the solubility of the metal salts. The solubility of the various alum [Al(III)] and iron [Fe(III)] species is illustrated on Fig. 6–8*a* and *b*, respectively, in which the log molar concentrations have been plotted versus pH. In preparing these diagrams, only the mononuclear species for alum and iron have been plotted. The various mononuclear species for alum and iron are given in Table 6–2, along with the corresponding range of acid solubility products reported in the literature. The formation of some of the mononuclear species is also illustrated in Eq. (6–7). It should be noted that Hayden and Rubin (1974) compared experimental and predicted



$\log [Al^{3+}] = 10.8 - 3pH$

$\log [AlOH^{2+}] = 5.8 - 2pH$

$\log [Al(OH)_4^-] = -12.2 + pH$

$C_T = [Al^{3+}] + [AlOH^{2+}] + [Al(OH)_4^-]$

(a)

$\log [Fe^{3+}] = 3.2 - 3pH$

$\log [FeOH^{2+}] = 1.0 - 2pH$

$\log [Fe(OH)_2^+] = -2.5 - pH$

$\log [Fe(OH)_4^-] = -18.4 + pH$

$C_T = [Fe^{3+}] + [FeOH^{2+}] + [Fe(OH)^{2+}] + [Fe(OH)_4^-]$

(b)

Figure 6–8

Solubility diagram for alum [Al(III)] and iron [Fe(III)]. It should be noted that only the mononuclear species have been plotted. The polynuclear species are extremely dependent on the chemistry of the wastewater. The mononuclear species $Al(OH)_2^+$ has not been included in the development of Fig. 6–8*a*. Further, because of the wide variation in the solubility and formation constants for the various metal hydroxides, the curves presented in this figure should only be used as a reference guide.

Table 6–2
Reactions and associated equilibrium constants for aluminum and iron species in equilibrium with amorphorous aluminum hydroxide and ferric hydroxide[a]

[b] Hayden and Rubin (1974) compared experimental and predicted values and concluded that $Al(OH)_2^+$ is not an important mononuclear species.

values and concluded that $Al(OH)_2^+$ is not an important mononuclear species. Accordingly, mononuclear species $Al(OH)_2^+$ has not been included in the development of Fig. 6–8*a*. The solid lines trace the approximate total concentration of residual soluble alum (see Fig. 6–8*a*) and iron (see Fig. 6–8*b*) after precipitation. Aluminum hydroxide and ferric hydroxide are precipitated within the shaded areas, and polynuclear and polymeric species are formed outside at higher and lower pH values. The region within the square boxes is where most precipitation operations are conducted when these coagulants are used in a sweep floc mode of operation. As shown, the operating region for alum precipitation is from a pH range of 5 to about 7, with minimum solubility occurring at a pH of 6.0, and from about 7 to 9 for iron precipitation, with minimum solubility occurring at a pH of 8.0. A more thorough development of the equations used to develop Fig. 6–8 may be found in Benefield et al. (1982), Benjamin (2001), Morel and Hering (1993), Pankow (1991), Snoeyink and Jenkins (1980), Sawyer et al. (1994), and Stumm and Morgan (1981).

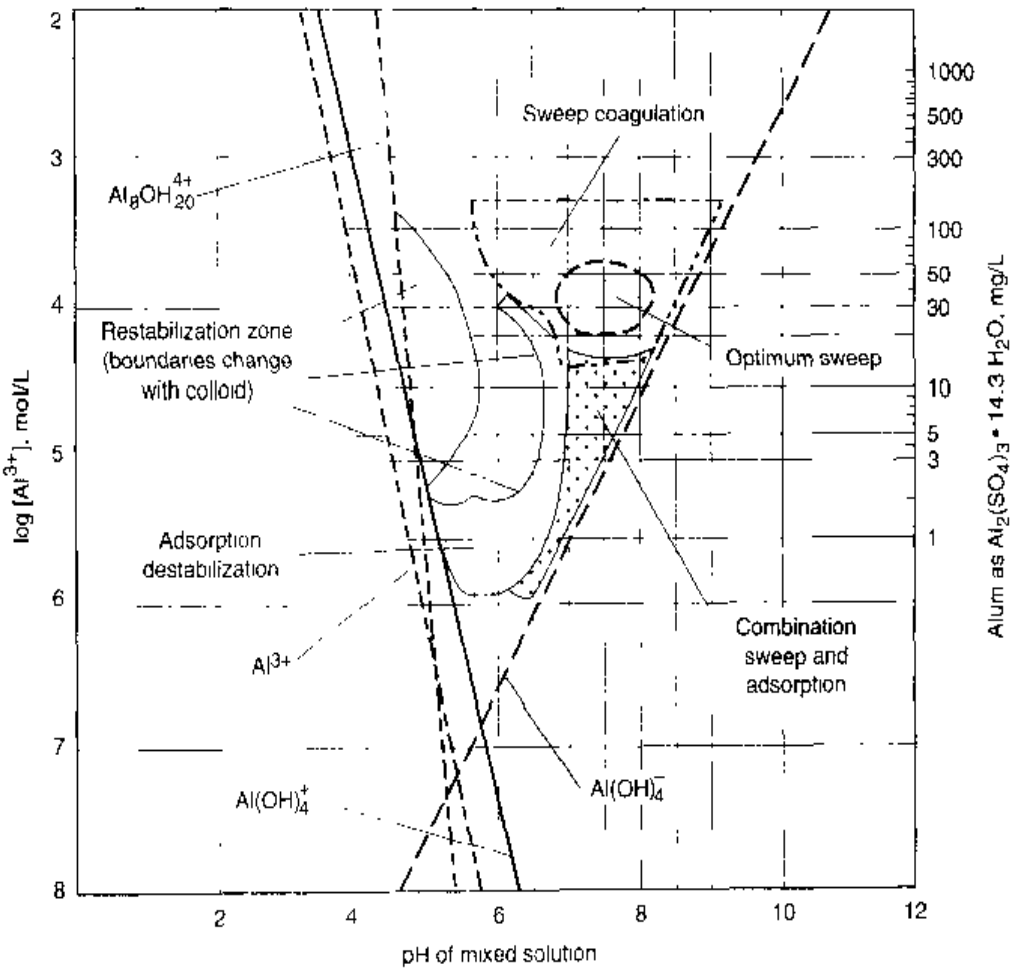

Figure 6–9

Typical operating ranges for alum coagulation. *(Adapted from Amirtharajah and Mills, 1982.)*

Operating Regions for Action of Metal Salts. Because the chemistry of the various reactions is so complex, there is no complete theory to explain the action of hydrolyzed metal ions. To quantify qualitatively the application of alum as a function of pH, taking into account the action of alum as described above, Amirtharajah and Mills (1982) developed the diagram shown on Fig. 6–9. Although Fig. 6–9 was developed for water treatment applications, it has been found to apply reasonably well to most wastewater applications, with minor variations. As shown on Fig. 6–9, the approximate regions in which the different phenomena associated with particle removal in conventional sedimentation and filtration processes are operative are plotted as a function of the alum dose and the pH of the treated effluent after alum has been added. For example, optimum particle removal by sweep floc occurs in the pH range of 7 to 8 with an alum dose of 20 to 60 mg/L. Generally, for many wastewater effluents that have high pH values (e.g., 7.3 to 8.5), low alum dosages in the range of 5 to 10 mg/L will not be effective. With proper pH control it is possible to operate with extremely low alum dosages. Because the characteristics of wastewater will vary from treatment plant to treatment plant, bench-scale and pilot-plant tests must be conducted to establish the appropriate chemical dosages.

Importance of Initial Chemical Mixing with Metal Salts. Perhaps the least appreciated fact about chemical addition of metal salts is the importance of the rapid initial mixing of the chemicals with the wastewater to be treated. In a 1967 arti-

cle, Hudson and Wolfner (1967) noted that "coagulants hydrolyze and begin to polymerize in a fraction of second after being added to water." Hahn and Stumm (1968) studied the coagulation of silica dispersions with Al(III). They reported that the time required for the formation of mono- and polynuclear hydroxide species appears to be extremely short, on the order of 10^{-7} s. The time of formation for the polymer species was on the order of 10^{-2} s. Further, they found that the rate-limiting step in the coagulation process was the time required for the colloidal transport step brought about by Brownian motion (i.e., perikinetic flocculation) which was estimated to be on the order of 1.5 to 3.3 $\times$ 10^{-1} s. The importance of initial and rapid mixing is also discussed by Amirtharajah and Mills (1982) and Vrale and Jorden (1971). Clearly, based on the literature and actual field evaluations, the instantaneous rapid and intense mixing of metal salts is of critical importance, especially where the metal salts are to be used as coagulants to lower the surface charge of the colloidal particles. It should be noted that although achieving extremely low mixing times in large treatment plants is often difficult, low mixing times can be achieved by using multiple mixers. Typical mixing times for various chemicals are reported in Table 6–19 in Sec. 6–8.

6–3 CHEMICAL PRECIPITATION FOR IMPROVED PLANT PERFORMANCE

Chemical precipitation, as noted previously, involves the addition of chemicals to alter the physical state of dissolved and suspended solids and facilitate their removal by sedimentation. In the past, chemical precipitation was often used to enhance the degree of TSS and BOD removal: (1) where there were seasonal variations in the concentration of the wastewater (such as in cannery wastewater), (2) where an intermediate degree of treatment was required, and (3) as an aid to the sedimentation process. Since about 1970, the need to provide more complete removal of the organic compounds and nutrients (nitrogen and phosphorus) contained in wastewater has brought about renewed interest in chemical precipitation. In current practice, chemical precipitation is used (1) as a means of improving the performance of primary settling facilities, (2) as a basic step in the independent physical-chemical treatment of wastewater, (3) for the removal of phosphorus, and (4) for the removal of heavy metals. The first two applications are considered in the following discussion. Phosphorus and heavy metals removal is considered in Secs. 6–4 and 6–5, respectively.

Aside from the determination of the required chemical dosages, the principal design considerations related to the use of chemical precipitation involve the analysis and design of the necessary sludge processing facilities, and the selection and design of the chemical storage, feeding, piping, and control systems. Chemical storage, feeding, piping, and control systems are considered in Sec. 6–8.

Chemical Reactions in Wastewater Precipitation Applications

Over the years a number of different substances have been used as precipitants. The degree of clarification obtained depends on the quantity of chemicals used and the care with which the process is controlled. It is possible by chemical precipitation to obtain a clear effluent, substantially free from matter in suspension or in the colloidal state. The chemicals added to wastewater interact with substances that are either normally present in the wastewater or added for this purpose. The most common chemicals are listed in

Table 6–3
Inorganic chemicals used most commonly for coagulation and precipitation processes in wastewater treatment

Chemical	Formula	Molecular weight	Equivalent weight	Availability	
				Form	Percent
Alum	$Al_2(SO_4)_3 \cdot 18H_2O$[a]	666.5		Liquid	8.5 (Al_2O_3)
				Lump	17 (Al_2O_3)
	$Al_2(SO_4)_3 \cdot 14H_2O$[a]	594.4	114	Liquid	8.5 (Al_2O_3)
				Lump	17 (Al_2O_3)
Aluminum chloride	$AlCl_3$	133.3	44	Liquid	
Calcium hydroxide (lime)	$Ca(OH)_2$	56.1 as CaO	40	Lump	63–73 as CaO
				Powder	85–99
				Slurry	15–20
Ferric chloride	$FeCl_3$	162.2	91	Liquid	20 (Fe)
				Lump	20 (Fe)
Ferric sulfate	$Fe_2(SO_4)_3$	400	51.5	Granular	18.5 (Fe)
Ferrous sulfate (copperas)	$FeSO_4 \cdot 7H_2O$	278.1	139	Granular	20 (Fe)
Sodium aluminate	$Na_2Al_2O_4$	163.9	100	Flake	46 (Al_2O_3)

[a] Number of bound water molecules will typically vary from 14 to 18.

Table 6–3. Information on the handling, storage, and feeding of these compounds may be found in Sec. 6–8. The reactions involved with (1) alum, (2) lime, (3) ferrous sulfate (copperas) and lime, (4) ferric chloride, (5) ferric chloride and lime, and (6) ferric sulfate and lime are considered in the following discussion (Metcalf & Eddy, 1935).

Alum. When alum is added to wastewater containing calcium and magnesium bicarbonate alkalinity, a precipitate of aluminum hydroxide will form. The overall reaction that occurs when alum is added to water may be illustrated as follows:

$$\underset{\substack{\text{Calcium}\\\text{bicarbonate}\\\text{(soluble)}}}{\overset{3 \times 100\ (\text{as } CaCO_3)}{3Ca(HCO_3)_2}} + \underset{\substack{\text{Aluminum}\\\text{sulfate}\\\text{(soluble)}}}{\overset{666.5}{Al_2(SO_4)_3 \cdot 18H_2O}} \leftrightarrow$$

$$\underset{\substack{\text{Aluminum}\\\text{hydroxide}\\\text{(insoluble)}}}{\overset{2 \times 78}{2Al(OH)_3}} + \underset{\substack{\text{Calcium}\\\text{sulfate}\\\text{(soluble)}}}{\overset{3 \times 136}{3CaSO_4}} + \underset{\substack{\text{Carbon}\\\text{dioxide}\\\text{(soluble)}}}{\overset{6 \times 44}{6CO_2}} + \overset{18 \times 18}{18H_2O} \qquad (6\text{–}9)$$

The numbers above the chemical formulas are the combining molecular weights of the different substances and, therefore, denote the quantity of each one involved. The pre-

cipitation reaction given above also occurs with the addition of aluminum chloride ($AlCl_3$). The insoluble aluminum hydroxide is a gelatinous floc that settles slowly through the wastewater, sweeping out suspended material and producing other changes. The reaction is exactly analogous when magnesium bicarbonate is substituted for the calcium salt.

Because alkalinity in Eq. (6–9) is reported in terms of calcium carbonate ($CaCO_3$), the molecular weight of which is 100, the quantity of alkalinity required to react with 10 mg/L of alum is

$$(10.0 \text{ mg/L})\left[\frac{3(100 \text{ g/mole})}{(666.5 \text{ g/mole})}\right] = 4.5 \text{ mg/L}$$

If less than this amount of alkalinity is available, it must be added. Lime is commonly used for this purpose when necessary, but it is seldom required in the treatment of wastewater.

Lime. When lime alone is added as a precipitant, the principles of clarification are explained by the following reactions for the carbonic acid [Eq. (6–10)] and the alkalinity [Eq. (6–11)]:

$$\underset{\text{Carbonic acid (soluble)}}{H_2CO_3} + \underset{\text{Calcium hydroxide (slightly soluble)}}{Ca(OH)_2} \leftrightarrow \underset{\text{Calcium carbonate (somewhat soluble)}}{CaCO_3} + 2H_2O \qquad (6\text{–}10)$$

(44 as CO_2; 56 as CaO; 100; 2×18)

$$\underset{\text{Calcium bicarbonate (soluble)}}{Ca(HCO_3)_2} + \underset{\text{Calcium hydroxide (slightly soluble)}}{Ca(OH)_2} \leftrightarrow \underset{\text{Calcium carbonate (somewhat soluble)}}{2CaCO_3} + 2H_2O \qquad (6\text{–}11)$$

(100 as $CaCO_3$; 56 as CaO; 2×100; 2×18)

A sufficient quantity of lime must therefore be added to combine with all the free carbonic acid and with the carbonic acid of the bicarbonates (half-bound carbonic acid) to produce calcium carbonate. Much more lime is generally required when it is used alone than when sulfate of iron is also used (see the following discussion). Where industrial wastes introduce mineral acids or acid salts into the wastewater, these must be neutralized before precipitation can take place.

Ferrous Sulfate and Lime. In most cases, ferrous sulfate cannot be used alone as a precipitant because lime must be added at the same time to form a precipitate. When ferrous sulfate alone is added to wastewater, the following reactions occur:

$$\underset{\text{Ferrous sulfate (soluble)}}{FeSO_4 \cdot 7H_2O} + \underset{\text{Calcium carbonate (soluble)}}{Ca(HCO_3)_2} \leftrightarrow \underset{\text{Ferrous bicarbonate (soluble)}}{Fe(HCO_3)_2} + \underset{\text{Calcium sulfate (soluble)}}{CaSO_4} + 7H_2O \qquad (6\text{–}12)$$

(278; 100 as $CaCO_3$; 178; 136; 7×18)

$$\underset{\text{Ferrous bicarbonate (soluble)}}{\overset{278}{Fe(HCO_3)_2}} \rightarrow \underset{\text{Ferrous hydroxide (very slightly soluble)}}{\overset{4 \times 89.9}{Fe(OH)_2}} + \underset{\text{Carbon dioxide (soluble)}}{CO_2} \qquad (6\text{–}13)$$

If sufficient alkalinity is not available, lime is often added in excess in conjunction with ferrous sulfate. The resulting reaction is

$$\underset{\text{Ferrous bicarbonate (soluble)}}{\overset{178}{Fe(HCO_3)_2}} + \underset{\text{Calcium hydroxide (slightly soluble)}}{\overset{2 \times 56 \text{ (as CaO)}}{2Ca(OH)_2}} \leftrightarrow \underset{\text{Ferrous hydroxide (very slightly soluble)}}{\overset{89.9}{Fe(OH)_2}} + \underset{\text{Calcium carbonate (somewhat soluble)}}{\overset{2 \times 100}{2CaCO_3}} + \overset{2 \times 18}{2H_2O} \qquad (6\text{–}14)$$

The ferrous hydroxide can be oxidized to ferric hydroxide, the final form desired, by oxygen dissolved in the wastewater. The reaction is:

$$\underset{\text{Ferrous hydroxide (very slightly soluble)}}{\overset{89.9}{Fe(OH)_2}} + \underset{\text{Oxygen (soluble)}}{\overset{1/4 \times 32}{1/4O_2}} + \overset{1/2 \times 18}{1/2\ H_2O} \leftrightarrow \underset{\text{Ferric hydroxide (insoluble)}}{\overset{106.9}{Fe(OH)_3}} \qquad (6\text{–}15)$$

The insoluble ferric hydroxide is formed as a bulky, gelatinous floc similar to the alum floc. The alkalinity required for a 10 mg/L dosage of ferrous sulfate [see Eq. (6–12)] is

$$(10.0 \text{ mg/L})\left[\frac{(100 \text{ g/mole})}{(278 \text{ g/mole})}\right] = 3.6 \text{ mg/L}$$

The lime required [see Eq. (6–14)] is

$$(10.0 \text{ mg/L})\left[\frac{2(56 \text{ g/mole})}{(278 \text{ g/mole})}\right] = 4.0 \text{ mg/L}$$

The oxygen required [see Eq. (6–15)] is

$$(10.0 \text{ mg/L})\left[\frac{(32 \text{ g/mole})}{4(278 \text{ g/mole})}\right] = 0.29 \text{ mg/L}$$

Because the formation of ferric hydroxide is dependent on the presence of dissolved oxygen, the reaction given in Eq. (6–15) cannot be completed in most wastewaters, and, as a result, ferrous sulfate is not used commonly in wastewater.

Ferric Chloride. Because of the many problems associated with the use of ferrous sulfate, ferric chloride is the iron salt used most commonly in precipitation applications. When ferric chloride is added to wastewater, the following reactions take place.

$$\underset{\text{Ferric chloride (soluble)}}{\overset{2 \times 162.2}{2FeCl_3}} + \underset{\text{Calcium bicarbonate (soluble)}}{\overset{3 \times 100 \text{ (as CaCO}_3\text{)}}{3Ca(HCO_3)_2}} \leftrightarrow \underset{\text{Ferric hydroxide (insoluble)}}{\overset{2 \times 106.9}{2Fe(OH)_3}} + \underset{\text{Calcium sulfate (soluble)}}{3CaCl_2} + \underset{\text{Carbon dioxide (soluble)}}{6CO_2} \qquad (6\text{–}16)$$

Ferric Chloride and Lime. If lime is added to supplement the natural alkalinity of the wastewater, the following reaction can be assumed to occur:

$$\underset{\text{Ferric chloride (soluble)}}{2\times 162.2\ 2FeCl_3} + \underset{\text{Calcium hydroxide (slightly soluble)}}{3\times 56\ (\text{as CaO})\ 3Ca(OH)_2} \leftrightarrow \underset{\text{Ferric hydroxide (insoluble)}}{2\times 106.9\ 2Fe(OH)_3} + \underset{\text{Calcium chloride (soluble)}}{3\times 111\ 3CaCl_2} \quad (6\text{–}17)$$

Ferric Sulfate and Lime. The overall reaction that occurs when ferric sulfate and lime are added to wastewater may be represented as follows:

$$\underset{\text{Ferric sulfate (soluble)}}{399.9\ Fe_2(SO_4)_3} + \underset{\text{Calcium hydroxide (slightly soluble)}}{3\times 56\ (\text{as CaO})\ 3Ca(OH)_2} \leftrightarrow \underset{\text{Ferric hydroxide (insoluble)}}{2\times 106.9\ 2Fe(OH)_3} + \underset{\text{Calcium sulfate (soluble)}}{3\times 136\ 3CaSO_4} \quad (6\text{–}18)$$

Enhanced Removal of Suspended Solids in Primary Sedimentation

The degree of clarification obtained when chemicals are added to untreated wastewater depends on the quantity of chemicals used, mixing times, and the care with which the process is monitored and controlled. With chemical precipitation, it is possible to remove 80 to 90 percent of the total suspended solids (TSS) including some colloidal particles, 50 to 80 percent of the BOD, and 80 to 90 percent of the bacteria. Comparable removal values for well-designed and well-operated primary sedimentation tanks without the addition of chemicals are 50 to 70 percent of the TSS, 25 to 40 percent of the BOD, and 25 to 75 percent of the bacteria. Because of the variable characteristics of wastewater, the required chemical dosages should be determined from bench- or pilot-scale tests. Recommended surface loading rates for various chemical suspensions to be used in the design of the sedimentation facilities are given in Table 6–4.

Table 6–4 Recommended surface loading rates for sedimentation tanks for various chemical suspensions

Suspension	Overflow rate			
	gal/ft²·d		m³/m²·d	
	Typical range	Peak flow	Typical range	Peak flow
Alum floc[a]	700–1400	1200	30–70	80
Iron floc[a]	700–1400	1200	30–70	80
Lime floc[a]	750–1500	1500	35–80	90
Untreated wastewater	600–1200	1200	30–70	80

[a] Mixed with the settleable suspended solids in the untreated wastewater and colloidal or other suspended solids swept out by the floc

Note: $m^3/m^2\cdot d \times 24.5424 = gal/ft^2\cdot d$

Independent Physical-Chemical Treatment

In some localities, industrial wastes have rendered municipal wastewater difficult to treat by biological means. In such situations, physical-chemical treatment may be an alternative approach. This method of treatment has met with limited success because of its lack of consistency in meeting discharge requirements, high costs for chemicals, handling and disposal of the great volumes of sludge resulting from the addition of chemicals, and numerous operating problems. Based on typical performance results of full-scale plants using activated carbon, the activated-carbon columns removed only 50 to 60 percent of the applied total BOD, and the plants did not meet consistently the effluent standards for secondary treatment. In some instances, substantial process modifications have been required to reduce the operating problems and meet performance requirements, or the process has been replaced by biological treatment. Because of these reasons, new applications of physical-chemical treatment for municipal wastewater are rare. Physical-chemical treatment is used more extensively for the treatment of industrial wastewater. Depending on the treatment objectives, the required chemical dosages and application rates should be determined from bench- or pilot-scale tests.

A flow diagram for the physical-chemical treatment of untreated wastewater is presented on Fig. 6–10. As shown, after first-stage precipitation and pH adjustment by recarbonation (if required), the wastewater is passed through a granular-medium filter to remove any residual floc and then through carbon columns to remove dissolved organic compounds. The filter is shown as optional, but its use is recommended to reduce the blinding and headloss buildup in the carbon columns. The treated effluent from the carbon column is usually chlorinated before discharge to the receiving waters.

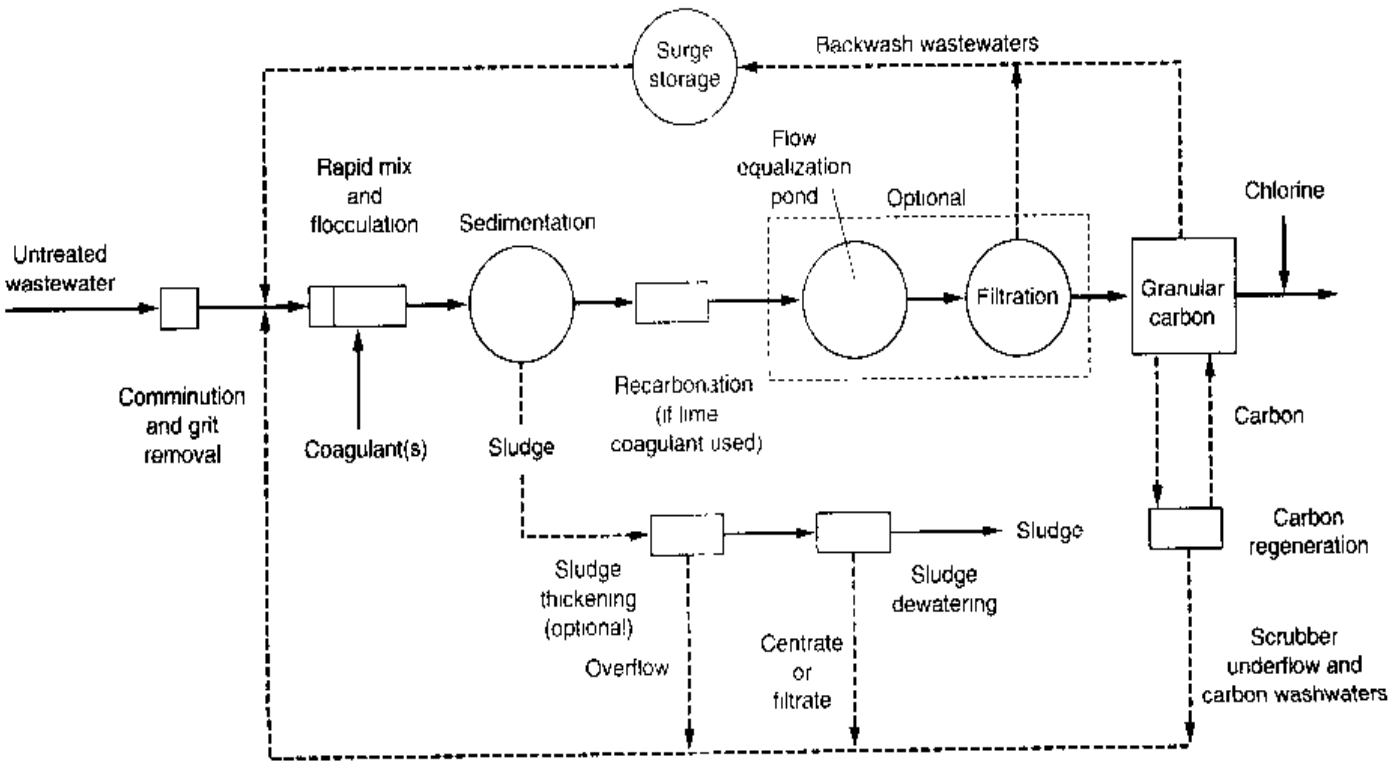

Figure 6–10

Typical flow diagram of an independent physical-chemical treatment plant

Estimation of Sludge Quantities from Chemical Precipitation

The handling and disposal of the sludge resulting from chemical precipitation is one of the greatest difficulties associated with chemical treatment. Sludge is produced in great volume from most chemical precipitation operations, often reaching 0.5 percent of the volume of wastewater treated when lime is used. The computational procedures involved in estimating the quantity of sludge resulting from chemical precipitation with ferric chloride and lime are illustrated in Example 6–1.

EXAMPLE 6–1 Estimation of Sludge Volume from Chemical Precipitation of Untreated Wastewater Estimate the mass and volume of sludge produced from untreated wastewater without and with the use of ferric chloride for the enhanced removal of TSS. Also estimate the amount of lime required for the specified ferric chloride dose. Assume that 60 percent of the TSS is removed in the primary settling tank without the addition of chemicals, and that the addition of ferric chloride results in an increased removal of TSS to 85 percent. Also, assume that the following data apply to this situation:

1.	Wastewater flowrate, m^3/d	1000
2.	Wastewater TSS, mg/L	220
3.	Wastewater alkalinity as $CaCO_3$, mg/L	136
4.	Ferric chloride ($FeCl_3$) added, kg/1000 m^3	40
5.	Raw sludge properties	
	Specific gravity	1.03
	Moisture content, %	94
6.	Chemical sludge properties (from Chap. 15)	
	Specific gravity	1.05
	Moisture content, %	92.5

Solution

1. Compute the mass of TSS removed without and with chemicals.
   a. Determine the mass of TSS removed without chemicals.

$$M_{TSS} = \frac{0.6(220\ g/m^3)(1000\ m^3/d)}{(10^3\ g/kg)} = 132.0\ kg/d$$

   b. Determine the mass of TSS removed with chemicals.

$$M_{TSS} = \frac{0.85(220\ g/m^3)(1000\ m^3/d)}{(10^3\ g/kg)} = 187.0\ kg/d$$

2. Using Eq. (6–16), determine the mass of ferric hydroxide [$Fe(OH)_3$] produced from the addition of 40 kg/1000 m^3 of ferrous sulfate ($FeCl_3$).

$$Fe(OH)_3 \text{ formed} = 40 \times \left(\frac{2 \times 106.9}{2 \times 162.2}\right) = 26.4\ kg/1000\ m^3$$

3. Using Eq. (6–17), determine the mass of lime required to convert the ferric chloride to ferric hydroxide $Fe(OH)_3$.

$$\text{Lime required} = 40 \times \left(\frac{3 \times 56}{2 \times 162.2}\right) = 20.7 \text{ kg}/1000 \text{ m}^3$$

Because there is sufficient natural alkalinity no lime addition will be required.

4. Determine the total amount of sludge on a dry basis resulting from chemical precipitation.

$$\text{Total dry solids} = 187 + 26.4 = 213.4 \text{ kg}/1000 \text{ m}^3$$

5. Determine the total volume of sludge resulting from chemical precipitation, assuming that the sludge has a specific gravity of 1.05 and a moisture content of 92.5 percent.

$$V_s = \frac{(213.4 \text{ kg/d})}{(1.05)(1000 \text{ kg/m}^3)(0.075)} = 2.71 \text{ m}^3/\text{d}$$

6. Determine the total volume of sludge without chemical precipitation, assuming that the sludge has a specific gravity of 1.03 and a moisture content of 94 percent.

$$V_s = \frac{(132 \text{ kg/d})}{(1.03)(1000 \text{ kg/m}^3)(0.06)} = 2.1 \text{ m}^3/\text{d}$$

7. Prepare a summary table of sludge masses and volumes without and with chemical precipitation.

	Sludge	
Treatment	**Mass, kg/d**	**Volume, m^3/d**
Without chemical precipitation	132.0	2.13
With chemical precipitation	213.4	2.71

Comment The magnitude of the sludge disposal problem when chemicals are used is evident from a review of the data presented in the summary table given in Step 7. Even larger volumes of sludge are produced when lime is used as the primary precipitant (see Example 6–3).

6–4 CHEMICAL PRECIPITATION FOR PHOSPHORUS REMOVAL

The removal of phosphorus from wastewater involves the incorporation of phosphate into TSS and the subsequent removal of those solids. Phosphorus can be incorporated into either biological solids (e.g., microorganisms) or chemical precipitates. The fundamentals of biological phosphorus removal are considered in Chap. 8. The removal of

phosphorus in chemical precipitates is introduced in this section. The topics to be considered include (1) the chemistry of phosphate precipitation, (2) strategies for phosphorus removal, (3) phosphorus removal using metal salts and polymers, and (4) phosphorus removal using lime.

Chemistry of Phosphate Precipitation

The chemical precipitation of phosphorus is brought about by the addition of the salts of multivalent metal ions that form precipitates of sparingly soluble phosphates. The multivalent metal ions used most commonly are calcium [Ca(II)], aluminum [Al(III)], and iron [Fe(III)]. Polymers have been used effectively in conjunction with alum and lime as flocculant aids. Because the chemistry of phosphate precipitation with calcium is quite different than with aluminum and iron, the two different types of precipitation are considered separately in the following discussion.

Phosphate Precipitation with Calcium. Calcium is usually added in the form of lime $Ca(OH)_2$. From the equations presented previously, it will be noted that when lime is added to water it reacts with the natural bicarbonate alkalinity to precipitate $CaCO_3$. As the pH value of the wastewater increases beyond about 10, excess calcium ions will then react with the phosphate, as shown in Eq. (6–19), to precipitate hydroxylapatite $Ca_{10}(PO_4)_6(OH)_2$.

$$10Ca^{2+} + 6PO_4^{3-} + 2OH^- \leftrightarrow \underset{\text{Hydroxylapatite}}{Ca_{10}(PO_4)_6(OH)_2} \qquad (6\text{–}19)$$

Because of the reaction of lime with the alkalinity of the wastewater, the quantity of lime required will, in general, be independent of the amount of phosphate present and will depend primarily on the alkalinity of the wastewater (see Fig. 6–11). The quantity of lime required to precipitate the phosphorus in wastewater is typically about 1.4 to 1.5 times the total alkalinity expressed as $CaCO_3$. Because a high pH value is required to precipitate phosphate, coprecipitation is usually not feasible. When lime is added to raw

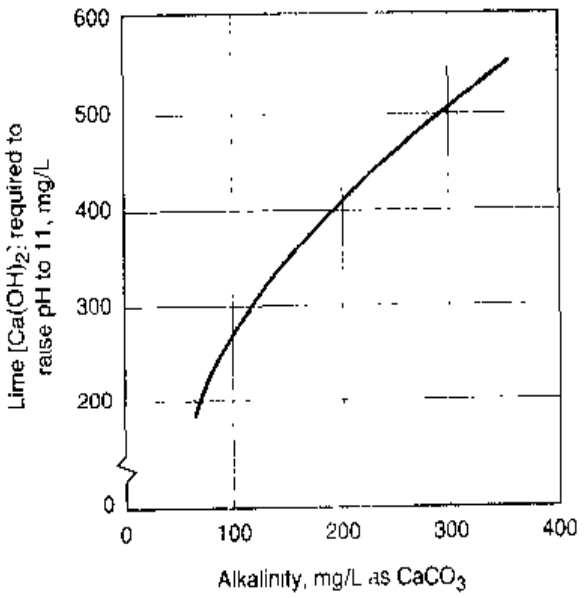

Figure 6–11
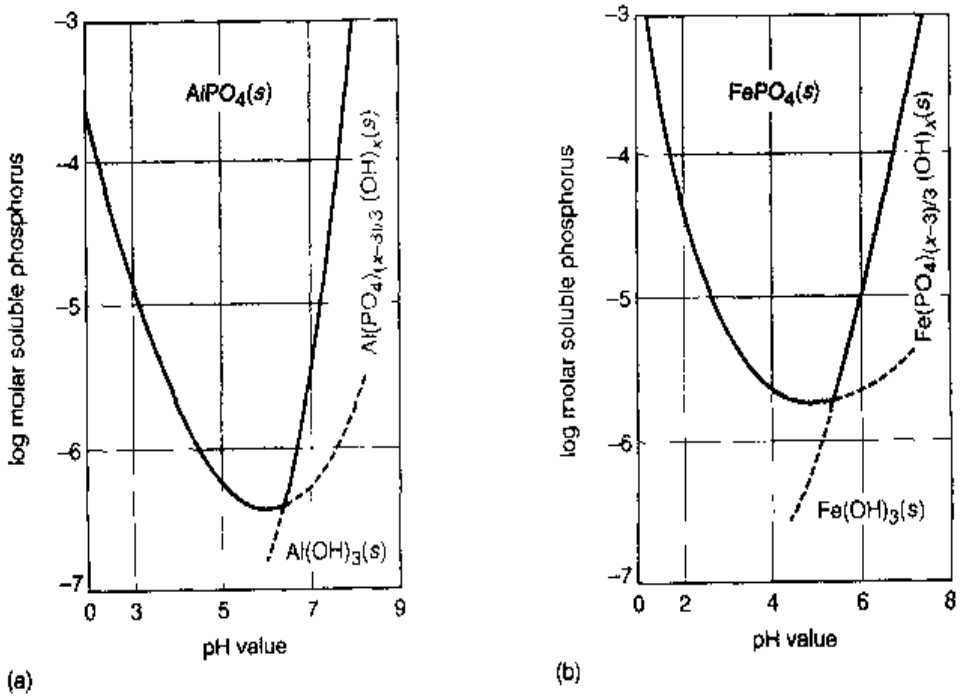
Lime dosage required to raise the pH to 11 as a function of untreated wastewater alkalinity.

wastewater or to secondary effluent, pH adjustment is usually required before subsequent treatment or disposal. Recarbonation with carbon dioxide (CO_2) is used to lower the pH value.

Phosphate Precipitation with Aluminum and Iron. The basic reactions involved in the precipitation of phosphorus with aluminum and iron are as follows.

Phosphate precipitation with aluminum:

$$Al^{3+} + H_nPO_4^{3-n} \leftrightarrow AlPO_4 + nH^+ \qquad (6\text{–}20)$$



Phosphate precipitation with iron:

$$Fe^{3+} + H_nPO_4^{3-n} \leftrightarrow FePO_4 + nH^+ \qquad (6\text{–}21)$$

In the case of alum and iron, 1 mole will precipitate 1 mole of phosphate; however, these reactions are deceptively simple and must be considered in light of the many competing reactions and their associated equilibrium constants, and the effects of alkalinity, pH, trace elements, and ligands found in wastewater. Because of the many competing reactions, Eqs. (6–20) and (6–21) cannot be used to estimate the required chemical dosages directly. Therefore, dosages are generally established on the basis of bench-scale tests and occasionally by full-scale tests, especially if polymers are used. For example, for equimolar initial concentrations of Al(III), Fe(III), and phosphate, the total concentration of soluble phosphate in equilibrium with both insoluble $AlPO_4$ and $FePO_4$ is shown on Fig. 6–12. The solid lines trace the concentration of residual soluble phosphate after precipitation. Pure metal phosphates are precipitated within the shaded area, and mixed complex polynuclear species are formed outside toward higher and lower pH values.

Figure 6–12

Concentration of aluminum and ferric phosphate in equilibrium with soluble phosphorus: (a) Al(III)-phosphate; (b) Fe(III)-phosphate.

EXAMPLE 6–2 Determination of Alum Dosage for Phosphorus Removal Determine the amount of liquid alum required to precipitate phosphorus in a wastewater that contains 8 mg P/L. Also determine the required alum storage capacity if a 30-d supply is to be stored at the treatment facility. Based on laboratory testing, 1.5 mole of Al will be required per mole of P. The flowrate is 12,000 m^3/d. The following data are for the liquid alum supply.

1. Formula for liquid alum $Al_2(SO_4)_3 \cdot 18H_2O$
2. Alum strength = 48 percent
3. Density of liquid alum solution = 1.2 kg/L

Solution

1. Determine the weight of aluminum (Al) available per liter of liquid alum.
   a. The weight of alum per liter is

      Alum/L = (0.48)(1.2 kg/L) = 0.576 kg/L

   b. The weight of aluminum per liter is

      Molecular weight of alum = 666.5 (see Table 6–2)

      Aluminum/L = (0.58 kg/L)(2 × 26.98/666.5) = 0.0466 kg/L

2. Determine the weight of Al required per unit weight of P.
   a. Theoretical dosage = 1.0 mole Al per 1.0 mole P [see Eq. (6–20)]
   b. Aluminum required = 1.0 kg × (mw Al/mw P)
      = 1.0 kg × (26.98/30.97) = 0.87 kg Al/kg P
3. Determine the amount of alum solution required per kg P.

$$\text{Alum dose} = 1.5 \times \left(\frac{0.87 \text{ kg Al}}{1.0 \text{ kg P}}\right)\left(\frac{\text{L alum solution}}{0.0466 \text{ kg}}\right)$$

$$= 28.0 \text{ L alum solution/kg P}$$

4. Determine the amount of alum solution required per day.

$$\text{Alum} = \frac{(12{,}000 \text{ m}^3/\text{d})(8 \text{ g P/m}^3)(28.0 \text{ L alum/kg P})}{(10^3 \text{ g/kg})}$$

$$= 2688 \text{ L alum solution/d}$$

5. Determine the required alum solution storage capacity based on average flow.

Storage capacity = (2688 L alum solution/d)(30 d)

= 80,640 L = 80.6 m^3

Strategies for Phosphorus Removal

The precipitation of phosphorus from wastewater can occur in a number of different locations within a process flow diagram (see Fig. 6–13). The general locations where

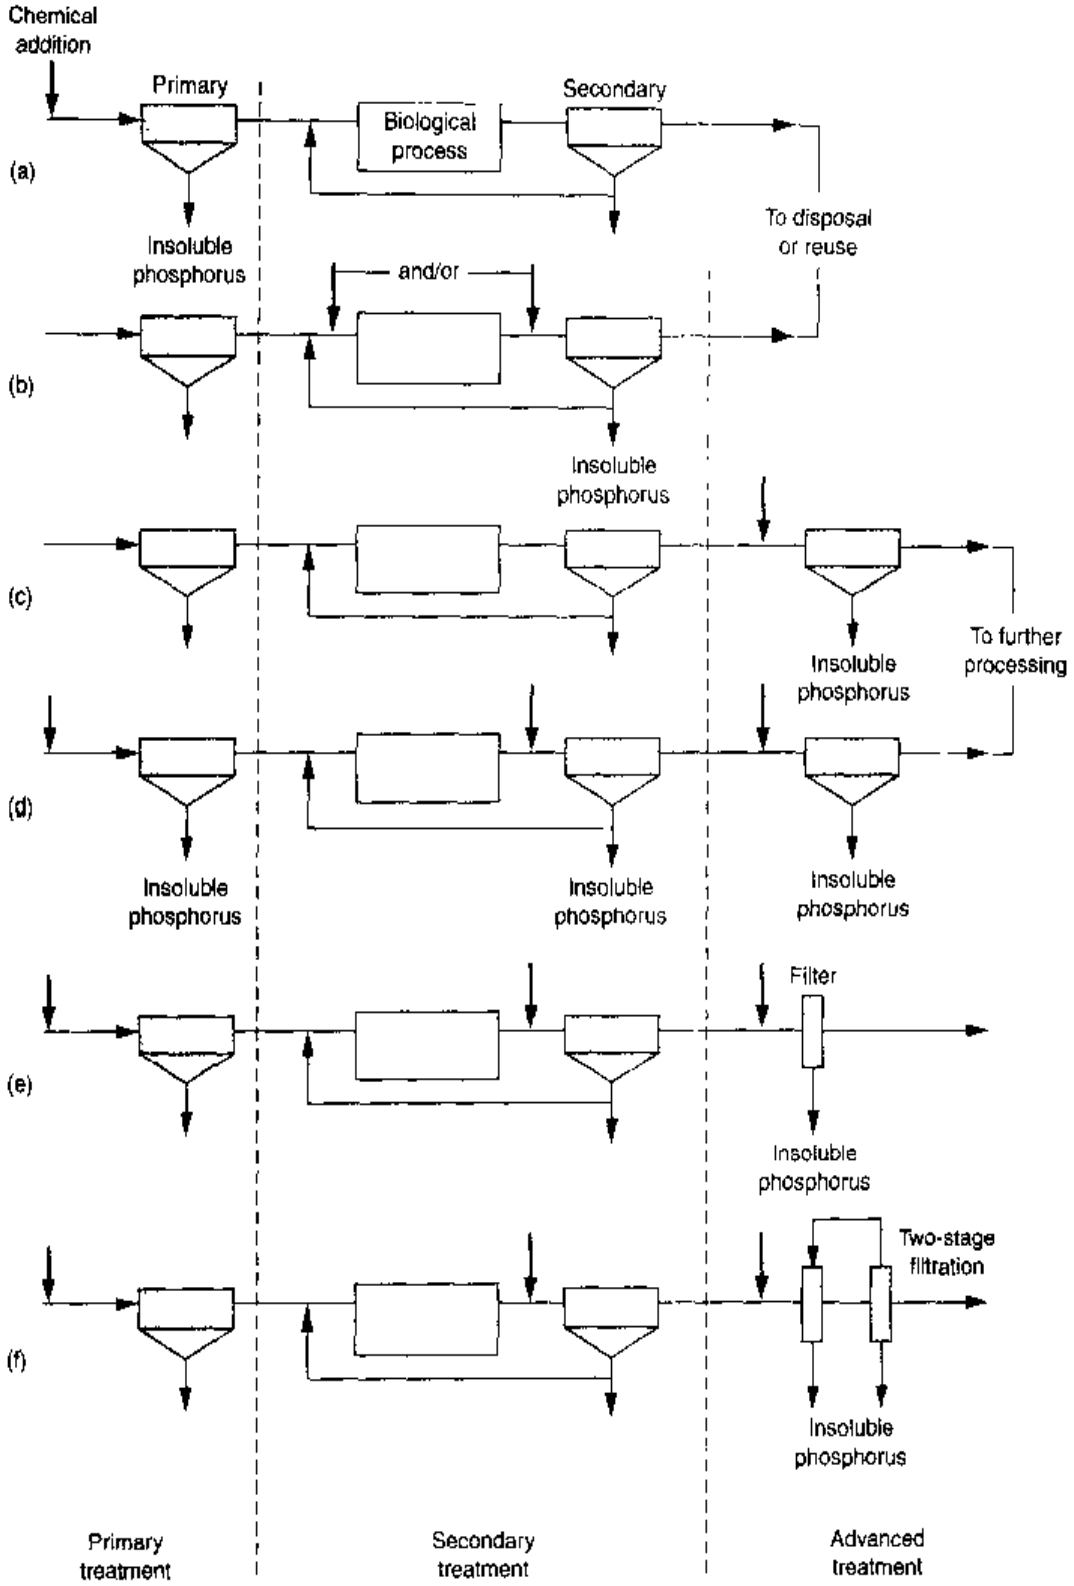


Figure 6–13

Alternative points of chemical addition for phosphorus removal: (a) before primary sedimentation, (b) before and/or following biological treatment, (c) following secondary treatment, and (d–f) at several locations in a process (known as "split treatment").

Table 6–5
Factors affecting the choice of chemical for phosphorus removal[a]

1. Influent phosphorus level
2. Wastewater suspended solids

[a]Adapted in part from Kugelman (1976).

phosphorus can be removed may be classified as (1) pre-precipitation, (2) coprecipitation, and (3) postprecipitation (Sedlak, 1991). Factors affecting the choice of chemical to use for phosphorus removal are reported in Table 6–5.

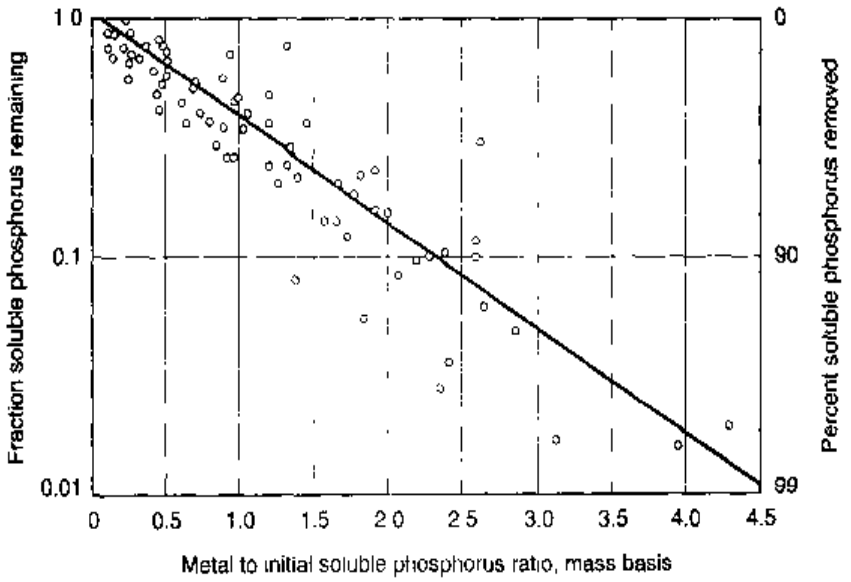
Pre-precipitation. The addition of chemicals to raw wastewater for the precipitation of phosphorus in primary sedimentation facilities is termed "pre-precipitation." The precipitated phosphate is removed with the primary sludge.

Coprecipitation. The addition of chemicals to form precipitates that are removed along with waste biological sludge is defined as "coprecipitation." Chemicals can be added to (1) the effluent from primary sedimentation facilities, (2) the mixed liquor (in the activated-sludge process), or (3) the effluent from a biological treatment process before secondary sedimentation.

Postprecipitation. Postprecipitation involves the addition of chemicals to the effluent from secondary sedimentation facilities and the subsequent removal of chemical precipitates. In this process, the chemical precipitates are usually removed in separate sedimentation facilities or in effluent filters (see Fig. 6–13).

Phosphorus Removal Using Metal Salts and Polymers

As noted above, iron or aluminum salts can be added at a variety of different points in the treatment process (see Fig. 6–13), but because polyphosphates and organic phosphorus are less easily removed than orthophosphorus, adding aluminum or iron salts after secondary treatment (where organic phosphorus and polyphosphorus are transformed into orthophosphorus) usually results in the best removal. Some additional nitrogen removal occurs because of better settling, but essentially no ammonia is removed unless chemical additions to primary treatment reduce BOD loadings to the point where nitrification can occur. A number of the important features of adding metal salts and polymers at different points in the treatment process are discussed in this section.



Metal Salt Addition to Primary Sedimentation Tanks. When aluminum or iron salts are added to untreated wastewater, they react with the soluble orthophosphate to produce a precipitate. Organic phosphorus and polyphosphate are removed by more complex reactions and by adsorption onto floc particles. The insolubilized

Table 6–6
Typical alum dosage requirements for various levels of phosphorus removal[a]

Phosphorus reduction, %	Mole ratio, Al:P	
	Range	Typical
75	1.25:1–1.5:1	1.4:1
85	1.6:1–1.9:1	1.7:1
95	2.1:1–2.6:1	2.3:1

[a]Developed in part from U.S. EPA (1976).

Figure 6–14
Soluble phosphorus removal by ferric chloride addition.

phosphorus, as well as considerable quantities of BOD and TSS, are removed from the system as primary sludge. Adequate initial mixing and flocculation are necessary upstream of primary facilities, whether separate basins are provided or existing facilities are modified to provide these functions. Polymer addition may be required to aid in settling. In low-alkalinity waters, the addition of a base is sometimes necessary to keep pH in the 5 to 7 range. Alum generally is applied in a molar ratio in the range of a 1.4 to 2.5 mole Al/mole P (see Table 6–6). Molar ratios for ferric chloride are shown on Fig. 6–14. The exact application rate is determined by onsite testing, and varies with the characteristics of the wastewater and the desired phosphorus removal.

Metal Salt Addition to Secondary Treatment. Metal salts can be added to the untreated wastewater, in the activated-sludge aeration tank, or the final clarifier influent channel. In trickling filter systems, the salts are added to the untreated wastewater or to the filter effluent. Multipoint additions have also been used. Phosphorus is removed from the liquid phase through a combination of precipitation, adsorption, exchange, and agglomeration, and removed from the process with either the primary or secondary sludges, or both. Theoretically, the minimum solubility of $AlPO_4$ occurs at about pH 6.3, and that of $FePO_4$ occurs at about pH 5.3; however, practical applications have yielded good phosphorus removal anywhere in the range of pH 6.5 to 7.0, which is compatible with most biological treatment processes.

The use of ferrous salts is limited because they produce low phosphorus levels only at high pH values. In low-alkalinity waters, either sodium aluminate and alum or ferric plus lime, or both, can be used to maintain the pH higher than 5.5. Improved settling and lower effluent BOD result from chemical addition, particularly if polymer is also added to the final clarifier. Dosages generally fall in the range of a 1 to 3 metal ion-phosphorus molar ratio.

Metal Salt and Polymer Addition to Secondary Clarifiers. In certain cases, such as trickling filtration and extended aeration activated-sludge processes, solids may not flocculate and settle well in the secondary clarifier. This settling problem may become acute in plants that are overloaded. The addition of aluminum or iron salts will cause the precipitation of metallic hydroxides or phosphates, or both. Aluminum and iron salts, along with certain organic polymers, can also be used to coagulate colloidal particles and to improve removals on filters. The resultant coagulated colloids and precipitates will settle readily in the secondary clarifier, reducing the TSS in the effluent and effecting phosphorus removal. Dosages of aluminum and iron salts usually fall in the range of 1 to 3 metal ion/phosphorus on a molar ratio basis if the residual phosphorus in the secondary effluent is greater than 0.5 mg/L. To achieve phosphorus levels below 0.5 mg/L, significantly higher metal salt dosages and filtration will be required.

Polymers may be added (1) to the mixing zone of a highly mixed or internally recirculated clarifier, (2) preceding a static or dynamic mixer, or (3) to an aerated channel. Although mixing times of 10 to 30 seconds have been used for polymers, shorter mixing times are favored (typically less than 10 s, see Table 6–19). Polymers should not be subjected to insufficient or excessive mixing, as noted previously, because the process efficiency will diminish, resulting in poor settling and thickening characteristics.

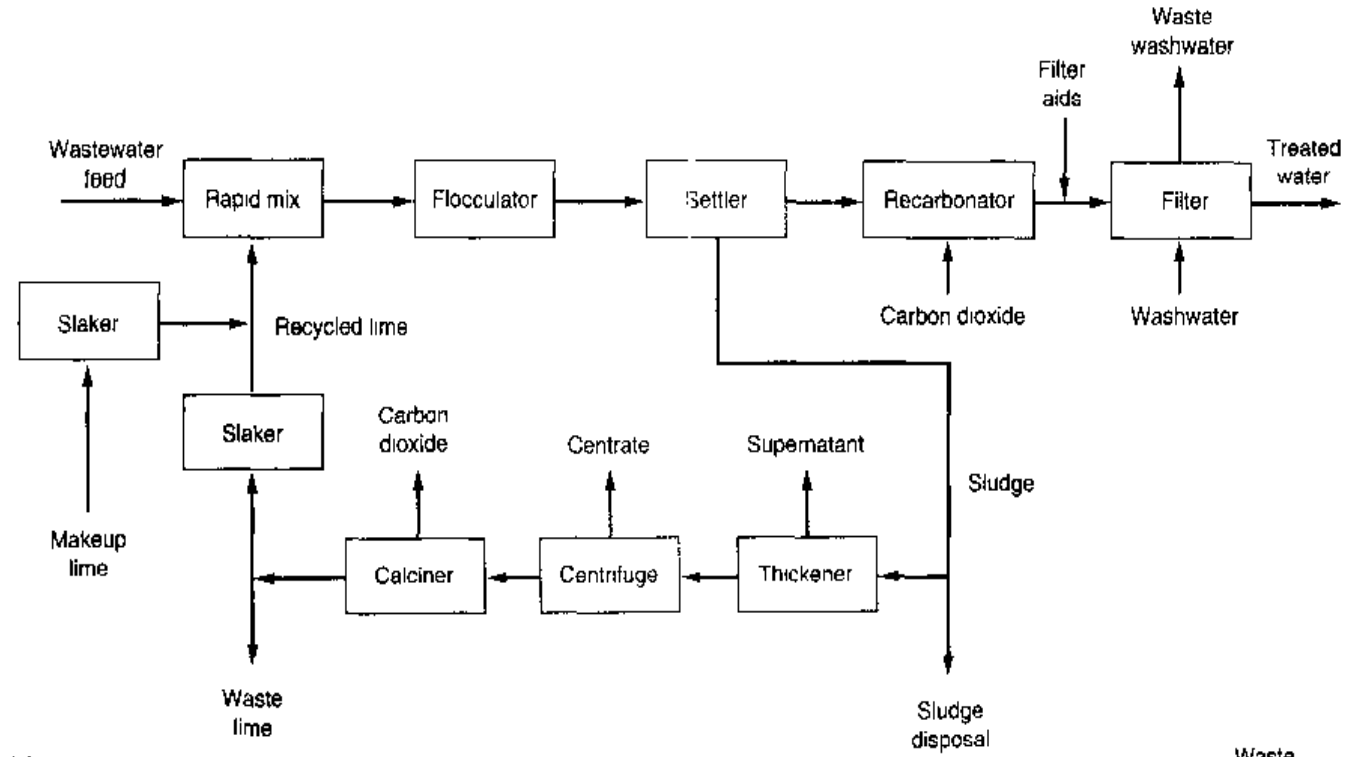
Phosphorus Removal Using Lime

The use of lime for phosphorus removal is declining because of (1) the substantial increase in the mass of sludge to be handled compared to metal salts and (2) the operation and maintenance problems associated with the handling, storage, and feeding of lime (U.S. EPA, 1987). When lime is used, the principal variables controlling the dosage are the degree of removal required and the alkalinity of the wastewater. The operating dosage must usually be determined by onsite testing. Lime has been used customarily either as a precipitant in the primary sedimentation tanks or following secondary treatment clarification.

Although lime recalcination lowers chemical costs, it is a feasible alternative only for large plants. Where a lime recovery system is required for a cost-effective operation, it includes a thermal regeneration facility, which converts the calcium carbonate in the sludge to lime by heating to 980°C (1800°F). The carbon dioxide from this process or other onsite stack gas (containing 10 to 15 percent carbon dioxide) is generally used as the source of recarbonation for pH adjustment of the wastewater.

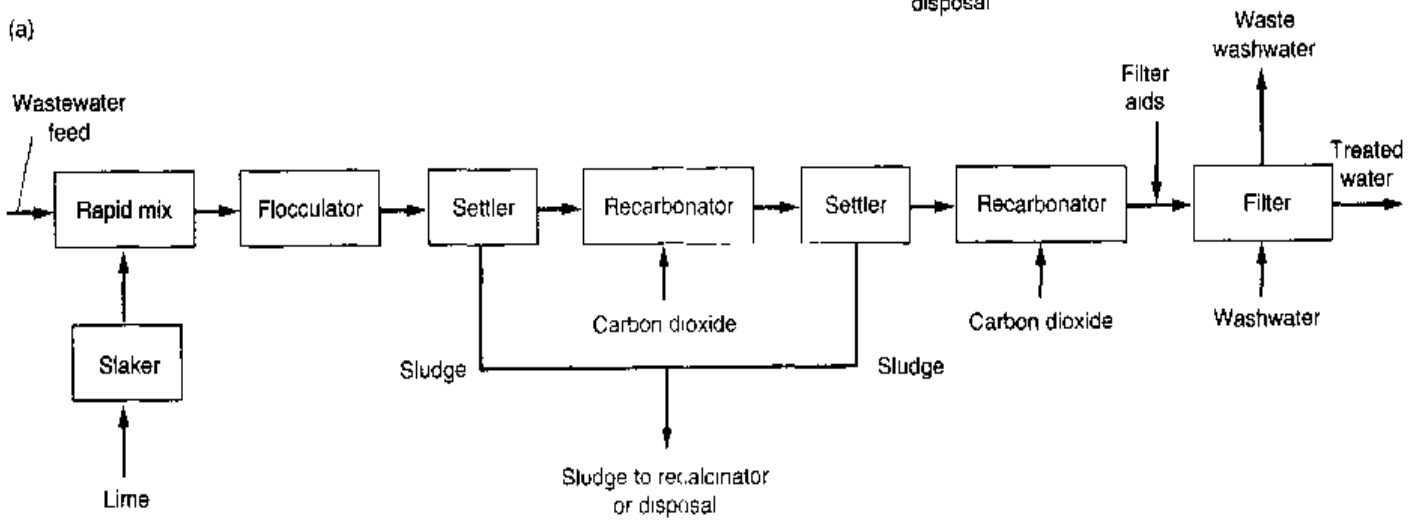
Lime Addition to Primary Sedimentation Tanks. Both low and high lime treatment can be used to precipitate a portion of the phosphorus (usually about 65 to 80 percent). When lime is used, both the calcium and the hydroxide react with the orthophosphorus to form an insoluble hydroxyapatite [$Ca_5(OH)(PO_4)_3$]. A residual

phosphorus level of 1.0 mg/L can be achieved with the addition of effluent filtration facilities to which chemicals can be added. In the high lime system, sufficient lime is added to raise the pH to about 11 (see Fig. 6–11). After precipitation, the effluent must be recarbonated before biological treatment. In activated-sludge systems, the pH of the primary effluent should not exceed 9.5 or 10; higher pH values can result in biological process upsets. In the trickling filter process, the carbon dioxide generated during treatment is usually sufficient to lower the pH without recarbonation. The dosage for low lime treatment is usually in the range of 75 to 250 mg/L as $Ca(OH)_2$ at pH values of 8.5 to 9.5. In low lime systems, however, the conditions required for precipitation are more specialized; the Ca^{2+}/Mg^{2+} mole ratio is $\leq 5/1$ (Sedlak, 1991).



Lime Addition Following Secondary Treatment. Lime can be added to the waste stream after biological treatment to reduce the level of phosphorus and TSS. Single-stage process and two-stage process flow diagrams for lime addition are shown on Fig. 6–15. On Fig. 6–15*a*, a single-stage lime precipitation process is used for the treatment of secondary effluent. In the first-stage clarifier of the two-stage process shown on Fig. 6–15*b*, sufficient lime is added to raise the pH above 11 to precipitate the soluble phosphorus as basic calcium phosphate (apatite). The calcium carbonate precipitate formed in the process acts as a coagulant for TSS removal. An example of a large lime precipitation unit is shown on Fig. 6–16. The excess soluble calcium is removed in the second-stage clarifier as a calcium carbonate precipitate by adding carbon dioxide gas to reduce the pH to about 10. Generally, there is a second injection of carbon dioxide to the second-stage effluent to reduce the formation of scale. To remove the residual levels of TSS and phosphorus, the secondary clarifier effluent is passed through a multimedia filter or a membrane filter. Care should be taken to limit excess calcium in the filter feed to ensure cementing of the filter media will not occur.

Phosphorus Removal with Effluent Filtration



Depending on the quality of the settled secondary effluent, chemical addition has been used to improve the performance of effluent filters. Chemical addition has also been used to achieve specific treatment objectives including the removal of specific contaminants such as phosphorus, metal ions, and humic substances. The removal of phosphorus by chemical addition to the contact filtration process is used in many parts of the country to remove phosphorus from wastewater treatment plant effluents which are discharged to sensitive water bodies. A two-stage filtration process (see Fig. 11–17 and discussion in Chap. 11) has proved to be very effective for the removal of phosphorus. Based on the performance data from full-scale installations, phosphorus levels equal to or less than 0.02 mg/L have been achieved in the filtered effluent. To achieve such low levels of phosphorus removal, the backwash water from the second filter which contains small particles and residual coagulant is recycled to the first filter to improve floc formation within the first-stage filter and the influent to waste ratio.

Comparison of Chemical Phosphorus Removal Processes

The advantages and disadvantages of the removal of phosphorus by the addition of chemicals at various points in a treatment system are summarized in Table 6–7. It is recommended that each alternative point of application be evaluated carefully.

(a)

(b)

Figure 6–15

Typical lime treatment process flow diagrams for phosphorus removal: (*a*) single-stage system, and (*b*) two-stage system.

Estimation of Sludge Quantities from Phosphorus Precipitation

The additional BOD and TSS removals afforded by chemical addition to primary treatment may also solve overloading problems on downstream biological systems, or may allow seasonal or year-round nitrification, depending on biological system designs. The BOD removal in the primary sedimentation operation is on the order of 50 to 60 percent

Figure 6–16

Large reactor clarifier used for the lime precipitation of secondary effluent. The settled effluent is treated further by microfiltration before reuse in industrial applications.

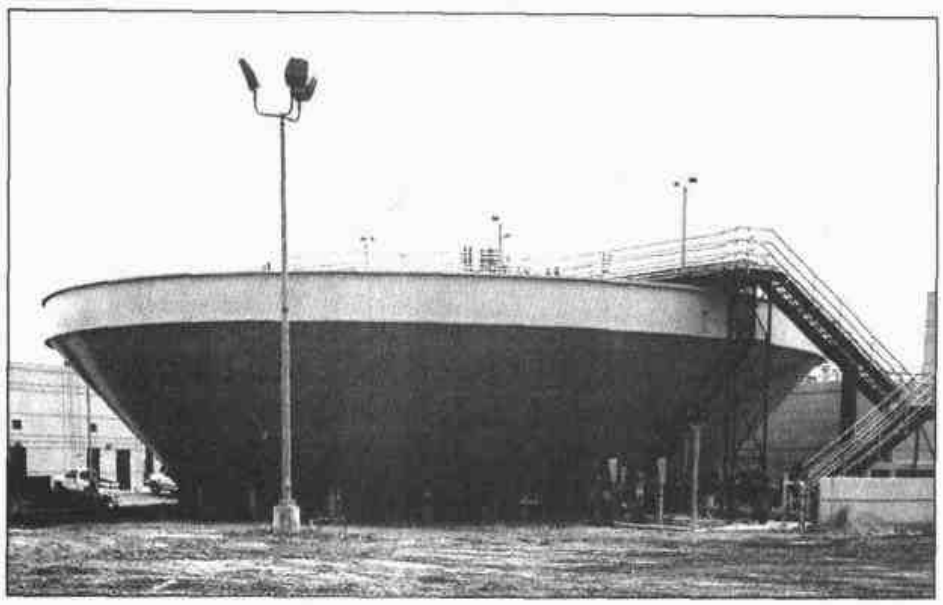


Table 6–7
Advantages and disadvantages of chemical addition in various sections of a treatment plant for phosphorus removal[a]

Level of treatment	Advantages	Disadvantages
Primary	Applicable to most plants; increased BOD and suspended solids removal; lowest degree of metal leakage; lime recovery demonstrated	Least efficient use of metal; polymer may be required for flocculation; sludge more difficult to dewater than primary sludge
Secondary	Lowest cost; lower chemical dosage than primary; improved stability of activated sludge; polymer not required	Overdose of metal may cause low pH toxicity; with low-alkalinity wastewaters, a pH control system may be necessary; cannot use lime because of excessive pH; inert solids added to activated-sludge mixed liquor, reducing the percentage of volatile solids
Advanced—precipitation	Lowest phosphorus effluent, most efficient metal use; lime recovery demonstrated	Highest capital cost; highest metal leakage
Advanced—single- and two-stage filtration	Low cost can be combined with the removal of residual suspended solids	Length of filter run may be reduced with single-stage filtration. Additional expense with two-stage filtration process

[a]Adapted from U.S. EPA (1976).

at a pH of 9.5. The amount of primary sludge will also increase significantly. A summary of the pertinent reactions required for determining the quantity of sludge when using alum, iron, or lime for the precipitation of phosphorus is given in Table 6–8. The computational procedures involved in estimating the quantity of sludge resulting from the chemical precipitation of phosphorus with lime are illustrated in Example 6–3.

Table 6–8
Summary of pertinent reactions required to determine quantities of sludge produced during the precipitation of phosphorus with lime, alum, and iron

Reaction	Equation	Chemical species in sludge
Lime, $CaCO_3$		
1. $10Ca^{2+} + 6PO_4^{3-} + 2OH \leftrightarrow Ca_{10}(PO_4)_6(OH)_2$	(6–19)	$Ca_{10}(PO_4)_6(OH)_2$
2. $Mg^{2+} + 2OH^- \leftrightarrow Mg(OH)_2$	(6–22)	$Mg(OH)_2$
3. $Ca^{2+} + CO_3^{2-} \leftrightarrow CaCO_3$	(6–23)	$CaCO_3$
Alum, Al (III)		
1. $Al^{3-} + PO_4^{3-} \leftrightarrow AlPO_4$	(6–24)	APO_4
2. $2Al^{3-} + 3OH^- \leftrightarrow Al(OH)_3$	(6–25)	$Al(OH)_3$
Iron, Fe (III)		
1. $Fe^{3+} + PO_4^{3-} \leftrightarrow FePO_4$	(6–26)	$FePO_4$
2. $Fe^{3+} + 3OH^- \leftrightarrow Fe(OH)_3$	(6–27)	$Fe(OH)_3$

EXAMPLE 6–3 Estimation of Sludge Volume from the Chemical Precipitation of Phosphorus with Lime in a Primary Sedimentation Tank Estimate the mass and volume of sludge produced in a primary sedimentation tank from the precipitation of phosphorus with lime. Assume that 60 percent of the TSS is removed without the addition of lime, and that the addition of 400 mg/L of $Ca(OH)_2$ results in an increased removal of TSS to 85 percent. Assume the following data apply:

1.	Wastewater flowrate, m^3/d	1000
2.	Wastewater TSS, mg/L	220
3.	Wastewater volatile TSS, mg/L	150
4.	Wastewater PO_4^{3-} as P, mg/L	10
5.	Wastewater total hardness as $CaCO_3$, mg/L	241.3
6.	Wastewater Ca^{2+}, mg/L	80
7.	Wastewater Mg^{2+}, mg/L	10
8.	Effluent PO_4^{3-} as P, mg/L	0.5
9.	Effluent Ca^{2+}, mg/L	60
10.	Effluent Mg^{2+}, mg/L	0
11.	Chemical sludge properties	
	Specific gravity	1.07
	Moisture content, %	92.5

Solution

1. Compute the mass and volume of solids removed without chemicals, assuming that the sludge contains 94 percent moisture and has a specific gravity of 1.03.
   a. Determine the mass of TSS removed.

$$M_{TSS} = \frac{0.6(220\ g/m^3)(1000\ m^3/d)}{(10^3\ g/kg)} = 132\ kg/d$$

   b. Determine the volume of sludge produced.

$$V_s = \frac{(132\ kg/d)}{(1.03)(1000\ kg/m^3)(0.06)} = 2.14\ m^3/d$$

2. Using the equations summarized in Table 6–8, determine the mass of $Ca_5(PO_4)_3OH$, $Mg(OH)_2$, and $CaCO_3$ produced from the addition of 400 mg/L of lime.
   a. Determine the mass of $Ca_5(PO_4)_3OH$ formed.
      i. Determine the moles of P removed.

$$\text{mole P removed} = \frac{(10 - 0.5)\ mg/L}{(30.97\ g/mole)(10^3\ mg/g)}$$

$$= 0.307 \times 10^{-3}\ mole/L$$

      ii. Determine the moles of $Ca_5(PO_4)_3OH$ formed.

$$\text{mole } Ca_5(PO_4)_3OH \text{ formed} = 1/3 \times 0.307 \times 10^{-3}\ mole/L$$

$$= 0.102 \times 10^{-3}\ mole/L$$

      iii. Determine the mass of $Ca_5(PO_4)_3OH$ formed.

$$\text{Mass } Ca_5(PO_4)_3OH = 0.102 \times 10^{-3}\ mole/L \times 502\ g/mole \times 10^3\ mg/g$$

$$= 51.3\ mg/L$$

   b. Determine the mass of $Mg(OH)_2$ formed.
      i. Determine the moles of Mg^{2+} removed.

$$\text{mole } Mg^{2+} \text{ removed} = \frac{(10\ mg/L)}{(24.31\ g/mole)(10^3\ mg/g)}$$

$$= 0.411 \times 10^{-3}\ mole/L$$

      ii. Determine the mass of $Mg(OH)_2$ formed.

$$\text{mole } Mg(OH)_2 = 0.411 \times 10^{-3}\ mole/L \times 58.3\ g/mole \times 10^3\ mg/g$$

$$= 24.0\ mg/L$$

   c. Determine the mass of $CaCO_3$ formed.
      i. Determine the mass of Ca^{2+} in $Ca_5(PO_4)_3(OH)$.

$$\text{Mass } Ca^{2+} \text{ in } Ca_5(PO_4)_3(OH)$$

$$= 5(40\ g/mole)(0.102 \times 10^{-3}\ mole/L)(10^3\ mg/g)$$

$$= 20.4\ mg/L$$

ii. Determine the mass of Ca^{2+} added in the original dosage.

$$\text{Mass } Ca^{2+} \text{ in } Ca(OH)_2 = \frac{(40 \text{ g/mole})(400 \text{ mg/L})}{(74 \text{ g/mole})}$$

$$= 216.2 \text{ mg/L}$$

iii. Determine the mass of Ca present as $CaCO_3$.

$$Ca^{2+} \text{ in } CaCO_3 = \text{Ca in } Ca(HO)_2 + Ca^{2+} \text{ in influent wastewater} - Ca^{2+} \text{ in } Ca_5(PO_4)_3OH - Ca^{2+} \text{ in effluent wastewater}$$

$$= 216.2 + 80 - 20.4 - 60$$

$$= 215.8 \text{ mg/L}$$

iv. Determine the mass of $CaCO_3$.

$$\text{Mass } CaCO_3 = \frac{(100 \text{ g/mole})(215.8 \text{ mg/L})}{(40 \text{ g/mole})}$$

$$= 540 \text{ mg/L}$$

3. Determine the total mass of solids removed as a result of the lime dosage.
   a. TSS in wastewater

$$M_{TSS} = \frac{0.85(220 \text{ g/m}^3)(1000 \text{ m}^3/\text{d})}{(10^3 \text{ g/kg})} = 187 \text{ kg/d}$$

   b. Chemical solids

$$M_{Ca_5(PO_4)_3OH} = \frac{(51.2 \text{ g/m}^3)(1000 \text{ m}^3/\text{d})}{(10^3 \text{ g/kg})} = 51.2 \text{ kg/d}$$

$$M_{Mg(OH)_2} = \frac{(24 \text{ g/m}^3)(1000 \text{ m}^3/\text{d})}{(10^3 \text{ g/kg})} = 24.0 \text{ kg/d}$$

$$M_{CaCO_3} = \frac{(540 \text{ g/m}^3)(1000 \text{ m}^3/\text{d})}{(10^3 \text{ g/kg})} = 540 \text{ kg/d}$$

   c. Total mass of solids removed

$$M_T = (187 + 51.3 + 24 + 540) \text{ kg/d}$$

$$= 802.3 \text{ kg/d}$$

4. Determine the total volume of sludge resulting from chemical precipitation, assuming that the sludge has a specific gravity of 1.07 and a moisture content of 92.5 percent (see Chap. 14).

$$V_s = \frac{(802.3 \text{ kg/d})}{(1.07)(1000 \text{ kg/m}^3)(0.075)} = 10.0 \text{ m}^3/\text{d}$$

5. Prepare a summary table of sludge masses and volumes without and with chemical precipitation.

Treatment	Sludge	
	Mass, kg/d	Volume, m^3/d
Without chemical precipitation	132.0	2.14
With chemical precipitation	802.3	10.0

Comment The magnitude of the sludge disposal problem associated with high lime treatment for phosphorus removal as compared to biological phosphorus removal is illustrated in this example.

6–5 CHEMICAL PRECIPITATION FOR REMOVAL OF HEAVY METALS AND DISSOLVED INORGANIC SUBSTANCES

The technologies available for the removal of heavy metals from wastewater include chemical precipitation, carbon adsorption, ion exchange, and reverse osmosis. Of these technologies, chemical precipitation is most commonly employed for most of the metals. Common precipitants include hydroxide (OH) and sulfide (S^{2-}). Carbonate (CO_3^{2-}) has also been used in some special cases. Metal may be removed separately or coprecipitated with phosphorus.

Precipitation Reactions

Metals of interest include arsenic (As), barium (Ba), cadmium (Cd), copper (Cu), mercury (Hg), nickel (Ni), selenium (Se), and zinc (Zn). Most of these metals can be precipitated as hydroxides or sulfides. Solubility products for free metal concentrations in equilibrium with hydroxide and sulfide precipitates are reported in Table 6–9. In wastewater treatment facilities, metals are precipitated most commonly as metal hydroxides through the addition of lime or caustic to a pH of minimum solubility. However, several of these compounds are, as discussed previously, amphoteric (i.e., capable of either accepting or donating a proton) and exhibit a point of minimum solubility. The pH value at minimum solubility varies with the metal in question as illustrated on Fig. 6–17 for hydroxide precipitation. The solid line on Fig. 6–17 represents the total metal in solution in equilibrium with the precipitate. The curves were developed based on the mononuclear hydroxide species using the same procedures as illustrated on Fig. 6–8 for Al^{3+} and Fe^{3+}. It is important to remember that the location of the minimum solubility will vary depending on the constituents in the wastewater. The curves given on Fig. 6–17 are useful in establishing the pH ranges for testing. Metals can also be precipitated as the sulfides as illustrated on Fig. 6–18. The minimum effluent concentration levels that

Table 6–9
Solubility products for free metal ion concentrations in equilibrium with hydroxides and sulfides[a,b]

Zinc hydroxide	$Zn(OH)_2 \leftrightarrow Zn^{2+} + 2OH^-$	16.7
Zinc sulfide	$ZnS \leftrightarrow 2Ag^{+} + S^{2-}$	22.8

[a] Adapted from Bard (1966).

[b] To obtain the complete solubility of a metal, all of the complex species must be considered such as reported in Table 6–2 for aluminum and iron.

Figure 6–17
Residual soluble metal concentration as a function of pH for the precipitation of metals as hydroxides. Because of the wide variation in the solubility and formation constants for the various metal hydroxides, the curves presented in this figure should only be used as a reference guide (see also Table 6–10).

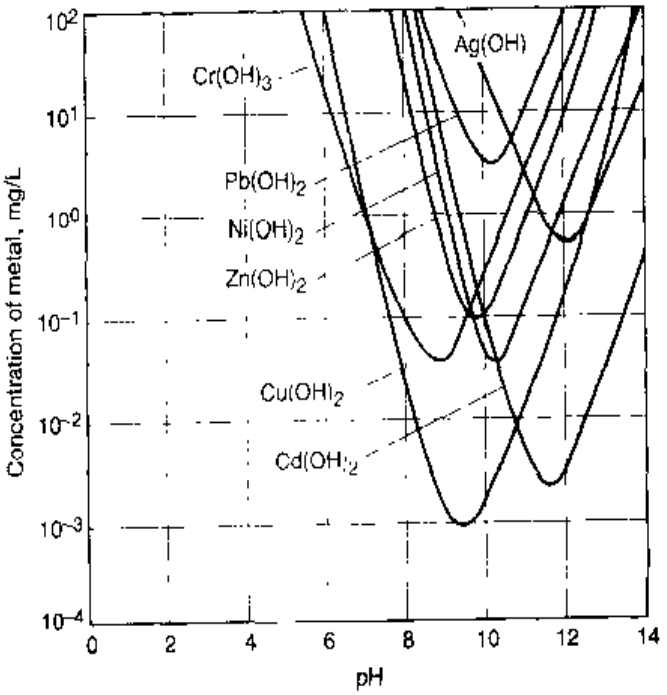

Figure 6–18

Residual soluble metal concentration as a function of pH for the precipitation of metals as sulfides. Because of the wide variation in the solubility and formation constants for the various metal sulfides, the curves presented in this figure should only be used as a reference guide (see also Table 6–10).

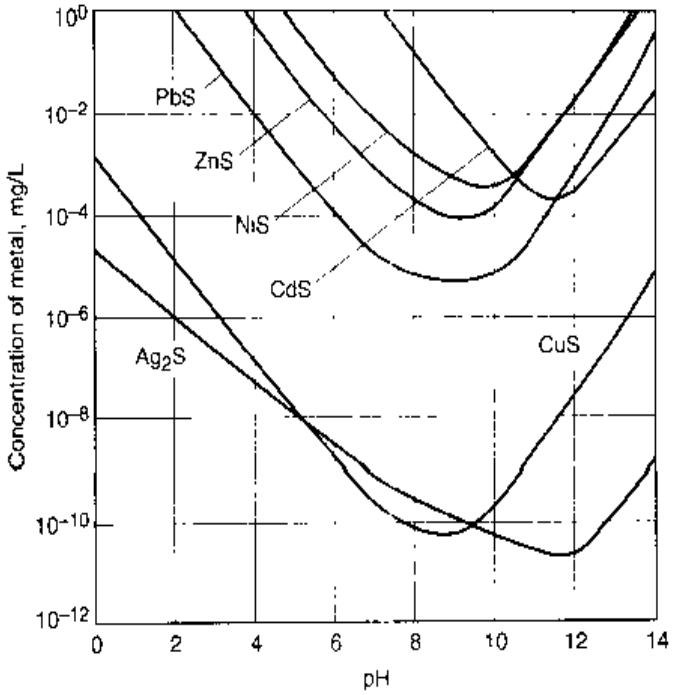

Table 6–10
Practical effluent concentration levels achievable in heavy metals removal by precipitation[a]

Metal	Achievable effluent concentration, mg/L	Type of precipitation and technology
Arsenic	0.05	Sulfide precipitation with filtration
	0.005	Ferric hydroxide coprecipitation
Barium	0.5	Sulfate precipitation
Cadmium	0.05	Hydroxide precipitation at pH 10–11
	0.05	Coprecipitation with ferric hydroxide
	0.008	Sulfide precipitation
Copper	0.02–0.07	Hydroxide precipitation
	0.01–0.02	Sulfide precipitation
Mercury	0.01–0.02	Sulfide precipitation
	0.001–0.01	Alum coprecipitation
	0.0005–0.005	Ferric hydroxide coprecipitation
	0.001–0.005	Ion exchange
Nickel	0.12	Hydroxide precipitation at pH 10
Selenium	0.05	Sulfide precipitation
Zinc	0.1	Hydroxide precipitation at pH 11

[a] From Eckenfelder (2000).

can be achieved in the chemical precipitation of heavy metals are reported in Table 6–10. In practice, the minimum achievable residual metal concentrations will also depend on the nature and concentration of the organic matter in the wastewater as well as the temperature. Because of the many uncertainties associated with the precipitation of metals, laboratory bench-scale or pilot-plant testing should be conducted.

Coprecipitation with Phosphorus

As discussed previously, precipitation of phosphorus in wastewater is usually accomplished by the addition of coagulants, such as alum, lime or iron salts, and polyelectrolytes. Coincidentally with the addition of these chemicals for the removal of phosphorus is the removal that occurs of various inorganic ions, principally some of the heavy metals. Where both industrial and domestic wastes are treated together, it may be necessary to add chemicals to the primary settling facilities, especially if onsite pretreatment measures prove to be ineffective. When chemical precipitation is used, anaerobic digestion for sludge stabilization may not be possible because of the toxicity of the precipitated heavy metals. As noted previously, one of the disadvantages of chemical precipitation is that it usually results in a net increase in the total dissolved solids of the wastewater that is being treated.

6–6 CHEMICAL OXIDATION

Chemical oxidation in wastewater treatment typically involves the use of oxidizing agents such as ozone (O_3), hydrogen peroxide (H_2O_2), permanganate (MnO_4), chloride dioxide (ClO_2), chlorine (Cl_2) or (HOCl), and oxygen (O_2), to bring about change in the chemical composition of a compound or a group of compounds. Included in the following discussion is an introduction of the fundamental concepts involved in chemical oxidation, an overview of the uses of chemical oxidation in wastewater treatment, and a discussion of the use of chemical oxidation for the reduction of BOD and COD, the oxidation of ammonia, and oxidation of nonbiodegradable organic compounds. Advanced oxidation process (AOPs) in which the free hydroxyl radical (HO°) is used as a strong oxidant to destroy specific organic constituents and compounds that cannot be oxidized by conventional oxidants such as ozone and chlorine are discussed in Chap. 11, which deals with advanced treatment methods.

Fundamentals of Chemical Oxidation

The purpose of the following discussion is to introduce the basic concepts involved in chemical oxidation reactions. The topics to be discussed include (1) oxidation-reduction reactions, (2) half reaction potentials, (3) reaction potentials, (4) equilibrium constants for redox equations, and (5) rate of oxidation-reduction reactions.

Oxidation-Reduction Reactions. Oxidation-reduction reactions (known as redox equations) take place between an *oxidizing agent* and a *reducing agent*. In oxidation-reduction reactions both electrons are exchanged as are the oxidation states of the constituents involved in the reaction. While an oxidizing agent causes the oxidation to occur, it is reduced in the process. Similarly, a reducing agent that causes a reduction to occur is oxidized in the process. For example, consider the following reduction:

$$Cu^{2+} + Zn \leftrightarrow Cu + Zn^{2+} \tag{6-28}$$

In the above reaction copper (Cu) changes from a +2 to zero oxidation state and the zinc (Zn) changes from a zero to a +2 state. Because of the electron gain or loss, oxidation-reduction reactions can be separated into two half reactions. The oxidation half reaction

involves the loss of electrons while the reduction half reaction involves the gain of electrons. The two half reactions that comprise Eq. (6–28) are as follows:

$$Zn - 2e^- \leftrightarrow Zn^{2+} \quad \text{(oxidation)} \tag{6–29}$$

$$Cu^{2+} + 2e^- \leftrightarrow Cu \quad \text{(reduction)} \tag{6–30}$$

Referring to the above equations, there is a two-electron change.

Half-Reaction Potentials. Because of the almost infinite number of possible reactions, there are no summary tables of equilibrium constants for oxidation-reduction reactions. What is done instead is the chemical and thermodynamic characteristics of the half reactions, such as those given by Eqs. (6–29) and (6–30), are determined and tabulated so that any combination of reactions can be studied. Half reactions for disinfection processes are given in Table 6–11 and other representative half reactions are given in Table 6–12. Of the many properties that can be used to characterize oxidation-reduction reactions, the electrical potential (i.e., voltage) or emf of the half reaction is used most commonly. Thus, every half reaction involving an oxidation or reduction has a *standard potential* $E°$ associated with it. The potentials for the half reactions given by Eqs. (6–29) and (6–30) are as follows:

$$Cu^{2-} + 2e \leftrightarrow Cu \quad E° = 0.34 \text{ volt} \tag{6–31}$$

$$Zn + 2e \leftrightarrow Zn^{2-} \quad E° = -0.763 \text{ volt} \tag{6–32}$$

The potentials for a number of half reactions are given in Table 6–12. The half-reaction potential is a measure of the tendency of a reaction to proceed to the right. Half reactions with large positive potential, $E°$, tend to proceed to the right as written. Conversely, half reactions with large negative potential, $E°$, tend to proceed to the left.

Table 6–11
Standard electrode potentials for oxidation half reactions for chemical disinfectants[a]

Disinfectant	Half reaction	Oxidation potential,[b] V
Ozone	$O_3 + 2e^- \leftrightarrow O_2 + H_2O$	+2.07
Hydrogen peroxide	$H_2O_2 + 2H^+ + 2e^- \rightarrow 2H_2O$	+1.78
Permanganate	$MnO_4^- + 4H^+ + 3e^- \leftrightarrow MnO_2 + 2H_2O$	+1.67
Chlorine dioxide	$ClO_2 + e \leftrightarrow ClO_2^-$	+1.50
Hypochlorous acid	$HOCl + H^+ + 2e \leftrightarrow Cl^- + H_2O$	+1.49
Hypoiodous acid	$HOI + H^+ + e^- \leftrightarrow 1/2I_2 + H_2O$	+1.45
Chlorine gas	$Cl_2 + 2e^- \leftrightarrow 2Cl^-$	+1.36
Oxygen	$O_2 + 4H^+ + 4e^- \leftrightarrow 2H_2O$	+1.23
Bromine	$Br_2 + 2e \leftrightarrow 2Br$	+1.09
Hypochlorite	$OCl^- + H_2O + 2e^- \leftrightarrow Cl^- + 2OH^-$	+0.90
Chlorite	$ClO_2^- + 2H_2O + 4e^- \leftrightarrow Cl^- + 4OH^-$	+0.76
Iodine	$I_2 + 2e^- \leftrightarrow 2I^-$	+0.54

Reaction Potentials. The half-reaction potentials, discussed above, can be used to predict whether a reaction comprised of two half reactions will proceed as written. The tendency of a reaction to proceed is obtained by determining the $E^\circ_{reaction}$ for the entire reaction as given by the following expression.

$$E^\circ_{reaction} = E^\circ_{reduction} - E^\circ_{oxidation} \quad (6\text{–}33)$$

where $E^\circ_{reaction}$ = potential of the overall reaction
$E^\circ_{reduction}$ = potential of the reduction half reaction
$E^\circ_{oxidation}$ = potential of the oxidation half reaction

For example, for the reaction between copper and zinc [see Eq. (6–28)] the $E^\circ_{reaction}$ of the reaction is determined as follows:

$$E^\circ_{reaction} = E^\circ_{Cu^{2+},Cu} - E^\circ_{Zn^{2+},Zn} \quad (6\text{–}34)$$

$$E^\circ_{reaction} = 0.34 - (-0.763) = +1.103 \text{ volts} \quad (6\text{–}35)$$

The positive value for the $E^\circ_{reaction}$ is taken as an indication that the reaction will proceed as written. The magnitude of the value, as will be illustrated subsequently, can be taken as a measure of the extent to which the reaction as written will proceed. For example, if Eq. (6–28) had been written as follows:

$$Cu + Zn^{2+} \leftrightarrow Cu^{2+} + Zn \quad (6\text{–}36)$$

The corresponding $E^\circ_{reaction}$ for this reaction is

$$E^\circ_{reaction} = E^\circ_{Zn^{2+},Zn} - E^\circ_{Cu^{2+},Cu} \quad (6\text{–}37)$$

$$E^\circ_{reaction} = (-0.763) - 0.34 = -1.103 \text{ volts} \quad (6\text{–}38)$$

Because the $E^\circ_{reaction}$ for the reaction is negative, the reaction will proceed in the opposite direction from what is written.

EXAMPLE 6–4 Determination of Reaction Potential Determine whether hydrogen sulfide (H_2S) can be oxidized with hydrogen peroxide (H_2O_2). The pertinent half reactions from Table 6–12 are as follows.

$$H_2S \leftrightarrow S + 2H^+ + 2e^- \qquad E^\circ = -0.14$$

$$H_2O_2 + 2H^+ + 2e^- \leftrightarrow 2H_2O \qquad E^\circ = +1.776$$

Solution

1. Determine the overall reaction by adding the two half reactions.

$$H_2S \leftrightarrow S + 2H^+ + 2e^-$$

$$\underline{H_2O_2 + 2H^+ + 2e^- \leftrightarrow 2H_2O}$$

$$H_2S + H_2O_2 \leftrightarrow S + 2H_2O$$

2. Determine the $E^\circ_{reaction}$ for overall reaction.

$$E^\circ_{reaction} = E^\circ_{H_2O_2,H^+} - E^\circ_{S^{2-}}$$

$$E^\circ_{reaction} = (1.78) - (-0.14) = +1.92 \text{ volts}$$

Because the $E^\circ_{reaction}$ for the reaction is positive, the reaction will proceed as written.

Equilibrium Constants for Redox Equations. The equilibrium constant for oxidation reduction reactions is calculated using the Nernst equation as defined below.

$$\ln K = -\frac{nFE^\circ_{reaction}}{RT} \tag{6–39a}$$

$$\log K = \frac{nFE^\circ_{reaction}}{2.303\,RT} \tag{6–39b}$$

where K = equilibrium constant
n = number of electrons exchanged in the overall reaction
F = Faraday's constant
= 96,485 a·s/g eq = 96,485 C/g eq (*Note:* C = coulomb)
$E^\circ_{reaction}$ = reaction potential
R = universal gas constant
= 8.3144 J (abs)/mole·K
T = temperature, K (273.15 + °C)

For example, at 25°C

$$\log K = \frac{n\,(96{,}485 \text{ C/g eq})\,E^\circ_{reaction}}{(2.303)(8.3144 \text{ J/mole·K})[(273.15 + 25)\text{K}]} = \frac{nE^\circ_{reaction}}{0.0592}$$

The application of this equation is illustrated in Example 6–5.

EXAMPLE 6–5 Determination of Equilibrium Constant for Oxidation-Reduction Reaction
Determine the equilibrium constant for the following oxidation-reduction reactions:

$$Cu^{2+} + Zn \leftrightarrow Cu + Zn^{2+}$$

$$H_2S + H_2O_2 \leftrightarrow S + 2H_2O$$

Solution

1. Determine the equilibrium constant for the following equation using Eq. (6–39):

$$Cu^{2+} + Zn \leftrightarrow Cu + Zn^{2+}$$

As computed above, the $E^{\circ}_{reaction}$ for the reaction is +1.1volts, and the number of electrons exchanged is 2. Using this information, the K value is determined as follows:

$$\log K = \frac{nE^{\circ}_{reaction}}{0.0592} = \frac{2(1.10)}{0.0592} = 37.2$$

$$K = 1.58 \times 10^{37} = \frac{[Zn^{2+}]}{[Cu^{2-}]}$$

2. Determine the equilibrium constant for the following equation using Eq. (6–39):

$$H_2S + H_2O_2 \Leftrightarrow S + 2H_2O$$

From Example 6–4, the $E^{\circ}_{reaction}$ for the above reactions is +1.92 volts. The value of the equilibrium constant is

$$\log K = \frac{nE^{\circ}_{reaction}}{0.0592} = \frac{2(1.92)}{0.0592} = 64.9$$

$$K = 7.94 \times 10^{64} = \frac{[S]}{[H_2S][H_2O_2]}$$

Rate of Oxidation-Reduction Reactions. As noted previously, the half-reaction potentials can be used to predict whether a reaction will proceed as written. Unfortunately, the reaction potential provides no information about the rate at which the reaction will proceed. Chemical oxidation reactions often require the presence of one or more catalysts for the reaction to proceed or to increase the rate of reaction. Transition metal cations, enzymes, pH adjustment, and a variety of proprietary substances have been used as catalysts.

Applications

Some of the more important applications of chemical oxidation in wastewater management are summarized in Table 6–13. In the past, chemical oxidation was used most commonly to (1) reduce the concentration of residual organics, (2) control odors, (3) remove ammonia, and (4) reduce the bacterial and viral content of wastewaters. Chemical oxidation is especially effective for the elimination of odorous compounds (e.g., oxidation of sulfides and mercaptans). Because of its importance, chemical disinfection is considered separately in Chap. 12. In addition to the applications reported in Table 6–13, chemical oxidation is now commonly used to (1) improve the treatability of nonbiodegradable (refractory) organic compounds, (2) eliminate the inhibitory effects of certain organic and inorganic compounds to microbial growth, and (3) reduce or eliminate the toxicity of certain organic and inorganic compounds to microbial growth and aquatic flora. The chemical oxidation of BOD and COD, ammonia, and

Table 6–13
Typical applications of chemical oxidation in wastewater collection, treatment, and disposal

Application	Chemicals used[a]	Remarks
Collection		
Slime-growth control	Cl_2, H_2O_2	Control of fungi and slime-producing bacteria
Corrosion control (H_2S)	Cl_2, H_2O_2, O_3	Control brought about by oxidation of H_2S
Odor control	Cl_2, H_2O_2, O_3	Especially in pumping stations and long, flat sewers
Treatment		
Grease removal	Cl_2	Added before preaeration
BOD reduction	Cl_2, O_3	Oxidation of organic substances
Ferrous sulfate oxidation	Cl_2[b]	Production of ferric sulfate and ferric chloride
Filter-ponding control	Cl_2	Maintaining residual at filter nozzles
Filter-fly control	Cl_2	Maintaining residual at filter nozzles during fly season
Sludge-bulking control	Cl_2, H_2O_2, O_3	Temporary control measure
Control of filamentous microorganisms	Cl_2	Dilute chlorine solution sprayed on foam caused by filamentous organisms
Digester supernatant oxidation	Cl_2	
Digester foaming control	Cl_2	
Ammonia oxidation	Cl_2	Conversion of ammonia to nitrogen gas
Odor contol	Cl_2, H_2O_2, O_3	
Oxidation of refractory organic compounds	O_3	
Dispersal		
Bacterial reduction	Cl_2, H_2O_2, O_3	Plant effluent, overflows, and stormwater
Odor control	Cl_2, H_2O_2, O_3	

[a] Cl_2 – chlorine, H_2O_2 = hydrogen peroxide, O_3 = ozone.
[b] $6FeSO_4 \cdot 7H_2O + 3Cl_2 \rightarrow 2FeCl_3 + 2Fe_2(SO_4)_3 + 42H_2O$.

refractory organic compounds is considered in this section. Advanced oxidation processes are considered in Chap. 11.

Chemical Oxidation of BOD and COD

The overall reaction for the oxidation of organic molecules comprising BOD, for example, with chlorine, ozone, and hydrogen peroxide, can be represented as follows:

$$\begin{array}{lllll} \text{Organic} & \text{Cl, } O_3 & \text{Intermediate} & \text{Cl, } O_3 & \text{Simple} \\ \text{molecule} & \rightarrow\rightarrow\rightarrow & \text{oxygenated} & \rightarrow\rightarrow\rightarrow & \text{end products} \\ \text{(e.g., BOD)} & H_2O_2 & \text{molecules} & H_2O_2 & \text{(e.g., } CO_2, H_2O, \text{ etc.)} \end{array} \qquad (6\text{–}40)$$

Multiple arrows in the direction of the reaction are used to signify that a number of steps are involved in the overall reaction sequence. The use of oxidizing agents such as oxygen, chlorine, ozone, and hydrogen peroxide is termed "simple oxidation." In general the overall reaction rates are usually too slow to be applicable generally for wastewater treatment (SES, 1994). Advanced oxidation processes (AOPs), which typically involve the use of the hydroxyl radical for the oxidation of complex organic molecules, are considered in Chap. 11.

Chemical Oxidation of Nonbiodegradable Organic Compounds. Typical chemical dosages for both chlorine and ozone for the oxidation of the organics in wastewater are reported in Table 6–14. As shown in Table 6–14, the dosages increase with the degree of treatment, which is reasonable when it is considered that the organic compounds that remain after biological treatment are typically composed of low-molecular-weight polar organic compounds and complex organic compounds built around the benzene ring structure. Because of the complexities associated with composition of wastewater, chemical dosages for the removal of refractory organic compounds cannot be derived from the chemical stoichiometry, assuming that it is known. Pilot-plant studies must be conducted when either chlorine, chlorine dioxide, or ozone is to be used for the oxidation of refractory organics to assess both the efficacy and required dosages. The application of AOPs involving more than one oxidizing agent (e.g., ozone/hydrogen peroxide) are considered in Chap. 11.

Chemical Oxidation of Ammonia

The chemical process in which chlorine is used to oxidize the ammonia nitrogen in solution to nitrogen gas and other stable compounds is known as breakpoint chlorination. Perhaps the most important advantage of this process is that, with proper control, all the ammonia nitrogen in the wastewater can be oxidized. However, because the process has a number of disadvantages including the buildup of acid (HCl) which will react with the alkalinity, the buildup of total dissolved solids, and the formation of unwanted chloro-organic compounds, ammonia oxidation is seldom used today.

Table 6–14
Typical chemical dosages for the oxidation of organics in wastewater[a]

Chemical	Use	Dosage, kg/kg destroyed	
		Range	Typical
Chlorine	BOD reduction		
	Settled wastewater	0.5–2.5	1.75
	Secondary effluent	1.0–3.0	2.0
Ozone	COD reduction		
	Settled wastewater	2.0–4.0	3.0
	Secondary effluent	3.0–8.0	6.0

[a] Derived in part from White (1999).

Analysis. Although the theory of breakpoint chlorination is described in greater detail in Sec. 12–3 in Chap. 12, it is, nevertheless, instructive to assess whether the reaction is feasible using the oxidation-reduction concepts presented above. The pertinent half reactions are as follows:

$$HOCl + H^+ + 2e^- \leftrightarrow Cl^- + H_2O \qquad E^\circ = +1.49 \text{ volts} \tag{6–41}$$

$$N_2 + 8H^- + 6e \leftrightarrow 2NH_4^- \qquad E^\circ = +0.27 \text{ volt} \tag{6–42}$$

Rewrite Eq. (6–42) as a reduction

$$2NH_4^+ \leftrightarrow N_2 + 8H^+ + 6e^- \qquad E^\circ = -0.27 \text{ volt} \tag{6–43}$$

Combining Eqs. (6–43) and (6–41) yields

$$2NH_4^+ \leftrightarrow N_2 + 8H^+ + 6e^-$$

$$\underline{(3)HOCl + (3)H^+ + (3)2e \leftrightarrow (3)Cl^- + (3)H_2O}$$

$$3HOCl + 2NH_4^+ \leftrightarrow N_2 + 3HCl + 8H^+ + 3H_2O \tag{6–44}$$

Determine the $E^\circ_{\text{reaction}}$ for overall reaction

$$E^\circ_{\text{reaction}} = E^\circ_{HOCl,Cl^-} - E^\circ_{NH^+,N_2}$$

$$E^\circ_{\text{reaction}} = (1.49) - (-0.27) = +1.96 \text{ volts}$$

Because the $E^\circ_{\text{reaction}}$ for the reaction is positive, the reaction will proceed as written. The stoichiometric mass ratio of chlorine as Cl_2 to ammonia as N, as computed using Eq. (6–44), is 7.6:1. In practice, the ratio has been found to vary from 8:1 to 10:1.

From both laboratory studies and full-scale testing, it has been found that the optimum operating pH range for breakpoint chlorination is between 6 and 7. If breakpoint chlorination is accomplished outside this range, it has been observed that the chlorine dosage required to reach the breakpoint increases significantly and that the rate of reaction is slower. Temperature does not appear to have a major effect on the process in the ranges normally encountered in wastewater treatment.

Application. The breakpoint chlorination process can be used for the removal of ammonia nitrogen from treatment-plant effluents, either alone or in combination with other processes. To avoid the large chlorine dosages required when used alone, breakpoint chlorination can be used following biological nitrification to achieve low levels of ammonia in the effluent.

To optimize the performance of this process and to minimize equipment and facility costs, flow equalization is usually required. Also, because of the potential toxicity problems that may develop if chlorinated compounds are discharged to the environment (see Sec. 12-3, Chap. 12), it is usually necessary to dechlorinate the effluent. The use of the breakpoint chlorination process for seasonal nitrogen control is considered in Example 6–6.

EXAMPLE 6–6 Analysis of Breakpoint Chlorination Process Used for Seasonal Control of Nitrogen Estimate the daily required chlorine dosage and the resulting buildup of total dissolved solids when breakpoint chlorination is used for the seasonal control of nitrogen. Assume that the following data apply to this problem:

1. Plant flowrate = 3800 m^3/d
2. Effluent characteristics after conventional treatment
   a. BOD = 20 g/m^3 (mg/L)
   b. TSS = 25 g/m^3
   c. NH_3 − N concentration = 23 g/m^3
3. Required effluent NH_3 − N concentration = 1.0 g/m^3

Solution

1. Estimate the required Cl_2 dosage. Assume that the required mass ratio of chlorine to ammonia is 9:1.

$$\text{kg } Cl_2/d = \frac{(3800\ m^3/d)\,[(23 - 1)\ g/m^3]\,(9.0)}{(10^3\ g/kg)} = 752.4\ kg/d$$

2. Determine the increment of total dissolved solids added to the wastewater. Using the data reported in Table 12-10 in Chap. 12, the total dissolved solids increase per mg/L of ammonia consumed is equal to 6.2

   Total dissolved solids increment = 6.2 (23 − 1) g/m^3 = 136 g/m^3

Comment In this example, it was assumed that the acid produced from the breakpoint reaction would not require the addition of a neutralizing agent such as NaOH (sodium hydroxide). If the addition of NaOH were required, the total dissolved solids increase would have been significantly large. Although breakpoint chlorination can be used to control nitrogen, it may be counterproductive if in the process the treated effluent is rendered unusable for reuse applications because of the buildup of total dissolved solids.

6–7 CHEMICAL NEUTRALIZATION, SCALE CONTROL, AND STABILIZATION

The removal of excess acidity or alkalinity by treatment with a chemical of the opposite composition is termed *neutralization*. In general, all treated wastewaters with excessively low or high pH will require neutralization before they can be dispersed to the environment. Scaling control is required for nanofiltration and reverse osmosis treatment to control the formation of scale, which can severely impact performance. Chemical stabilization is often required for highly treated wastewaters to control their aggressiveness with respect to corrosion. These subjects are considered briefly below.

pH Adjustment

In a variety of wastewater-treatment operations and processes, there is often a need for pH adjustment. Because a number of chemicals are available that can be used, the choice will depend on the suitability of a given chemical for a particular application and pre-

vailing economics. General information on the chemicals used most commonly for pH adjustment is given in Table 6–15. Wastewater that is acidic can be neutralized with any number of basic chemicals, as reported in Table 6–15. Sodium hydroxide (NaOH, also known as caustic soda) and sodium carbonate, although somewhat expensive, are convenient and are used widely by small plants or for treatment where small quantities are adequate. Lime, which is cheaper but somewhat less convenient, is the most widely used chemical. Lime can be purchased as quicklime or slaked hydrated lime, high-calcium or

Table 6–15
Chemicals used most commonly for the control of pH (neutralization)[a]

Chemical	Formula	Molecular weight	Equivalent weight	Availability	
				Form	Percent
Chemicals used to raise pH					
Calcium carbonate	$CaCO_3$	100.0	50.0	Powder granules	96 to 99
Calcium hydroxide (lime)	$Ca(OH)_2$	74.1	37.1	Powder granules	82 to 95
Calcium oxide	CaO	56.1	28.0	Lump, pebble, ground	90 to 98
Dolomitic hydrated lime	$[Ca(OH)_2]_{0.6}$ $[Mg(OH)_2]_{0.4}$	67 8	33.8	Powder	58 to 65
Dolomitic quicklime	$(CaO)_{0.6}(MgO)_{0.4}$	49.8	24.8	Lump, pebble ground	55–58 CaO
Magnesium hydroxide	$Mg(OH)_2$	58.3	29.2	Powder	
Magnesium oxide	MgO	40.3	20.2	Powder, granules	99
Sodium bicarbonate	$NaHCO_3$	84.0	84.0	Powder, granules	99
Sodium carbonate (soda ash)	Na_2CO_3	106.0	53.0	Powder	99.2
Sodium hydroxide (caustic soda)	$NaOH$	40.0	40.0	Solid flake, ground flake, liquid	98
Chemicals used to lower pH					
Carbonic acid	H_2CO_3	62.0	31.0	Gas (CO_2)	
Hydrochloric acid	HCl	36.5	36.5	Liquid	27.9, 31.45, 35.2
Sulfuric acid	H_2SO_4	98.1	49.0	Liquid	77.7 (60° Be) 93.2 (66° Be)

[a]Adapted in part from Eckenfelder (2000).

dolomitic lime, and in several physical forms. Limestone and dolomitic limestone are cheaper but less convenient to use and slower in reaction rate. Because they can become coated in certain waste-treatment applications, their use is limited. Calcium and magnesium chemicals often form sludges that require disposal.

Alkaline wastes are less of a problem than acid wastes but nevertheless often require treatment. If acidic waste streams are not available or are not adequate to neutralize alkaline wastes, sulfuric acid is commonly employed. In some treatment plants, carbon dioxide (CO_2) in the form of flue gas has been used to neutralize alkaline wastewaters, as illustrated by the following reactions:

$$2OH^- + CO_2 \rightarrow CO_3^{2-} + H_2O \quad (6\text{–}45)$$

$$CO_3^{2-} + CO_2 + H_2O \rightarrow 2HCO_3^- \quad (6\text{–}46)$$

Based on the chlorine dose used for disinfection, the pH of the disinfected effluent will be lower than that allowed for reuse applications and for dispersal to the environment. In such cases, neutralization is controlled by automatic instruments using a feedback loop, and the final effluent pH is recorded. Depending on the sensitivity of the environment, two-stage neutralization may be required. The reagent chemicals can be fed automatically, in the form of solutions, slurries, or dry materials. If the reaction rate is slow, instrumentation and control design must take this factor into account.

Analysis of Scaling Potential

With the increasing use that is being made of nanofiltration, reverse osmosis, and electrodialysis in wastewater reuse applications, adjustment of the scaling characteristics of the effluent to be treated is important to avoid calcium carbonate and sulfate scale formation. Depending on the recovery rate, the concentration of salts can increase by a factor of up to 10 within the treatment module. When such a salt concentration increase occurs, it is often possible to exceed the solubility product of calcium carbonate and other scale-forming compounds. The formation of scale within the treatment module will cause a deterioration in the performance, ultimately leading to the failure of the membrane module.

The tendency to develop calcium carbonate ($CaCO_3$) scale during the advanced treatment of treated effluent can be approximated by calculating the Langelier saturation index (LSI) of the concentrate stream (Langelier, 1946).

$$LSI = pH - pH_s \quad (6\text{–}47)$$

where pH = measured pH in concentrate stream water sample
pH_s = saturation pH for calcium carbonate

The scaling criteria for the Langelier saturation index are:

$LSI > 0$	Water is supersaturated with respect to calcium carbonate ($CaCO_3$) and scaling may occur.
$LSI < 0$	Water is undersaturated with respect to calcium carbonate. Undersaturated water has a tendency to remove existing calcium carbonate protective coatings in pipelines and equipment.
$LSI = 0$	Water is considered to be neutral (i.e., neither scale-forming nor scale-removing).

It should be noted that undersaturated water is also sometimes referred to as *corrosive*, but use of the term corrosive is incorrect, as the LSI applies only to the presence or absence of a calcium carbonate scale.

An alternative index known as the *stability index* was proposed by Ryzner (1944) and is used in a number of industrial applications. The Ryzner index (RI) is given by the following expression:

$$RI = 2\,pH_s - pH \tag{6–48}$$

The scaling criteria for the Ryzner index are as follows:

$RI < 5.5$	Heavy scale will form
$5.5 < RI < 6.2$	Scale will form
$6.2 < RI < 6.8$	No difficulties
$6.8 < RI < 8.5$	Water is aggressive
$RI > 8.5$	Water is very aggressive

The saturation pH_s can be computed using the following expression:

$$pH_s = -\log\left(\frac{K_{a2}\gamma_{Ca^{2+}}[Ca^{2+}]\gamma_{HCO_3^-}[HCO_3^-]}{K_{sp}}\right) \tag{6–49}$$

where K_{a2} = equilibrium constant for the dissociation of bicarbonate
$\gamma_{Ca^{2+}}$ = activity coefficient for calcium
Ca^{2+} = concentration of calcium
$\gamma_{HCO_3^-}$ = activity coefficient for bicarbonate
HCO_3^- = concentration of bicarbonate
K_{sp} = solubility product constant for the dissociation of calcium carbonate

The activity coefficient can be estimated using Eq. (2–9) given in Chap. 2.

$$\log \gamma = \frac{0.5\,(Z_i)^2\sqrt{I}}{1 + \sqrt{I}} \tag{2–9}$$

where Z = charge on ionic species
I = ionic strength

The ionic strength can be estimated using Eq. (2–11) given in Chap. 2.

$$I = 2.5 \times 10^{-5} \times \text{TDS} \tag{2–11}$$

The saturation pH_s for calcium carbonate ($CaCO_3$) solubility in the pH range from 6.5 to 9.0 is given by

$$pH_s = pK_{a2} - pK_{sp} + p[Ca^{2+}] + p[HCO_3^-] - \log \gamma_{Ca^{2+}} - \log \gamma_{HCO_3^-} \tag{6–50}$$

where pK_{a2} = negative logarithm of the equilibrium constant for the dissociation of bicarbonate
pK_{sp} = negative logarithm of solubility product constant for the dissociation of calcium carbonate
pCa^{2+} = negative logarithm of calcium concentration
$pHCO_3^-$ = negative logarithm of bicarbonate concentration

Values of K_1, K_2, and K_{sp} for the carbonate system are given in Table 6–16 as a function of temperature. The application of these equations is illustrated in Example 6–7. The diagram presented on Fig. 6–19 can also be used to estimate LSI for concentrated solutions as illustrated in the accompanying computation.

Table 6–16 Carbonate equilibrium constants as function of temperature[a]

Temperature, °C	Equilibrium constant[b]		
	$K_{a1} \times 10^7$	$K_{a2} \times 10^{11}$	$K_{sp} \times 10^9$
5	3.020	2.754	8.128
10	3.467	3.236	7.080
15	3.802	3.715	6.02
20	4.169	4.169	5.248
25	4.467	4.477	4.571
40	5.012	6.026	3.090

[a] Adapted from Snoeyink and Jenkins (1980).

[b] The reported values have been multiplied by the indicated exponents. Thus, the value K_{a2} at 20°C is equal to $4\ 169 \times 10^{-11}$.

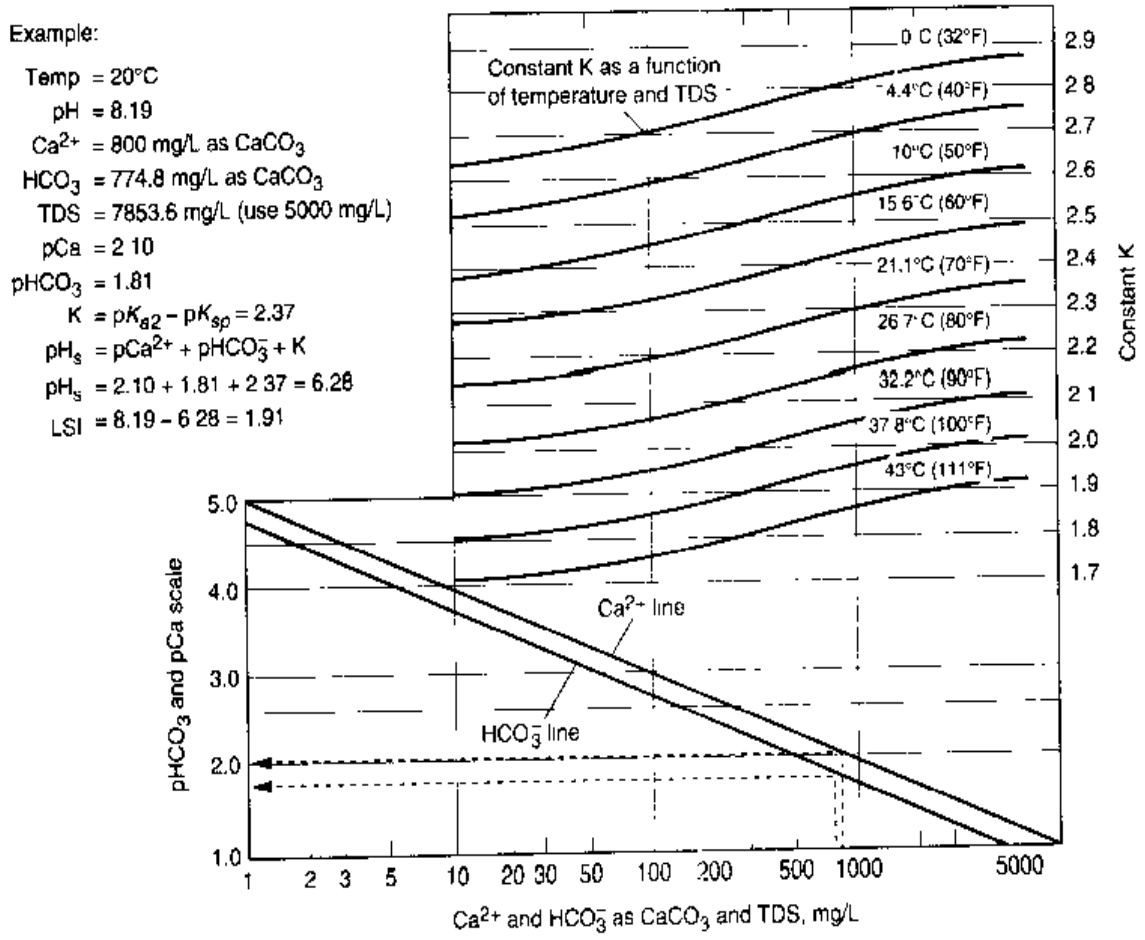

Figure 6–19

Chart for determining the value of the Langelier saturation index. *(Adapted from Du Pont Company, 1992.)*

EXAMPLE 6-7 Analysis of Scaling Potential Estimate the scaling potential at 20°C using both the Langelier and Ryzner indexes for a treated wastewater with the following chemical characteristics.

Constituent	Concentration	
	g/m³	mole/L
Ca^{2+}	5	0.125×10^{-3}
HCO_3^-	10	0.164×10^{-3}
TDS	20	
pH	7.7	

Solution

1. Determine the ionic strength of the treated water using Eq. (2–11).

   $I = 2.5 \times 10^{-5} \times \text{TDS}$

   $I = 2.5 \times 10^{-5} \times 20 = 50 \times 10^{-5}$

2. Determine the activity coefficients for calcium and bicarbonate using Eq. (2–10).
   a. For calcium

   $$\log \gamma_{Ca^{2+}} = -\frac{0.5(Z_i)^2\sqrt{I}}{1+\sqrt{I}} = -\frac{0.5(2)^2\sqrt{50\times10^{-5}}}{1+\sqrt{50\times10^{-5}}} = -0.0437$$

   $\gamma_{Ca^{2+}} = 0.903$

   b. For bicarbonate

   $$\log \gamma_{HCO_3^-} = -\frac{0.5(Z_i)^2\sqrt{I}}{1+\sqrt{I}} = -\frac{0.5(1)^2\sqrt{50\times10^{-5}}}{1+\sqrt{50\times10^{-5}}} = -0.0109$$

   $\gamma_{HCO_3^-} = 0.975$

3. Determine the saturation pH_s using Eq. (6–49).

   $$pH_s = -\log\left(\frac{K_{a2}\gamma_{Ca^{2+}}[Ca^{2+}]\gamma_{HCO_3^-}[HCO_3^-]}{K_{sp}}\right)$$

   $$pH_s = -\log\left(\frac{(4.17\times10^{-11})(0.903)(0.125\times10^{-3})(0.975)(0.164\times10^{-3})}{5.25\times10^{-9}}\right)$$

   $pH_s = -\log(1.43\times10^{-10}) = 9.84$

4. Determine the Langelier and Ryzner indexes.
   a. Langelier saturation index

   $LSI = pH - pH_s = 7.7 - 9.84 = -2.14$

   LSI < 0 (water is undersaturated with respect to calcium carbonate)

b. Ryzner Index

$RI = 2pH_s - pH = 2(9.84) - 7.7 = 11.98$

$(RI = 11.98) > 8.5$ (water is very aggressive)

Comment Although both indexes are used, the Langelier index is used most commonly in the water and wastewater field whereas the Ryzner index is used most commonly in industrial applications.

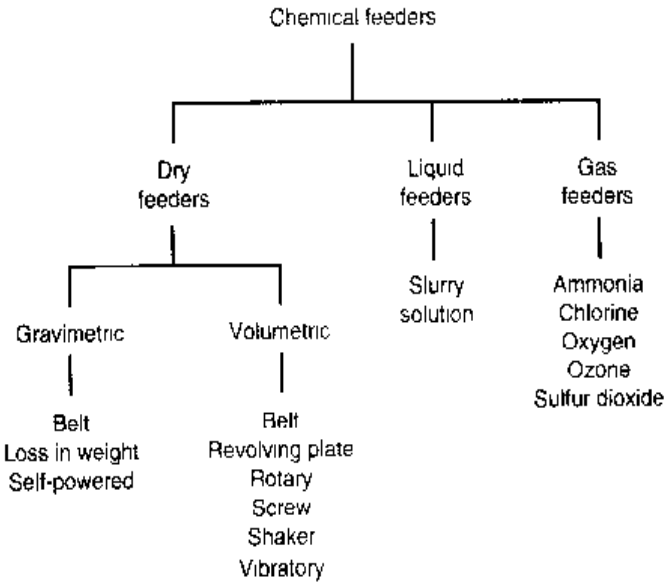
Scaling Control

Usually, $CaCO_3$ scale control can be achieved using one or more of the following methods:

- Acidifying to reduce pH and alkalinity
- Reducing calcium concentration by ion exchange or lime softening
- Adding a scale inhibitor chemical (antiscalant) to increase the apparent solubility of $CaCO_3$ in the concentrate stream
- Lowering the product recovery rate

Because it is not possible to predict a priori the value of pH in water treated with reverse osmosis, it is usually necessary to conduct pilot-scale studies using the same modules that will be used in the full-scale installation.

Stabilization



Wastewater effluent that is demineralized with reverse osmosis will generally require pH and calcium carbonate adjustment (stabilization) to prevent metallic corrosion, due to the contact of the demineralized water with metallic pipes and equipment. Corrosion occurs because material from the solid is removed (solubilized) to satisfy the various solubility products. Demineralized water typically is stabilized by adding lime to adjust the LSI, using the procedure outlined above.

6–8 CHEMICAL STORAGE, FEEDING, PIPING, AND CONTROL SYSTEMS

The design of chemical precipitation operations involves not only the sizing of the various unit operations and processes but also the necessary appurtenances. Because of the corrosive nature of many of the chemicals used and the different forms in which they are available, special attention must be given to the design of chemical storage, feeding, piping, and control systems. The following discussion is intended to serve as an introduction to this subject.

In domestic wastewater-treatment systems, the chemicals employed can be in a solid, liquid, or gaseous form. Coagulants in the dry solid form generally are converted to solution or slurry form prior to introduction into the wastewater. Coagulants in the liquid form are usually delivered to the plant in a concentrated form and have to be

Figure 6–20
Classification of chemical-feed systems.

diluted prior to introduction into the wastewater. Chemicals in the gas form (generally stored as a liquid), typically used for disinfection purposes, are either dissolved in water before injection or are injected directly into the wastewater. The types of chemical-feed systems used for these chemicals are termed *dry, liquid* (also known as wet), or *gas* feed. The various types of feeders are classified on Fig. 6–20. Chemical feeders are generally designed to be (1) proportioning, feeding chemical in proportion to the influent wastewater flowrate, and (2) constant feed, designed to deliver chemical at a fixed rate regardless of the influent flowrate.

Chemical Storage and Handling

General information on the handling, storage, and feeding requirements for various chemicals is presented in Table 6-17. The specific storage facilities required will depend on the form in which the chemical is available locally. For small treatment plants the available forms are usually limited. A typical storage facility for chemicals for a small treatment facility is shown on Fig. 6–21.

Dry Chemical-Feed Systems

A dry chemical-feed system typically consists of a storage hopper, dry chemical feeder, a dissolving tank, and a pumped or gravity distribution system (see Figs. 6–22 and 6–23). The units are sized according to the volume of wastewater, treatment rate, and optimum length of time for chemical feeding and dissolving. Hoppers used with powdered chemicals that are compressible and can form an arch such as lime are equipped with positive agitators and a dust-collection system. As shown on Fig. 6–20, dry chemical feeders are of either the volumetric or the gravimetric type. In the volumetric type the volume of the dry chemical fed is measured whereas in the gravimetric type the weight of chemical fed is measured. A brief description of the chemical feeders used most commonly is presented in Table 6-18, and the chemical feeders are illustrated on Figs. 6–24 and 6–25. Of the dry chemical-feed systems, the loss in weight (see Fig. 6–25*b*) feed system is used most commonly in wastewater-treatment operations.

With a dry feed system, the dissolving operation is critical. The capacity of the dissolving tank is based on the detention time, which is directly related to the wettability

Table 6–17
Handling, storage, and feeding requirements for various chemicals used in wastewater treatment[a]

Chemical	Formula	Shipping form	Feeding form	Feeding type	Accessory equipment	Handling materials
Chemicals used for precipitation						
Aluminum sulfate	$Al_2(SO_4)_3 \cdot 18H_2O$	Lump, ground, or powdered solutions	Liquid	Metering pump	Slurry tank, slaker	Iron, steel
Aluminum chloride	$AlCl_3$	Liquid	Liquid	Metering pump	Storage tank	Hastelloy B. plastic
Calcium hydroxide (lime)	$Ca(OH)_2$	Bags, barrels, and bulk	Liquid	Metering pump	Slurry tank	Iron, steel
Ferric chloride	$FeCl_3$	Bags, carboys, and bulk	Liquid	Metering pump	Slurry tank	Iron, steel
Ferric sulfate	$Fe_2(SO_4)_3$	Bags, barrels, and bulk	Liquid	Metering pump	Slurry tank	Iron, steel
Copperas	$FeSO_4 \cdot 7H_2O$		Liquid	Metering pump	Slurry tank	Iron, steel
Chemicals used for neutalization						
Calcium carbanate	$CaCO_3$	Bags, drums, or bulk	Slurry, dry slurry in fixed beds	Metering pump Volumetric pump	Slurry tank	Iron, steel
Calcium oxide	CaO	Bags (22.5 kg), barrels, or bulk	Dry or slurry, slaked to $Ca(OH)_2$	Metering pump	Slurry tank, slaker	Iron, steel, plastic, rubber hose
Sodium bicarbonate	$NaHCO_3$	Bags or drums	Dry or slurry	Metering pump	Dissolving tank	Iron, steel, rubber, plastic
Sodium carbonate	Na_2CO_3	Bags (45.5 kg), bulk	Dry or slurry	Metering pump	Dissolving tank	Iron, steel, rubber, plastic
Sodium hydroxide	NaOH	Drum (45.5, 204.5, 367.5 kg)	Dry or slurry	Metering pump	Solution tank	Iron, steel, plastic, rubber hose
Carbonic acid	H_2CO_3		Gas (CO_2)	Gas feeder		
Hydrochloric acid	HCl	Barrels, drums, bulk	Liquid	Metering pump	Dilution tank	Hastelloy A, plastic, rubber[b]
Sulfuric acid	H_2SO_4	Carboys, drums, and bulk	Liquid	Metering pump		Iron, steel, plastic, glass

or rate of solution of the chemical. When the water supply is controlled for the purpose of forming a constant-strength solution, mechanical mixers should be used. Depending on the flow pattern within the mixing tank, it may be necessary to add baffles for effective mixing. In smaller mixing tanks, the mixer can be set at an angle to avoid the use of baffles. Solutions or slurries are often stored after dissolving and discharged to the application point at metered rates by chemical-feed pumps.

Liquid Chemical-Feed Systems

Liquid chemical-feed systems typically include a solution storage tank, transfer pump, day tank for diluting the concentrated solution, and chemical-feed pump for distribution to the application point (see Figs. 6–26 and 6–27). In general, liquid feed systems provide for better initial contact and dispersion of the chemical and the wastewater. In systems where the liquid chemical does not require dilution, the chemical-feed pumps draw liquid directly from the solution storage tank. The storage tank is sized based upon the stability of the chemical, feed rate requirements, delivery constraints (cost, size of tank truck, etc.), and availability of the supply. Solution feed pumps are usually of the positive-displacement type for accurate metering of the chemical feed.

Table 6–18 Typical characteristics of chemical feeders[a]

Type of feeder	Description
Volumetric	
Conveyor belt	Consists of a belt located below a hopper. The feed rate is adjusted by varying the speed of the belt (see Fig. 6–24*a*)
Revolving plate	Consists of a rotating plate below the storage hopper (see Fig 6–24*b*). As the plate is rotated, material to be fed is drawn from the hopper. The amount of material feed is controlled by the rate of rotation
Rotary	Consists of rotating shaft with vanes that form pockets (see Fig. 6–24*c*). The amount of material feed is controlled by the rate of rotation
Shaker	Consists of a shaker pan mounted below a storage hopper (see Fig 6–24*d*). As the pan oscillates, the material to be fed is moved forward and dropped into the feed chute
Screw	Consists of a variable-pitch screw mounted below a feed hopper (see Fig. 6–24*e*). The amount of material feed is controlled by the rate of rotation of the screw
Vibratory	Consists of vibrating pan or chute positioned below a chemical storage hopper. The pan or chute, which vibrates back and forth by the oscillating electromagnetic driver, delivers the material to be fed forward. The amount of material feed can be controlled by adjusting the rate of oscillation (see Fig. 6–24*f*)
Gravimetric	
Belt	Consists of volumetric feeder that transfers the material to be fed from the feed hopper to the weigh belt. The signal generated from the weigh belt is used to control the volumetric feeder (see Fig. 6–25*a*)
Loss in weight	Consists of a feed hopper mounted on scale and a chemical feeder (see Fig. 6–25*b*). The chemical feed rate can be controlled with a screw or vibratory feeder. The feed rate is controlled by the loss in weight measured by the scale
Self-powered	Consists of a counterbalanced control gate mounted below a storage hopper (see Fig. 6–25*c*). As shown in Fig. 6–25*c*, the weight of the material in the hopper is counterbalanced by the setting on the beam balance. The rate at which material is fed is controlled by the impact pan. Although not very accurate, this device does not require any power source

[a] Adapted from Liptak (1974).

Gas Chemical-Feed Systems

Chemicals that are used as a gas include ammonia, chlorine, oxygen, ozone, and sulfur dioxide. Gas feed systems are used mostly for feeding chemicals used for disinfection and dechlorination. Chlorine, the most commonly used chemical for disinfection, is supplied in a liquid form within the storage container and evaporates continuously as the gas is drawn from the headspace above the liquid in the storage container. Feed systems for disinfection chemicals are illustrated in Chap. 12, which deals with disinfection.

Typical outdoor liquid chemical-feed systems. The chemical feeders are covered to limit deterioration due to exposure to the elements.

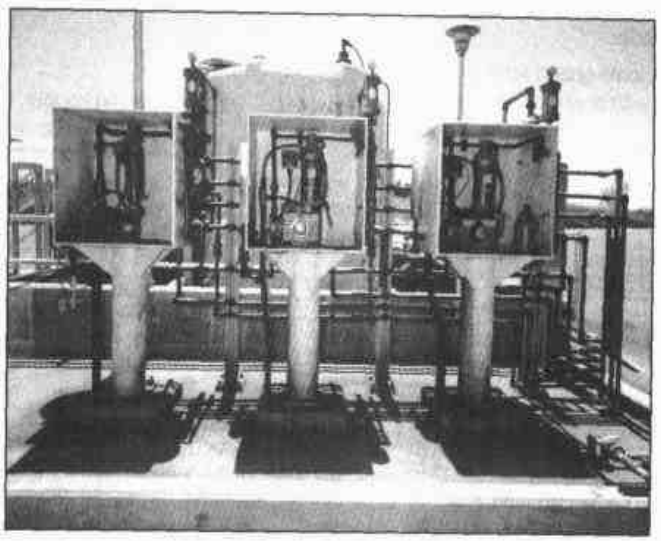

Table 6–19
Typical mixing times for various chemicals used in wastewater-treatment facilities

Chemical	Applications	Recommended mixing times, s
Alum, Al^{3+}, Ferric chloride, Fe^{3+}	Coagulation of colloidal particles	<1
Alum, Al^{3+}, Ferric chloride, Fe^{3+}	Sweep floc precipitation	1–10
Lime $Ca(OH)_2$	Chemical precipitation	10–30
Chlorine, Cl_2	Chemical disinfection	<1
Chloramine, NH_2Cl	Chemical disinfection	5–10
Cationic polymers	Destabilization of colloidal particles	<1
Anionic polymers	Particle bridging	1–10
Polymers, nonionic	Filter aids	1–10

Initial Chemical Mixing

Perhaps the least appreciated fact about chemical addition is the importance of both the initial and uniform mixing of the chemical with the wastewater to be treated. The optimal time for mixing can, as discussed in this section, vary from a fraction of a second to several seconds or more. Because of the difficulties in achieving extremely low mixing times in large treatment plants with a single mixing device, the use of multiple mixing devices is recommended. The particular mixing device selected for a given application must be based on a consideration of the reaction times and operative mechanisms for the chemicals that are being used. Typical mixing times for the chemicals used in wastewater-treatment facilities are reported in Table 6–19. Typical devices used for mixing chemicals in wastewater-treatment plants are discussed in Chap. 5 and throughout this textbook. Approximate mixing times achievable with various mixing devices may be found in Table 5–9 in Chap. 5.

PROBLEMS AND DISCUSSION TOPICS

6–1 To aid sedimentation in the primary settling tank, 25, 40, 60, or 75 g/m^3 (value to be selected by instructor) of ferrous sulfate ($FeSO_4 \cdot 7H_2O$) is added to the wastewater. Determine the minimum alkalinity required to react initially with the ferrous sulfate. How many grams of lime should be added as CaO to react with $Fe(HCO_3)_2$ and the dissolved oxygen in the wastewater to form insoluble $Fe(OH)_3$?

6–2 Copperas ($FeSO_4 \cdot 7H_2O$) is to be added at a rate of 20, 25, 30, or 40 kg/1000 m^3 (value to be selected by instructor) to a wastewater to improve the efficiency of an existing primary sedimentation tank. Assuming sufficient alkalinity is present as $Ca(HCO_3)_2$ determine:

a. How many kg of lime should be added as CaO to complete the reaction.
b. The concentration of oxygen needed in the wastewater to oxidize the ferrous hydroxide that is formed,
c. The mass of sludge that will result per 1000 m^3 of wastewater, and
d. The amount (kg) of alum needed to obtain the same quantity of sludge as in Part (c), assuming $Al(OH)_3$ is the precipitate that is formed.

6–3 Assume that 40, 45, 50, and 55 kg (value to be selected by instructor) of (a) alum (mol wt 666.5) and (b) ferrous sulfate and lime as $Ca(OH)_2$ is added per 4000 m^3 of wastewater. Also assume that all insoluble and very slightly soluble products of the reactions, with the exception of 15 g/m^3 $CaCO_3$, are precipitated as sludge. How many kg of sludge/1000 m^3 will result in each case?

6–4 Raw wastewater is to be treated chemically for the removal of total suspended-solids and phosphorus through coagulation, flocculation, and sedimentation. The wastewater characteristics are as follows: Q = 0.75 m^3/s; orthophosphorus = 10 g/m^3 as P; alkalinity = 200 g/m^3 expressed as $CaCO_3$ [essentially all due to the presence of $Ca(HCO_3)_2$]; total TSS = 220 g/m^3.

a. Determine the sludge production in kg dry wt/d and m^3/d under the following conditions: (1) alum [$Al_2(SO_4)_3 \cdot 14.3\ H_2O$] dosage of 120, 130, 140, or 150 g/m^3 (to be selected by instructor); (2) 100 percent removal of orthophosphorus as insoluble $AlPO_4$; (3) 95 percent removal of original TSS; (4) all alum not required for reaction with phosphate reacts with alkalinity to form $Al(OH)_3$, which is 100 percent removed; (5) wet sludge has a water content of 93 percent and a specific gravity of 1.04.
b. Determine the sludge production in a kg dry wt/d and m^3/d under the following conditions: (1) Lime [$Ca(OH)_2$] dosage of 450 g/m^3 to give pH of approximately 11.2; (2) 100 percent removal of orthophosphorus as insoluble hydroxylapatite [$Ca_{10}(PO_4)_6(OH)_2$]; (3) 95 percent removal of original TSS; (4) added lime (i) reacts with phosphate, (ii) reacts with all alkalinity to form $CaCO_3$, 20 g/m^3 of $CaCO_3$ is soluble and remains in solution and the rest is 100 percent removed, and (iii) remainder stays in solution; (5) wet sludge has a water content of 92 percent and a specific gravity of 1.05.
c. Determine the net increase in calcium hardness in g/m^3 as $CaCO_3$ for the treatment specified in part b.

6–5 Verify the correctness of the plots given on Fig. 6–8, using the equations given below the figures.

6–6 Obtain equilibrium values from the literature and verify one of the solubility curves given on Fig. 6–17.

6–7 Obtain equilibrium values from the literature and verify one of the solubility curves given on Fig. 6–18.

6–8 Using the potentials for the following two half reactions given in Table 6–12, estimate the equilibrium constant for the ionization of water.

$2H_2O + 2e^- \rightarrow H_2 + 2OH$

$2H^+ + 2e^- \rightarrow H_2$

6–9 Using the half reactions given in Table 6–12, evaluate the feasibility of the following reaction.

$2Fe^{2+} + 2H_2O_2 \leftrightarrow 2Fe^{3-} + 2OH^- + H_2O$

6–10 Using the half reactions given in Table 6–12, evaluate the feasibility of the following reaction.

$2Fe^{2+} + Cl_2 \leftrightarrow 2Fe^{3+} + 2Cl^-$

6–11 Using the half reactions given in Table 6–12, evaluate the feasibility of the following reaction.

$H_2S + Cl_2 \leftrightarrow S + 2HCl$

6–12 Using the half reactions given in Table 6–12, evaluate the feasibility of the following reaction.

$H_2S + O_3 \leftrightarrow S + O_2 + H_2O$

6–13 Estimate the scaling potential of one the treated wastewater samples (to be selected by instructor) using both the Langelier and Ryzner indexes for a treated wastewater with the following chemical characteristics.

		Wastewater sample			
Constituent	**Unit**	**A[a]**	**B**	**C**	**D**
Ca^{2+}	mg/L as $CaCO_3$	5	12	245	15
HCO_3^-	mg/L as $CaCO_3$	7	9	200	16
TDS	mg/L	30	275	600	500
pH	unitless	6.5	8.0	6.9	6.5

[a]Typical values are for runoff from snow melt (adapted from Benefield et al. (1982).

6–14 Estimate the scaling potential of one the treated wastewater samples (to be selected by instructor) using both the Langelier and Ryzner indexes for a treated wastewater with the following chemical characteristics.

	Concentration, mg/L					Concentration, mg/L			
Cation	**A**	**B**	**C**	**D**	**Anion**	**A**	**B**	**C**	**D**
Ca^{2+}	121.3	64.0	42.1	44.0	HCO_3^-	280	96.0	158.7	91.5
Mg^{2+}	36.2	15.1	14.6	25.2	SO_4^{2-}	116	80	48.0	57.6
Na^+	8.1	20.5	46.0	4.6	Cl^-	61	17.3	63.8	17.7
K^+	12	10.0	11.7		NO_3^-	15.6	5		
					H_2CO_3				8.8
					CO_3^{2-}			12.0	

6–15 Review the literature concerning the Langelier (1946) and Ryzner (1944) indexes and discuss the difference in approach to scaling used in the development of these two indexes.

With proper analysis and environmental control, almost all wastewaters containing biodegradable constituents can be treated biologically. Therefore, it is essential that the environmental engineer understand the characteristics of each biological process to ensure that the proper environment is produced and controlled effectively. The principal purposes of this chapter are (1) to provide fundamental background information on the microorganisms used to treat wastewater and (2) to consider the application of biological process fundamentals for the biological treatment of wastewater. The information presented in this chapter provides the necessary background material needed for the design of biological treatment processes discussed in Chaps. 8 through 10. For ease of computation, constituent concentrations in this chapter and in Chaps. 8, 9, and 10 are expressed in g/m^3 instead of mg/L because flowrate is given in units of m^3/s or m^3/d.

The fundamentals of biological treatment introduced in the first seven sections of this chapter include (1) an overview of biological wastewater treatment, (2) the composition and classification of the microorganisms used for wastewater treatment, (3) an introduction to important aspects of microbial metabolism, (4) bacterial growth and energetics, (5) microbial growth kinetics, (6) modeling suspended growth treatment processes, and (7) modeling attached-growth treatment processes. Following the presentation of fundamentals, the remaining seven sections deal with an introduction to the general classes of biological processes used for the treatment of wastewater. The topics covered include (1) aerobic oxidation, (2) biological nitrification, (3) biological denitrification, (4) biological phosphorus removal, (5) anaerobic oxidation, (6) biological removal of toxic and recalcitrant organic compounds, and (7) biological removal of heavy metals.

7–1 OVERVIEW OF BIOLOGICAL WASTEWATER TREATMENT

The objectives of biological treatment, some useful definitions, the role of microorganisms in the biological treatment of wastewater, and biological processes used for wastewater treatment are introduced in this section to provide a perspective for the material to be presented in this chapter.

Objectives of Biological Treatment

The overall objectives of the biological treatment of domestic wastewater are to (1) transform (i.e., oxidize) dissolved and particulate biodegradable constituents into acceptable end products, (2) capture and incorporate suspended and nonsettleable colloidal solids into a biological floc or biofilm, (3) transform or remove nutrients, such as nitrogen and phosphorus, and (4) in some cases, remove specific trace organic constituents and compounds. For industrial wastewater, the objective is to remove or reduce the concentration of organic and inorganic compounds. Because some of the constituents and compounds found in industrial wastewater are toxic to microorganisms, pretreatment may be required before the industrial wastewater can be discharged to a municipal collection system. For agricultural irrigation return wastewater, the objective is to remove nutrients, specifically nitrogen and phosphorus, that are capable of stimulating the growth of aquatic plants. Schematic flow diagrams of various treatment processes for domestic wastewater incorporating biological processes are shown on Fig. 7–1.

Some Useful Definitions

Common terms used in the field of biological wastewater treatment and their definitions are presented in Table 7–1. All of the terms presented in Table 7–1 are discussed in greater detail in the remainder of this chapter and in Chaps. 8, 9, and 10, which follow. The first five entries in Table 7–1 refer to the metabolic function of the processes. As reported, the principal processes used for the biological treatment of wastewater can be classified with respect to their metabolic function as aerobic processes, anaerobic processes, anoxic processes, facultative processes, and combined processes. Terminology used to describe the types of treatment processes is presented in the second group of entries in Table 7–1. The principal processes used for wastewater treatment are classified as suspended-growth, attached-growth, or combinations thereof. The third group of terms are descriptors for the different types of treatment functions.

Role of Microorganisms in Wastewater Treatment

The removal of dissolved and particulate carbonaceous BOD and the stabilization of organic matter found in wastewater is accomplished biologically using a variety of microorganisms, principally bacteria. Microorganisms are used to oxidize (i.e., convert) the dissolved and particulate carbonaceous organic matter into simple end products and additional biomass, as represented by the following equation for the aerobic biological oxidation of organic matter.

$$\nu_1 \text{ (organic material)} + \nu_2 O_2 + \nu_3 NH_3 + \nu_4 PO_4^{3-} \xrightarrow{\text{microorganisms}}$$

$$\nu_5 \text{(new cells)} + \nu_6 CO_2 + \nu_7 H_2O \quad (7\text{–}1)$$

where ν_i = the stoichiometric coefficient, as defined previously in Sec. 4–6 in Chap. 4.

In Eq. (7–1), oxygen (O_2), ammonia (NH_3), and phosphate (PO_4^{3-}) are used to represent the nutrients needed for the conversion of the organic matter to simple end products [i.e., carbon dioxide (CO_2) and water]. The term shown over the directional arrow is used to denote the fact that microorganisms are needed to carry out the oxidation process. The term *new cells* is used to represent the biomass produced as a result of the oxidation of the organic matter. Microorganisms are also used to remove nitrogen and

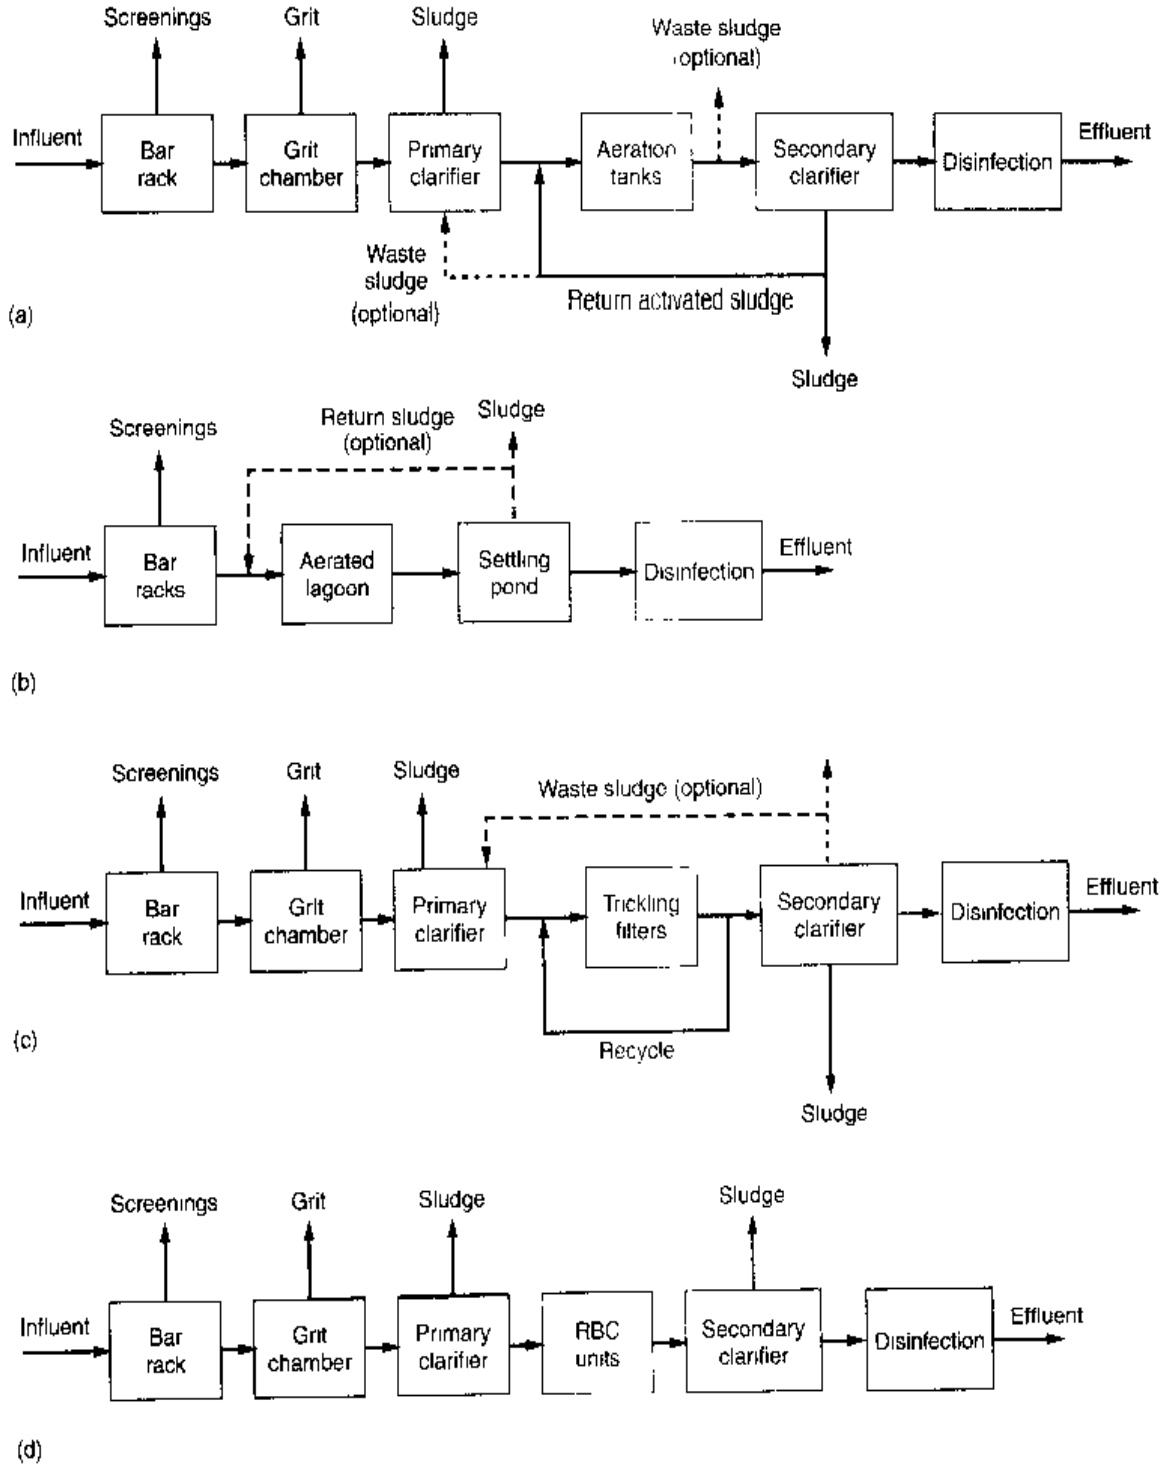

Figure 7-1

phosphorus in wastewater treatment processes. Specific bacteria are capable of oxidizing ammonia (nitrification) to nitrite and nitrate, while other bacteria can reduce the oxidized nitrogen to gaseous nitrogen. For phosphorus removal, biological processes are configured to encourage the growth of bacteria with the ability to take up and store large amounts of inorganic phosphorus.

Table 7-1
Definitions of common terminology used for biological wastewater treatment[a]

Term	Definition
Metabolic function	
Aerobic (oxic) processes	Biological treatment processes that occur in the presence of oxygen
Anaerobic processes	Biological treatment processes that occur in the absence of oxygen
Anoxic processes	The process by which nitrate nitrogen is converted biologically to nitrogen gas in the absence of oxygen. This process is also known as denitrification
Facultative processes	Biological treatment processes in which the organisms can function in the presence or absence of molecular oxygen
Combined aerobic/ anoxic/anaerobic processes	Various combinations of aerobic, anoxic, and anaerobic processes grouped together to achieve a specific treatment objective
Treatment processes	
Suspended-growth processes	Biological treatment processes in which the microorganisms responsible for the conversion of the organic matter or other constituents in the wastewater to gases and cell tissue are maintained in suspension within the liquid
Attached-growth processes	Biological treatment processes in which the microorganisms responsible for the conversion of the organic matter or other constituents in the wastewater to gases and cell tissue are attached to some inert medium, such as rocks, slag, or specially designed ceramic or plastic materials. Attached-growth treatment processes are also known as fixed-film processes
Combined processes	Term used to describe combined processes (e.g., combined suspended and attached growth processes)
Lagoon processes	A generic term applied to treatment processes that take place in ponds or lagoons with various aspect ratios and depths
Treatment functions	
Biological nutrient removal	The term applied to the removal of nitrogen and phosphorus in biological treatment processes
Biological phosphorus removal	The term applied to the biological removal of phosphorus by accumulation in biomass and subsequent solids separation
Carbonaceous BOD removal	Biological conversion of the carbonaceous organic matter in wastewater to cell tissue and various gaseous end products. In the conversion, it is assumed that the nitrogen present in the various compounds is converted to ammonia
Nitrification	The two-step biological process by which ammonia is converted first to nitrite and then to nitrate
Denitrification	The biological process by which nitrate is reduced to nitrogen and other gaseous end products
Stabilization	The biological process by which the organic matter in the sludges produced from the primary settling and biological treatment of wastewater is stabilized, usually by conversion to gases and cell tissue. Depending on whether this stabilization is carried out under aerobic or anaerobic conditions, the process is known as aerobic or anaerobic digestion
Substrate	The term used to denote the organic matter or nutrients that are converted during biological treatment or that may be limiting in biological treatment. For example, the carbonaceous organic matter in wastewater is referred to as the substrate that is converted during biological treatment

[a] Adapted from Crites and Tchobanoglous (1998).

Because the biomass has a specific gravity slightly greater than that of water, the biomass can be removed from the treated liquid by gravity settling. It is important to note that unless the biomass produced from the organic matter is removed on a periodic basis, complete treatment has not been accomplished because the biomass, which itself is organic, will be measured as BOD in the effluent. Without the removal of biomass from the treated liquid, the only treatment achieved is that associated with the bacterial oxidation of a portion of the organic matter originally present.

Types of Biological Processes for Wastewater Treatment

The principal biological processes used for wastewater treatment can be divided into two main categories: *suspended growth* and *attached growth* (or *biofilm*) processes (see Table 7–1). Typical process applications for suspended and attached growth biological treatment processes are given in Table 7–2, along with other treatment processes. The successful design and operation of the processes listed in Table 7–2 require an understanding of the types of microorganisms involved, the specific reactions that they perform, the environmental factors that affect their performance, their nutritional needs, and their reaction kinetics. These subjects are considered in the sections that follow.

Suspended Growth Processes. In suspended growth processes, the microorganisms responsible for treatment are maintained in liquid suspension by appropriate mixing methods. Many suspended growth processes used in municipal and industrial wastewater treatment are operated with a positive dissolved oxygen concentration (aerobic), but applications exist where suspended growth anaerobic (no oxygen present) reactors are used, such as for high organic concentration industrial wastewaters and organic sludges. The most common suspended growth process used for municipal wastewater treatment is the activated-sludge process shown on Fig. 7–2 and discussed below.

The activated-sludge process was developed around 1913 at the Lawrence Experiment Station in Massachusetts by Clark and Gage (Metcalf and Eddy, 1930), and by Ardern and Lockett (1914) at the Manchester Sewage Works in Manchester, England. The activated-sludge process was so named because it involved the production of an activated mass of microorganisms capable of stabilizing a waste under aerobic conditions. In the aeration tank, contact time is provided for mixing and aerating influent wastewater with the microbial suspension, generally referred to as the mixed liquor suspended solids (MLSS) or mixed liquor volatile suspended solids (MLVSS). Mechanical equipment is used to provide the mixing and transfer of oxygen into the process. The mixed liquor then flows to a clarifier where the microbial suspension is settled and thickened. The settled biomass, described as *activated sludge* because of the presence of active microorganisms, is returned to the aeration tank to continue biodegradation of the influent organic material. A portion of the thickened solids is removed daily or periodically as the process produces excess biomass that would accumulate along with the nonbiodegradable solids contained in the influent wastewater. If the accumulated solids are not removed, they will eventually find their way to the system effluent.

An important feature of the activated-sludge process is the formation of floc particles, ranging in size from 50 to 200 μm, which can be removed by gravity settling, leaving a relatively clear liquid as the treated effluent. Typically, greater than 99 percent of the suspended solids can be removed in the clarification step. As will be discussed in

Table 7–2
Major biological treatment processes used for wastewater treatment.

Type	Common name	Use[a]
Aerobic processes		
Suspended growth	Activated sludge process(es)	Carbonaceous BOD removal, nitrification
	Aerated lagoons	Carbonaceous BOD removal, nitrification
	Aerobic digestion	Stabilization, carbonaceous BOD removal
Attached growth	Trickling filters	Carbonaceous BOD removal, nitrification
	Rotating biological contactors	Carbonaceous BOD removal, nitrification
	Packed-bed reactors	Carbonaceous BOD removal, nitrification
Hybrid (combined) suspended and attached growth processes	Trickling filter/activated sludge	Carbonaceous BOD removal, nitrification
Anoxic processes		
Suspended growth	Suspended-growth denitrification	Denitrification
Attached growth	Attached-growth denitrification	Denitrification
Anaerobic processes		
Suspended growth	Anaerobic contact processes	Carbonaceous BOD removal
	Anaerobic digestion	Stabilization, solids destruction, pathogen kill
Attached growth	Anaerobic packed and fluidized bed	Carbonaceous BOD removal, waste stabilization, denitrification
Sludge blanket	Upflow anaerobic sludge blanket	Carbonaceous BOD removal, especially high-strength wastes
Hybrid	Upflow sludge blanket/attached growth	Carbonaceous BOD removal
Combined aerobic, anoxic, and anaerobic processes		
Suspended growth	Single- or multistage processes, various proprietary processes	Carbonaceous BOD removal, nitrification, denitrification, and phosphorus removal
Hybrid	Single- or multistage processes with packing for attached growth	Carbonaceous BOD removal, nitrification, denitrification, and phosphorus removal
Lagoon processes		
Aerobic lagoons	Aerobic lagoons	Carbonaceous BOD removal
Maturation (tertiary) lagoons	Maturation (tertiary) lagoons	Carbonaceous BOD removal, nitrification
Facultative lagoons	Facultative lagoons	Carbonaceous BOD removal
Anaerobic lagoons	Anaerobic lagoons	Carbonaceous BOD removal, waste stabilization

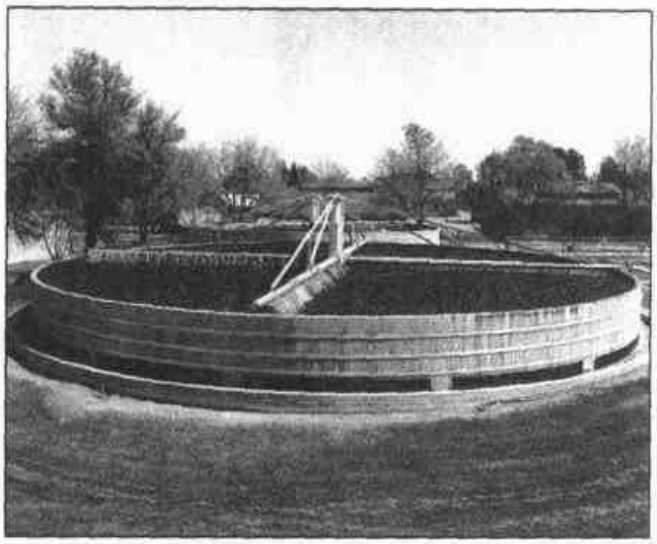
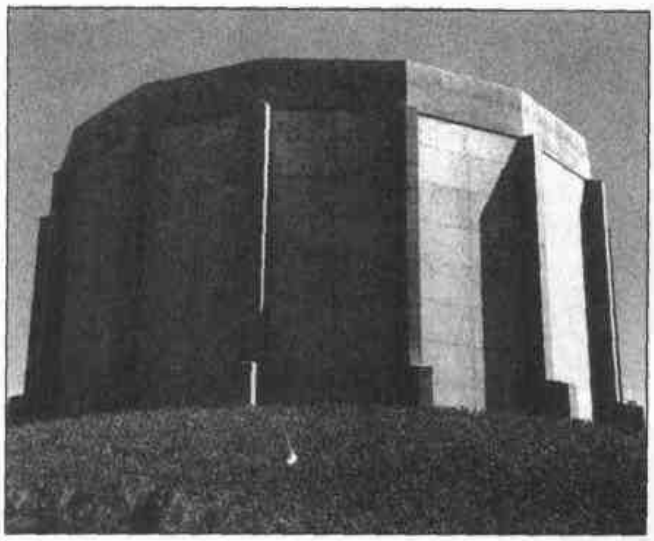
Chap. 8, the characteristics and thickening properties of the flocculent particles will affect the clarifier design and performance.

Attached Growth Processes. In attached growth processes, the microorganisms responsible for the conversion of organic material or nutrients are attached to an inert packing material. The organic material and nutrients are removed from the wastewater flowing past the attached growth also known as a biofilm. Packing materials used in attached growth processes include rock, gravel, slag, sand, redwood, and a wide range of plastic and other synthetic materials. Attached growth processes can also be operated as aerobic or anaerobic processes. The packing can be submerged completely in liquid or not submerged, with air or gas space above the biofilm liquid layer.



The most common aerobic attached growth process used is the trickling filter in which wastewater is distributed over the top area of a vessel containing nonsubmerged packing material (see Fig. 7–3). Historically, rock was used most commonly as the packing material for trickling filters, with typical depths ranging from 1.25 to 2 m (4 to



(a-1)

(b-1)

(a-2)

(b-2)

Figure 7–3

Attached growth biological treatment process (*a*-1) schematic and (*a*-2) view of tricking filter with rock packing and (*b*-1) schematic and (*b*-2) view of tower tricking filter with plastic packing (see Fig. 7–15*b*). The tower filter is 10 m high and 50 m in diameter.

6 ft). Most modern trickling filters vary in height from 5 to 10 m (16 to 33 ft) and are filled with a plastic packing material for biofilm attachment. The plastic packing material is designed such that about 90 to 95 percent of the volume in the tower consists of void space. Air circulation in the void space, by either natural draft or blowers, provides oxygen for the microorganisms growing as an attached biofilm. Influent wastewater is distributed over the packing and flows as a nonuniform liquid film over the attached biofilm. Excess biomass sloughs from the attached growth periodically and clarification is required for liquid/solids separation to provide an effluent with an acceptable suspended solids concentration. The solids are collected at the bottom of the clarifier and removed for waste-sludge processing.

7–2 COMPOSITION AND CLASSIFICATION OF MICROORGANISMS

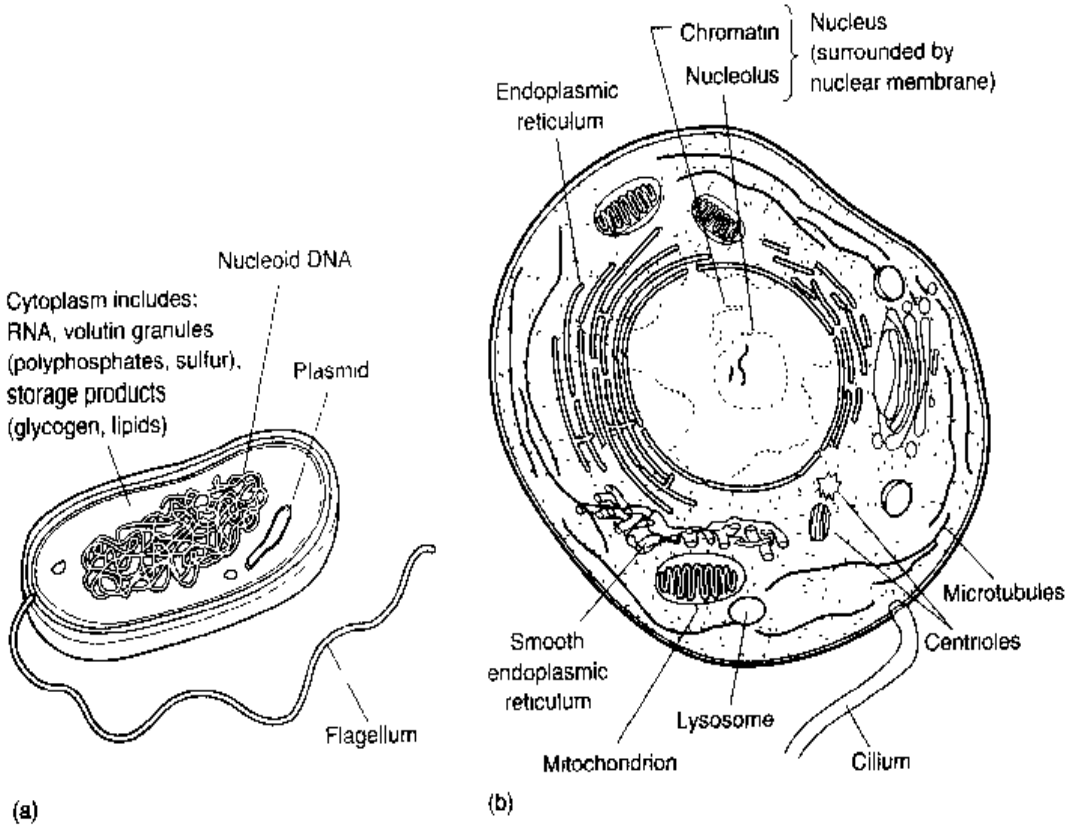
Biological processes for wastewater treatment consist of mixed communities with a wide variety of microorganisms, including bacteria, protozoa, fungi, rotifers, and possibly algae. The basic characteristics and important roles of these organisms have been described in Chap. 2. In some cases, biological treatment goals can only be accomplished by the presence of a specific microbial species. To provide a basic understanding of the nature of microorganisms, the topics introduced in this section are: (1) cell components, (2) cell composition, (3) environmental factors that affect microbial activity, and (4) methods used to identify and classify microorganisms. The focus here is mainly on prokaryotes (see Sec. 2–8 in Chap. 2), because of their major role in biological wastewater treatment.

Cell Components

The important components of the prokaryotic cell and their functions are illustrated on Fig. 7–4*a* and described in Table 7–3; the eukaryotic cell is illustrated on Fig. 7–4*b*. Key components that relate to the cell's genetic information and specific enzymes produced, which determine the capability of the microorganism in wastewater treatment, are deoxyribose nucleic acid (DNA) and the ribosomes. Ribosomes are the sites of protein synthesis, which are necessary for enzyme production, and the DNA provides the genetic information used to determine the protein structure synthesized. To understand how DNA codes for the cell proteins, the DNA structure and nucleotide sequence and the structure and role of ribose nucleic acid (RNA) are reviewed.

Figure 7–4

Typical internal structure of cells: (*a*) prokaryotic and (*b*) eukaryotic.



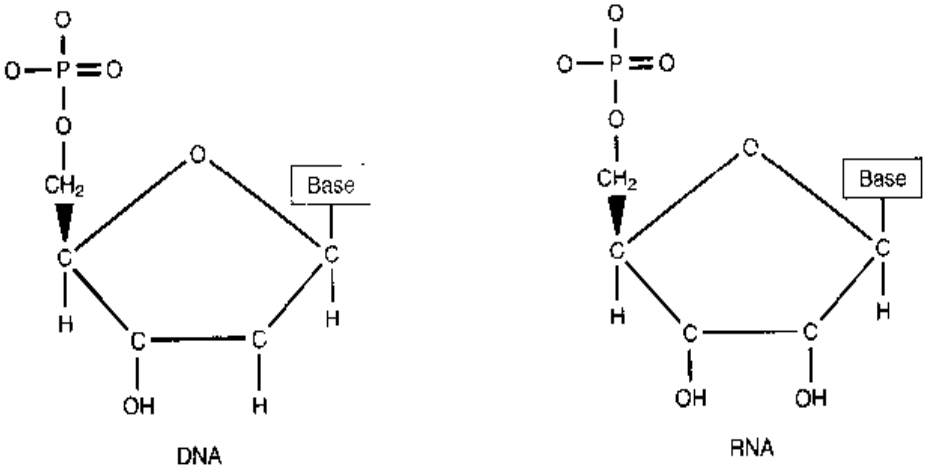


Table 7–3
Description of bacteria cell components

Cell component	Function
Cell wall	Provides strength to maintain the cell shape and protects the cell membrane. Some bacteria can produce a sticky polysaccharide layer outside the cell wall, called a capsule or slime layer
Cell membrane	Controls the passage of dissolved organics and nutrients into the cell and the waste materials and metabolic by-products out of the cell
Cytoplasm	Contains the material within the cell to carry out cell functions and includes water, nutrients, enzymes, ribosomes, and small organic molecules
Cytoplasmic inclusions	Contains storage material that can provide carbon, nutrients, or energy. These may be carbohydrate deposits, such as polyhydroxybutyrate (PHB) or glycogen, polyphosphates, lipids, and sulfur granules
Deoxyribonucleic acid (DNA)	A double-stranded helix-shaped molecule that contains genetic information that determines the nature of the cell protein and enzymes that are produced
Plasmid DNA	Small circular DNA molecules that can also provide genetic characteristics for the bacteria
Ribosomes	Particles in the cytoplasm that are composed of ribonucleic acid (RNA) and protein and are the sites where proteins are produced
Flagella	Protein hairlike structures that extend from the cytoplasm membrane several bacteria lengths out from the cell and provide mobility by rotating at high speeds
Fimbriae and pili	Short protein hairlike structures (pili is longer) that enable bacteria to stick to surfaces. Pili also enable bacteria to attach to each other

Figure 7–5
Nucleotide structure of deoxyribose nucleic acid (DNA) and ribose nucleic acid (RNA).

The nucleic acids, DNA and RNA, are composed of a series of nucleotides. Each nucleotide consists of a five-carbon sugar compound, a nitrogen base, and a phosphate molecule (see Fig. 7–5). To form the nucleotide chain of DNA or RNA, the phosphate group bonds to the third carbon (clockwise from the oxygen bond) of the sugar molecule. The nitrogen bases for DNA can be one of four pyrimidine or purine compounds:

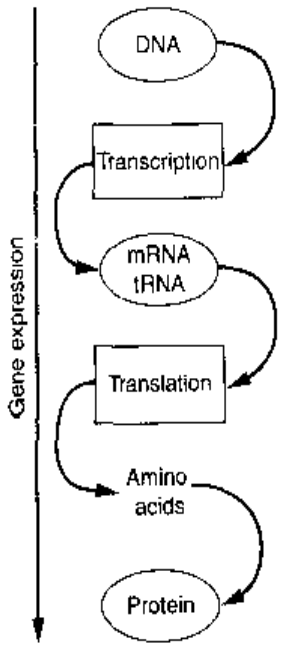

Figure 7-6

Gene expression leads to the formation of proteins by transcription of a segment of the DNA genetic code and translation in the ribosome via messenger RNA (mRNA) and transfer RNA (tRNA) to form a series of amino acids, which form polypeptides and finally protein.

cytosine (C), thymine (T), adenine (A), and guanine (G). For RNA, four nitrogen bases are also involved, including A, C, and G, and thymine is replaced with uracil (U). The DNA is a double-strand helix structure with bonding between the nitrogen bases of each strand. Base bonding is very specific with bonds only between G and C, and A and T. The RNA is a single strand of a nucleotide sequence of various combinations of A, C, G, and U. The sequence of nucleotides in DNA contains the necessary genetic codes for the cell, which determine the specific proteins and enzymes that the bacteria can produce. The number of nucleotides in DNA is very high, and the size of the DNA molecule is described in terms of the number of thousands of nucleotide bases (kilobase) per molecule. The bacterium *Escherichia coli* has 4.7 million nucleotides in each DNA strand or 4700 kilobase pairs

Gene expression as illustrated on Fig. 7–6 involves the transcription and translation of a segment (gene) of the DNA to form a specific protein. The first step in the process is transcription, in which a small segment of the DNA is unraveled to form a single strand that is used to form a single strand on RNA by complementing base pairing of the nitrogen bases in the DNA nucleotides. For example, adenine (A) in the DNA strand pairs with uracil (U), and guanine (G) with cytosine (C) in the mRNA. The order of the nucleotides in the mRNA will determine the order of amino acids that form polypeptides and the protein structure produced. Translation of the mRNA occurs in the ribosome by tRNA. Each of the nucleotides on the mRNA in series is matched by complementary base pairing with the tRNA in the ribosome, and for each match, another segment of the tRNA, containing three nucleotides, selects a specific amino acid. The three nucleotide sequences in the mRNA are called codons. In essence, each codon selects for a specific amino acid, and there is more than one codon for each of the possible 21 amino acids that can be found in living cells. Thus, the length and nucleotide sequence expressed in the DNA represents a gene that determines what specific protein is formed. Because protein is an essential component of cellular enzymes, the DNA gene composition then determines the microbial cell functions and degradative capabilities. Additional details on gene expression may be found in Madigan et al. (2000).

Cell enzymes, consisting of protein and a cofactor such as a metal ion (e.g., zinc, iron, copper, manganese, or nickel), determine the metabolic capability of microorganisms in wastewater treatment. Enzymes are large organic molecules with molecular weights in the range of 10,000 to 1,000,000. Enzymes catalyze biological reactions necessary for cell functions, such as hydrolysis, oxidation-reduction reactions, and cell synthesis reactions. Cells may also produce enzymes for activity outside the cell wall (extracellular enzymes). An example of the function of extracellular enzymes is the hydrolysis of particulates and large molecules so that the material can be transported across the cell membrane for use by the cell. Enzymes can also be *constitutive* or *inducible*. Constitutive enzymes are produced continuously by the cell, while inducible enzymes are produced in response to the presence of a particular compound. The rate of enzyme activity is affected by temperature and pH.

Cell Composition

To support microbial growth in biological systems, appropriate nutrients must be available. Reviewing the composition of a typical microbial cell will provide a basis for understanding the nutrients needed for growth. Prokaryotes are composed of about 80 percent water and 20 percent dry material, of which 90 percent is organic and 10 percent

Table 7–4
Typical composition of bacteria cells[a]

Constituent or element	Percent of dry weight
Major cellular material	
Protein	55.0
Polysaccharide	5.0
Lipid	9.1
DNA	3.1
RNA	20.5
Other (sugars, amino acids)	6.3
Inorganic ions	1.0
As cell elements	
Carbon	50.0
Oxygen	22.0
Nitrogen	12.0
Hydrogen	9.0
Phosphorus	2.0
Sulfur	1.0
Potassium	1.0
Sodium	1.0
Calcium	0.5
Magnesium	0.5
Chlorine	0.5
Iron	0.2
Other trace elements	0.3

[a] Adapted from Madigan et al. (1997).

is inorganic. Typical values for the composition of prokaryote cells are reported in Table 7–4. The most widely used empirical formula for the organic fraction of cells is $C_5H_7O_2N$ first proposed by Hoover and Porges (1952). About 53 percent by weight of the organic fraction is carbon. The formulation $C_{60}H_{87}O_{23}N_{12}P$ can be used when phosphorus is also considered. It should be noted that both formulations are approximations and may vary with time and species, but they are used for practical purposes. Nitrogen and phosphorus are considered macronutrients because they are required in comparatively large amounts. Prokaryotes also require trace amounts of metallic ions, or micronutrients, such as zinc, manganese, copper, molybdenum, iron, and cobalt. Because all of these elements and compounds must be derived from the environment, a shortage of any of these substances would limit and, in some cases, alter growth.

Environmental Factors

Environmental conditions of temperature and pH have an important effect on the selection, survival, and growth of microorganisms. In general, optimal growth for a particu-

Table 7–5 Temperature classification of biological processes

Type	Temperature range, °C	Optimum range, °C
Psychrophilic	10–30	12–18
Mesophilic	20–50	25–40
Thermophilic	35–75	55–65

lar microorganism occurs within a fairly narrow range of temperature and pH, although most microorganisms can survive within much broader limits. Temperatures below the optimum typically have a more significant effect on growth rate than temperatures above the optimum; it has been observed that growth rates double with approximately every 10°C increase in temperature until the optimum temperature is reached. According to the temperature range in which they function best, bacteria may be classified as *psychrophilic*, *mesophilic*, or *thermophilic*. Typical temperature ranges for microorganisms in each of these categories are presented in Table 7–5. For a more detailed discussion of the organisms in the various temperature ranges, see Madigan et al. (1997, 2000).

The pH of the environment is also a key factor in the growth of organisms. Most bacteria cannot tolerate pH levels above 9.5 or below 4.0. Generally, the optimum pH for bacterial growth lies between 6.5 and 7.5. Different archaea are able to grow at thermophilic and ultrathermophilic (60 to 80°C) temperatures, extremely low pH, and high salinity.

Microorganism Identification and Classification

With the use of more sophisticated biological treatment processes and developments in the use of molecular tools for microbial applications, environmental engineers have expanded their interests from the general functionality of microorganisms to understanding the presence and role of specific bacterial species in biological treatment systems. Environmental engineers have also shown how certain conditions in engineered systems may be controlled to create selective pressures that will favor the growth of preferred microorganisms. Thus, the identification of microorganisms and their metabolic characteristics is very important, and is described here along with molecular methods used in biological processes.

In the past, the methods used to identify bacteria relied on physical taxonomic (morphologic) and metabolic characteristics (phenotypic analysis). With modern tools from molecular biology, bacterial identification is now based on cellular genetic information. The basic taxonomic unit in the identification of bacteria is the species, which represents a collection of similar strains of bacteria that exhibit characteristics significantly different from other groups of bacteria. Species that share one or more major properties are grouped and this collection is termed a genus (plural genera). All bacteria are given a genus and species name. The genus name is capitalized and placed before the species name and can be abbreviated ahead of the species name after first identified. The genus and species names are italicized. For example, the genus *Bacillus* contains several species including *B. subtilis*, *B. cerus*, and *B. stearothermophilis*, based on different morphological, physiological, and ecological traits (Madigan et al., 1997, 2000).

Taxonomic Classification. Conventional taxonomic methods used to identify a bacterium rely on physical properties of the bacteria and metabolic characteristics. To

apply this approach, a pure culture must first be isolated. The culture may be isolated by serial dilution and growth in selective growth media. The cells are harvested and grown as pure culture using sterilization techniques to prevent contamination. In some cases, isolation of a species is not possible, which may be due to the need for synergistic growth with other species or the lack of a specific growth factor. Historically, the types of tests that are used to characterize a pure culture include (1) microscopic observations, to determine morphology (size and shape); (2) gram staining, to determine if the bacteria cell wall will absorb crystal violet dye; (3) the type of electron acceptor (i.e., oxygen, CO_2, etc.) used in oxidation-reduction reactions; (4) the type of carbon source used for cell growth; (5) the ability to use various nitrogen and sulfur sources; (6) nutritional needs; (7) cell wall chemistry; (8) cell characteristics including pigments, segments, cellular inclusions, and storage products; (9) resistance to antibiotics; and (10) environmental effects of temperature and pH. An alternative to taxonomic classification is a newer method, termed phylogeny.

Phylogenetic Classification. In the late 1970s, microbiologists began to use tools that allowed them to study microorganisms at the molecular level, and to observe genetic relationships related to the evolutionary history of living cells. The characterization of microorganisms based on genetic information and evolutionary location in time is termed *phylogeny*, which is the more current method of identification and classification. To identify accurately the microbes and determine the true evolutionary relationships between species, the choice of cellular genetic material is critical. The genetic code for ribosomal RNA was chosen as the evolutionary chronometer for cell identification because the code (1) is of evolutionary significance, (2) is well conserved across broad phylogenetic distances, and (3) contains a large number of nucleotide sequences so that similarity in sequences between two organisms indicates a phylogenetic relationship.

Ribosomal RNA can be separated into two components, 30 S (Svedberg units) and 50 S, based on different centrifugal forces in ultracentrifugation. The 30 S units consist of 16S rRNA, containing about 1500 nucleotides, and 21 proteins. While the 16S rRNA can be extracted from cells for nucleotide sequencing using molecular techniques, more recent developments have led to using a section of DNA that contains the rRNA genes (the DNA that encodes the 16S rRNA). This method includes genome DNA extraction from the cell material, followed by a polymerase chain reaction (PCR) procedure that uses DNA primers and a DNA polymerase enzyme to reproduce and amplify artificially the DNA material by a factor of 10^6 or more from the small amount of material extracted from the cell. The amplified 16S rRNA gene is then subjected to sequencing to determine its nucleotide sequence. The sequencing result is compared to the ribosome sequences available in a data base to determine the identity of the organism and its phylogenetic relationship to known organisms.

Molecular phylogeny involves a systematic organization and classification of microorganisms based on their genetic traits. The phylogenetic tree of life with distinct kingdoms as determined from rRNA sequencing is shown on Fig. 7–7. Cellular life is divided into three basic domains, two composed of prokaryotic cells (Archaea and Bacteria), as indicated earlier, and the third composed of Eukarya cells. For the bacteria, some were recognized based on similar morphology and physiology, but most contain a mixture of phenotypic properties. In addition to having different rRNA sequencing properties, the archaea have a number of different phenotypic properties compared to bacte-

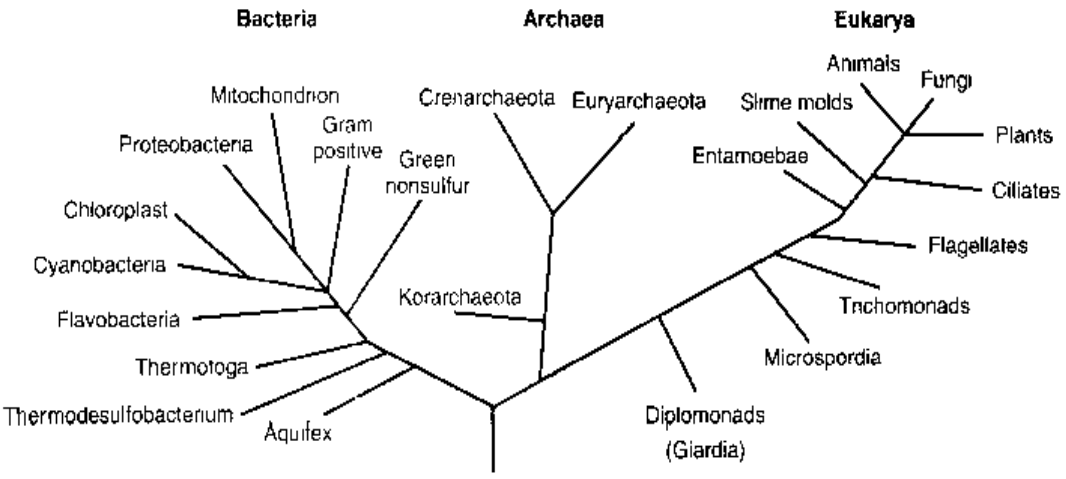

Figure 7–7

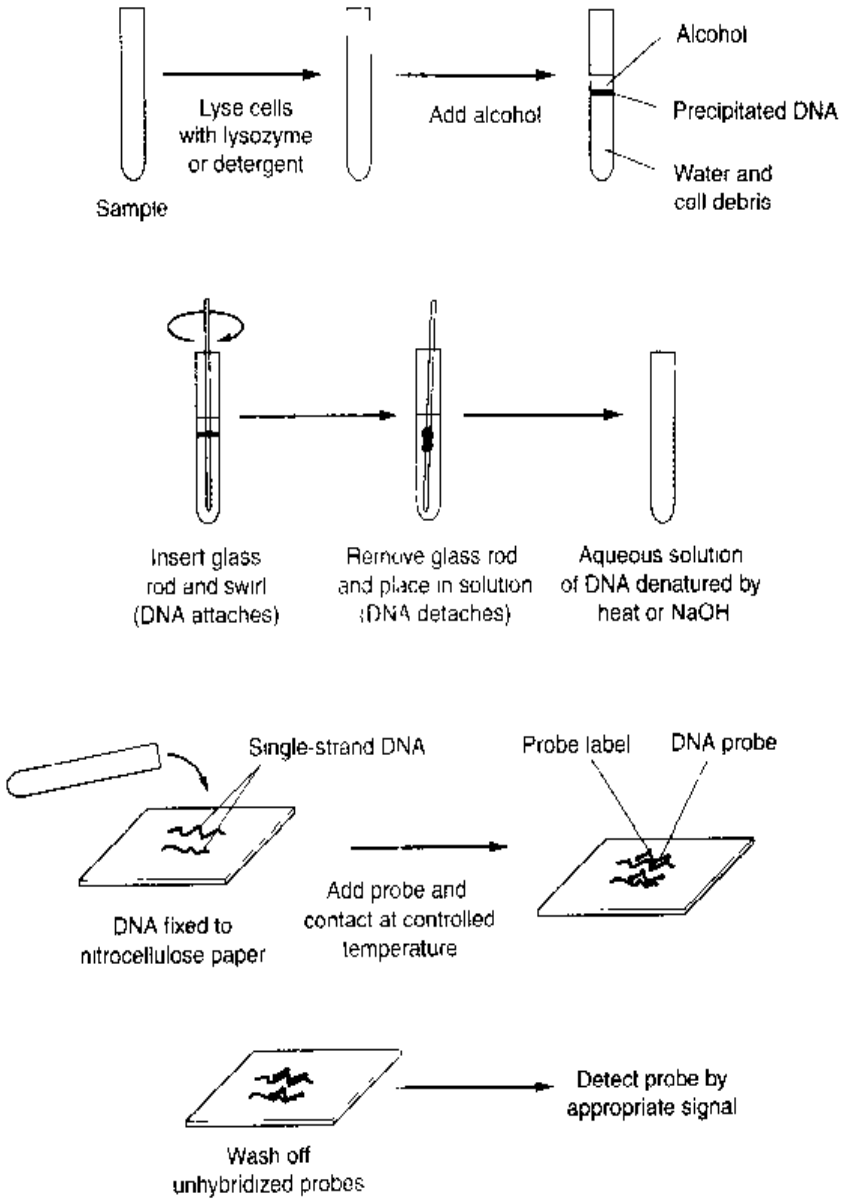
Phylogenetic tree of life. *(Adapted from Madigan et al., 2000.)*

ria. These differences are found in cell wall composition, cell membrane lipid chemistry, RNA polymerase composition, and protein synthesis mechanisms in the ribosome.



Use of Molecular Tools

Besides the ability to identify and classify specific bacteria, molecular tools can be used to provide information previously unavailable about active microbial communities, and to study water or wastewater treatment plant effluents for specific pathogenic organisms. Molecular techniques are evolving continuously as a result of the interest in microbial cell research. These techniques were introduced and described in Sec. 2–8 in Chap. 2. Two significant techniques involve the use of oligonucleotide probes and restrictive fragment length polymorphism (RFLP). An oligonucleotide or nucleic acid probe takes advantage of the fact that unique nucleic acid sequences exist in rRNA or in DNA for a particular microorganism. In RFLP, DNA is extracted from cells in a mixed microbial community and analyzed in a way that provides a genetic fingerprint of the community.

The oligonucleotide probe is constructed so that it will form a double-stranded nucleic acid by complementary base pairing with a single-strand nucleic acid representing the target genetic information in the microorganism. The number of base pairs may be as low as 15 to 18 to over 100. The complementary base pairing of two single-stranded nucleic acids is termed hybridization. The probe is labeled so that it can be detected by fluorescent or radioactive techniques. With the more common fluorescent techniques, the probe contains a reagent that produces a color product or fluorescence, which can be detected with x-ray film. Reagents used to tag the nucleic acid probe include digoxigenin, biotin, and fluorescein. Radioactive labeling of the probe is used less often and is done by using a radio-labeled substance such as ^{32}P, which is incorporated into the phosphate structure of the nucleotide. Autoradiography is used to detect the radio-labeled hybridized probe, which involves the use of a scintillation counter or photographic film. Probes can be used to analyze DNA or RNA extracted from cells or can be transferred to react with rRNA and fluoresce within the cell (see Fig. 7–8). The latter is referred to as fluorescence in situ hybridization (FISH) (Maier et al., 2000).

Figure 7–8

Dot blot technique to probe DNA genetic information.

Wagner et al. (1995) demonstrated the use of FISH to identify dense clusters (up to 3000 cells) of ammonia-oxidizing (*Nitrosomonas*) bacteria in several activated-sludge plant samples. The probe, termed the NEU probe, contained 18 nucleotides. A probe used for the study of *E. coli* developed to study UV disinfection was illustrated previously on Fig. 2–36 in Chap. 2. One of the distinct advantages of FISH is that the distribution of a species in its environment can be observed. Also, FISH techniques have been employed with more than one nucleic acid probe added to the sample. Using this technique, a number of bacterial species or strains can be identified and their relative distribution within the matrix can be observed.

In most applications RFLP is not used to identify a particular organism, but to characterize a microbial community. In RFLP, restriction enzymes are used to cut DNA extracted from the microbial cells into various fragments. Different organisms will yield different DNA fragment lengths and different nucleotide sequences within these fragments. From an analysis of the DNA fragments, it is possible to obtain information about the diversity of the microbial community, and the identification of a particular organism responsible for the type of microbial degradation observed.

Table 7–6
Classification of microorganisms by electron donor, electron acceptor, sources of cell carbon, and end products

Type of bacteria	Common reaction name	Carbon source	Electron donor (substrate oxidized)	Electron acceptor	Products
Aerobic heterotrophic	Aerobic oxidation	Organic compounds	Organic compounds	O_2	CO_2, H_2O
Aerobic autotrophic	Nitrification	CO_2	NH_3^-, NO_2^-	O_2	NO_2, NO_3
	Iron oxidation	CO_2	Fe (II)	O_2	Ferric Iron Fe (III)
	Sulfur oxidation	CO_2	H_2S, S^o, $S_2O_3^{2-}$	O_2	SO_4^{2-}
Facultative heterotrophic	Denitrification anoxic reaction	Organic compounds	Organic compounds	NO_2, NO_3^-	N_2, CO_2, H_2O
Anaerobic heterotrophic	Acid fermentation	Organic compounds	Organic compounds	Organic compounds	Volatile fatty acids (VFAs) (acetate, propionate, butyrate)
	Iron reduction	Organic compounds	Organic compounds	Fe (III)	Fe (II), CO_2, H_2O
	Sulfate reduction	Organic compounds	Organic compounds	SO_4	H_2S, CO_2, H_2O
	Methanogenesis	Organic compounds	Volatile fatty acids (VFAs)	CO_2	Methane

7–3 INTRODUCTION TO MICROBIAL METABOLISM

Basic to the design of a biological treatment process, or to the selection of the type of biological process to be used, is an understanding of the biochemical activities of microorganisms. The classification of microorganisms by sources of cell carbon, electron donor, electron acceptor, and end products is summarized in Table 7–6. Different microorganisms can use a wide range of electron acceptors, including oxygen, nitrite, nitrate, iron (III), sulfate, organic compounds, and carbon dioxide. Schematic representations of some common types of bacterial metabolism are given on Fig. 7–9 showing the energy production and cell carbon sources. The two major topics considered in this section are (1) the general nutritional requirements of the microorganisms commonly encountered in wastewater treatment, and (2) the nature of microbial metabolism based on the need for molecular oxygen.

Carbon and Energy Sources for Microbial Growth

To continue to reproduce and function properly, an organism must have sources of energy, carbon for the synthesis of new cellular material, and inorganic elements (nutrients) such as nitrogen, phosphorus, sulfur, potassium, calcium, and magnesium. Organic nutrients (growth factors) may also be required for cell synthesis. Carbon and

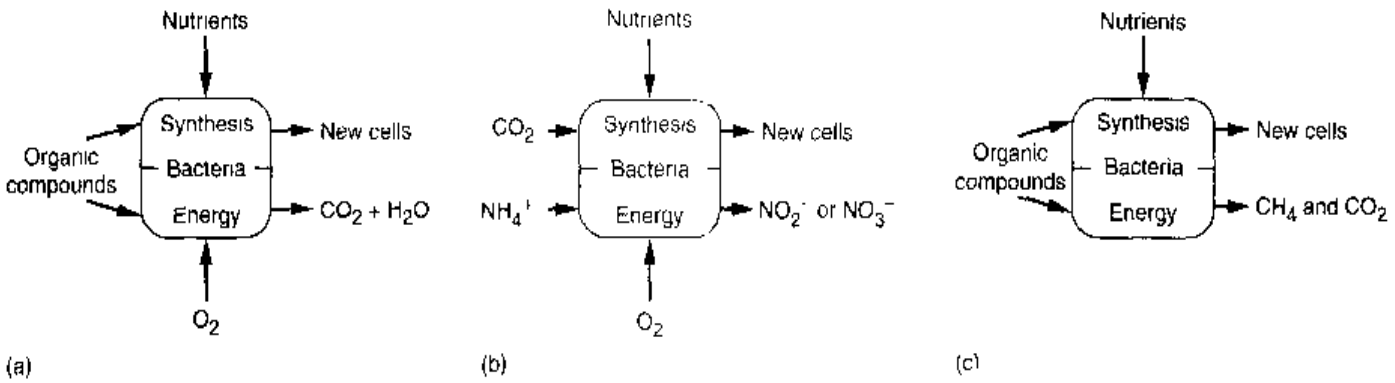


Figure 7–9

Examples of bacteria metabolism: (*a*) aerobic, heterotrophic (*b*) aerobic autotrophic, (*c*) anaerobic, heterotrophic

energy sources, usually referred to as *substrates*, and nutrient and growth factor requirements for various types of organisms are considered in the following discussion.

Carbon Sources. Microorganisms obtain their carbon for cell growth from either organic matter or carbon dioxide. Organisms that use organic carbon for the formation of new biomass are called *heterotrophs*, while organisms that derive cell carbon from carbon dioxide are called *autotrophs*. The conversion of carbon dioxide to cellular carbon compounds requires a reductive process, which requires a net input of energy. Autotrophic organisms must therefore spend more of their energy for synthesis than do heterotrophs, resulting in generally lower yields of cell mass and growth rates.

Energy Sources. The energy needed for cell synthesis may be supplied by light or by a chemical oxidation reaction. Bacteria can oxidize organic or inorganic compounds to gain energy. Those organisms that are able to use light as an energy source are called *phototrophs*. Phototrophic organisms may be either heterotrophic (certain sulfur-reducing bacteria) or autotrophic (algae and photosynthetic bacteria). Organisms that derive their energy from chemical reactions are known as *chemotrophs*. As with the phototrophs, chemotrophs may be either heterotrophic (protozoa, fungi, and most bacteria) or autotrophic (i.e., nitrifying bacteria). *Chemoautotrophs* obtain energy from the oxidation of reduced *inorganic* compounds, such as ammonia, nitrite, ferrous iron, and sulfide. *Chemoheterotrophs* usually derive their energy from the oxidation of *organic* compounds.

The energy-producing chemical reactions by chemotrophs are oxidation-reduction reactions that involve the transfer of electrons from an electron donor to an electron acceptor. The electron donor is oxidized and the electron acceptor is reduced. The electron donors and acceptors can be either organic or inorganic compounds, depending on the microorganism. The electron acceptor may be available within the cell during metabolism (endogenous) or it may be obtained from outside the cell (i.e., dissolved oxygen) (exogenous). Organisms that generate energy by enzyme-mediated electron transport to an *external* electron acceptor are said to have a *respiratory metabolism*. The use of an internal electron acceptor is termed *fermentative metabolism* and is a less efficient energy-yielding process than respiration. Heterotrophic organisms that are strictly fermentative are characterized by lower growth rates and cell yields than respiratory heterotrophs.

When oxygen is used for the electron acceptor the reaction is termed *aerobic*, and reactions involving other electron acceptors are considered anaerobic. The term *anoxic* is used to distinguish the use of nitrite or nitrate for electron acceptors from the others under anaerobic conditions. Under anoxic conditions nitrite or nitrate reduction to gaseous nitrogen occurs, and this reaction is also referred to as biological denitrification. Organisms that can only meet their energy needs with oxygen are called *obligate aerobic* microorganisms. Some bacteria can use oxygen or nitrate/nitrite as electron acceptors when oxygen is not available. These bacteria are called *facultative aerobic* bacteria.

Organisms that generate energy by fermentation and that can exist only in an environment that is devoid of oxygen are *obligate anaerobes*. *Facultative anaerobes* have the ability to grow in either the presence or absence of molecular oxygen and fall into two subgroups, based on their metabolic abilities. True facultative anaerobes can shift from fermentative to aerobic respiratory metabolism, depending upon the presence or absence of molecular oxygen. *Aerotolerant anaerobes* have a strictly fermentative metabolism but are relatively insensitive to the presence of molecular oxygen.

Nutrient and Growth Factor Requirements

Nutrients, rather than carbon or energy sources, may at times be the limiting material for microbial cell synthesis and growth. The principal inorganic nutrients needed by microorganisms are N, S, P, K, Mg, Ca, Fe, Na, and Cl. Minor nutrients of importance include Zn, Mn, Mo, Se, Co, Cu, and Ni (Madigan et al., 2000). Required organic nutrients, known as growth factors, are compounds needed by an organism as precursors or constituents of organic cell material, which cannot be synthesized from other carbon sources. Although growth factor requirements differ from one organism to another, the major growth factors fall into the following three classes: (1) amino acids, (2) nitrogen bases (i.e., purines and pyrimidines), and (3) vitamins.

For municipal wastewater treatment sufficient nutrients are generally present, but for industrial wastewaters nutrients may need to be added to the biological treatment processes. The lack of sufficient nitrogen and phosphorus is common especially in the treatment of food-processing wastewaters or wastewaters high in organic content. Using the formula $C_{12}H_{87}O_{23}N_{12}P$ (given previously) for the composition of cell biomass, about 12.2 g of nitrogen and 2.3 g of phosphorus are needed per 100 g of cell biomass.

7–4 BACTERIAL GROWTH AND ENERGETICS

In the description of microbial metabolism it was noted that as microorganisms consume substrate and carry out oxidation-reduction reactions, growth occurs by the production of additional cells. Thus, in wastewater treatment applications biomass is produced continuously as the substrate in the wastewater is consumed and biodegraded. Topics considered in this section include (1) bacterial reproduction, (2) bacterial growth patterns in a batch reactor, (3) bacterial growth and biomass yield, (4) methods used to measure biomass growth, (5) estimating cell yield and oxygen requirements from stoichiometry, (6) estimating cell yield from bioenergetics, and (7) observed versus synthesis yield. The material presented in this section will serve as a basis for the sections that follow and the material presented in Chaps. 8, 9, and 10.

Bacterial Reproduction

Bacteria can reproduce, as noted in Chap. 2, by binary fission, by asexual mode, or by budding. Generally, they reproduce by binary fission, in which the original cell becomes two new organisms. The time required for each division, which is termed the generation time, can vary from days to less than 20 min. For example, if the generation time is 30 min, one bacterium would yield 16,777,216 (i.e., 2^{24}) bacteria after a period of 12 h. Assuming spherical-shaped bacteria with a 1 μm diameter and specific gravity of 1.0, the weight of 1 cell is approximately 5.0×10^{-13} g. In 12 h the bacteria mass would be about 8.4×10^{6} g or 8.4 μg; thus the number of cells is quite large compared to the mass. This rapid change in biomass with time is a hypothetical example, for in biological treatment systems bacteria would not continue to divide indefinitely because of environmental limitations, such as substrate and nutrient availability.

Bacterial Growth Patterns in a Batch Reactor

Bacterial growth in a batch reactor is characterized by identifiable phases as illustrated on Fig. 7–10. The curves shown on Fig. 7–10 represent what occurs in a batch reactor in which, at time zero, substrate and nutrients are present in excess and only a very small population of biomass exists. As substrate is consumed, four distinct growth phases develop sequentially.

1. The lag phase. Upon addition of the biomass, the lag phase represents the time required for the organisms to acclimate to their new environment before significant cell division and biomass production occur. During the lag phase enzyme induction may be occurring and/or the cells may be acclimating to changes in salinity, pH, or temperature. The apparent extent of the lag phase may also be affected by the ability to measure the low biomass concentration during the initial batch phase.
2. The exponential-growth phase. During the exponential-growth phase, bacterial cells are multiplying at their maximum rate, as there is no limitation due to substrate or nutrients. The biomass growth curve increases exponentially during this period. With unlimited substrate and nutrients the only factor that affects the rate of exponential growth is temperature.

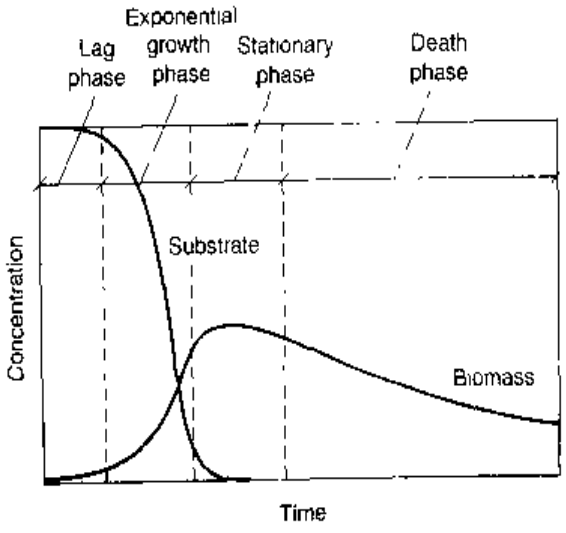

Figure 7–10
Batch process biomass growth phases with changes in substrate and biomass versus time.

3. The stationary phase. During this phase, the biomass concentration remains relatively constant with time. In this phase, bacterial growth is no longer exponential and the amount of growth is offset by the death of cells.
4. The death phase. In the death phase, the substrate has been depleted so that no growth is occurring, and the change in biomass concentration is due to cell death. An exponential decline in the biomass concentration is often observed as an approximate constant fraction of the biomass remaining that is lost each day.

Bacterial Growth and Biomass Yield

In biological treatment processes, cell growth occurs concurrent with the oxidation of organic or inorganic compounds, as described above. The ratio of the amount of biomass produced to the amount of substrate consumed (g biomass/g substrate) is defined as the *biomass yield*, and typically is defined relative to the electron donor used.

$$\text{Biomass yield } Y = \frac{\text{g biomass produced}}{\text{g substrate utilized (i.e., consumed)}} \tag{7-2}$$

For example, for aerobic heterotrophic reactions with organic substrates, the yield is expressed as g biomass/g organic substrate; for nitrification the yield is expressed as g biomass/g NH_4-N oxidized; and for the anaerobic degradation of volatile fatty acids (VFAs) to produce methane, the yield is expressed as g biomass/g VFAs used. Where specific compounds are measured and known such as ammonia, the yield is quantified relative to the amount of compound used. For aerobic or anaerobic treatment of municipal and industrial wastewater containing a large number of organic compounds, the yield is based on a measurable parameter reflecting the overall organic compound consumption, such as COD or BOD. Thus, the yield would be g biomass/g COD removed or g biomass/g BOD removed.

Measuring Biomass Growth

Because biomass is mostly organic material, an increase in biomass can be measured by volatile suspended solids (VSS) or particulate COD (total COD minus soluble COD). Other parameters that are used to indicate biomass growth are protein content, DNA, and ATP, a cellular compound involved in energy transfer. Of these growth measurement parameters, VSS is the parameter used most commonly to follow biomass growth in full-scale biological wastewater treatment systems because its measurement is simple and minimal time is required for analysis. It should be noted that the VSS measured includes other particulate organic matter in addition to biomass. Most wastewaters contain some amount of nonbiodegradable VSS and possibly influent VSS that may be slowly degraded in the biological reactor. These solids are included with biomass in the VSS measurement. Nevertheless the VSS measurement is used as an apparent indicator of biomass production and also provides a useful measurement of reactor solids in general.

For laboratory research on biological treatment processes, growth parameters that can be related to true microbial mass are often used. Of these, protein is the most popular growth parameter due to the relative ease of measurement and the fact that about 50 percent of biomass dry weight is protein. Both ATP and DNA have also been used, especially where the reactor solids contain proteins and other solids that are not associated with biomass. Where very low biomass concentrations are involved, turbidity

measurements may be used to provide a rapid and simple means of observing cell growth. Bacterial cell counts have also been used to enumerate the biomass population. A portion of a diluted sample is applied to an agar growth plate, and after incubation, the number of colonies formed are counted and used to determine the number of bacterial cells in the culture. It should be noted, however, that not all bacteria are culturable.

Estimating Biomass Yield and Oxygen Requirements from Stoichiometry

As given by Eq. (7–1), a definite stoichiometric relationship exists between the substrate removed, the amount of oxygen consumed during aerobic heterotrophic biodegradation, and the observed biomass yield. The most common approach used to define the fate of the substrate is to prepare a COD mass balance. The COD is used because the substrate concentration in the wastewater can be defined in terms of its oxygen equivalence, which can be accounted for by being conserved in the biomass or oxidized. In general, the exact stoichiometry involved in the biological oxidation of a mixture of wastewater compounds is never known. However, for the purpose of illustration, assume organic matter can be represented as $C_6H_{12}O_6$ (glucose) and new cells can be represented as $C_5H_7NO_2$ (Hoover and Porges, 1952). Thus, neglecting nutrients other than nitrogen, Eq. (7–1) can be written as

$$\underset{3(180)}{3C_6H_{12}O_6} + \underset{8(32)}{8O_2} + \underset{2(17)}{2NH_3} \rightarrow \underset{2(113)}{2C_5H_7NO_2} + 8CO_2 + 14H_2O \qquad (7\text{–}3)$$

As given by the above equation, the substrate used (glucose in this case) is divided between that found in new cells and that oxidized. The yield based on the glucose consumed can be obtained as follows:

$$Y = \frac{\Delta(C_5H_7NO_2)}{\Delta(C_6H_{12}O_6)} = \frac{2(113\text{ g/mole})}{3(180\text{ g/mole})}$$

$$= 0.42\text{ g cells/g glucose used}$$

In practice, COD and VSS are used to represent the organic matter and the new cells, respectively. To express the yield on a COD basis, the COD of glucose must be determined. The COD of glucose can be determined by writing a balanced stoichiometric reaction for the oxidation of glucose to carbon dioxide as follows:

$$\underset{(180)}{C_6H_{12}O_6} + \underset{6(32)}{6O_2} \rightarrow 6CO_2 + 6H_2O \qquad (7\text{–}4)$$

The COD of glucose is

$$\text{COD} = \frac{\Delta(O_2)}{\Delta(C_6H_{12}O_6)} = \frac{6(32\text{ g/mole})}{(180\text{ g/mole})} = 1.07\text{ g } O_2\text{/g glucose}$$

The theoretical yield expressed in terms of COD, accounting for the portion of the substrate converted to new cells, is

$$Y = \frac{\Delta(C_5H_7NO_2)}{\Delta(C_6H_{12}O_6\text{ as COD})} = \frac{2(113\text{ g/mole})}{3(180\text{ g/mole})(1.07\text{ g COD/g glucose})}$$

$$= 0.39\text{ g cells/g COD used}$$

It should be noted that the actual observed yield in a biological treatment process will be less than the value given above, because a portion of the substrate incorporated into the cell mass will be oxidized with time by the bacteria to obtain energy for cell maintenance.

The quantity of oxygen utilized can be accounted for by considering (1) the oxygen used for substrate oxidation to CO_2 and H_2O, (2) the COD of the biomass, and (3) the COD of any substrate not degraded. Based on the formula $C_5H_7NO_2$, the oxygen equivalent of the biomass (typically measured as VSS) is approximately 1.42 g COD/g biomass VSS, as given below.

$$\underset{(113)}{C_5H_7NO_2} + \underset{5(32)}{5O_2} \rightarrow 5CO_2 + NH_3 + 2H_2O \tag{7–5}$$

The COD of cell tissue is

$$\text{COD} = \frac{\Delta(O_2)}{\Delta(C_5H_7NO_2)} = \frac{5(32\text{ g/mole})}{(113\text{ g/mole})} = 1.42\text{ g } O_2/\text{g cells}$$

Based on the above relationships, the oxygen consumed per unit of COD utilized for the reaction given by Eq. (7–3) can be determined from a mass balance on COD as follows:

$$\text{COD utilized} = \text{COD cells} + \text{COD of oxidized substrate} \tag{7–6}$$

The COD of the oxidized substrate is equal to oxygen consumed; thus

$$\text{Oxygen consumed} = \text{COD utilized} - \text{COD cells} \tag{7–7}$$

$$= \left(\frac{1.07\text{ g } O_2}{\text{g glucose}}\right)\left(3\text{ mole} \times \frac{180\text{ g glucose}}{\text{mole}}\right) - \left(\frac{1.42\text{ g } O_2}{\text{g cells}}\right)\left(2\text{ moles} \times \frac{113\text{ g cells}}{\text{mole}}\right)$$

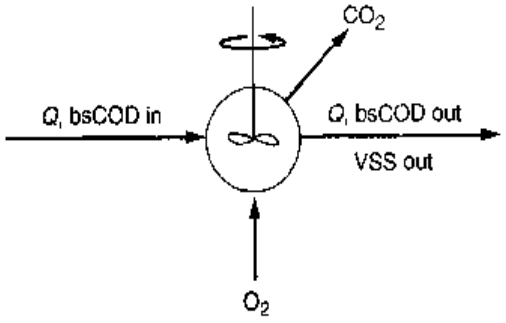
$$= 577.8\text{ g } O_2 - 320.9\text{ g } O_2 = 256.9\text{ g } O_2$$

Thus, the oxygen consumed per unit of COD used is

$$\frac{\text{Oxygen consumed}}{\text{Glucose as COD}} = \frac{256.9\text{ g } O_2}{3\text{ mole}\,(1.07\text{ g COD/g glucose})(180\text{ g glucose/mole})}$$

$$= 0.44\text{ g } O_2/\text{g COD used}$$

The amount of oxygen required based on the COD balance as given above is in agreement with the oxygen use based on the stoichiometry as defined by Eq. (7–3) in which 8 moles of oxygen are required for 3 moles of glucose.



$$\frac{\text{Oxygen used}}{\text{Glucose as COD}} = \frac{8(32\text{ g } O_2/\text{mole})}{3(180\text{ g/mole})\,(1.07\text{ g COD/g glucose})}$$

$$= 0.44\text{ g } O_2/\text{g COD used}$$

The relationship of the observed biomass yield to the oxygen consumed for substrate oxidation by aerobic heterotrophic biomass based on typical measurements made at wastewater-treatment plants is illustrated in Example 7–1.

EXAMPLE 7-1 Observed Biomass Yield and Oxygen Consumption The aerobic complete-mix biological treatment process without recycle, as shown below, receives wastewater with a biodegradable soluble COD (bsCOD) concentration of 500 g/m^3. The flowrate is 1000 m^3/d and the reactor effluent bsCOD and VSS concentrations are 10 and 200 g/m^3, respectively. Based on these data:

1. What is the observed yield in g VSS/g COD removed?
2. What is the amount of oxygen used in g O_2/g COD removed and in g/d?

Solution

1. Determine the observed yield. Assume the following general reaction is applicable:

$$\underset{500\text{ g COD/m}^3}{\text{Organic matter}} + O_2 + \text{nutrients} \rightarrow \underset{200\text{ g VSS/m}^3}{C_5H_7NO_2} + CO_2 + H_2O$$

   a. The g VSS/d produced is

$$\text{g VSS/d} = 200\text{ g/m}^3\ (1000\text{ m}^3\text{/d}) = 200{,}000\text{ g VSS/d}$$

   b. The g bsCOD/d removed is

$$\text{g COD /d} = (500 - 10)\text{ g COD/m}^3\ (1000\text{ m}^3\text{/d})$$
$$= 490{,}000\text{ g COD/d}$$

   c. The observed yield is

$$Y_{obs} = \frac{(200{,}000\text{ g VSS/d})}{(490{,}000\text{ g COD/d})} = 0.41\text{ g VSS/g COD removed}$$

2. Determine the amount of oxygen used per g bsCOD removed.
   a. Prepare a steady-state COD mass balance around the reactor.

$$\text{Accumulation} = \text{inflow} - \text{outflow} + \text{conversion}$$

$$0 = COD_{in} - COD_{out} - \text{oxygen used (expressed as COD)}$$

$$\text{Oxygen used} = COD_{in} - COD_{out}$$

$$COD_{in} = 500\text{ g COD/m}^3\ (1000\text{ m}^3\text{/d}) = 500{,}000\text{ g COD/d}$$

$$COD_{out} = bsCOD_{out} + \text{biomass } COD_{out}$$

$$bsCOD_{out} = 10\text{ g/m}^3\ (1000\text{ m}^3\text{/d}) = 10{,}000\text{ g COD/d}$$

Biomass COD_{out} = 200,000 g VSS/d (1.42 g COD/g VSS)

= 284,000 g COD/d

Total COD_{out} = 10,000 g/d + 284,000 g/d = 294,000 g COD/d

b. The oxygen used is

Oxygen used = 500,000 g COD/d − 294,000 g COD/d

− 206,000 g COD/d = 206,000 g O_2/d

c. Amount of oxygen used per unit COD removed is

Oxygen/COD = (206,000 g/d)/(490,000 g/d) = 0.42 g O_2/g COD

Comment *Note:* The general COD balance that accounts for cell production and COD oxidation is:

g COD cells + g COD oxidized = g COD removed

(0.41 g VSS/g COD)(1.42 g O_2/g VSS) + 0.42 g O_2/g COD = 1.0 g O_2/g COD

Estimating Biomass Yield from Bioenergetics

Most cell yield values are based on measurements from laboratory reactors, pilot plants, or full-scale systems. However, an approach that has been developed to estimate cell yield, based on bioenergetics, involves the application of thermodynamic principles to biological reactions. An introduction to bioenergetics and the application of bioenergetics to estimate the biomass yield for different types of biological reactions is provided in this section (McCarty 1971, 1975).

Chemical reactions, which involve changes in energy, can be described thermodynamically by a change in the free energy $G°$, known as the *Gibbs free energy.* The change in energy due to the reaction is termed $\Delta G°$. The superscript is used to indicate that the free energy values were obtained at standard conditions of pH = 7.0 and 25°C. The net Gibbs free energy, positive or negative, can be evaluated for reactants and products based on standard free energy values available for the half reactions. Half reactions describe the transfer of 1 mole of electron in oxidation-reduction and synthesis reactions. Free energy changes for various half reactions are listed in Table 7–7. Reactions that result in a negative change in the free energy release energy are called *exergonic* reactions. These reactions will proceed spontaneously in the direction shown. However, if the free energy change results in a positive value, the reaction is termed *endergonic,* and such a reaction will not occur spontaneously. Reactions with positive free energy values require energy to proceed in the direction indicated.

The basis of the analysis of free energy changes for reactions is that in oxidation reduction reactions one compound loses electrons (electron donor) and the other compound gains electrons (electron acceptor) (see discussion in Sec. 6–6 in Chap. 6). Half reactions that show the moles of compound used as an electron acceptor and electron donor per mole of electron (e^-) transferred along with the change in free energy are

Table 7-7
Half reactions for biological systems[a]

Reaction number	Half reaction	ΔG^o (W),[b] kJ per electron equivalent
	Reactions for bacterial cell synthesis (R_{cs})	
	Ammonia as nitrogen source:	
1.	$\frac{1}{5}CO_2 + \frac{1}{20}HCO_3^- + \frac{1}{20}NH_4^+ + H^+ + e^- = \frac{1}{20}C_5H_7O_2N + \frac{9}{20}H_2O$	
	Nitrate as nitrogen source:	
2.	$\frac{1}{28}NO_3^- + \frac{5}{28}CO_2 + \frac{29}{28}H^+ + e^- = \frac{1}{28}C_5H_7O_2N + \frac{11}{28}H_2O$

[b] Reactants and products at unit activity except $[H^+] = 10^{-7}$

used to develop energy balances in bioenergetic analyses. Determination of the free energy change resulting from the oxidation of hydrogen by oxygen is illustrated in Example 7–2.

EXAMPLE 7–2 Free Energy Change from Hydrogen Oxidation by Molecular Oxygen
Determine the free energy change resulting from the oxidation of hydrogen by molecular oxygen.

Solution

1. Identify the electron donor and acceptor
   Electron donor: hydrogen
   Electron acceptor: oxygen
2. Determine the change in free energy. From Table 7–7, the free energy change values for the half reactions are:

		G°, kJ/mole e^-
No. 28	$H_2 \rightarrow 2H^+ + 2e^-$	−40.46
No. 4	$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O$	−78.14
Overall	$H_2 + \frac{1}{2}O_2 \rightarrow H_2O$	$\Delta G = -118.60$

Because the ΔG value is negative for this oxidation reduction reaction, energy is released and the overall reaction will proceed as written.

Exergonic reactions are catalyzed by enzymes within the microbial cell, making energy available to support cell growth. Only a portion (40 to 80 percent) of the energy produced is captured by the bacteria, while the rest escapes as heat. McCarty (1971) assumed 60 percent energy capture efficiency, but the exact amount varies. The energy that is not captured or released can result in an elevated temperature in the surrounding liquid, where high biomass concentrations exist and high reaction rates are occurring. An example is autothermal aerobic digestion in which liquid temperatures are increased from 20°C to as high as 60°C due to biological oxidation and energy release. The volatile solids concentration in autothermal aerobic digesters may be in the range of 20 to 40 g/L.

The key steps in bioenergetics analysis are to (1) identify the electron donor (substrate oxidized) and electron acceptor, (2) determine the energy produced from the bacteria oxidation reduction reaction, (3) determine the amount of energy needed for converting the growth carbon source into cell matter, and (4) calculate the cell yield based on a balance between energy produced and energy needed for cell yield. The energy production step was illustrated above for oxidation of hydrogen with oxygen as the electron acceptor.

The amount of energy required for cell synthesis depends on the specific carbon and nitrogen compounds used for growth. The bioenergetics analysis discussed here is for heterotrophic bacteria. A different procedure is used for the case of autotrophic bac-

teria, and additional details can be found in McCarty (1971, 1975) and Rittman and McCarty (2001). For heterotrophic bacteria, many carbon sources may be used for growth with different energetic effects. The analysis assumes pyruvate as an intermediate organic compound in cell synthesis, and energy will be either produced or consumed depending on the free energy of the organic compound relative to pyruvate. Pyruvate was selected by McCarty (1971) because it is at the end of the glycolysis pathway and just ahead of the Kreb cycle. When CO_2 is used for the carbon source, as for autotrophic bacteria, a considerable amount of energy is needed to incorporate CO_2 into cell mass. If nitrogen is not available in the form of ammonia, additional energy is needed to convert the nitrogen source to ammonia. The energy required for cell synthesis is estimated as follows, with pyruvate as the organic intermediate for cellular carbon constituents:

$$\Delta G_s = \frac{\Delta G_P}{Km} - \Delta G_C + \frac{\Delta G_N}{K} \tag{7–8}$$

where ΔG_s = free energy to convert 1 electron equivalent (e^- eq) of the carbon source to cell material
ΔG_P = free energy to convert 1 e^- eq of the carbon source to the pyruvate intermediate
K = fraction of energy transfer captured
m = +1 if ΔG_P is positive and −1 if energy is produced
ΔG_C = free energy to convert 1 e^- eq of pyruvate intermediate to 1 e^- eq of cells
ΔG_N = free energy per e^- eq of cells to reduce nitrogen to ammonia

The value for ΔG_c is −31.41 kJ/e^- eq of cells (McCarty, 1971) and the ΔG_N for the following nitrogen sources are +17.46, +13.61, +15.85, and 0.00 kJ/e^- eq of cells for NO_3^-, NO_2^-, N_2, and NH_4^+, respectively. The value for ΔG_P is estimated by using the free energy half reactions to convert the carbon source to the pyruvate intermediate.

The electron donor used for heterotrophic reactions is divided between portions oxidized to produce energy or used in cell synthesis. The energy balance relative to the substrate used is illustrated in the following equation in which the energy made available (on the left side of the equation) equals the energy used for cell growth (right side of the equation).

$$K\Delta G_R\left(\frac{f_e}{f_s}\right) = -\Delta G_s \tag{7–9}$$

$$f_e + f_s = 1.0 \tag{7–10}$$

where K = fraction of energy captured
ΔG_R = energy released from oxidation reduction reactions, kJ/mole e^- transferred
f_e = e^- mole of substrate oxidized per e^- mole of substrate used
f_s = e^- mole of substrate used for cell synthesis per e^- mole of substrate used
ΔG_S = energy used for cell growth, kJ/mole e^- transfer for cell growth

Equations (7–9) and (7–10) are used with half reactions and their free energy values to estimate cell yield by solving for f_e and f_s. The terms f_e and f_s represent the fraction of substrate oxidized or used in cell synthesis, respectively. The substrate is

expressed as COD because a mole of COD contains a set quantity of electron moles of oxygen transfer. Thus, the values for f_e and f_s can also be expressed as COD fractions. The oxidation of acetate by heterotrophic bacteria with different acceptors is used in Example 7–3 to illustrate the bioenergetics analysis.

EXAMPLE 7–3 Estimate Biomass Yield Using Energetics Compare the cell yield in g cells as COD/g COD used and g cells as VSS/g COD used for acetate utilization by heterotrophic bacteria with oxygen and then carbon dioxide as the electron acceptor, and ammonia as the nitrogen source. Assume 60 percent energy capture efficiency.

Solution Part A—Oxygen as the Electron Acceptor

1. Solve for the energy produced and captured ($K\Delta G_R$) using reaction No. 18 for acetate oxidation and reaction No. 4 for oxygen reduction from Table 7–7.

		kJ/mole e⁻
No. 18	$\frac{1}{8}CH_3COO^- + \frac{3}{8}H_2O \rightarrow \frac{1}{8}CO_2 + \frac{1}{8}HCO_3^- + H^+ + e$	−27.68
No. 4	$\frac{1}{4}O_2 + H^+ + e^- \rightarrow \frac{1}{2}H_2O$	−78.14
	$\frac{1}{8}CH_3COO^- + \frac{1}{4}O_2 \rightarrow \frac{1}{8}CO_2 + \frac{1}{8}HCO_3^- + \frac{1}{8}H_2O$	$\Delta G_R = -105.82$

Energy captured by cell:

$K(\Delta G_R) = 0.60(-105.82) = -63.42$ kJ/mole e⁻

2. Solve for the energy needed per electron mole of cell growth (ΔG_S).

$\Delta G_C = 31.41$ kJ/mole e⁻ cells

$\Delta G_N = 0$

ΔG_P [acetate (reaction No. 18) to pyruvate (reaction No. 15)]

		ΔG kJ/mole e⁻
No. 18	$\frac{1}{8}CH_3COO^- + \frac{3}{8}H_2O \rightarrow \frac{1}{8}CO_2 + \frac{1}{8}HCO_3^- + e^-$	−27.66
No. 15	$\frac{1}{5}CO_2 + \frac{1}{10}HCO_3^- + H^+ + e^- \rightarrow \frac{1}{10}CH_3COCOO^- + \frac{2}{5}H_2O$	+35.78
	$\frac{1}{8}CH_3COO^- + \frac{3}{40}CO_2 \rightarrow \frac{1}{10}CH_3COCOO^- + \frac{1}{40}HCO_3^- + \frac{1}{40}H_2O$	$\Delta G_P = +8.12$

Because ΔG_P is positive, energy is required and $m = +1$

$$\Delta G_S = \left[\frac{8.12}{(0.6)(1.0)} + 31.41 + 0\right] = 44.94 \text{ kJ/mole e}^-$$

3. Determine f_e and f_s using Eq. (7–9).

$$\frac{f_e}{f_s} = \frac{-\Delta G_S}{K\Delta G_R} = \frac{-44.94 \text{ kJ/mole e}^-}{-63.42 \text{ kJ/mole e}^-}$$

$$\frac{f_e}{f_s} = 0.707$$

$$f_e + f_s = 1.0$$

Solve for f_e and f_s:

$$f_e = 0.41$$

$$f_s = 0.59 \frac{\text{g cell COD}}{\text{g COD used}}$$

4. Determine the yield based on COD.

   For biomass ($C_5H_7NO_2$), 1 g cells = 1.42 g COD

   Thus, the yield is

$$Y = \frac{(0.59 \text{ g COD/g COD})}{(1.42 \text{ g COD/g VSS})} = 0.42 \text{ gVSS/g COD}$$

5. Determine the yield based on BOD assuming a conversion factor of 1.6 g COD/g BOD (see discussion in Sec. 8–2 in Chap. 8).

   Thus, the yield is

$$Y = \frac{(0.42 \text{ g VSS/g COD})}{(\text{g BOD}/1.6 \text{ g COD})} = 0.67 \text{ g VSS/g BOD}$$

Solution Part B—Carbon Dioxide as the Electron Acceptor

1. Solve for energy produced and captured ($K\Delta G_R$) using reaction No. 18 for acetate oxidation and reaction No. 8 for CO_2 reduction to methane from Table 7–7.

		ΔG kJ/mole e
No. 18	$\frac{1}{8}CH_3COO^- + \frac{3}{8}H_2O \rightarrow \frac{1}{8}CO_2 + \frac{1}{8}HCO_3^- + H^+ + e^-$	−27.66
No. 8	$\frac{1}{8}CO_2 + H^+ + e^- \rightarrow \frac{1}{8}CH_4 + \frac{1}{8}HCO_3^-$	+24.11
	$\frac{1}{8}CH_3COO^- + \frac{3}{8}HO_2 \rightarrow \frac{1}{8}CH_4 + \frac{1}{4}HCO_3^-$	$\Delta G_R = -3.57$

   Energy captured by cell:

$$(K\Delta G_R) = 0.60\ (-3.57) = 2.142 \text{ kJ/mole e}^-$$

2. Solve for the energy needed per electron mole at cell growth ΔG_S.

$$\Delta G_C = 31.41 \text{ kJ/mole e}^- \text{ cells}$$

$$\Delta G_N = 0$$

$$\Delta G_P \text{ (same as for acetate/O}_2\text{)}$$

$$\Delta G_S = 44.94 \text{ kJ/mole e}^-$$

3. Determine the values of f_e and f_s using Eq. (7–9).

$$\frac{f_e}{f_s} = \frac{-\Delta G_S}{K\Delta G_R} = \frac{-44.94}{-2.142} = 21.0$$

$$f_e + f_s = 1.0$$

Solve for f_e and f_s.

$f_e = 0.954$ $f_s = 0.046$ g cell COD/g COD used

4. Determine the yield based on COD

$$Y = \frac{(0.046 \text{ g cell COD/g COD used})}{(1.42 \text{ g COD/g VSS})} = 0.032 \text{ g VSS/g COD}$$

5. Compare yields for acetate oxidation.

Electron acceptor	Yield, g VSS/g COD	Product
O_2	0.42	CO_2, H_2O
CO_2	0.032	CH_4

Comment Based on bioenergetics calculations, estimated yield values for anaerobic reactions using carbon dioxide as the electron acceptor are much lower as compared to oxygen. The lower yield values are due to the much lower energy production with carbon dioxide as the electron acceptor in lieu of oxygen. The cell synthesis yield values calculated for these electron acceptors are very similar to yield values reported in the literature.

Stoichiometry of Biological Reactions

With the values determined for f_e and f_s, the stoichiometry of the biological reactions can be described according to the following relationship (McCarty, 1971, 1975):

$$R = f_e R_a + f_s R_{cs} - R_d \qquad (7\text{–}11)$$

where R = overall balanced reaction
f_e = fraction of electron donor used for energy
R_a = half reaction for electron acceptor
f_s = fraction of electron donor used for cell synthesis
R_{cs} = half reaction for synthesis of cell tissue
R_d = half reaction for electron donor
$f_s + f_e = 1$

The minus sign in Eq. (7–11) means that the electron donor equation given in Table 7–7 must be reversed and then added to the other two equations. In the first equation given in Table 7–7, the term $C_5H_7O_2N$ (Hoover and Porges, 1952), is used to represent bacterial cell tissue. Application of Eq. (7–11) is illustrated in Example 7–4.

EXAMPLE 7–4 Write a Balanced Reaction for the Biological Oxidation of Acetate Using Oxygen Using Eq. (7–11) and the half reactions given in Table 7–7, write a balanced reaction for the biological oxidation of acetate with oxygen. Use the values for f_e and f_s determined in Example 7-3, Part A ($f_e = 0.41$ and $f_s = 0.59$). The COD of acetate is 1.07 g COD/g acetate, computed as illustrated in Eq. (7–4).

Solution

1. Develop the balanced stoichiometric reaction for the oxidation of acetate.

$$R = f_e R_a + f_s R_{cs} - R_d$$

$$R = 0.41\ (\text{No. 4}) + 0.59\ (\text{No. 1}) - \text{No. 18}$$

$$(0.41)\,(\text{No. 4}) = 0.103O_2 + 0.41H^+ + 0.4e^- \rightarrow 0.205H_2O$$

$$(0.59)(\text{No. 1}) = 0.118CO_2 + 0.0295HCO_3^- + 0.0295NH_4^+ + 0.59H^+ + 0.59e^- \rightarrow 0.0295C_5H_7O_2N + 0.2655H_2O$$

$$-\text{No. 18} = \quad 0.125CH_3COO^- + 0.375H_2O \rightarrow 0.125CO_2 + 0.125HCO_3^- + H^+ + e^-$$

$$R = \quad 0.125CH_3COO^- + 0.0295NH_4^+ + 0.103O_2 \rightarrow 0.0295C_5H_7O_2N + 0.0955H_2O + 0.095HCO_3^- + 0.007CO_2$$

2. Determine the cell yield from the stoichiometry.
   a. Cells produced from oxidation of acetate

   Cells produced = 0.0295 moles (113 g VSS/mole) = 3.334 g VSS

   b. Acetate utilized for cell production

   Acetate used = 0.125 mole acetate (60 g/mole)(1.07 g COD/g acetate)
   = 8.03 g COD

   c. Determine the cell yield.

$$Y = \frac{3.334\ \text{g VSS}}{8.03\ \text{g COD}} = 0.42\ \text{g VSS/g COD}$$

The results are the same as in Example 7–3.

Biomass Synthesis Yields for Different Growth Conditions

In Example 7–3, it was demonstrated that the biomass synthesis yield is related to the energy produced by the electron transfer from the electron donor (acetate) to the electron acceptor (oxygen). From a review of the half reaction ΔG° values in Table 7–7, it can be seen that the energy production that occurs from the oxidation reduction reactions is reduced as the electron acceptor is changed from oxygen to nitrate to sulfate and to carbon dioxide. Accordingly, a lower cell yield would be predicted theoretically. Observed cell synthesis yields have been in accordance with predicted values using the half reactions given in Table 7–7. Typical synthesis yield coefficients are given in Table 7–8 for common electron donors and acceptors in wastewater treatment.

Table 7-8
Typical bacteria synthesis yield coefficients for common biological reactions in wastewater treatment

Growth Condition	Electron donor	Electron acceptor	Synthesis yield
Aerobic	Organic compound	Oxygen	0.40 g VSS/g COD
Aerobic	Ammonia	Oxygen	0.12 g VSS/g NH_4-N
Anoxic	Organic compound	Nitrate	0.30 g VSS/g COD
Anaerobic	Organic compound	Organic compound	0.06 g VSS/g COD
Anaerobic	Acetate	Carbon dioxide	0.05 g VSS/g COD

Observed versus Synthesis Yield

In the evaluation and modeling of biological treatment systems a distinction is made between the *observed yield* and the *synthesis yield* (or *true yield*). The observed biomass yield is based on the actual measurements of biomass production and substrate consumption and is actually less than the synthesis yield, because of cell loss (Sec. 7–6) concurrent with cell growth. In full-scale wastewater treatment processes the term *solids production* (or *solids yield*) is also used to describe the amount of VSS generated in the treatment process. The term is different from the synthesis biomass yield values because it contains other organic solids from the wastewater that are measured as VSS, but are not biological.

The synthesis yield is the amount of biomass produced immediately upon consumption of the growth substrate or oxidation of the electron donor in the case of autotrophic bacteria. The synthesis yield is seldom measured directly and is often interpreted from evaluating biomass production data for reactors operating under different conditions. Synthesis yield values for bacterial growth are affected by the energy that can be derived from the oxidation reduction reaction, by the growth characteristics of the carbon source, by the nitrogen source, and by environmental factors such as temperature, pH, and osmotic pressure. As illustrated in this section, the synthesis yield can be estimated if the stoichiometry or the amount of energy produced in the oxidation reduction reaction is known.

7–5 MICROBIAL GROWTH KINETICS

The performance of biological processes used for wastewater treatment depends on the dynamics of substrate utilization and microbial growth. Effective design and operation of such systems requires an understanding of the biological reactions occurring and an understanding of the basic principles governing the growth of microorganisms. Further, the need to understand all of the environmental conditions that affect the substrate utilization and microbial growth rate cannot be overemphasized, and it may be necessary to control such conditions as pH and nutrients to provide effective treatment. The purpose of this section is to present an introduction to microbial growth kinetics. The topics considered in this section include (1) microbial growth kinetics terminology, (2) rate of utilization of soluble substrate, (3) other rate expressions for the utilization of soluble substrate, (4) rate of soluble substrate production from biodegradable particulate organic matter, (5) the rate of biomass growth with soluble substrates, (6) kinetic coefficients for substrate utilization and biomass growth, (7) the rate of oxygen uptake,

(8) effects of temperature, (9) total volatile suspended solids and active biomass, and (10) net biomass and observed yield.

Microbial Growth Kinetics Terminology

The kinetics of microbial growth govern the oxidation (i.e., utilization) of substrate and the production of biomass, which contributes to the total suspended solids concentration in a biological reactor. Common terms used to describe the transformations that occur in substrate oxidation and biomass growth as well as in biological treatment processes are presented in Table 7–1. Because municipal and industrial wastewaters contain numerous substrates, the concentration of organic compounds is defined, most commonly, by the *biodegradable COD* (bCOD) or UBOD, both of which are comprised of soluble (dissolved), colloidal, and particulate biodegradable components. Both bCOD and UBOD represent measurable quantities that apply to all of the compounds. In the formulation of kinetic expressions in this chapter *biodegradable soluble COD* (bsCOD) will be used to quantify the fate of biodegradable organic compounds because it easily relates to the stoichiometry of substrate oxidized or used in cell growth [see Eq. (7–7)]. It should be noted that in Sec. 8.2 in Chap. 8, bsCOD is fractionated further into readily and slowly biodegradable components.

The biomass solids in a bioreactor are commonly measured as *total suspended solids* (TSS) and *volatile suspended solids* (VSS). The mixture of solids resulting from combining recycled sludge with influent wastewater in the bioreactor is termed *mixed liquor suspended solids* (MLSS) and *mixed liquor volatile suspended solids* (MLVSS). The solids are comprised of biomass, *nonbiodegradable volatile suspended solids* (nbVSS), and *inert inorganic total suspended solids* (iTSS). The nbVSS is derived from the influent wastewater and is also produced as cell debris from endogenous respiration. The iTSS originates in the influent wastewater. Additional wastewater characterization terminology is considered in Sec. 8–2 in Chap. 8.

Rate of Utilization of Soluble Substrates

In the introduction to this chapter, it was noted that one of the principal concerns in wastewater treatment is the removal of substrate. Stated another way, the goal in biological wastewater treatment is, in most cases, to deplete the electron donor (i.e., organic compounds in aerobic oxidation). For heterotrophic bacteria the electron donors are the organic substances being degraded; for autotrophic nitrifying bacteria it is ammonia or nitrite or other reduced inorganic compounds. The substrate utilization rate in biological systems can be modeled with the following expression for soluble substrates. Because the mass of substrate is decreasing with time due to substrate utilization and Eq. (7–12) is used in substrate mass balances, a negative value is shown.

$$r_{su} = -\frac{kXS}{K_s + S} \tag{7–12}$$

where r_{su} = rate of substrate concentration change due to utilization, g/m^3·d
k = maximum specific substrate utilization rate, g substrate/g microorganisms·d
X = biomass (microorganism) concentration, g/m^3
S = growth-limiting substrate concentration in solution, g/m^3

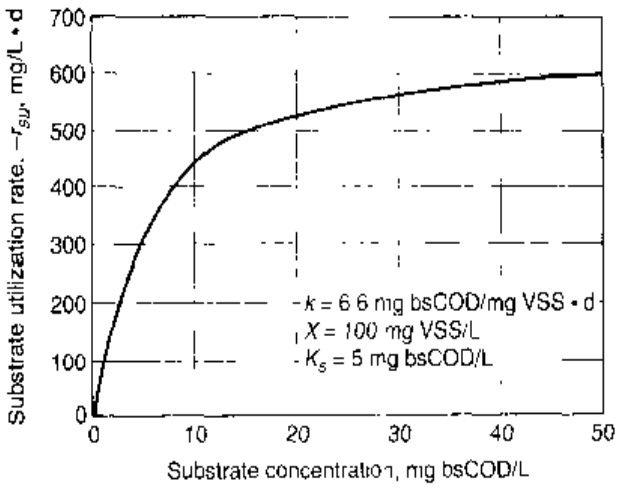

Figure 7–11
Rate of change of substrate utilization versus biodegradable soluble COD concentration based on the saturation-type model [see Eq. (7–12)].

K_s = half-velocity constant, substrate concentration at one-half the maximum specific substrate utilization rate, g/m^3

Equation (7–12) will be recognized as a saturation-type equation, as described previously in Chap. 4. For substrate removal, Eq. (7–12) has been referred to as the Michaelis-Menten equation (Bailey and Ollis, 1986). Equation (7–12) is also of the form proposed by Monod for the specific growth rate of bacteria in which the limiting substrate is available to the microorganisms in a dissolved form (Monod, 1942, 1949). A plot of r_{su} as a utilization rate versus the substrate concentration is shown on Fig. 7–11. As shown on Fig. 7- 11, the maximum substrate utilization rate occurs at high substrate concentrations. Further, as the substrate concentration decreases below some critical value, the value of $-r_{su}$ also decreases almost linearly. In practice, biological treatment systems are designed to produce an effluent with extremely low substrate values.

When the substrate is being used at its maximum rate, the bacteria are also growing at their maximum rate. The maximum specific growth rate of the bacteria is thus related to the maximum specific substrate utilization rate as follows.

$$\mu_m = kY \tag{7-13}$$

and

$$k = \frac{\mu_m}{Y} \tag{7-14}$$

where μ_m = maximum specific bacterial growth rate, g new cells/g cells·d
k = maximum specific substrate utilization rate, g/g·d
Y = true yield coefficient, g/g (defined earlier)

Using the definition for the maximum specific substrate utilization rate given by Eq. (7–12), the substrate utilization rate is also reported in the literature as

$$r_{su} = -\frac{\mu_m XS}{Y(K_s + S)} \tag{7-15}$$

Other Rate Expressions for the Utilization of Soluble Substrate

In reviewing kinetic expressions used to describe substrate utilization and biomass growth rates, it is very important to remember that the expressions used to model bio-

logical processes are all empirical, based on experimentally determined coefficient values. Besides the substrate limited relationship presented above, other expressions that have been used to describe substrate utilization rates include the following:

$$r_{su} = -k \tag{7-16}$$

$$r_{su} = -kS \tag{7-17}$$

$$r_{su} = -kXS \tag{7-18}$$

$$r_{su} = -kX\frac{S}{S_o} \tag{7-19}$$

The particular rate expression used to define kinetics of substrate utilization depends mainly on the experimental data available to fit the kinetic equations and the application of the kinetic model. In some cases, the first-order model shown by Eq. (7–18) is satisfactory for describing substrate utilization rates when the biological treatment process will be operated at relatively low substrate concentrations. Fundamental in the use of any rate expression is its application in a mass-balance analysis to be discussed in the following section. Also with regard to modeling biological treatment processes, kinetic models should not be applied outside of the range of the conditions used to develop model coefficients.

Rate of Soluble Substrate Production from Biodegradable Particulate Organic Matter

The rate expressions for substrate utilization and biomass growth presented thus far are based on the utilization of soluble substrates. In municipal wastewater treatment only about 20 to 50 percent of the degradable organic material enters as soluble compounds, and for some industrial wastewaters the soluble organic material may be a low to moderate fraction of the total degradable organic substrates. Bacteria cannot consume the particulate substrates directly and employ extracellular enzymes to hydrolyze the particulate organics to soluble substrates, which can be used according to the rate expressions described above. The particulate substrate conversion rate is also a rate-limiting process that is dependent on the particulate substrate and biomass concentrations. A rate expression for particulate substrate conversion is shown as follows (Grady et al., 1999):

$$r_{sc,P} = -\frac{k_P(P/X)X}{(K_X + P/X)} \tag{7-20}$$

where $r_{sc,P}$ = rate of change of particulate substrate concentration due to conversion to soluble substrate, g/m^3·d
k_P = maximum specific particulate conversion rate, g P/g X·d
P = particulate substrate concentration, g/m^3
X = biomass concentration, g/m^3
K_X = half-velocity degradation coefficient, g/g

The particulate degradation concentration is expressed relative to the biomass concentration, because the particulate hydrolysis is related to the relative contact area between the nonsoluble organic material and the biomass. The effect of particulate organic constituents is considered further in Chap. 8.

Rate of Biomass Growth with Soluble Substrates

In Sec. 7–4, the biomass growth rate was shown to be proportional to the substrate utilization rate by the synthesis yield coefficient, and biomass decay was shown to be proportional to the biomass present. Thus, the following relationship between the rate of growth and the rate of substrate utilization is applicable in both batch and continuous culture systems.

$$r_g = -Yr_{su} - k_d X \tag{7-21}$$

$$= Y\frac{kXS}{K_s + S} - k_d X \tag{7-22}$$

where r_g = net biomass production rate, g VSS/m^3·d
Y = synthesis yield coefficient, g VSS/g bsCOD
k_d = endogenous decay coefficient, g VSS/g VSS·d
Other terms are as defined above.

If both sides of Eq. (7–22) are divided by the biomass concentration X, the specific growth rate is defined as follows:

$$\mu = \frac{r_g}{X} = Y\frac{kS}{K_s + S} - k_d \tag{7-23}$$

where μ = specific biomass growth rate, g VSS/g VSS·d

As shown, the specific growth rate corresponds to the change in biomass per day relative to the amount of biomass present, and is a function of the substrate concentration and the endogenous decay coefficient.

The endogenous decay coefficient accounts for the loss in cell mass due to oxidation of internal storage products for energy for cell maintenance, cell death, and predation by organisms higher in the food chain. It should be noted that microorganisms in all growth phases require energy for cell maintenance; however, it appears that the decay coefficient most probably changes with cell age. Usually, these factors are lumped together, and it is assumed that the decrease in cell mass caused by them is proportional to the concentration of organisms present. The decrease in mass is often identified in the literature as the *endogenous decay*. In Eq. (7–21) the coefficient k_d is the *endogenous decay* rate coefficient. An alternative approach used to describe the endogenous decay known as a *lysis-regrowth* model is described in Sec. 8–10 in Chap. 8.

In biological treatment processes, both the substrate utilization and biomass growth rates are controlled by some limiting substrate, as given by Eqs. (7–15) and (7–22). The growth limiting substrate can be any of the essential requirements for cell growth (i.e., electron donor, electron acceptor, or nutrients), but often it is the electron donor that is limiting, as other requirements are usually available in excess. Thus, when the term substrate is used to describe growth kinetics, it generally refers to the electron donor.

Kinetic Coefficients for Substrate Utilization and Biomass Growth

The coefficient values (k, K_s, Y, and k_d) used to predict the rate of substrate utilization and biomass growth can vary as a function of the wastewater source, microbial population, and temperature. Kinetic coefficient values are determined from bench-scale testing or full-scale plant test results. For municipal and industrial wastewater the coeffi-

Table 7-9
Typical kinetic coefficients for the activated-sludge process for the removal of organic matter from domestic wastewater

Coefficient	Unit	Value[a]	
		Range	Typical
k	g bsCOD/g VSS·d	2–10	5
K_s	mg/L BOD	25–100	60
	mg/L bsCOD	10–60	40
Y	mg VSS/mg BOD	0.4–0.8	0.6
	mg VSS/mg bsCOD	0.3–0.6	0.4
k_d	g VSS/g VSS·d	0.06–0.15	0.10

[a] Values reported are for 20°C.

cient values represent the net effect of microbial kinetics on the simultaneous degradation of a variety of different wastewater constituents. Typical kinetic coefficient values are reported in Table 7–9 for the aerobic oxidation of BOD in domestic wastewater. Additional kinetic coefficient values are given in Chaps. 8, 9, and 10.

Rate of Oxygen Uptake

The rate of oxygen uptake is related stoichiometrically to the organic utilization rate and growth rate (see Sec. 7–4). Thus, the oxygen uptake rate can be defined as

$$r_o = -r_{su} - 1.42r_g \tag{7-24}$$

where r_o = oxygen uptake rate, g $O_2/m^3 \cdot d$
r_{su} = rate of substrate utilization, g bsCOD/$m^3 \cdot d$
1.42 = the COD of cell tissue, g bsCOD/g VSS
r_g = rate of biomass growth, g VSS/$m^3 \cdot d$

A negative sign is required in front of the term r_{su} in Eq. (7–24), because the rate of substrate utilization as given by Eq. (7–12) is negative (i.e., the substrate concentration decreases with time). The factor 1.42 represents the COD of cell tissue as defined previously by Eq. (7–5).

Effects of Temperature

The temperature dependence of the biological reaction-rate constants is very important in assessing the overall efficiency of a biological treatment process. Temperature not only influences the metabolic activities of the microbial population but also has a profound effect on such factors as gas-transfer rates and the settling characteristics of the biological solids. The effect of temperature on the reaction rate of a biological process is expressed using the same type of relationship developed previously in Chap. 2 [see Eq. (2–25)] and repeated here for ease of reference.

$$k_T = k_{20}\theta^{(T-20)} \tag{2-25}$$

where k_T = reaction-rate coefficient at temperature T, °C
k_{20} = reaction-rate coefficient at 20°C
θ = temperature-activity coefficient
T = temperature, °C

Values for θ in biological systems can vary from 1.02 to 1.25. Temperature correction factors for various kinetic coefficients are given in Chap. 8.

Total Volatile Suspended Solids and Active Biomass

The kinetic expressions used to describe biological kinetics and growth are related to the active biomass concentration X in the treatment reactor. In reality the VSS in a reactor consists of more than active biomass, and the fraction of active biomass can vary depending on the wastewater characteristics and operating conditions. The other components that contribute to the VSS concentration are cell debris, following endogenous decay, and nonbiodegradable VSS (nbVSS) in the influent wastewater fed to the biological reactor.

During cell death, cell lysis occurs with the release of cellular materials into the liquid for consumption by other bacteria. A portion of the cell mass (cell wall) is not dissolved and remains as nonbiodegradable particulate matter in the system. The remaining nonbiodegradable material is referred to as cell debris and represents about 10 to 15 percent of the original cell weight. Cell debris is also measured as VSS and contributes to the total VSS concentration measured in the reactor mixed liquor. The rate of production of cell debris is directly proportional to the endogenous decay rate.

$$r_{Xd} = f_d(k_d)X \tag{7-25}$$

where r_{Xd} = rate of cell debris production, g VSS/m^3·d
f_d = fraction of biomass that remains as cell debris, 0.10 − 0.15 g VSS/g VSS

The nbVSS concentration resulting from cell debris is typically a relatively small fraction of the VSS in a bioreactor used to treat municipal and some industrial wastewaters. As noted above, a variable amount of MLVSS that is not biomass originates from the nbVSS in the influent wastewater. For typical untreated municipal wastewaters the nbVSS concentration may be in the range from 60 to 100 mg/L, and following primary treatment may range from 10 to 40 mg/L.

Total Volatile Suspended Solids. The VSS production rate in the aeration tank can be defined as the sum of the biomass production given by Eq. (7–21), the nbVSS production given by Eq. (7–25), and the nbVSS in the influent:

$$r_{X_T,\text{VSS}} = \underbrace{-Yr_{su}}_{\substack{\text{net nbVSS}\\ \text{from soluble}\\ \text{bCOD}}} \underbrace{- k_d X}_{\substack{\text{nbVSS}\\ \text{from cells}}} \underbrace{+ f_d(k_d)X}_{\substack{\text{nbVSS}\\ \text{in influent}}} + \frac{Q X_{o,i}}{V} \tag{7-26}$$

where $r_{X_T,\text{VSS}}$ = total VSS production rate, g/m^3·d
Q = influent flowrate, m^3/d
$X_{o,i}$ = influent nbVSS concentration, g/m^3
V = volume of reactor, m^3

Other terms are as defined previously.

Active Biomass. From Eq. (7–26), the fraction of active biomass in the mixed-liquor VSS (MLVSS) is the ratio of the sum of the growth and decay term divided by the total MLVSS production:

$$F_{X,\text{act}} = (-Yr_{su} - k_d X)/r_{X_T,\text{VSS}} \tag{7-27}$$

where $F_{X,\text{act}}$ = active fraction of biomass in MLVSS, g/g

Net Biomass Yield and Observed Yield

The term true yield was defined in Sec. 7–4 as the amount of biomass produced during cell synthesis relative to the amount of substrate degraded. In the design and analysis of biological treatment processes, two other yield terms are important: (1) the *net biomass yield* and (2) the *observed solids yield*. The first is used as an estimate of the amount of active microorganisms in the system, and the second as the amount of sludge production.

Net Biomass Yield. The net biomass yield is the ratio of the net biomass growth rate to the substrate utilization rate:

$$Y_{bio} = -r_g/r_{su} \tag{7–28}$$

where Y_{bio} = net biomass yield, g biomass/g substrate used

Observed Yield. The observed yield accounts for the actual solids production that would be measured for the system and is shown as follows:

$$Y_{obs} = -r_{X_T,VSS}/r_{su} \tag{7–29}$$

where Y_{obs} = observed yield, g VSS produced/g substrate removed

EXAMPLE 7–5 Determine Biomass and Solids Yields For an industrial wastewater activated-sludge process, the amount of bsCOD in the influent wastewater is 300 g/m^3 and the influent nbVSS concentration is 50 g/m^3. The influent flowrate is 1000 m^3/d, the biomass concentration is 2000 g/m^3, the reactor bsCOD concentration is 15 g/m^3, and the reactor volume is 105 m^3. If the cell debris fraction f_d is 0.10, determine the net biomass yield, the observed solids yield, and the biomass fraction in the MLVSS. Use the kinetic coefficients given in Table 7–9.

Solution

1. Determine the net biomass yield using Eq. (7–28).

$$Y_{bio} = -r_g/r_{su}$$

a. Solve for r_{su} using Eq. (7–12) and the information given in Table 7–9.

$$r_{su} = -\frac{kXS}{K_S + S}$$

$$= -\frac{(5/\text{d})(2000\ \text{g/m}^3)(15\ \text{g bsCOD/m}^3)}{(40 + 15)\ \text{g/m}^3}$$

$$= -2727\ \text{g bsCOD/m}^3\cdot\text{d}$$

b. Determine the net biomass production rate r_g using Eq. (7–21).

$$r_g = -Yr_{su} - k_dX$$

$$= -(0.40\ \text{g VSS/g bsCOD})(-2727\ \text{g bsCOD/m}^3\cdot\text{d})$$

$$-(0.10\ \text{g VSS/g VSS}\cdot\text{d})(2000\ \text{g VSS/m}^3)$$

$$= 891\ \text{g VSS/m}^3\cdot\text{d}$$

c. Calculate the net biomass yield.

$$Y_{bio} = -r_g/r_{su} = (891 \text{ g VSS/m}^3\cdot\text{d})/(2727 \text{ g bsCOD/m}^3\cdot\text{d})$$
$$= 0.33 \text{ g VSS/g bsCOD}$$

2. Determine VSS production rate using Eq. (7–26).

$$r_{X_n,VSS} = -Yr_{su} - k_dX + f_d(k_d)X + QX_{o,i}/V$$
$$= 891 \text{ g VSS/m}^3\cdot\text{d}$$
$$+(0.10 \text{ g VSS/g VSS})(0.10 \text{ g VSS/g VSS}\cdot\text{d})(2000 \text{ g VSS/m}^3)$$
$$+ (1000 \text{ m}^3/\text{d})(50 \text{ g VSS/m}^3)/105 \text{ m}^3$$
$$= (891 + 20 - 476) \text{ g VSS/m}^3\cdot\text{d}$$
$$= 1387 \text{ g VSS/m}^3\cdot\text{d}$$

3. Calculate the observed solids yield using Eq. (7–29).

$$Y_{obs} = -r_{X_n,VSS}/r_{su}$$
$$= -(1387 \text{ g VSS/m}^3\cdot\text{d})/(-2727 \text{ g bsCOD/m}^3\cdot\text{d})$$
$$= 0.51 \text{ g VSS/g bsCOD}$$

4. Calculate the active biomass fraction in the MLVSS. Using Eq. (7–27),

$$F_{X,act} = (-Yr_{su} - k_dX)/r_{X_n,VSS}$$
$$= (891 \text{ g VSS/m}^3\cdot\text{d})/(1387 \text{ g VSS/m}^3\cdot\text{d})$$
$$= 0.64$$

Comment Thus, accounting for the nbVSS in the wastewater influent and cell debris produced, the MLVSS contains 64 percent active biomass.

7–6 MODELING SUSPENDED GROWTH TREATMENT PROCESSES

Before discussing the individual biological processes used for the treatment of wastewater as given in Secs. 7–8 through 7–14, the general application of the kinetics of biological growth and substrate removal will be explained. The purpose here is to illustrate (1) the development of biomass and substrate balances, (2) the prediction of effluent biomass and soluble substrate concentrations, (3) the prediction of the reactor biomass and MLSS/MLVSS concentrations and amount of waste sludge produced daily, and (4) the prediction of the oxygen requirements. Attached growth processes are considered in Sec. 7–7.

Description of Suspended Growth Treatment Processes

The complete-mix reactor with recycle will be considered in the following discussion as a model for suspended growth processes. The schematic flow diagrams shown on Fig. 7–12 include the nomenclature used in the following mass-balance equations. A similar complete-mix reactor may be used in laboratory studies to assess wastewater treatability and to obtain model kinetic coefficients.

All biological treatment reactor designs are based on using mass balances across a defined volume for each specific constituent of interest (i.e., biomass, substrate, etc.). The mass balance includes the flowrates for the mass of the constituent entering and/or leaving the system and appropriate reaction rate terms for the depletion or production of the constituent within the system. The units for a mass balance are usually given in mass per volume per time. For all mass balances a check of the units is recommended to assure that the mass-balance equations are correct.

Biomass Mass Balance

A mass balance for the mass of microorganisms in the complete-mix reactor shown on Fig. 7-12*a* can be written as follows: As discussed in Chap. 4, the sign of the generation or formation term [net growth in Eq. (7–30)] is always positive. The actual sign for the process is always part of the rate expression. For example, if the rate expression is $r = -kC$, the generation term is negative and a decrease will occur; similarly if $r = +kC$ the generation term is positive and an increase will occur.

1. General word statement:

Rate of accumulation of microorganism within the system boundary	=	rate of flow of microorganism into the system boundary	−	rate of flow of microorganism out of the system boundary	+	net growth of microorganism within the boundary	(7–30)

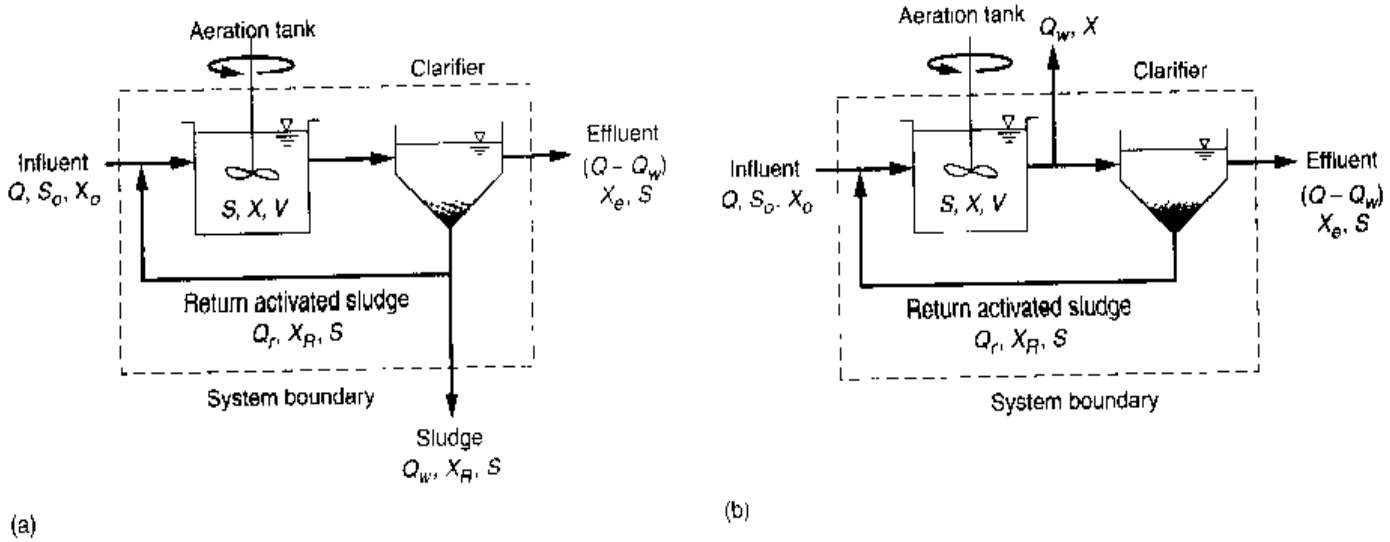

Figure 7–12

Schematic diagram of activated-sludge process with model nomenclature: (*a*) with wasting from the sludge return line and (*b*) with wasting from the aeration tank.

2. Simplified word statement:

$$\text{Accumulation} = \text{inflow} - \text{outflow} + \text{net growth} \tag{7–31}$$

3. Symbolic representation:

$$\frac{dX}{dt}V = QX_o - [(Q - Q_w)X_e - Q_w X_R] + r_g V \tag{7–32}$$

where dX/dt = rate of change of biomass concentration in reactor measured as g VSS/m^3·d
V = reactor volume (i.e., aeration tank), m^3
Q = influent flowrate, m^3/d
X_o = concentration of biomass in influent, g VSS/m^3
Q_w = waste sludge flowrate, m^3/d
X_e = concentration of biomass in effluent, g VSS/m^3
X_R = concentration of biomass in return line from clarifier, g VSS/m^3
r_g = net rate of biomass production, g VSS/m^3·d

If it is assumed that the concentration of microorganisms in the influent can be neglected and that steady-state conditions prevail ($dX/dt = 0$), Eq. (7–32) can be simplified to yield

$$(Q - Q_w)X_e + Q_w X_R = r_g V \tag{7–33}$$

If Eq. (7–33) is combined with Eq. (7–21), the result is

$$\frac{(Q - Q_w)X_e + Q_w X_R}{VX} = -Y\frac{r_{su}}{X} - k_d \tag{7–34}$$

where X = concentration of the biomass in the reactor, g/m^3

The inverse of the term on the left-hand side of Eq. (7–34) is defined as the average *solids retention time* (SRT) as given below.

$$\text{SRT} = \frac{VX}{(Q - Q_w)X_e + Q_w X_R} \tag{7–35}$$

Note that the numerator in Eq. (7–35) represents the total mass of solids in the aeration tank and the denominator corresponds to the amount of solids lost per day in the effluent and by intentional wasting (Q_w). By definition the SRT is the solids in the system divided by the mass of solids removed per day. Using the above definition of SRT, Eq. (7–34) can be written as

$$\frac{1}{\text{SRT}} = -Y\frac{r_{su}}{X} - k_d \tag{7–36}$$

The term 1/SRT is also related to μ, the specific biomass growth rate, as given by Eq. (7–37):

$$\frac{1}{\text{SRT}} = \mu \tag{7–37}$$

Equation (7–37) is derived from Eq. (7–36) by dividing by X and substituting r_g from Eq. (7–21) for the right-hand side of the equation, and using the definition for μ given in Eq. (7–23).

Thus, for a complete-mix activated-sludge process, the SRT (which can be controlled by solids wasting) is the inverse of the average specific rate that relates to the process biokinetics.

In Eq. (7–36) the term $(-r_{su}/X)$ is known as the *specific substrate utilization rate* U. The specific substrate utilization rate U is calculated as follows:

$$U = \frac{r_{su}}{X} = \frac{Q(S_o - S)}{VX} = \frac{S_o - S}{\tau X} \tag{7-38}$$

where U = specific substrate utilization rate, g BOD or COD/g VSS·d
Q = wastewater flowrate, m³/d
S_o = influent soluble substrate concentration, g BOD or bsCOD/m³
S = effluent soluble substrate concentration, g BOD or bsCOD/m³
V = volume of aeration tank, m³
X = biomass concentration, g/m³
τ = hydraulic detention time, V/Q, d
Other terms as defined above.

Substituting Eq. (7–12) into Eq (7–36) yields

$$\frac{1}{\text{SRT}} = \frac{YkS}{K_s + S} - k_d \tag{7-39}$$

The solids retention time (SRT) is an important design and operating parameter for the activated-sludge process. The SRT is the average time the activated-sludge solids are in the system. Assuming that the solids inventory in the clarifier shown on Fig. 7–12*a* is negligible compared to that in the aeration tank, the SRT is determined by dividing the mass of solids in the aeration tank by the solids removed daily via the effluent and by wasting for process control. For many activated-sludge processes, where good flocculation occurs and the clarifier is designed properly, the effluent VSS is typically less than 15 g/m³. Where the effluent VSS is low, excess solids must be removed from the system by wasting. Wasting is accomplished most commonly by removing biomass (sludge) from the clarifier underflow recycle line as shown on Fig. 7–12*a*. Alternatively, wasting can be accomplished from the aeration tank as shown on Fig. 7–12*b*.

Solving Eq. (7–39) for the effluent dissolved substrate concentration S yields

$$S = \frac{K_s[1 + (k_d)\text{SRT}]}{\text{SRT}(Yk - k_d) - 1} \tag{7-40}$$

It should be noted that in Eq. (7–40), the effluent soluble substrate concentration for a complete-mix activated-sludge process is only a function of the SRT and kinetic coefficients for growth and decay. The effluent substrate concentration is not related to the influent soluble substrate concentration, but as will be shown in other mass balances, the influent concentration affects the biomass concentration.

Substrate Mass Balance

The mass balance for substrate utilization in the aeration tank (see Fig. 7–12*a*) is

Accumulation = inflow − outflow − generation

$$\frac{dS}{dt}V = QS_o - QS + r_{su}V \tag{7–41}$$

where S_o = influent soluble substrate concentration, g/m^3

Substituting the value for r_{su} [Eq. (7–12)] and assuming steady-state conditions ($dS/dt = 0$), Eq. (7–41) can be rewritten as

$$S_o - S = \left(\frac{V}{Q}\right)\left(\frac{kXS}{K_s + S}\right) \tag{7–42}$$

The volume of the aeration tank divided by the influent flowrate is τ, the hydraulic retention time.

If Eq. (7–39) is solved for the term $S/(K_s + S)$ and substituted into Eq. (7–42), the following expression is obtained for the biomass concentration in the aeration tank:

$$X = \left(\frac{\text{SRT}}{\tau}\right)\left[\frac{Y(S_o - S)}{1 + (k_d)\text{SRT}}\right] \tag{7–43}$$

As given by Eq. (7–43), the reactor biomass concentration is a function of the system SRT, the aerobic aeration tank τ, the synthesis yield coefficient, the amount of substrate removed ($S_o - S$), and the endogenous decay coefficient.

The same equations can be applied to describe an activated-sludge process with no clarifier and thus no return sludge flow. For the case with no return sludge, all of the solids produced are present in the effluent from the aeration tank and the SRT equals the τ.

$$\text{SRT} = VX/QX = \tau \tag{7–44}$$

The importance of the system SRT in determining the effluent soluble substrate concentration and aeration tank biomass concentration is clear from an examination of Eqs. (7–40) and (7–43). As indicated by the waste sludge flow term (Q_w) in Eq. (7–35), a selected SRT value can be maintained by the amount of solids wasted per day to control the process performance. Similarly, it can be shown that by wasting from the aeration tank, the SRT can be controlled by wasting a given percentage of the aeration tank volume each day.

Mixed Liquor Solids Concentration and Solids Production

The solids production from a biological reactor represents the mass of material that must be removed each day to maintain the process. It is of interest to quantify the solids production in terms of TSS, VSS, and biomass. By definition, the SRT also provides a convenient expression to calculate the total sludge produced daily from the activated-sludge process:

$$P_{X_T\text{VSS}} = \frac{X_T V}{\text{SRT}} \tag{7–45}$$

where $P_{X_T,VSS}$ = total solids wasted daily, g VSS/d
X_T = total MLVSS concentration in aeration tank, g VSS/m^3
V = volume of reactor, m^3
SRT = solids retention time, d

Because the 1/SRT in Eq. (7–45) represents the fraction of solids wasted per day and the mixed liquor can be assumed to be a homogeneous mixture of biomass and other solids, Eq. (7–45) can be used to calculate the amount of solids wasted for any of the mixed liquor components. For the amount of biomass wasted per day (P_X), the biomass concentration X can be used in place of X_T in Eq. (7–45).

Mixed Liquor Solids Concentration. The total MLVSS in the aeration tank equals the biomass concentration X plus the nbVSS concentration X_i:

$$X_T = X + X_i \tag{7-46}$$

A mass balance is needed to determine the nbVSS concentration in addition to the active biomass VSS concentration. The MLVSS nbVSS concentration is affected by the amount of nbVSS in the influent wastewater, the amount of nbVSS wasted per day, and the amount of cell debris produced from cell decay. A materials balance on the inert material is as follows:

Accumulation = inflow − outflow + generation

$$(dX_i/dt)V = QX_{o,i} - X_iV/\text{SRT} + r_{X,i}V \tag{7-47}$$

where $X_{o,i}$ = nbVSS concentration in influent, g/m^3
X_i = nbVSS concentration in aeration tank, g/m^3
$r_{X,i}$ = rate of nbVSS production from cell debris, g/m^3·d

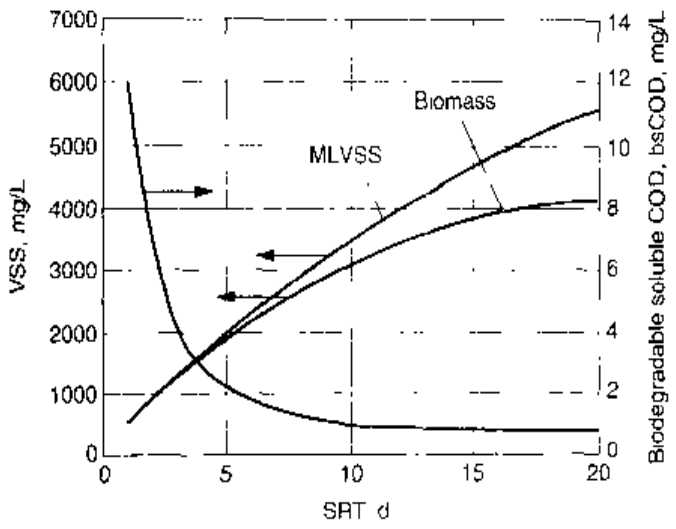
At steady-state ($dX_i/dt = 0$) and substituting Eq. (7–25) for $r_{X,i}$ in Eq. (7–47) yields

$$0 = QX_{o,i} - X_iV/\text{SRT} + (f_d)(k_d)XV \tag{7-48}$$

$$X_i = X_{o,i}(\text{SRT})/\tau + (f_d)(k_d)X(\text{SRT}) \tag{7-49}$$

Combining Eq. (7–43) and Eq. (7–49) for X and X_i produces the following equation that can be used to determine the total MLVSS concentration:

$$X_T = \left(\frac{\text{SRT}}{\tau}\right)\left[\frac{Y(S_o - S)}{1 + (k_d)\text{SRT}}\right] + (f_d)(k_d)(X)\text{SRT} + \frac{(X_{o,i})\text{SRT}}{\tau} \tag{7-50}$$



(A) Heterotrophic biomass (B) Cell debris (C) Nonbiodegradable VSS in influent

Solids Production. By substituting Eq. (7–50) for X_T in Eq. (7–45) and replacing τ with V/Q, the amount of VSS produced and wasted daily is determined as follows:

$$P_{X,VSS} = \frac{QY(S_o - S)}{1 + (k_d)\text{SRT}} + f_d(k_d)X(V) + QX_{o,i} \tag{7-51}$$

Figure 7-13

Biodegradable soluble COD, biomass, and MLVSS concentrations versus SRT for complete-mix activated-sludge process.

Equation (7–43) is substituted for the biomass concentration (X) in Eq. (7–51) to show the daily VSS production rate in terms of the substrate removed, influent nbVSS, and kinetic coefficients as follows:

$$P_{X,VSS} = \underbrace{\frac{QY(S_o - S)}{1 + (k_d)\text{SRT}}}_{(A)\ \text{Heterotrophic biomass}} + \underbrace{\frac{(f_d)(k_d)YQ(S_o - S)\text{SRT}}{1 + (k_d)\text{SRT}}}_{(B)\ \text{Cell debris}} + \underbrace{Q\,X_{no}}_{(C)\ \text{Nonbiodegradable VSS in influent}} \qquad (7\text{–}52)$$

The effect of SRT on the performance of an activated-sludge system for soluble substrate removal is illustrated on Fig. 7–13. In addition to the soluble substrate concentration, the total VSS concentration which includes nbVSS is also shown. As the SRT increases, more biomass decays and thus more cell debris accumulates, so that the difference between MLVSS and biomass VSS concentration increases with SRT. Also illustrated on Fig. 7–13 is the fact that the soluble substrate concentration is very low (<5 mg/L) at SRTs above 2 d. The low substrate concentration is typical of the activated-sludge process when used for the treatment of municipal wastewaters, and illustrates how effectively the organic compounds are degraded in the activated-sludge process. As will be shown in Chap. 8, organic substrate degradation is usually not the major factor in selecting a design SRT value.

The total mass of dry solids wasted per day is based on the TSS, which includes the VSS plus inorganic solids. Inorganic solids are in the influent wastewater (TSS − VSS) and the biomass contains 10 to 15 percent inorganic solids by dry weight. The influent inorganic solids are not soluble, and are assumed captured in the mixed liquor solids and removed in the wasted solids. Equation (7–52) is modified to calculate the solids production in terms of TSS by adding the influent inorganic solids and by calculating the biomass in terms of TSS by assuming a typical biomass VSS/TSS ratio of 0.85. The ratio of VSS/TSS may vary from 0.80 to 0.90.

$$P_{X,TSS} = \frac{A}{0.85} + \frac{B}{0.85} + C + Q(\text{TSS}_o - \text{VSS}_o) \qquad (7\text{–}53)$$

where $P_{X,TSS}$ = net waste activated sludge produced each day, measured in terms of total suspended solids, kg/d
TSS_o = influent wastewater TSS concentration, g/m^3
VSS_o = influent wastewater VSS concentration, g/m^3

The mass of MLVSS and MLSS can be obtained by using Eqs. (7–52) and (7–53), respectively, with Eq. (7–45) as follows:

$$\text{Mass of MLVSS} = (X_{VSS})(V) = (P_{X,VSS})\,\text{SRT} \tag{7–54}$$

$$\text{Mass of MLSS} = (X_{TSS})(V) = (P_{X,TSS})\,\text{SRT} \tag{7–55}$$

By selecting an appropriate MLSS concentration, the aeration volume can be determined from Eq. (7–55). MLSS concentrations in the range of 2000 to 4000 mg/L may be selected, and must be compatible with the sludge settling characteristics and clarifier design as discussed in Sec. 8–7 in Chap. 8.

The Observed Yield

The observed yield Y_{obs} is based on the amount of solids production measured relative to the substrate removal, and may be calculated in terms of g TSS/g bsCOD or g BOD, or relative to VSS as g VSS/g bsCOD or g BOD. The measured solids production is the sum of the solids in the system effluent flow and the solids intentionally wasted, which equals the term P_X defined in Eqs. (7–45), (7–52), and (7–53). The observed yield for VSS can be calculated by dividing Eq. (7–52) by the substrate removal rate, which is $Q(S_o - S)$:

$$Y_{obs} = \underbrace{\frac{Y}{1 + (k_d)\text{SRT}}}_{(A)\ \text{Heterotrophic biomass}} + \underbrace{\frac{(f_d)(k_d)(Y)\text{SRT}}{1 + (k_d)\text{SRT}}}_{(B)\ \text{Cell debris}} + \underbrace{\frac{X_{o,i}}{S_o - S}}_{(C)\ \text{Nonbiodegradable VSS in influent}} \tag{7–56}$$

where Y_{obs} = g VSS/g substrate removed

For wastewaters with no nbVSS in the influent the solids production consists of only active biomass and cell debris, and the observed yield for VSS is as follows:

$$Y_{obs} = \frac{Y}{1 + (k_d)\text{SRT}} + \frac{(f_d)(k_d)(Y)\text{SRT}}{1 + (k_d)\text{SRT}} \tag{7–57}$$

The impact of nonbiodegradable influent VSS in Eq. (7–56) on the observed yield depends on the wastewater characteristics and the type of pretreatment. The effluent substrate concentration is generally very low compared to S_o and the term $X_{o,i}/(S_o - S)$ can be approximated by $X_{o,i}/S_o$, which is the g nbVSS/g influent substrate. For municipal wastewater $X_{o,i}/S_o$ values range from 0.10 to 0.30 g/g with primary treatment and 0.30 to 0.50 without primary treatment.

Oxygen Requirements

The oxygen required for the biodegradation of carbonaceous material is determined from a mass balance using the bCOD concentration of the wastewater treated and the amount of biomass wasted from the system per day. If all of the bCOD were oxidized

to CO_2 and H_2O, the oxygen demand would equal the bCOD concentration, but bacteria only oxidize a portion of the bCOD to provide energy and use a portion of the bCOD for cell growth. Oxygen is also consumed for endogenous respiration, and the amount will depend on the system SRT. For a given SRT, a mass balance on the system can be done where the bCOD removal equals the oxygen used plus the biomass VSS remaining (in terms of an oxygen equivalent), as was shown by Eq. (7–7). Thus, for a suspended growth process, the oxygen used is

$$\text{Oxygen used} = \text{bCOD removed} - \text{COD of waste sludge} \tag{7-58}$$

$$R_o = Q(S_o - S) - 1.42\,P_{X,bio} \tag{7-59}$$

where R_o = oxygen required, kg/d
$P_{X,bio}$ = biomass as VSS wasted per day, kg/d

It is important to note that $P_{X,bio}$ includes active biomass and cell debris derived from cell growth and is thus the sum of terms A and B in Eq. (7–52).

EXAMPLE 7–6 Design of a Complete-Mix Suspended Growth Process A complete-mix activated-sludge system with recycle is used to treat municipal wastewater after primary sedimentation. The characteristics of the primary effluent are: flow = 1000 m^3/d, bsCOD = 192 g/m^3, nbVSS = 30 g/m^3, and inert inorganics = 10 g/m^3. The aeration tank MLVSS = 2500 g/m^3. Using these data and the kinetic coefficients given below, design a system with a 6-d SRT and determine the following:

1. What is the effluent bsCOD concentration?
2. What value of τ should be used so that the MLVSS concentration is 2500 g/m^3?
3. What is the daily sludge production in kg/d as VSS and TSS?
4. What is the fraction of biomass in the MLVSS?
5. What is the observed solids yield in g VSS/g bsCOD and g TSS/g bsCOD?
6. What is the oxygen requirement in kg/d?

Kinetic coefficients:

k = 12.5 g COD/g VSS·d	K_s = 10 g COD/m^3
Y = 0.40 g VSS/g COD used	f_d = 0.15 g VSS/g VSS
k_d = 0.10 g VSS/g VSS·d	Biomass VSS/TSS = 0.85

Solution

1. Determine the effluent bsCOD concentration using Eq. (7–40).

$$S = \frac{K_s[1 + (k_d)\,\text{SRT}]}{\text{SRT}(Yk - k_d) - 1}$$

$$= \frac{(10\ \text{g bsCOD/m}^3)[1 + (0.10\ \text{g VSS/g VSS·d})(6\ \text{d})]}{(6\ \text{d})[(0.40\ \text{g VSS/g COD})(12.5\ \text{g COD/g VSS·d}) - (0.10\ \text{g VSS/g VSS·d})] - 1}$$

$$= 0.56\ \text{g bsCOD/m}^3$$

2. Determine τ for 2500 g/m^3 MLVSS concentration.

Solve for τ in Eq. (7–50).

$$X_T = Y(S_o - S)\text{SRT}/[1 + (k_d)\text{SRT}](\tau) + (f_d)(k_d)(X)\text{SRT} + (X_{o,i})\text{SRT}/\tau$$

$$2500 \text{ g VSS/m}^3 = (0.40 \text{ g VSS/g COD})[(192 - 0.56) \text{ g COD/m}^3](6 \text{ d})/$$
$$[(1 + 0.10 \text{ g VSS/g VSS·d } (6 \text{ d})(\tau)]$$
$$- (0.15 \text{ g VSS/g VSS})(0.10 \text{ g VSS/g VSS·d})(X)(6 \text{ d})$$
$$+ 30 \text{ g VSS/m}^3 (6 \text{ d}/\tau)$$

$$2500 = 287.2/\tau + 0.09(X) + 180/\tau$$

The biomass concentration X is determined using Eq. (7–43).

$$X - [Y(S_o - S)]\text{SRT}/[1 - (k_d)\text{SRT}](\tau)$$

$$= \frac{(0.40 \text{ g VSS/g COD})[(192 - 0.56) \text{ g COD/m}^3](6 \text{ d})}{[1 + (0.10 \text{ g VSS/g VSS})(6 \text{ d})](\tau)}$$

$$= (287.2 \text{ g/m}^3\text{·d})/\tau$$

Substituting for X in the above expression yields:

$$2500 = 287.2/\tau + 180/\tau + 25.8/\tau = 493/\tau$$

and solving the above expression for τ yields

$$\tau = 0.197 \text{ d}$$

Aeration tank volume $= \tau(Q) = 0.197$ d (1000 m^3/d) = 197 m^3

3. Determine the total sludge production as kg VSS/d using Eq. (7–45).

$$Px_{T,\text{VSS}} = X_T(V)/(\text{SRT})$$
$$= (2500 \text{ g VSS/m}^3)(197 \text{ m}^3)(1 \text{ kg}/10^3 \text{ g})/6 \text{ d} = 82.1 \text{ kg VSS/d}$$

4. Determine the total sludge production as kg TSS/d using Eq. (7–53) and the assumed coefficients.

$$P_{X,\text{TSS}} = \frac{QY(S_o - S)}{1 + (k_d)\text{SRT}}\left(\frac{1}{0.85}\right) + \frac{(f_d)(k_d)YQ(S_o - S)\text{SRT}}{1 + (k_d)\text{SRT}}\left(\frac{1}{0.85}\right) + QX_{o,i} + Q(\text{TSS}_o - \text{VSS}_o)$$

$$= \frac{(1000 \text{ m}^3/\text{d})(0.40 \text{ g VSS/g COD})[(192 - 0.56) \text{ g COD/m}^3]}{[1 + (0.10 \text{ g VSS/g VSS·d})(6 \text{ d})](0.85)}$$

$$+ \frac{(0.15)(0.10)(1000 \text{ m}^3/\text{d})(0.40)[(192 - 0.56)\text{g COD/m}^3](6 \text{ d})}{[1 + (0.10 \text{ g VSS/ g VSS·d})(6 \text{ d})](0.85)}$$

$$+ (1000 \text{ m}^3/\text{d})(30 \text{ g/m}^3) + (1000 \text{ m}^3/\text{d})(10 \text{ g/m}^3)$$

$$= (56.3 + 5.1 + 30 + 10)(10^3 \text{ g/d}) = 101.4 \times 10^3 \text{ g/d} = 101.4 \text{ kg/d}$$

5. Determine the biomass fraction from the values for X and X_T.

   $X = (287.2 \text{ g/m}^3\text{·d})/\tau = (287.2 \text{ g/m}^3\text{·d})/0.197 \text{ d} = 1458 \text{ g VSS/m}^3$

   Biomass fraction $= X/X_T = 1458/2500 = 0.58$

6. Calculate the observed solids yield, g VSS/g bsCOD removed and g TSS/g bsCOD removed.

   Solids wasted/d $= P_{X_T} = 82.2$ kg VSS/d and 101.4 kg TSS/d

   bsCOD removed/d $= Q(S_o - S)$

   $= (1000 \text{ m}^3/\text{d})[(192 - 0.56) \text{ g COD/m}^3](1 \text{ kg}/10^3 \text{ g})$

   $= 191{,}440 \text{ g COD/d} = 191.4 \text{ kg/d}$

   As VSS, $Y_{obs} = 82.2/191.4 = 0.43$ g VSS/g bsCOD

   As TSS, $Y_{obs} = 101.4/191.4 = 0.53$ g TSS/g bsCOD

7. Determine the oxygen required using Eq. (7–59).

   $R_o = Q(S_o - S) - 1.42 P_{X,bio}$

   $P_{X,bio} = P_{X_T,VSS} - P_{nbVSS}$

   $= 82.2 \text{ kg/d} - (1000 \text{ m}^3/\text{d})(30 \text{ g VSS/m}^3)(1 \text{ kg}/10^3 \text{ g}) = 52.2 \text{ kg/d}$

   $R_o = (1000 \text{ m}^3/\text{d})[(192 - 0.56) \text{ g COD/m}^3](1 \text{ kg}/10^3 \text{ g}) - 1.42 (52.2 \text{ kg VSS/d})$

   $= 117.7 \text{ kg } O_2/\text{d}$

Comment The same approach can be used to treat wastewater with particulate biodegradable COD by assuming it is equal to bsCOD. For complete-mix suspended growth designs if the SRT is 3 d or more, essentially all of the degradable particulate COD will be converted to bsCOD.

Design and Operating Parameters

In the mass balance for the complete-mix reactor, presented above, the SRT was introduced as the fundamental process parameter that affects the treatment efficiency and general performance for the activated-sludge process. Two other activated-sludge process parameters used for the design and operation of the activated-sludge process, the food to microorganism ratio and the volumetric loading rate, are introduced below.

Food to Microorganism (F/M) Ratio. The F/M ratio is defined as the rate of BOD or COD applied per unit volume of mixed liquor:

$$\text{F/M} = \frac{\text{total applied substrate rate}}{\text{total microbial biomass}} = \frac{QS_o}{VX} \tag{7–60}$$

and

$$\text{F/M} = \frac{S_o}{\tau X} \tag{7–61}$$

where F/M = food to biomass ratio, g BOD or bsCOD/g VSS·d
Q = influent wastewater flowrate, m^3/d
S_o = influent BOD or bsCOD concentration, g/m^3
V = aeration tank volume, m^3
X = mixed liquor biomass concentration in the aeration tank, g/m^3
τ = hydraulic retention time of aeration tank, V/Q, d

Specific Substrate Utilization Rate. The F/M ratio can be related to the specific substrate utilization rate U, defined earlier [see Eq. (7–38)], by the process efficiency:

$$U = \frac{(F/M)E}{100} \tag{7–62}$$

where E = BOD or bsCOD process removal efficiency as defined by Eq. (7–63):

$$E, \% = \frac{S_o - S}{S_o} \times 100 \tag{7–63}$$

Substituting Eq. (7–61) for the F/M ratio and the term $[(S_o - S)/S_o](100)$ for the process efficiency yields the specific substrate utilization rate U, as given previously:

$$U = \frac{S_o - S}{\tau X} \tag{7–38}$$

The value of U can also be calculated by dividing $-r_{su}$ in Eq. (7–12) by X.

$$U = \frac{kS}{K_S + S} \tag{7–64}$$

By combining Eqs. (7–64) and (7–39),

$$\frac{1}{\text{SRT}} = YU - k_d \tag{7–65}$$

Again, the net specific growth rate μ is also equal to 1/SRT. In turn, as given by Eq. (7–65), the specific growth rate is equal to the synthesis yield times the specific substrate utilization rate minus the endogenous decay rate. By substituting Eq. (7–62) into Eq. (7–65) the SRT can be related to the F/M ratio as follows:

$$\frac{1}{\text{SRT}} = Y(F/M)\frac{E}{100} - k_d \tag{7–66}$$

For systems designed for the treatment of municipal wastewater with activated-sludge SRT values in the 20- to 30-d range, the F/M value may range from 0.10 to 0.05 g BOD/g VSS·d, respectively. At SRTs in the range of 5 to 7 d, the value may range from 0.3 to 0.5 g BOD/g VSS·d, respectively.

Organic Volumetric Loading Rate. The organic volumetric loading rate, defined as the amount of BOD or COD applied to the aeration tank volume per day, is

$$L_{org} = \frac{(Q)(S_o)}{(V)(10^3\ g/kg)} \tag{7-67}$$

where L_{org} = volumetric organic loading, kg BOD/m^3·d
Q = influent wastewater flowrate, m^3/d
S_o = influent BOD concentration, g/m^3
V = aeration tank volume, m^3

Process Performance and Stability

The effects of the kinetics considered above on the performance and stability of the system shown on Fig. 7–14 will now be examined further. It was shown in Eqs. (7–65) and (7–37) that 1/SRT, the net microorganism specific growth rate, and U, the specific substrate utilization ratio, are related directly. For a specified waste, a given biological community, and a particular set of environmental conditions, the kinetic coefficients Y, k, K_s, and k_d are fixed. It is important to note that domestic wastewater may have significant variability in its composition and may not always be treated as a single waste type in evaluating the kinetic coefficients. For given values of the coefficients, the effluent substrate concentration from the reactor is a direct function of the SRT, as shown in Eq. (7–40). Setting the SRT value fixes the values of U and μ and also defines the efficiency of biological waste stabilization. Equation (7–40) for substrate is plotted on Fig. 7–14 for a growth-specified complete-mix system with recycle. As shown, the treatment efficiency and the substrate concentration are related directly to the SRT, and the reactor hydraulics (i.e., complete-mix or plug-flow).

It can also be seen from Fig. 7–14 that there is a certain value of SRT below which waste stabilization does not occur. The critical SRT value is called the minimum solids retention residence time SRT_{min}. Physically, SRT_{min} is the residence time at which the cells are washed out or wasted from the system faster than they can reproduce. The min-

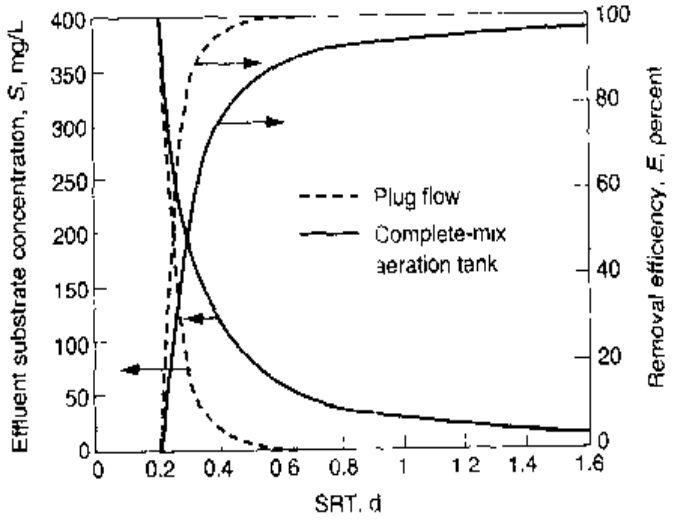


Figure 7–14
Effluent substrate concentration and removal efficiency for complete-mix and plug-flow reactors with recycle versus SRT.

imum SRT can be calculated using Eq. (7–39), in which $S = S_o$. When washout occurs, the influent concentration S_o is equal to the effluent waste concentration S.

$$\frac{1}{\text{SRT}_{\text{min}}} = \frac{YkS_o}{K_s + S_o} - k_d \tag{7–68}$$

In many situations encountered in waste treatment, S_o is much greater than K_s so that Eq. (7–68) can be rewritten to yield

$$\frac{1}{\text{SRT}_{\text{min}}} \approx Yk - k_d \tag{7–69}$$

or

$$\frac{1}{\text{SRT}_{\text{min}}} \approx \mu_m - k_d \tag{7–70}$$

Equations (7–69) and (7–70) can be used to determine the SRT_{min}. Typical kinetic coefficients that can be used to solve for SRT_{min} for BOD removal systems are given in Table 7–9. Obviously, biological treatment processes should not be designed with SRT values equal to SRT_{min}. To ensure adequate waste treatment, biological treatment processes are usually designed and operated with a design SRT value from 2 to 20 times SRT_{min}. In effect, the ratio of the design SRT (SRT_{des}) to SRT_{min} can be considered to be a process safety factor SF against system failure (Lawrence and McCarty, 1970).

$$\text{SF} = \frac{\text{SRT}_{\text{des}}}{\text{SRT}_{\text{min}}} \tag{7–71}$$

Modeling Plug-Flow Reactors

The plug-flow system with cellular recycle, shown schematically on Fig. 7–2*a*-1 and pictorially on Fig. 7–2*a*-2, can be used to model certain forms of the activated-sludge process. The distinguishing feature of this recycle system is that the hydraulic regime of the reactor is of a plug-flow nature. In a true plug-flow model, all the particles entering the reactor stay in the reactor an equal amount of time. Some particles may make more passes through the reactor because of recycle, but while they are in the tank, all pass through in the same amount of time.

A kinetic model of the plug-flow system is mathematically difficult, but Lawrence and McCarty (1970) have made two simplifying assumptions that lead to a useful kinetic model of the plug-flow reactor:

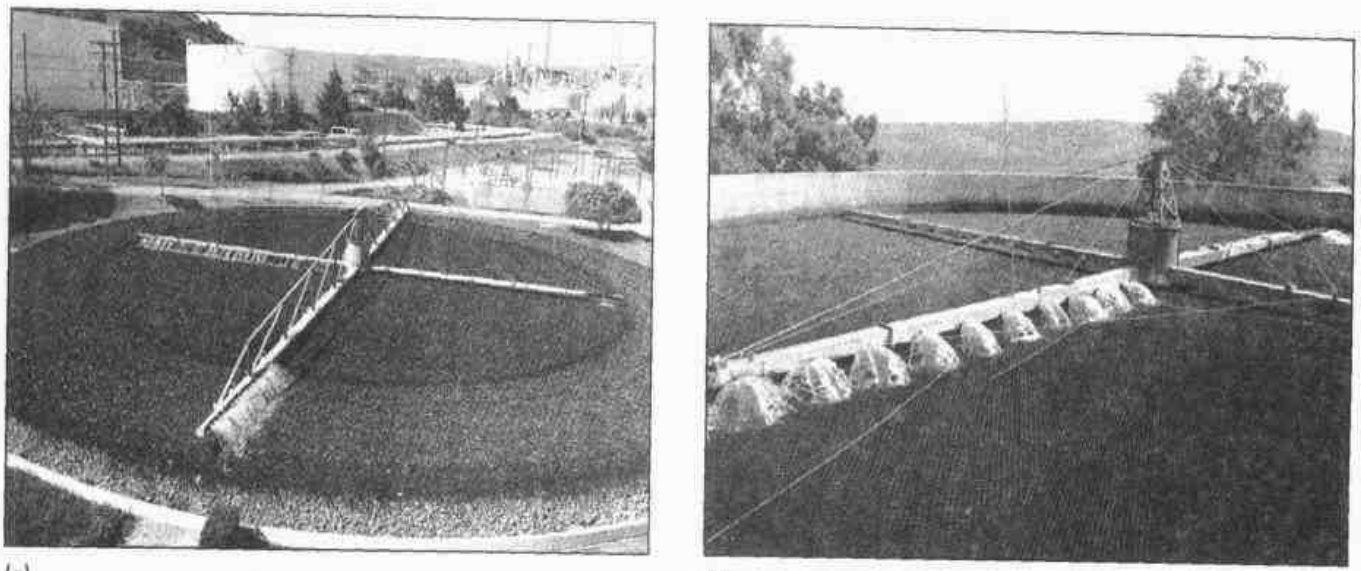
1. The concentration of microorganisms in the influent to the reactor is approximately the same as that in the effluent from the reactor. This assumption applies only if $\text{SRT}/\tau > 5$. The resulting average concentration of microorganisms in the reactor is symbolized as $\bar{X}$.
2. The rate of substrate utilization as the waste passes through the reactor is given by the following expression:

$$r_{su} = -\frac{kS\bar{X}}{K_s + S} \tag{7–72}$$

Integrating Eq. (7–72) over the retention time of the wastewater in the tank, substituting Eq. (7–43) for X, and simplifying, the following expression is obtained:

$$\frac{1}{\text{SRT}} = \frac{Yk(S_o - S)}{(S_o - S) + (1 + \alpha)K_s \ln (S_i/S)} - k_d \tag{7–73}$$

where S_o = influent concentration
S = effluent concentration
S_i = influent concentration to reactor after dilution with recycle flow
$= \dfrac{S_o + \alpha S}{1 + \alpha}$
α = recycle ratio
Other terms are as defined previously.



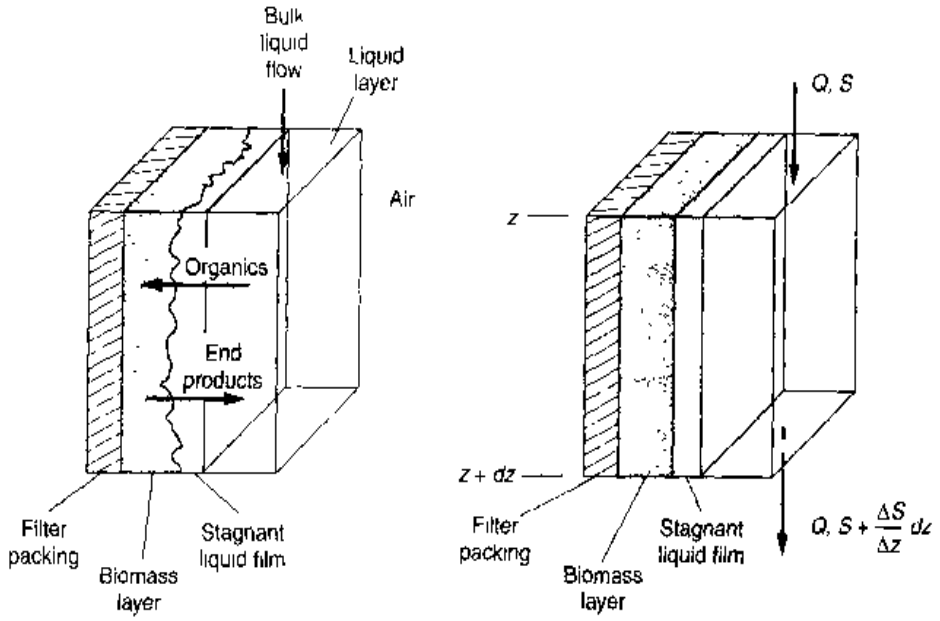
Equation (7–73) is similar to Eq. (7–36), which is applied to complete-mix systems, with or without recycle. The main difference in the two equations is that in Eq. (7–73), SRT is also a function of the influent waste concentration S_o. A version of Eq. (7–73) in which Eq. (7–43) is not substituted for $\bar{X}$ is shown in Chap. 8 in the design of sequencing batch reactors.

The true plug-flow recycle system is theoretically more efficient in the stabilization of most soluble wastes than in the continuous-flow stirred-tank recycle system. A graphical representation is shown on Fig. 7–14. In actual practice, a true plug-flow regime is essentially impossible to obtain because of longitudinal dispersion caused by aeration and mixing. By dividing the aeration tank into a series of reactors, the process approaches plug-flow kinetics with improved treatment efficiency compared to a complete-mix process. Because of the greater dilution with the influent wastewater, the complete-mix system can handle shock loads better than staged reactors in series. Reactor selection is discussed further in Chap. 8.

7–7 SUBSTRATE REMOVAL IN ATTACHED GROWTH TREATMENT PROCESSES

In an attached growth treatment process, a biofilm consisting of microorganisms, particulate material, and extracellular polymers is attached and covers the support packing material, which may be plastic, rock, or other material (see Fig. 7–15). The growth and substrate utilization kinetics described for the suspended growth process were related to the dissolved substrate concentration in the bulk liquid. For attached growth processes, substrate is consumed within a biofilm. Depending on the growth conditions and the hydrodynamics of the system, the biofilm thickness may range from 100 μm to 10 mm (WEF, 2000). A stagnant liquid layer (diffusion layer) separates the biofilm from the bulk liquid that is flowing over the surface of the biofilm or is mixed outside of the fixed film (see Fig. 7–16*a*). Substrates, oxygen, and nutrients diffuse across the stagnant liquid layer to the biofilm, and products of biodegradation from the biofilm enter the bulk liquid after diffusion across the stagnant film.

The substrate concentration at the surface of the biofilm, S_s as shown on Fig. 7–17, decreases with biofilm depth as the substrate is consumed and diffuses into the biofilm layers. As a result, the process is said to be *diffusion limited*. The substrate and oxygen



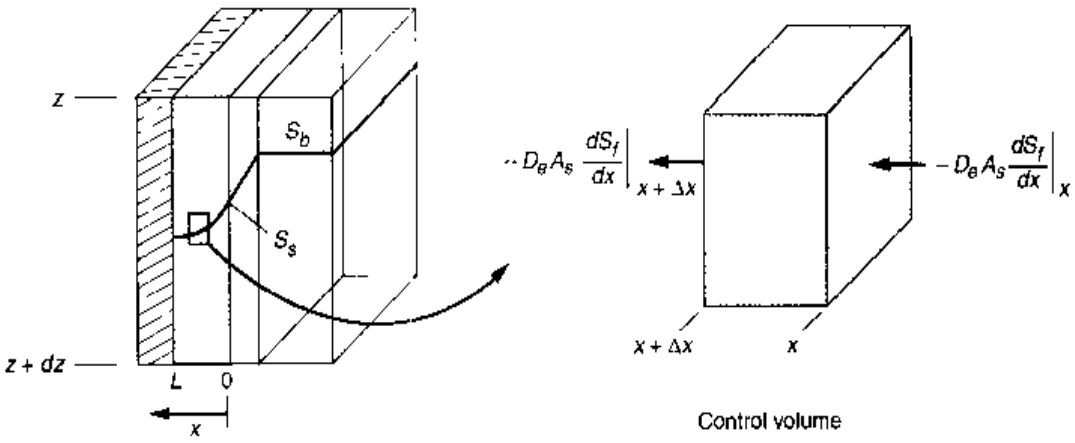
(a) (b)

Figure 7–15

Typical packing for trickling filters: (a) rock and (b) plastic

Figure 7–16

Schematic representation of the cross section of a biological slime in a trickling filter: (a) pictorial and (b) idealized.



concentrations within the film are lower than the bulk liquid concentration and change with biofilm depth and the substrate utilization rate. The overall substrate utilization rate is less than would be predicted based on the bulk liquid substrate concentration.

The total amount of substrate used per unit of biofilm cross-sectional area must diffuse across the stagnant layer. This rate of mass transfer is termed the surface flux and is expressed as mass per unit area per unit time ($g/m^2 \cdot d$). The biofilm layer is not simply a planar surface as depicted on Fig. 7–16*b* (Costerton et al., 1995). The biofilm layers are in fact very complex nonuniform structures with uneven protrusions much like

Figure 7-17

Definition sketch for the analysis of substrate concentration in the biofilm.

peaks and valleys, and are believed to have vertical and horizontal pores through which liquid flows. The biomass can be very dense in biofilms, and may also vary in density and depth. Biofilm VSS concentrations may range from 40 to 100 g/L. Uniform growth across the support packing also does not occur, because of periodic sloughing, as well as the hydrodynamics and media configuration (Hinton and Stensel, 1991).

Mechanistic models have been developed by a number of investigators to describe mass transfer and biological substrate utilization kinetics in biofilms (Williamson and McCarty, 1976; Rittman and McCarty, 1980; Kissel et al., 1984; Saez and Rittman, 1992; Suidan and Wang, 1985; Wanner and Gujer, 1986; and Rittman and McCarty, 2001) and provide useful tools for the evaluation of biofilm processes. However, because of the complexity of attached growth reactors and the inability to define accurately the physical parameters and model coefficients, empirical relationships, based on observed performance, are used for design. The empirical relationships used for design are presented and illustrated in Chap. 8. Fundamental concepts of mass transfer and substrate utilization that can be used to model the behavior of substrate removal in attached growth processes are presented here.

Substrate Flux in Biofilms

The substrate flux across the stagnant layer to the biofilm, a function of the substrate diffusion coefficient and concentration, is given by Eq. (7–74). The negative sign is used because the substrate concentration is decreasing along the stagnant layer and substrate is removed from the bulk liquid.

$$r_{sf} = -D_w \frac{dS}{dx} = -D_w \frac{(S_b - S_s)}{L} \tag{7-74}$$

where r_{sf} = rate of substrate surface flux, g/m^2·d
D_w = diffusion coefficient of substrate in water, m^2/d
dS/dx = substrate concentration gradient, g/m^3·m
S_b = bulk liquid substrate concentration, g/m^3
S_s = substrate concentration at outer layer of biofilm, g/m^3
L = effective thickness of stagnant film, m

The thickness of the stagnant layer will vary with the fluid properties and fluid velocity. Higher velocities result in thinner films with greater substrate flux rates (Grady et al., 1999).

Mass transfer within the biofilm is described by Fick's law for diffusion (see Sec. 4–8 in Chap. 4) in an aqueous solution, with a modification to the diffusivity constant to account for the effect of the biofilm structure on the effective diffusion.

$$r_{bf} = -D_e \frac{\partial S_f}{\partial x} \tag{7–75}$$

where r_{bf} = rate of substrate flux in biofilm due to mass transfer, g/m^2·d
D_e = effective diffusivity coefficient in biofilm, m^2/d
$\partial S_f/\partial x$ = substrate concentration gradient, g/m^3·m

The substrate utilization rate within the biofilm at any point can be defined as a saturation-type reaction (Eq. 7–12) for the substrate concentration (S_f) at that location:

$$r_{su} = -\frac{kS_fX}{K_s + S_f} \tag{7–76}$$

where r_{su} = rate of substrate utilization in biofilm, g/m^2·d
S_f = substrate concentration at a point in the biofilm, g/m^3

Substrate Mass Balance for Biofilm

A substrate mass balance around a differential element (dx) shown on Fig. 7–17 within the biofilm yields:

$$\begin{array}{l}\text{Rate of substrate}\\ \text{accumulation within}\\ \text{differential element}\end{array} = \begin{array}{c}\text{rate of substrate}\\ \text{flow into}\\ \text{differential element}\end{array} - \begin{array}{c}\text{rate of substrate}\\ \text{flow out of}\\ \text{differential element}\end{array} + \begin{array}{c}\text{rate of substrate}\\ \text{utilization in}\\ \text{differential element}\end{array} \tag{7–77}$$

For steady-state conditions, the mass balance is

Accumulation = inflow − outflow + generation

$$0 = -D_eA_s\left.\frac{dS_f}{dx}\right|_x + D_eA_s\left.\frac{dS_f}{dx}\right|_{x+\Delta x} - \Delta xA_s\left(\frac{kS_fX}{K_s + S_f}\right) \tag{7–78}$$

where A_s = biofilm area normal to the substrate flux, m^2
Δx = width of differential section, m

Dividing both sides by A_s and dx, and taking the limit as Δx approaches zero yields the following general equation for the change in substrate concentration within the biofilm:

$$D_e\frac{d^2S_f}{dx^2} - \left(\frac{kS_fX}{K_s + S_f}\right) = 0 \tag{7–79}$$

Solutions to the above equation require two boundary conditions. The first boundary condition is that the substrate flux at the biofilm surface equals the substrate flux through the stagnant film, as given by Eq. (7–74). The second boundary condition is that there is no flux at the packing surface.

$$\left.\frac{dS_f}{dx}\right|_{x=L} = 0 \tag{7–80}$$

Solutions for Eq. (7–79) vary, depending on (1) whether a deep biofilm exists such that the biofilm substrate concentration approaches zero toward the support surface,

(2) whether a shallow film exists such that S_f is a finite value throughout the film, and (3) the relative concentration of S_f compared to K_s. Solution approaches are provided in a number of references, including Williamson and McCarty (1976), Grady et al. (1999), and Rittman and McCarty (2001).

Substrate Flux Limitations

An important implication of diffusion-limited processes is the relationship between the bulk liquid electron donor and electron acceptor concentrations. An assumption in the mechanistic models used is that either the electron donor or electron acceptor (i.e., oxygen or nitrate) is limiting. The substrate limitation may be due to reaction rates within the biofilm or to bulk liquid concentrations and diffusion rates across the stagnant layer. These are referred to by Williamson and McCarty (1976) as substrate and surface flux limitations, respectively. There are situations where the substrate limitation may switch between electron donor and electron acceptor with depth in the biofilm. For the situation where the substrate limitation can switch, numerical analysis techniques must be used to evaluate the biofilm behavior. A simple method that can be used to evaluate whether a surface flux limitation exists has been proposed by Williamson and McCarty (1976). The proposed method can also be used to assess the relative electron acceptor bulk liquid substrate concentrations needed to sustain electron donor utilization within the biofilm.

The effect of surface flux substrate limitation described by Williamson and McCarty (1976) is summarized in the following two equations:

$$\nu_d + \nu_a + \text{growth requirements} \rightarrow \text{end products} + \text{cells} \qquad [7\text{–}81]$$

$$S_{ba} < \frac{D_{wd}\nu_a mw_a}{D_{wa}\nu_a mw_d} S_{bd} \qquad [7\text{–}82]$$

where ν_d = molar stoichiometric reaction coefficient for electron donor, moles
ν_a = molar stoichiometric reaction coefficient for electron acceptor, moles
S_{ba} = bulk liquid electron acceptor substrate concentration, mg/L
S_{bd} = bulk liquid electron donor substrate concentration, mg/L
D_{wd} = diffusivity coefficient of electron donor in water, cm^2/d
D_{wa} = diffusivity coefficient of electron acceptor in water, cm^2/d
mw_a = molecular weight of electron acceptor, g
mw_d = molecular weight of electron donor, g

Nitrification rates in fixed-film systems are often limited by the bulk liquid DO concentration, and the following example uses Eqs. (7–81) and (7–82) to illustrate this important issue regarding fixed-film process applications.

EXAMPLE 7–7 Oxygen Limitation for Nitrification in a Biofilm For bulk liquid NH_4-N concentrations of 1.0, 2.0, and 3.0 mg/L, respectively, what bulk liquid DO concentration must be present so that the nitrification rate in the biofilm is not limited due to the surface flux rate of oxygen? Assume the following conditions apply:

Electron donor = NH_4-N, $mw_d = 14$

Electron acceptor = oxygen, $mw_a = 32$

NH_4-N diffusivity coefficient at 20°C = D_{wd} = 1.6 cm²/d

Oxygen diffusivity coefficient at 20°C = D_{wa} = 2.6 cm²/d

Solution

1. Determine the stoichiometric coefficients from the reaction stoichiometry.

   $$NH_4^+ + 2O_2 \rightarrow NO_3^- + 2H^+ + H_2O$$

   $\nu_d = 1.0$

   $\nu_a = 2.0$

2. Determine the DO concentration where oxygen is flux-limited using Eq. (7–82).

   $$S_{ba} < \frac{D_{wd}\nu_a mw_a}{D_{wa}\nu_d mw_d} S_{bd} < \frac{(1.6\ \text{cm}^2/\text{d})(2.0)(32\ \text{g/mole})}{(2.6\ \text{cm}^2/\text{d})(1.0)(14\ \text{g/mole})} S_{bd} = 2.8\, S_{bd}$$

   Thus, if S_{ba} is equal to 2.8 (S_{bd}), the nitrification rate is not hindered by the oxygen flux rate through the stagnant layer. Bulk liquid DO concentrations necessary to prevent an oxygen flux limitation for nitrification are summarized in the following table.

Bulk liquid NH_4-N concentration, g/m³	Bulk liquid DO concentration, g/m³
1.0	2.8
2.0	5.6
3.0	8.4

Comment For low bulk liquid NH_4-N concentrations, which result in lower nitrification rates in the biofilm, lower DO concentrations can be tolerated.

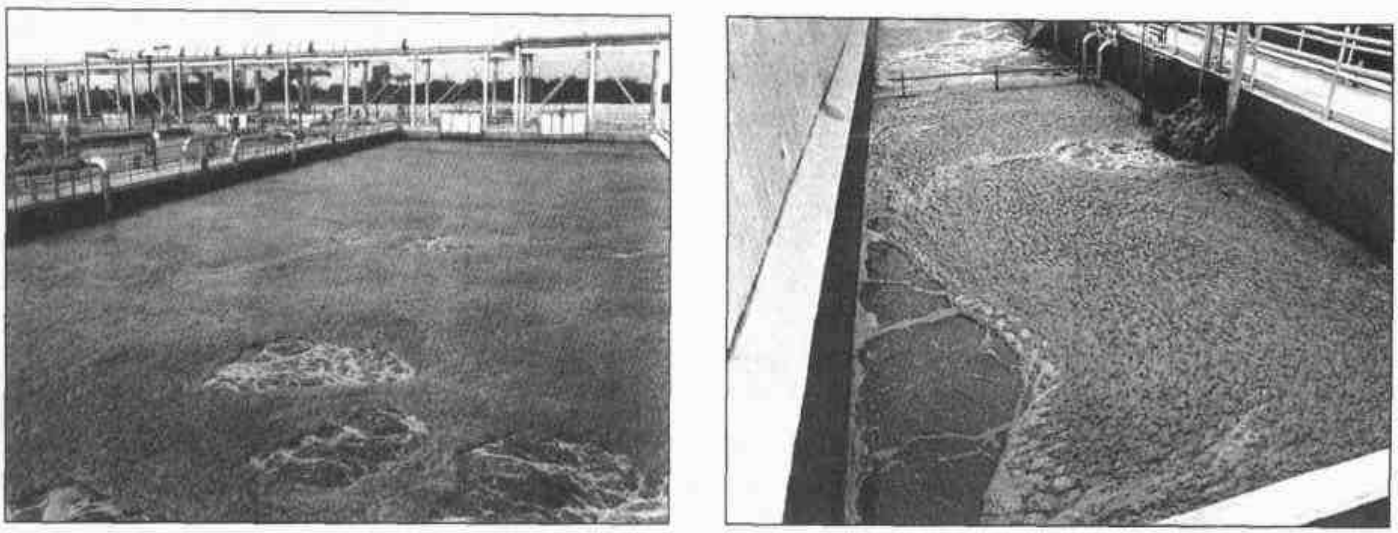
7–8 AEROBIC BIOLOGICAL OXIDATION

Dating back to the early 1900s, the primary purpose of biological wastewater treatment has been to (1) remove organic constituents and compounds to prevent excessive DO depletion in receiving waters from municipal or industrial point discharges, (2) remove colloidal and suspended solids to avoid the accumulation of solids and the creation of nuisance conditions in receiving waters, and (3) reduce the concentration of pathogenic organisms released to receiving waters. The U.S. EPA secondary treatment regulatory standards, set in 1972 and still in effect, were focused mainly on the removal of BOD and TSS, and require 85 percent removal of each (see Table 1–3 in Chap. 1). Most treatment applications involve the removal of organic constituents and compounds. Because a wide range of constituents and compounds exist in wastewater, the organic content is quantified in terms of biodegradable soluble COD (bsCOD) or BOD. Additional information on

the characterization of the organic constituents in wastewater is presented in Sec. 8–2 in Chap. 8.

Process Description

The removal of BOD can be accomplished in a number of aerobic suspended growth or attached (fixed film) growth treatment processes as illustrated on Figs. 7–2 and 7–3, respectively, and described in detail in Chaps. 8 and 9. Both require sufficient contact time between the wastewater and heterotrophic microorganisms, and sufficient oxygen and nutrients. During the initial biological uptake of the organic material, more than half of it is oxidized and the remainder is assimilated as new biomass, which may be further oxidized by endogenous respiration. For both suspended and attached growth processes, the excess biomass produced each day is removed and processed to maintain proper operation and performance. The biomass is separated from the treated effluent by gravity separation, and more recent designs using membrane separation are finding applications.



Microbiology

A wide variety of microorganisms are found in aerobic suspended and attached growth treatment processes used for the removal of organic material. Aerobic heterotrophic bacteria found in these processes are able to produce extracellular biopolymers that result in the formation of biological flocs (or biofilms for attached growth processes) that can be separated from the treated liquid by gravity settling with relatively low concentrations of free bacteria and suspended solids.

Protozoa also play an important role in aerobic biological treatment processes. By consuming free bacteria and colloidal particulates, protozoa aid effluent clarification. Protozoa require a longer SRT than aerobic heterotrophic bacteria, prefer dissolved oxygen concentrations above 1.0 mg/L, and are sensitive to toxic materials. Thus, their presence is a good indicator of a trouble-free stable process operation. Because of their size, protozoa can easily be observed with a light microscope at 100 to 200 magnifications. Rotifers can also be found in activated sludge and in biofilms, as well as nematodes and other multicellular microorganisms. These organisms occur at longer biomass retention times, and their importance has not been well defined.

Aerobic attached growth processes, depending on the biofilm thickness, generally have a much more complex microbial ecology than activated sludge with films containing bacteria, fungi, protozoan, rotifers, and possibly annelid worms, flatworms, and nematodes (WEF, 2000). The nature of biofilms and their microbial composition will be discussed in more detail in Chap. 9.

Depending on process loadings and environmental conditions, a number of nuisance organisms can also develop in the activated-sludge process. The principal problem caused by nuisance organisms is a condition known as *bulking sludge*, in which the biological floc has poor settling characteristics. In the extreme, bulking sludge can result in high effluent suspended solids concentrations and poor treatment performance. Another nuisance condition, foaming, has been related to the development of two bacteria genera *Nocardia* and *Microthrix* (Pitt and Jenkins, 1990), which have hydrophobic cell surfaces and attach to air bubble surfaces, where they stabilize the bubbles to cause foam (see Fig. 7–18). The organisms can be found at high concentrations in the

(a) (b)

Figure 7–18

Examples of foam caused by *Nocardia* accumulated on the surface of activated-sludge aeration tanks.

foam above the activated-sludge liquid. The above types of nuisance organisms along with others are considered in Chap. 8.

Stoichiometry of Aerobic Biological Oxidation

The stoichiometry for aerobic oxidation was discussed previously but is repeated here for completeness. In aerobic oxidation, the conversion of organic matter is carried out by mixed bacterial cultures in general accordance with the stoichiometry shown below.

Oxidation and synthesis:

$$\underset{\text{Organic matter}}{COHNS} + O_2 + \text{nutrients} \xrightarrow{\text{bacteria}} CO_2 + NH_3 + \underset{\text{new cells}}{C_5H_7NO_2} + \underset{\text{products}}{\text{other end}} \qquad (7\text{–}83)$$

Endogenous respiration:

$$\underset{\substack{\text{Cells}\\ mw = 113\\ 1}}{C_5H_7NO_2} + 5O_2 \xrightarrow{\text{bacteria}} \underset{1\,42}{5CO_2 + 2H_2O} + NH_3 + \text{energy} \qquad (7\text{–}84)$$

$mw = 160$

In Eq. (7–83), COHNS is used to represent the organic matter in wastewater, which serves as the electron donor while the oxygen serves as the electron acceptor. Although the endogenous respiration reaction [Eq. (7–84)] is shown as resulting in relatively simple end products and energy, stable organic end products are also formed. From Eq. (7–5), it was shown that if all of the cells (i.e., the electron donor) were oxidized completely, the UBOD or COD of the cells is equal to 1.42 times the concentration of cells as VSS. At longer SRT values, a greater portion of the cells will be oxidized.

Using the half reactions given in Table 7–7, the stoichiometry for the aerobic oxidation of acetate (the electron donor) can be represented as given below. Assuming

ammonia will serve as the nitrogen source for cell tissue, oxygen is the electron acceptor, and f_s for the reaction is 0.59 (see Example 7–4).

$$0.125CH_3COO^- + 0.0295NH_4^+ + 0.103O_2 \rightarrow 0.0295C_5H_7O_2N + 0.0955H_2O + 0.0955HCO_3^- + 0.007CO_2 \quad (7\text{–}85)$$

Growth Kinetics

The form of the rate expressions for substrate utilization and biomass growth for the heterotrophic oxidation of organic substrates, based on the stoichiometry given above, were presented previously but are repeated below for ease of reference.

$$r_{su} = -\frac{kXS}{K_s + S} \quad (7\text{–}12)$$

$$r_g = -Yr_{su} - k_d X \quad (7\text{–}21)$$

$$= Y\frac{kXS}{K_s + S} - k_d X \quad (7\text{–}22)$$

Both of the above expressions are of the saturation type. As noted previously, these expressions are similar to the saturation equation proposed by Monod (1942) for growth and the Michaelis-Menten equation for substrate utilization (Bailey and Ollis, 1986). Typical k and K_s values at 20°C vary from 8 to 12.0 g COD/g VSS·d and 10 to 40 g bsCOD/m^3, respectively. As noted in Sec. 7–5, the K_s value can vary depending on the nature and complexity of the bsCOD components. For easily biodegradable single substrates, K_s values of less than 1.0 mg bsCOD/L have been measured (Bielefeldt and Stensel, 1999).

Applying the above expressions for substrate utilization and biomass growth leads to the development of a series of design parameters including the solids retention time (SRT), the food to microorganism ratio (F/M), and the specific utilization rate (U). These design parameters are applied to the design of a variety of activated-sludge processes in Chap. 8. With the exception of some difficult-to-degrade constituents in industrial wastewaters, the kinetics for aerobic oxidation of organic substrates seldom control the SRT design value for the activated-sludge process. For good floc formation, sufficient time is needed for the biomass in the activated-sludge aeration tank to develop extracellular polymers and a floc structure. More optimal flocculation and TSS removal in clarification occur typically at SRT values greater than 2.5 to 3.0 d at 20°C and 3 to 5 d at 10°C. However, some wastewater-treatment plants in warmer climates operate at SRT values varying from less than 1 to 1.5 d. Excessively long SRTs (>20 d) may lead to floc deterioration with the development of small pinpoint floc particles that produce a more turbid effluent. However, even with pinpoint floc, effluent suspended solids concentrations of less than 30 g/m^3 are generally achieved. The SRT may be varied in treatment plant operations to find the most optimal settling condition.

Environmental Factors

For carbonaceous removal, pH in the range of 6.0 to 9.0 is tolerable, while optimal performance occurs near a neutral pH. A reactor DO concentration of 2.0 mg/L is commonly used, and at concentrations above 0.50 mg/L there is little effect of the DO concentration on the degradation rate. For industrial wastewaters care must be taken to

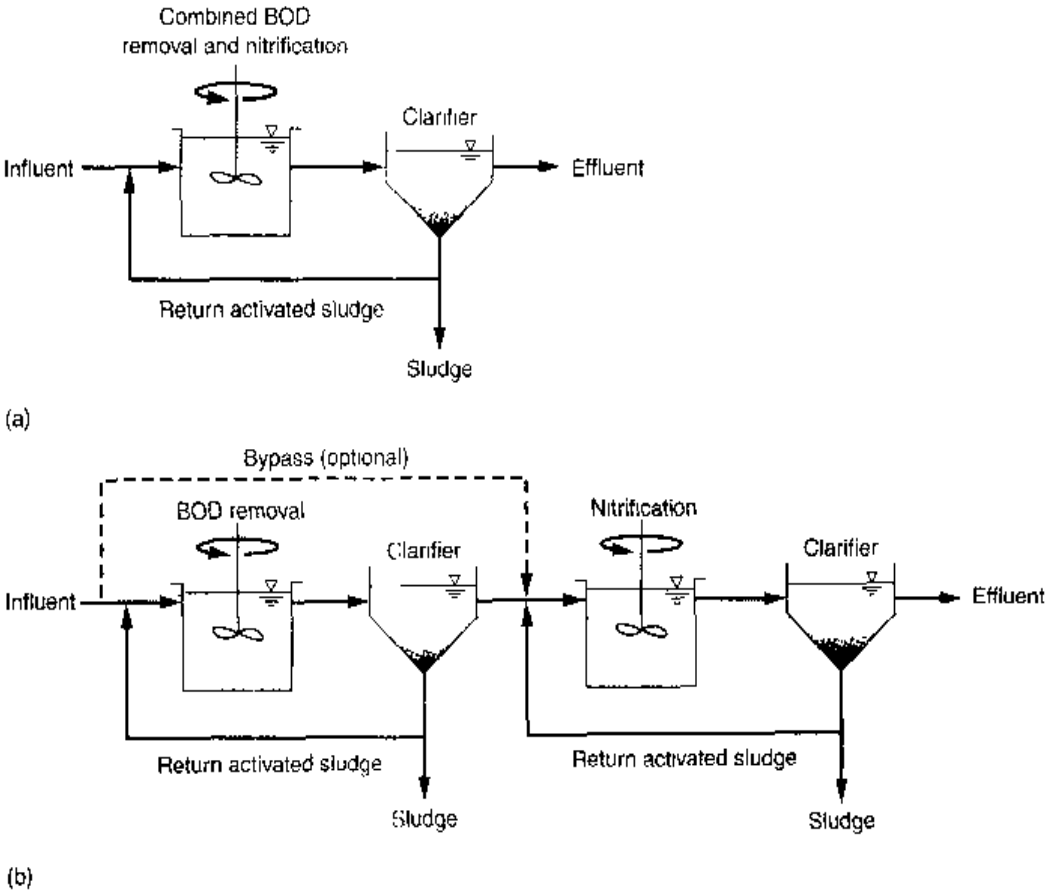
assure that sufficient nutrients (N and P) are available for the amount of bsCOD to be treated. Heterotrophic bacteria responsible for BOD removal can tolerate higher concentrations of toxic substances as compared to the bacteria responsible for ammonia oxidation or the production of methane.

7–9 BIOLOGICAL NITRIFICATION

Nitrification is the term used to describe the two-step biological process in which ammonia (NH_4-N) is oxidized to nitrite (NO_2-N) and nitrite is oxidized to nitrate (NO_3-N). The need for nitrification in wastewater treatment arises from water quality concerns over (1) the effect of ammonia on receiving water with respect to DO concentrations and fish toxicity, (2) the need to provide nitrogen removal to control eutrophication, and (3) the need to provide nitrogen control for water-reuse applications including groundwater recharge. For reference, the current (2001) drinking water maximum contaminant level (MCL) for nitrate nitrogen is 45 mg/L as nitrate or 10 mg/L as nitrogen. The total concentration of organic and ammonia nitrogen concentration in municipal wastewaters is typically in the range from 25 to 45 mg/L as nitrogen based on a flowrate of 450 L/capita·d (120 gal/capita·d). In many parts of the world with limited water supplies, total nitrogen concentrations in excess of 200 mg/L as N have been measured in domestic wastewater.

Process Description

As with BOD removal, nitrification can be accomplished in both suspended growth and attached growth biological processes. For suspended growth processes, a more common approach is to achieve nitrification along with BOD removal in the same single-sludge process, consisting of an aeration tank, clarifier, and sludge recycle system (see Fig. 7–19*a*). In cases where there is a significant potential for toxic and inhibitory substances in the wastewater, a two-sludge suspended growth system may be considered (see Fig. 7–19*b*). The two sludge system consists of two aeration tanks and two clarifiers in series with the first aeration tank/clarifier unit operated at a short SRT for BOD removal. The BOD and toxic substances are removed in the first unit, so that nitrification can proceed unhindered in the second. A portion of influent wastewater usually has to be bypassed to the second sludge system to provide a sufficient amount of solids for efficient solids flocculation and clarification. Because the bacteria responsible for nitrification grow much more slowly than heterotrophic bacteria, systems designed for nitrification generally have much longer hydraulic and solids retention times than those for systems designed only for BOD removal.



In attached growth systems used for nitrification, most of the BOD must be removed before nitrifying organisms can be established. The heterotrophic bacteria have a higher biomass yield and thus can dominate the surface area of fixed-film systems over nitrifying bacteria. Nitrification is accomplished in an attached growth reactor after BOD removal or in a separate attached growth system designed specifically for nitrification. The design of attached growth biological systems is described in Chap. 9.

Microbiology

Aerobic autotrophic bacteria are responsible for nitrification in activated sludge and biofilm processes. Nitrification, as noted above, is a two-step process involving two

Figure 7-19

Process configuration used for biological nitrification: (*a*) single-sludge suspended growth system and (*b*) two-sludge suspended growth system.

groups of bacteria. In the first stage, ammonia is oxidized to nitrite by one group of autotrophic bacteria. In the second stage, nitrite is oxidized to nitrate by another group of autotrophic bacteria. It should be noted that the two groups of autotrophic bacteria are distinctly different. Starting with classical experiments on nitrification by Winogradsky (1891), the bacteria genera commonly noted for nitrification in wastewater treatment are the autotrophic bacteria *Nitrosomonas* and *Nitrobacter*, which oxidize ammonia to nitrite and then to nitrate, respectively. Other autotrophic bacteria genera capable of obtaining energy from the oxidation of ammonia to nitrite (prefix with *Nitroso-*) are *Nitrosococcus, Nitrosospira, Nitrosolobus,* and *Nitrosorobrio* (Painter, 1970). It should be noted that during the 1990s, many more autotrophic bacteria were identified as being capable of oxidizing ammonia.

Besides *Nitrobacter,* nitrite can also be oxidized by other autotrophic bacteria (*Nitro-*) genera: *Nitrococcus, Nitrospira, Nitrospina,* and *Nitroeystis.* Using oligonucleotide probes for ammonia-oxidizing bacteria, Wagner et al. (1995) showed that *Nitrosomonas* was common in activated-sludge systems. For nitrite oxidation in activated sludge, Teske et al. (1994) found that *Nitrococcus* was quite prevalent. Whether different growth conditions can select for different genera of nitrifying bacteria or if their nitrification kinetics are significantly different is unknown at present.

Stoichiometry of Biological Nitrification

The energy-yielding two-step oxidation of ammonia to nitrate is as follows:

Nitroso-bacteria:

$$2NH_4^+ + 3O_2 \rightarrow 2NO_2^- + 4H^+ + 2H_2O \qquad (7\text{-}86)$$

Nitro-bacteria:

$$2NO_2^- + O_2 \rightarrow 2NO_3 \tag{7–87}$$

Total oxidation reaction:

$$NH_4^+ + 2O_2 \rightarrow NO_3^- + 2H^+ - H_2O \tag{7–88}$$

Based on the above total oxidation reaction, the oxygen required for complete oxidation of ammonia is 4.57 g O_2/g N oxidized with 3.43 g O_2/g used for nitrite production and 1.14 g O_2/g NO_2 oxidized. When synthesis is considered, the amount of oxygen required is less than 4.57 g O_2/g N. In addition to oxidation, oxygen is obtained from fixation of carbon dioxide and nitrogen into cell mass.

Neglecting cell tissue, the amount of alkalinity required to carry out the reaction given in Eq. (7–88) can be estimated by writing Eq. (7–88) as follows:

$$NH_4^+ + 2HCO_3^- + 2O_2 \rightarrow NO_3^- + 2CO_2 + 3H_2O \tag{7–89}$$

In the above equation, for each g of ammonia nitrogen (as N) converted, 7.14 g of alkalinity as $CaCO_3$ will be required [2 × (50 g $CaCO_3$/eq)/14].

Along with obtaining energy, a portion of the ammonium ion is assimilated into cell tissue. The biomass synthesis reaction can be represented as follows:

$$4CO_2 + HCO_3^- + NH_4^+ + H_2O \rightarrow C_5H_7O_2N + 5O_2 \tag{7–90}$$

As noted previously, the chemical formula $C_5H_7O_2N$ is used to represent the synthesized bacterial cells.

The half reactions provided in Table 7–7 can be used to create an equation for the overall nitrification reaction. As demonstrated in Example 7–4, half reactions for cell synthesis, oxidation of ammonia to nitrate, and reduction of oxygen to water can be combined to create Eq. (7–91) (f_s = 0.05). Due to rounding of the coefficients, the equation does not balance exactly; however, the error introduced by rounding is negligible (Crites and Tchobanoglous, 1998).

$$NH_4^+ + 1.863O_2 + 0.098CO_2 \rightarrow 0.0196C_5H_7NO_2 + 0.98NO_3^- + 0.0941H_2O + 1.98H^+ \tag{7–91}$$

From the above equation it will be noted that for each g of ammonia nitrogen (as N) converted, 4.25 g of O_2 are utilized, 0.16 g of new cells are formed, 7.07 g of alkalinity as $CaCO_3$ are removed, and 0.08 g of inorganic carbon are utilized in the formation of new cells. The oxygen required to oxidize 1.0 g of ammonia nitrogen to nitrate (4.25 g) is less than the theoretical value of 4.57 g computed using Eq. (7–88), because the ammonia for cell synthesis is not considered in Eq. (7–87). Similarly, the alkalinity required for nitrification in Eq. (7–91) (7.07 g/g) is less than the value of 7.14 g calculated without considering the conversion of some of the ammonia to cellular nitrogen [Eq. (7–89)]. It should be recognized that the coefficient values in Eq. 7–91 are dependent upon the value of f_s that is used (see Sec. 7–4). [Note that f_s = 0.05 was assumed for Eq. (7–91).] Werzernak and Gannon (1967) found that the actual total oxygen consumption was 4.33 g O_2/g N with 3.22 g O_2/g N used for ammonia oxidation and 1.11 g O_2/g N used for nitrite oxidation.

The wastewater nitrogen concentration, BOD concentration, alkalinity, temperature, and potential for toxic compounds are major issues in the design of biological nitrification processes. Nitrifying bacteria need CO_2 and phosphorus for cell growth, as

well as trace elements. With such a low cell yield, the CO_2 in air is adequate and phosphorus is seldom limiting. Trace element concentrations that have been found to stimulate the growth of nitrifying bacteria in pure culture work are: Ca = 0.50, Cu = 0.01, Mg = 0.03, Mo = 0.001, Ni = 0.10, and Zn = 1.0 mg/L (Poduska, 1973).

Growth Kinetics

For nitrification systems operated at temperatures below 28°C ammonia-oxidation kinetics versus nitrite-oxidation kinetics are rate-limiting, so that designs are based on saturation kinetics for ammonia oxidation as given below, assuming excess DO is available.

$$\mu_n = \left(\frac{\mu_{nm} N}{K_n + N}\right) - k_{dn} \tag{7-92}$$

where μ_n = specific growth rate of nitrifying bacteria, g new cells/g cells·d
μ_{nm} = maximum specific growth rate of nitrifying bacteria, g new cells/g cells·d
N = nitrogen concentration, g/m^3
K_n = half-velocity constant, substrate concentration at one-half the maximum specific substrate utilization rate, g/m^3
k_{dn} = endogenous decay coefficient for nitrifying organisms, g VSS/g VSS·d

A wide range of maximum specific growth rates have been reported as a function of temperature (Randall et al., 1992). At 20°C, reported μ_{nm} varies from 0.25 to 0.77 g VSS/g VSS. The wide range of nitrification growth rates may be due to the presence of inhibitory substances in the wastewater and/or variations in experimental techniques and methods of analysis. In any event, the μ_{nm} values for nitrifying organisms are much lower than the corresponding values for heterotrophic organisms, requiring much longer SRT values for nitrifying activated-sludge systems. Typical design SRT values may range from 10 to 20 d at 10°C to 4 to 7 d at 20°C. Above 28°C, both ammonia and nitrite oxidation kinetics should be considered. At elevated temperatures, the relative kinetics of NH_4-N and NO_2-N oxidation change, and NO_2-N will accumulate at lower SRT values.

For fully acclimated complete-mix activated sludge nitrification systems, at temperatures below 25°C with sufficient DO present, the NO_2-N concentration may be less than 0.10 mg/L as compared to NH_4-N concentrations in the range of 0.50 to 1.0 mg/L. However, during the initiation of nitrification, NO_2-N concentrations will be greater than NH_4-N concentrations, as the growth of nitrite-oxidizing bacteria cannot occur until the ammonia-oxidizing bacteria generate nitrite. Under transient conditions, NO_2-N concentrations of 5 to 20 mg/L are possible.

Nitrification rates are affected by the liquid DO concentration in activated sludge (attached growth effects are described in Chap. 9). In contrast to what has been observed for aerobic heterotrophic bacteria degradation of organic compounds, nitrification rates increase up to DO concentrations of 3 to 4 mg/L. To account for the effects of DO, the expression for the specific growth rate [Eq. (7–92)] is modified as follows:

$$\mu_n = \left(\frac{\mu_{nm} N}{K_n + N}\right)\left(\frac{\text{DO}}{K_o + \text{DO}}\right) - k_{dn} \tag{7-93}$$

where DO = dissolved oxygen concentration, g/m^3
K_o = half-saturation coefficient for DO, g/m^3
Other terms as defined previously.

While the above kinetic model and coefficients, based on observed results, can be used to describe nitrification in systems at low to modest organic loadings, the use of these models will generally overpredict nitrification rates in systems with high organic loadings. Stenstrom and Song (1991) have shown experimentally that the effect of DO on nitrification is affected by the activated-sludge floc size and density, and total oxygen demand of the mixed liquor. Nitrifying bacteria are distributed within a floc containing heterotrophic bacteria and other solids, with floc diameters ranging from 100 to 400 μm. Oxygen from the bulk liquid diffuses into floc particles, and bacteria deeper within the floc are exposed to lower DO concentrations. At higher organic loadings, there is a greater substrate concentration in the mixed liquor, which causes a higher oxygen consumption rate within the floc. Therefore, a higher bulk liquid DO concentration is needed to maintain the same internal floc DO concentration and subsequent nitrification rate.

At low DO concentrations (<0.50 mg/L) where nitrification rates are greatly inhibited, the low DO inhibition effect has been shown to be greater for *Nitrobacter* than for *Nitrosomonas*. In such cases, incomplete nitrification will occur with increased NO_2-N concentrations in the effluent. The presence of nitrite in the effluent is particularly troublesome for plants that use chlorination for disinfection, as nitrite is readily oxidized by chlorine requiring 4 g chlorine/g NO_2-N.

Environmental Factors

Nitrification is affected by a number of environmental factors including pH, toxicity, metals, and un-ionized ammonia.

Hydrogen-Ion Concentration (pH). Nitrification is pH-sensitive and rates decline significantly at pH values below 6.8. At pH values near 5.8 to 6.0, the rates may be 10 to 20 percent of the rate at pH 7.0 (U.S. EPA, 1993). Optimal nitrification rates occur at pH values in the 7.5 to 8.0 range. A pH of 7.0 to 7.2 is normally used to maintain reasonable nitrification rates, and for locations with low-alkalinity waters, alkalinity is added at the wastewater-treatment plant to maintain acceptable pH values. The amount of alkalinity added depends on the initial alkalinity concentration and amount of NH_4-N to be oxidized. Alkalinity may be added in the form of lime, soda ash, sodium bicarbonate, or magnesium hydroxide depending on costs and chemical handling issues.

Toxicity. Nitrifying organisms are sensitive to a wide range of organic and inorganic compounds and at concentrations well below those concentrations that would affect aerobic heterotrophic organisms. In many cases, nitrification rates are inhibited even though bacteria continue to grow and oxidize ammonia and nitrite, but at significantly reduced rates. In some cases, toxicity may be sufficient to kill the nitrifying bacteria.

Nitrifiers have been shown to be good indicators of the presence of organic toxic compounds at low concentrations (Blum and Speece, 1991). Toxic organic compounds have been listed by Hockenbury and Grady (1977) and Sharma and Ahlert (1977). Compounds that are toxic include solvent organic chemicals, amines, proteins, tannins, phenolic compounds, alcohols, cyanates, ethers, carbamates, and benzene. Because of the numerous compounds that can inhibit nitrification, it is difficult to pinpoint the source of nitrification toxicity for wastewater plants with inhibition, and extensive sampling of the collection system is normally needed to find the source.

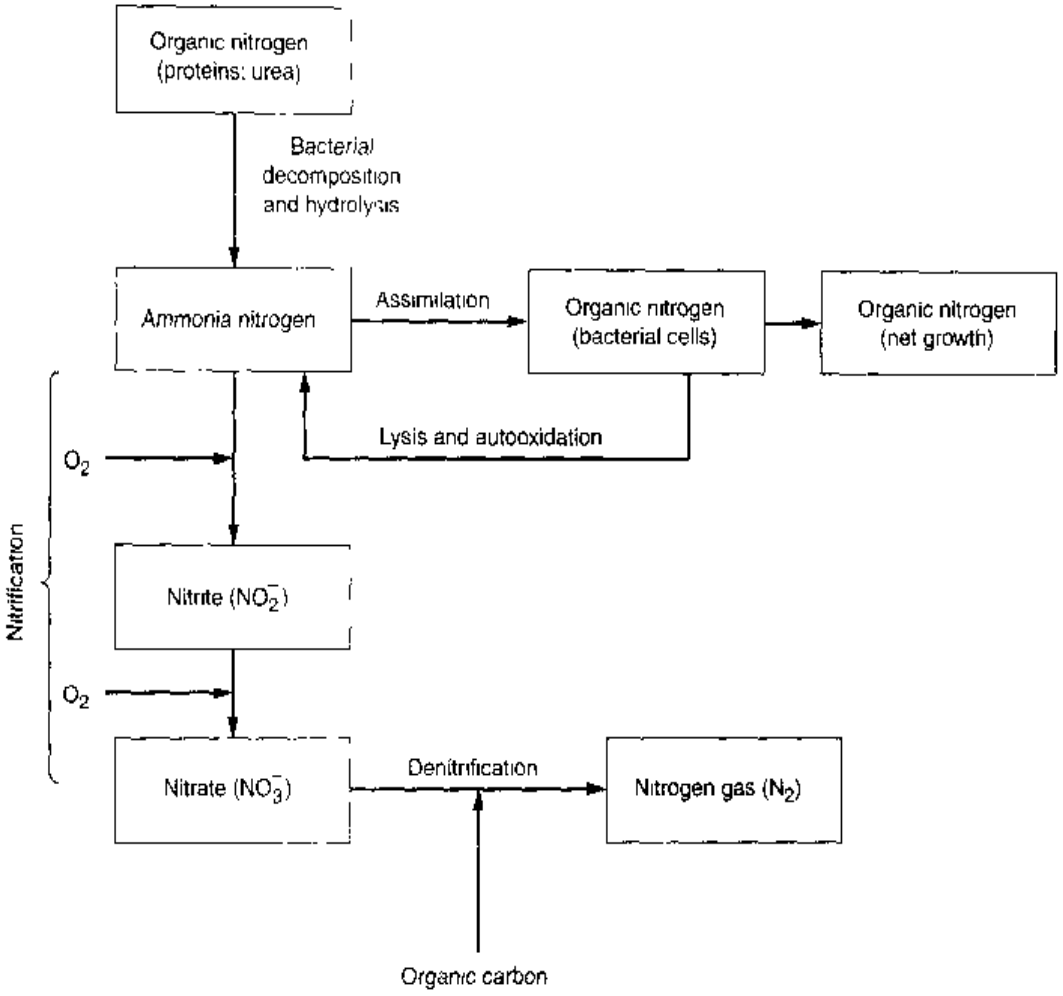
Metals. Metals are also of concern for nitrifiers, and Skinner and Walker (1961) have shown complete inhibition of ammonia oxidation at 0.25 mg/L nickel, 0.25 mg/L chromium, and 0.10 mg/L copper.

Un-ionized Ammonia. Nitrification is also inhibited by un-ionized ammonia (NH_3) or free ammonia, and un-ionized nitrous acid (HNO_2). The inhibition effects are dependent on the total nitrogen species concentration, temperature, and pH. At 20°C and pH 7.0, the NH_4-N concentrations at 100 mg/L and 20 mg/L may initiate inhibition of NH_4-N and NO_2-N oxidation, respectively, and NO_2-N concentrations at 280 mg/L may initiate inhibition of NO_2-N oxidation (U.S. EPA, 1993).

7–10 BIOLOGICAL DENITRIFICATION

The biological reduction of nitrate to nitric oxide, nitrous oxide, and nitrogen gas is termed *denitrification*. Biological denitrification is an integral part of biological nitrogen removal, which involves both nitrification and denitrification. Compared to alternatives of ammonia stripping (see Chap. 11), breakpoint chlorination (see Chap. 12), and ion exchange (see Chap. 11), biological nitrogen removal is generally more cost-effective and used more often. Biological nitrogen removal is used in wastewater treatment where there are concerns for eutrophication, and where groundwater must be protected against elevated NO_3-N concentrations where wastewater-treatment plant effluent is used for groundwater recharge and other reclaimed water applications.

Process Description



Two modes of nitrate removal can occur in biological processes, and these are termed assimilating and dissimilating nitrate reduction (see Fig. 7–20). Assimilating nitrate reduction involves the reduction of nitrate to ammonia for use in cell synthesis. Assimilation occurs when NH_4-N is not available and is independent of DO concentration. On the other hand, dissimilating nitrate reduction or biological denitrification is coupled to the respiratory electron transport chain, and nitrate or nitrite is used as an electron acceptor for the oxidation of a variety of organic or inorganic electron donors.

Two basic flow diagrams for activated-sludge denitrification and the conditions that drive the denitrification reaction rates are illustrated on Fig. 7–21. The first flow diagram (Fig. 7–21*a*) is for the Modified Ludzak-Ettinger (MLE) process (U.S. EPA, 1993), the most common process used for biological nitrogen removal in municipal wastewater treatment. The process consists of an anoxic tank followed by the aeration tank where nitrification occurs. Nitrate produced in the aeration tank is recycled back to the anoxic tank. Because the organic substrate in the influent wastewater provides the electron donor for oxidation reduction reactions using nitrate, the process is termed *substrate denitrification*. Further, because the anoxic process precedes the aeration tank, the process is known as a *preanoxic denitrification*.

In the second process shown on Fig. 7–21*b*, denitrification occurs after nitrification and the electron donor source is from endogenous decay. The process illustrated on Fig. 7–21*b* is generally termed a *postanoxic denitrification* as BOD removal has occurred first and is not available to drive the nitrate reduction reaction. When a postanoxic denitrification process depends solely on endogenous respiration for energy, it has a much slower rate of reaction than for the preanoxic processes using wastewater

Figure 7-20

Nitrogen transformations in biological treatment processes. *(Adapted from Sedlak, 1991.)*

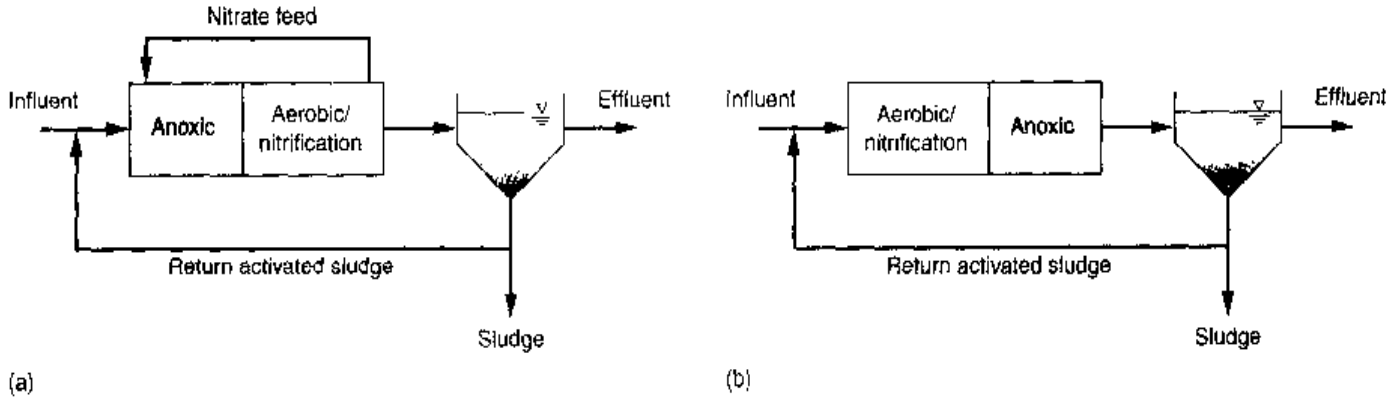


Figure 7-21

Types of denitrification processes and the reactors used for their implementation: (*a*) substrate driven (preanoxic denitrification) and (*b*) endogenous driven (postanoxic denitrification).

BOD. Often an exogenous carbon source such as methanol or acetate is added to postanoxic processes to provide sufficient BOD for nitrate reduction and to increase the rate of denitrification. Postanoxic processes include both suspended and attached growth systems. In one attached growth granular-medium filtration process, both nitrate reduction and effluent suspended solids removal occur in the same reactor.

The denitrification preanoxic and postanoxic processes described employ heterotrophic bacteria for nitrate reduction, but other pathways for biological nitrogen removal exist. Ammonia can be converted to nitrogen gas by novel autotrophic bacteria under anaerobic conditions and by heterotrophic-nitrifying bacteria under aerobic conditions. The organisms identified with these reactions are presented in the Microbiology section below. Littleton et al. (2000) looked for the possible influence of these autotrophic-denitrifying bacteria or to heterotrophic nitrifying bacteria for nitrogen removal in aerated full-scale, long-SRT, single-sludge, activated-sludge systems but could not find any significant activity for them. However, the use of novel autotrophic denitrifying bacteria has been demonstrated in a process for the treatment of high ammonia strength anaerobic digestion centrate in a fluidized bed reactor at 30 to 35°C (Strous et al. 1997, Jetten et al. 1999). The fluidized bed reactor is effective in maintaining these relatively slow-growing bacteria. Under anaerobic conditions NH_4^+ is oxidized by NO_2^- to produce nitrogen gas and a small amount of nitrate. About 1.3 moles of NO_2^- are used per mole of NH_4^+ (Strous et al. 1999a). A portion of the centrate stream must be nitrified to nitrite, but no carbon source is needed for nitrogen removal. The process is termed the Anammox process, which stands for anaerobic ammonium oxidation. The oxidation of ammonia to nitrite in anaerobic digester centrate has been done in a process termed the SHARON process, which can be used with the Anammox process (Jetten et al. 1999) and is described in Chap. 8.

Microbiology

A wide range of bacteria has been shown capable of denitrification, but similar microbial capability has not been found in algae or fungi. Bacteria capable of denitrification are both heterotrophic and autotrophic. The heterotrophic organisms include the following genera: *Achromobacter, Acinetobacter, Agrobacterium, Alcaligenes, Arthrobacter, Bacillus, Chromobacterium, Corynebacterium, Flavobacterium, Hypomicrobium, Moraxella, Neisseria, Paracoccus, Propionibacterium, Pseudomonas, Rhizobium, Rhodopseudomonas, Spirillum,* and *Vibrio* (Payne, 1981). In addition, Gayle (1989) lists *Halobacterium* and *Methanomonas. Pseudomonas* species are the most common and widely distributed of all the denitrifiers, and have been shown to use a wide array of organic compounds including hydrogen, methanol, carbohydrates, organic acids, alcohols, benzoates, and other aromatic compounds (Payne, 1981). Most of these bacteria are facultative aerobic organisms with the ability to use oxygen as well as nitrate or nitrite, and some can also carry out fermentation in the absence of nitrate or oxygen. Other autotrophic bacteria that can denitrify use hydrogen and reduced sulfur compounds as electron donors during denitrification. Both groups of organisms can grow heterotrophically if an organic carbon source is present (Gayle, 1989).

Nitrogen removal can also be accomplished by heterotrophic- and autotrophic-nitrifying bacteria under certain conditions, and by a unique bacteria associated with the Anammox process, which was discovered in the mid-1990s. Denitrification can occur under aerobic conditions by heterotrophic nitrifying bacteria (Robertson and Kuenen, 1990, and Patureau et al. 1994), so that simultaneous nitrification and denitrification exist with the conversion of ammonia to gaseous nitrogen products. The heterotrophic bacteria, *Paracoccus pantotropha,* have been studied extensively for simultaneous ammonia oxidation and nitrate reduction. The oxidation of ammonia by heterotrophic bacteria requires energy, which can be obtained by nitrate or nitrite reduction by *P. pan-*

totropha under aerobic conditions. A readily available substrate, such as acetate, is also needed. Due to the need for the carbon substrate, which is in limited supply in aerobic activated-sludge systems, little growth of heterotrophic nitrifiers is expected (van Loosdrecht and Jetten, 1998) in aerobic wastewater treatment systems.

Autotrophic nitrifying bacteria, such as *Nitrosomonas europaea*, can use nitrite to oxidize ammonia, with the production of nitrogen gas, when dissolved oxygen is not present (Bock et al. 1995). With oxygen present, these bacteria oxidize the ammonia with oxygen as the electron acceptor.

Ammonia oxidation with the reduction of nitrite under anaerobic conditions has also been shown at temperatures above 20°C in the Anammox process (Strous et al. 1997). The bacteria in the Anammox process are different than the autotrophic nitrifying bacteria described above, in that it cannot use oxygen for ammonia oxidation (Jetten et al. 1999). The Anammox bacteria could not be isolated and grown in pure culture (Strous et al. 1999b), but an enrichment was obtained by density purification for 16S rRNA extraction and analysis. Phylogenetic analysis showed that the bacteria is in the order *Planctomycetales*, a division with the domain Bacteria. Under anaerobic conditions the ammonia oxidation rate by the Annamox bacteria was shown to be 6 to 10 times faster than that for *N. Europaea* (Jetten et al. 1999).

Stoichiometry of Biological Denitrification

Biological denitrification involves the biological oxidation of many organic substrates in wastewater treatment using nitrate or nitrite as the electron acceptor instead of oxygen. In the absence of DO or under limited DO concentrations, the nitrate reductase enzyme in the electron transport respiratory chain is induced, and helps to transfer hydrogen and electrons to nitrate as the terminal electron acceptor. The nitrate reduction reactions involve the following reduction steps from nitrate to nitrite, to nitric oxide, to nitrous oxide, and to nitrogen gas:

$$NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2 \qquad (7\text{-}94)$$

In biological nitrogen removal processes, the electron donor is typically one of three sources: (1) the bsCOD in the influent wastewater, (2) the bsCOD produced during endogenous decay, and (3) an exogenous source such as methanol or acetate. The latter has been added in separate treatment units, such as polishing filters, after nitrification where almost no bsCOD remains. Reaction stoichiometry for different electron donors is shown as follows. The term $C_{10}H_{19}O_3N$ is often used to represent the biodegradable organic matter in wastewater (U.S. EPA, 1993).

Wastewater:

$$C_{10}H_{19}O_3N + 10NO_3^- \rightarrow 5N_2 + 10CO_2 + 3H_2O + NH_3 + 10OH^- \qquad (7\text{-}95)$$

Methanol:

$$5CH_3OH + 6NO_3^- \rightarrow 3N_2 + 5CO_2 + 7H_2O + 6OH^- \qquad (7\text{-}96)$$

Acetate:

$$5CH_3COOH + 8NO_3^- \rightarrow 4N_2 + 10CO_2 + 6H_2O + 8OH^- \qquad (7\text{-}97)$$

In all the above heterotrophic denitrification reactions, one equivalent of alkalinity is produced per equivalent of NO_3-N reduced, which equates to 3.57 g of alkalinity (as

$CaCO_3$) production per g of nitrate nitrogen reduced. Recall from nitrification that 7.14 g alkalinity (as $CaCO_3$) was consumed per g of NH_4-N oxidized, so that by denitrification about one-half of the amount destroyed by nitrification can be recovered.

From oxidation reduction half reactions, the oxygen equivalent of using nitrate or nitrite as electron acceptors can be determined. The half reactions per mole e^- transferred are determined from Table 7–7 and are shown as follows:

For oxygen:

$$0.25O_2 + H^+ + e^- \rightarrow 0.5H_2O \quad (7\text{–}98)$$

For nitrate:

$$0.20NO_3^- + 1.2H^+ + e^- \rightarrow 0.1N_2 + 0.6H_2O \quad (7\text{–}99)$$

For nitrite:

$$0.33NO_2^- + 1.33H^+ + e^- \rightarrow 0.67H_2O + 0.17N_2 \quad (7\text{–}100)$$

Comparing the above half reactions for oxygen [Eq. (7–98)] and nitrate [Eq. (7–99)], it should be noted that 0.25 mole of oxygen is equivalent to 0.2 mole of nitrate for electron transfer in oxidation reduction. Thus, the oxygen equivalent of nitrate is (0.25 × 32 g O_2/mole) divided by the nitrate gram equivalent (0.20 × 14 g N/mole) equals 2.86 g O_2/g NO_3-N. The oxygen equivalent is a useful design factor when calculating the total oxygen required for nitrification-denitrification biological treatment systems. Similarly, for nitrite as the electron acceptor, the oxygen equivalent of nitrite is 1.71 g O_2/g NO_2-N.

In biological denitrification, the principal design goal is to reduce nitrate biologically. Thus, an important design parameter for denitrification processes is the amount of bsCOD or BOD needed to provide a sufficient amount of electron donor for nitrate removal. As a general rule, Barth et al. (1968) estimated that 4 g of BOD is needed per g of NO_3 reduced. However, the actual value will depend on the system operating conditions and the type of electron donor used for denitrification. Based on information presented in Sec. 7–6, in which it was shown that the amount of oxygen used per unit of bsCOD was related to the biomass yield, the bsCOD/NO_3-N ratio is similarly related to the system biomass yield. An expression that can be used to determine the bsCOD/NO_3-N ratio can be developed based on the following assumptions and facts (Randall et al., 1992). It should be noted that because of the long SRT values involved in nitrification, the following analysis also applies to bCOD, which includes colloidal and particulate components. From a steady-state COD balance it can be shown that the bsCOD removed is oxidized or accounted for in cell growth.

$$bsCOD_r = bsCOD_{syn} + bsCOD_o \quad (7\text{–}101)$$

where $bsCOD_r$ = bsCOD utilized, g bsCOD/d
$bsCOD_{syn}$ = bsCOD incorporated into cell synthesis, g bsCOD/d
$bsCOD_o$ = bsCOD oxidized, g bsCOD/d

For cell synthesis, the $bsCOD_{syn}$ is calculated from the net biomass yield and the ratio of 1.42 g O_2/g VSS. The oxygen equivalent of the biomass is equal to the bsCOD incorporated into biomass.

$$bsCOD_{syn} = 1.42\ Y_n\ bsCOD_r \quad (7\text{–}102)$$

where Y_n = net biomass yield, g VSS/g $bsCOD_r$

and

$$Y_n = \frac{Y}{1 - (k_{dn})\text{SRT}} \qquad (7\text{–}103)$$

Thus

$$\text{bsCOD}_r = \text{bsCOD}_0 + 1.42 Y_n \text{bsCOD}_t \qquad (7\text{–}104)$$

Rearranging yields

$$\text{bsCOD}_0 = (1 \quad 1.42\ Y_n)\ \text{bsCOD}_r \qquad (7\text{–}105)$$

In Eq. (7–105), bsCOD_0 is the COD oxidized and is equal to the oxygen equivalent of the NO_3-N used for bsCOD oxidation. Hence,

$$\text{bsCOD}_0 - 2.86\ NO_t \qquad (7\text{–}106)$$

where 2.86 = O_2 equivalent of NO_3-N, g O_2/g NO_3-N

NO_t = NO_3-N reduced, g/d

Substituting Eq. (7–105) in Eq. (7–106) yields

$$2.86\ NO_3 = (1 - 1.42\ Y_n)\ \text{bsCOD}_r \qquad (7\text{–}107)$$

or

$$\frac{\text{bsCOD}}{NO_3\text{-N}} = \frac{2.86}{1 - 1.42 Y_n} \qquad (7\text{–}108)$$

Thus, g bsCOD/g NO_3-N = $\dfrac{2.86}{1 \quad 1.42 Y_n}$

Growth Kinetics

For biological denitrification, the biokinetic equations used to describe bacteria growth and substrate utilization are similar to those described previously in this chapter for aerobic heterotrophic bacteria. The rate of soluble substrate utilization is also controlled by the soluble substrate concentration [Eq. (7–40)], with nitrate serving as the electron acceptor in lieu of oxygen. The nitrate concentration controls the substrate utilization kinetics only at very low NO_3-N concentrations, near 0.1 mg/L. Nitrate serves as an electron acceptor in the same way as oxygen from a biokinetics perspective, and thus the nitrate utilization rate (denitrification rate) is proportional to the substrate utilization rate.

There are two general cases where the substrate utilization rate controls the denitrification rate. The first is for anoxic/aerobic processes where the organic substrate (electron donor) is from the influent wastewater fed into the anoxic reactor. The second is for postanoxic denitrification, where nitrate reduction is done after secondary treatment in a reactor receiving another carbon source. Because the BOD is depleted from secondary treatment, an exogenous carbon source is used to drive the nitrate reduction reaction. In most cases methanol is supplied to create the demand for the electron acceptor in suspended growth or attached growth processes. Endogenous respiration creates a demand for nitrate in addition to that caused by substrate utilization and oxidation. This reaction occurs in the mixed liquor of anoxic tanks and is at a much lower rate than the denitrification rate caused by substrate utilization.

In the case where wastewater provides the electron donor, an anoxic reactor receives the influent wastewater and it is followed in the treatment system by an aerobic reactor where nitrification occurs. Heterotrophic bacterial growth occurs in both the anoxic and aerobic zones with nitrate and oxygen consumption, respectively. The mixed liquor biomass concentration can be calculated based on the total amount of BOD removed, but only a portion of that biomass can use both nitrate and oxygen as electron acceptors. The microorganisms in the other portion are strict aerobes and can only use oxygen as the electron acceptor. To apply biokinetic expressions for denitrification, the substrate utilization rate expression is modified to account for the fact that only a portion of the biomass is active in the anoxic zone.

The substrate utilization rate r_{su} expression [Eq. (7–12)] is modified by a term to show a lower utilization rate in the anoxic zone as follows:

$$r_{su} = -\frac{k\,XS\eta}{K_s + S} \tag{7–109}$$

where η = fraction of denitrifying bacteria in the biomass, g VSS/g VSS
k, X, S, K_s are as defined previously

When nitrate is used as an electron acceptor instead of oxygen, the maximum specific substrate utilization rate (k) may be lower than the rate with oxygen as the electron acceptor. In Eq. (7–109), the k value used is the same as that used for oxygen, and any effect of lower kinetic rate is incorporated into the η term. The K_s value has been found to be similar, whether nitrate or oxygen is the electron acceptor (Stensel and Horne, 2000).

The value for η has been found to vary from 0.20 to 0.80 for preanoxic denitrification reactors fed domestic wastewaters (Stensel and Horne, 2000). The activated-sludge configuration, the system SRT, and the fraction of influent BOD removed with nitrate appear to affect the η value. For anoxic/aerobic processes with substantial substrate and nitrate removal in the preanoxic zone η may be close to 0.80. In spite of the fact that only a portion of the mixed liquor biomass can use nitrate, the anoxic reactor volumes used for anoxic/aerobic processes range from only 10 to 30 percent of the total volume (anoxic plus aerobic) for treating domestic wastewater.

For postanoxic suspended growth or attached growth processes the biomass is developed under mainly anoxic conditions and with a selected single organic substrate. In this case the η term is not necessary because the biomass consists of mainly denitrifying bacteria. The biokinetic equations presented previously can then be used with the appropriate kinetic coefficient values (k, K_s, Y, k_d) to design a postanoxic complete-mix suspended growth process. The kinetic coefficient values for growth using methanol have been developed at 10°C and 20°C in laboratory studies (Randall et al., 1992), and a suspended growth design with methanol as the electron donor substrate is illustrated in Chap. 10.

The kinetics for methanol utilization are such that the SRTs required for a denitrification suspended growth process are in the same range as SRTs for aerobic systems designed for BOD removal only, about 3 to 6 d.

Effect of Dissolved Oxygen Concentration. Dissolved oxygen can inhibit nitrate reduction by repressing the nitrate reduction enzyme. In activated-sludge flocs and biofilms, denitrification can proceed in the presence of low bulk liquid DO con-

centrations. A dissolved oxygen concentration of 0.2 mg/L and above has been reported to inhibit denitrification for a *Pseudomonas* culture (Skerman and MacRae, 1957; Terai and Mori, 1975) and by Dawson and Murphy (1972) for activated-sludge treating domestic wastewater. Nelson and Knowles (1978) reported that denitrification ceased in a highly dispersed growth at a DO concentration of 0.13 mg/L. The effect of nitrate and DO concentration on the biokinetics is accounted for by two correction factors to Eq. (7-109) expressed in the form of two saturation terms as follows:

$$r_{sR} = -\left(\frac{kXS}{K_s + S}\right)\left(\frac{NO_3}{K_{s,NO} + NO_3}\right)\left(\frac{K'_o}{K'_o + DO}\right)(\eta) \qquad (7\text{-}110)$$

where K'_o = DO inhibition coefficient for nitrate reduction, mg/L
K_{s,NO_3} = half velocity coefficient for nitrate limited reaction, mg/L
Other terms are as defined previously.

The value of K'_o is system-specific. Values in the range from 0.1 to 0.2 mg/L have been proposed for K'_o and 0.1 mg/L for K_{s,NO_3} (Barker and Dold, 1997). Assuming a K_o value of 0.1 mg/L the rate of substrate utilization with nitrate as the electron acceptor at DO concentrations of 0.10, 0.20, and 0.50 mg/L would be at 50, 33, and 17 percent of the maximum rate, respectively.

Effect of Simultaneous Nitrification-Denitrification. In activated-sludge systems, the issue of DO concentration is confounded by the fact that the measured bulk liquid DO concentration does not represent the actual DO concentration within the activated-sludge floc. Under low DO concentration conditions, denitrification can occur in the floc interior, while nitrification is occurring at the floc exterior. Also in activated-sludge tanks operated at low DO concentrations, both aerobic and anaerobic zones exist depending on mixing conditions and distance from the aeration point, so that nitrification and denitrification can be occurring in the same tank. Under these conditions, nitrogen removal that occurs in a single aeration tank is referred to as simultaneous nitrification and denitrification. Although both nitrification and denitrification are occurring at reduced rates as indicated by the DO effects described for both processes, if a sufficient SRT and τ exist, the overall nitrogen removal can be significant. Rittman and Langeland (1985) reported greater than 90 percent nitrogen removal by nitrification and denitrification in an activated-sludge system used to treat municipal wastewater at DO concentrations below 0.50 mg/L and with values of τ greater than 25 hours.

Environmental Factors

Alkalinity is produced in denitrification reactions and the pH is generally elevated, instead of being depressed as in nitrification reactions. In contrast to nitrifying organisms, there has been less concern about pH influences on denitrification rates. No significant effect on the denitrification rate has been reported for pH between 7.0 and 8.0, while Dawson and Murphy (1972) showed a decrease in the denitrification rate as the pH was decreased from 7.0 to 6.0 in batch unacclimated tests.

7-11 BIOLOGICAL PHOSPHORUS REMOVAL

The removal of phosphorus by biological means is known as *biological phosphorus removal*. Phosphorus removal is generally done to control eutrophication because

phosphorus is a limiting nutrient in most freshwater systems. Treatment plant effluent discharge limits have ranged from 0.10 to 2.0 mg/L of phosphorus depending on plant location and potential impact on receiving waters. Chemical treatment using alum or iron salts is the most commonly used technology for phosphorus removal (see Sec. 6–4 in Chap. 6), but since the early 1980s success in full-scale plant biological phosphorus removal has encouraged further use of the technology. The principal advantages of biological phosphorus removal are reduced chemical costs and less sludge production as compared to chemical precipitation.

Process Description

In the biological removal of phosphorus, the phosphorus in the influent wastewater is incorporated into cell biomass, which subsequently is removed from the process as a result of sludge wasting. Phosphorus accumulating organisms (PAOs) are encouraged to grow and consume phosphorus in systems that use a reactor configuration that provides PAOs with a competitive advantage over other bacteria. The reactor configuration utilized for phosphorus removal is comprised of an anaerobic tank having a τ value of 0.50 to 1.0 h that is placed ahead of the activated-sludge aeration tank (see Fig. 7–22). The contents of the anaerobic tank are mixed to provide contact with the return activated sludge and influent wastewater. Anaerobic contact tanks have been placed in front of many different types of suspended growth processes (see detailed discussion in Sec. 8–6 in Chap. 8), with aerobic SRT values ranging from 2 to 40 d.

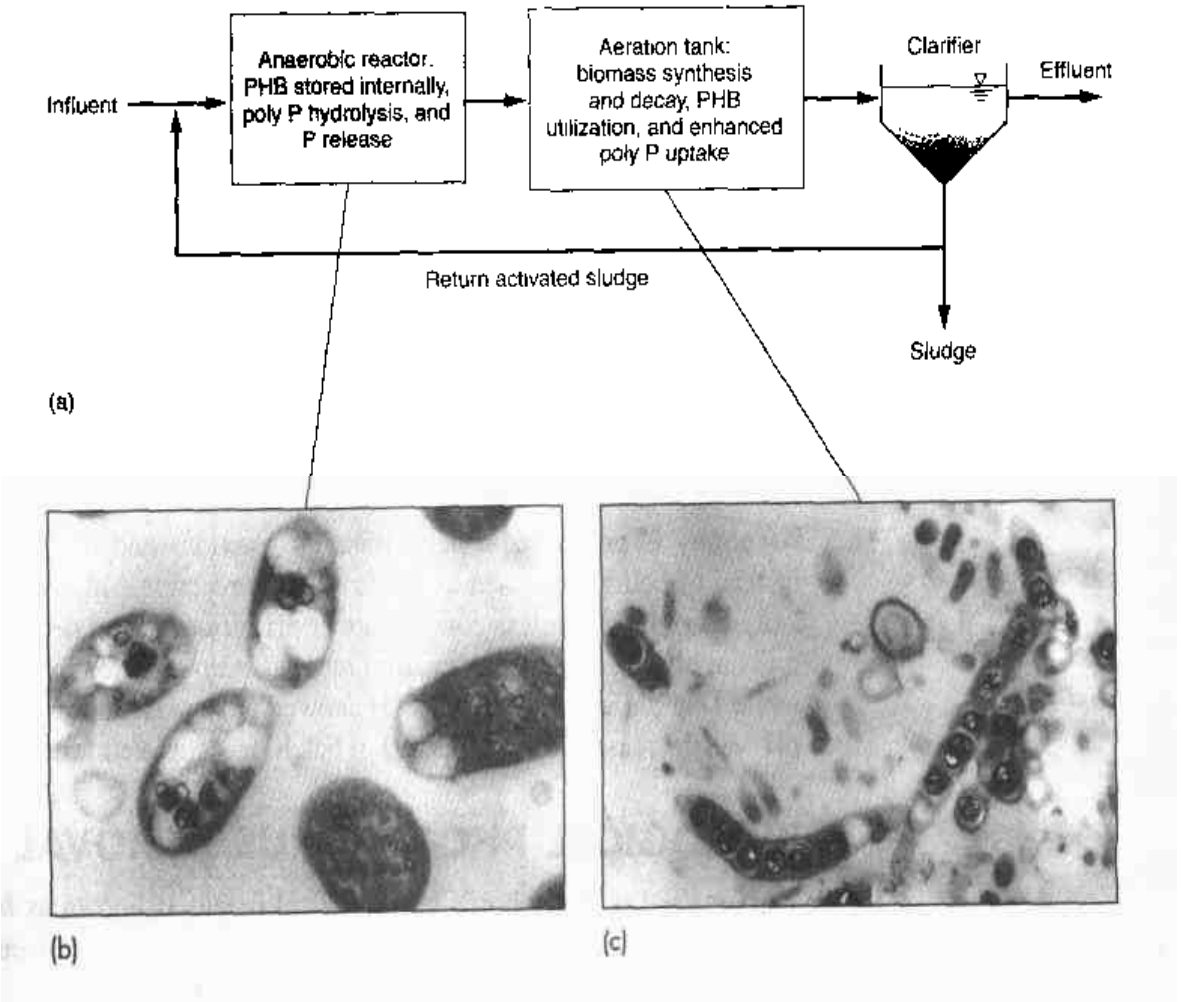

Figure 7-22

Biological phosphorus removal: (a) typical reactor configuration. Photos below flow diagram are of (b) transmission electron microscope images of polyhydroxybutyrate storage and (c) polyphosphate storage granules.

Phosphorus removal in biological systems is based on the following observations (Sedlak, 1991):

1. Numerous bacteria are capable of storing excess amounts of phosphorus as polyphosphates in their cells.
2. Under anaerobic conditions, PAOs will assimilate fermentation products (e.g., volatile fatty acids) into storage products within the cells with the concomitant release of phosphorus from stored polyphosphates.
3. Under aerobic conditions, energy is produced by the oxidation of storage products and polyphosphate storage within the cell increases.

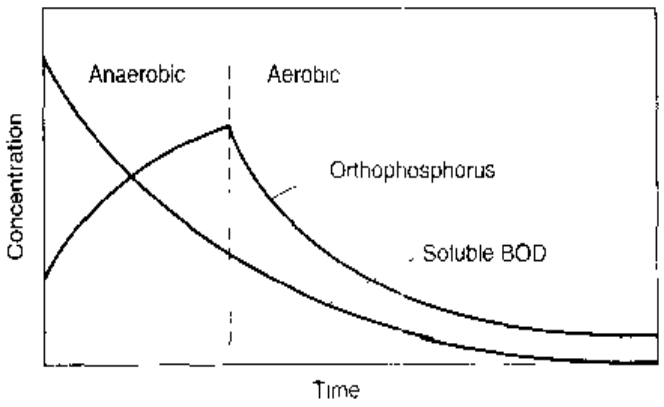
A simplified version of the processes occurring in the anaerobic and aerobic/anoxic reactors or zones is presented below. In many applications for phosphorus removal, an anoxic reactor follows the anaerobic reactor and precedes the aerobic reactor. Most PAOs can use nitrite in place of oxygen to oxidize their stored carbon source. A more comprehensive description of the biochemistry and intracellular transformations can be found in Wentzel et al. (1991).

Processes Occurring in the Anaerobic Zone

- Acetate is produced by fermentation of bsCOD which, as defined earlier, is dissolved degradable organic material that can be assimilated easily by the biomass. Depending on the value of τ for the anaerobic zone, some colloidal and particulate COD is also hydrolyzed and converted to acetate, but the amount is generally small compared to that from the bsCOD conversion.
- Using energy available from stored polyphosphates, the PAOs assimilate acetate and produce intracellular polyhydroxybutyrate (PHB) storage products. Some glycogen contained in the cell is also used. Concurrent with the acetate uptake is the release of orthophosphate ($O\text{-}PO_4$), as well as magnesium, potassium, and calcium cations.
- The PHB content in the PAOs increases while the polyphosphate decreases.

Processes Occurring in the Aerobic/Anoxic Zone

- Stored PHB is metabolized, providing energy from oxidation and carbon for new cell growth.
- Some glycogen is produced from PHB metabolism.
- The energy released from PHB oxidation is used to form polyphosphate bonds in cell storage so that soluble orthophosphate ($O\text{-}PO_4$) is removed from solution and incorporated into polyphosphates within the bacterial cell. Cell growth also occurs due to PHB utilization and the new biomass with high polyphosphate storage accounts for phosphorus removal.
- As a portion of the biomass is wasted, stored phosphorus is removed from the biotreatment reactor for ultimate disposal with the waste sludge.



The events occurring in the anaerobic and aerobic zones are illustrated graphically on Fig. 7–23.

Microbiology

Phosphorus is important in cellular energy transfer mechanisms via adenosine triphosphate (ATP) and polyphosphates. As energy is produced in oxidation reduction reactions,

Figure 7–23

Fate of soluble BOD and phosphorus in nutrient removal reactor. *(Adapted from Sedlak, 1991.)*

adenosine diphosphate (ADP) is converted to ATP with 7.4 kcal/mole of energy captured in the phosphate bond. As the cell uses energy, ATP is converted to ADP with phosphorus release. For common heterotrophic bacteria in activated-sludge treatment the typical phosphorus composition is 1.5 to 2.0 percent. However, many bacteria are able to store phosphorus in their cells in the form of energy-rich polyphosphates, resulting in phosphorus content as high as 20 to 30 percent by dry weight. The polyphosphates are contained in volutin granules within the cell along with Mg^{2+}, Ca^{2+}, and K^{+} cations.

In the anaerobic zone, concentrations of $O\text{-}PO_4$ as high as 40 mg/L can be measured in the liquid, as compared to wastewater influent concentrations of 5 to 8 mg/L. The high concentration of $O\text{-}PO_4$ can be taken as an indication that phosphorus release by the bacteria has occurred in this zone. Also in this zone, significant amounts of poly-*b*-hydroxybutyrate (PHB) are found stored in bacteria cells, but the PHB concentration declines appreciably in the subsequent anoxic and/or aerobic zones and can be measured and quantified. The $O\text{-}PO_4$ is taken up from solution in the aerobic and anoxic zones, generally leading to very low remaining concentrations. Based on investigations of biological phosphorus removal, it was found that acetate was essential to forming the PHB under anaerobic conditions, which provided a competitive advantage for the PAOs.

The anaerobic zone in the anaerobic/aerobic treatment process is termed a "selector," because it provides conditions that favor the proliferation of the PAOs, by the fact that a portion of the influent bCOD is consumed by the PAOs instead of other heterotrophic bacteria. Because the PAOs prefer low-molecular-weight fermentation product substrates, the preferred food source would not be available without the anaerobic zone that provides for the fermentation of the influent bsCOD to acetate. Because of the polyphosphate storage ability, the PAOs have energy available to assimilate the acetate in the anaerobic zone. Other aerobic heterotrophic bacteria have no such mechanism for acetate uptake, and they are starved while the PAOs assimilate COD in the anaerobic zone. It should also be noted that the PAOs form very dense, good settling floc in the activated sludge, which is an added benefit. In some facilities, the anaerobic/aerobic process sequence has been used because of the sludge settling benefits, even though biological phosphorus removal was not required.

Care must be taken in the handling of the waste sludge from biological phosphorus removal systems. When the sludge is held under anaerobic conditions, phosphorus release will occur. Release of $O\text{-}PO_4$ is possible even without acetate addition as the bacteria use the stored polyphosphate for an energy source. The release of $O\text{-}PO_4$ can also occur after extended contact time in the anaerobic zone of the biological phosphorus treatment system. In that case the released phosphorus may not be taken up in the

aerobic zone because the release was not associated with acetate uptake and PHB storage for later oxidation. The release of O-PO_4 under these conditions is termed *secondary release* (Barnard, 1984), which can lead to a lower phosphorus removal efficiency for the biological process.

Stoichiometry of Biological Phosphorus Removal

Based on the description of the phosphorus removal mechanism, acetate uptake in the anaerobic zone is critical in determining the amount of PAOs that can be produced and, thus, the amount of phosphorus that can be removed by this pathway. If significant amounts of dissolved oxygen or nitrate enter the anaerobic zone, the acetate can be depleted before it is taken up by the PAOs, and treatment performance will be hindered. Biological phosphorus removal is not used in systems that are designed with nitrification without including a means for denitrification to minimize the amount of nitrate in the return sludge flow to the anaerobic zone.

The amount of phosphorus removed by biological storage can be estimated from the amount of bsCOD that is available in the wastewater influent as most of the bsCOD will be converted to acetate in the short anaerobic hydraulic detention time τ. Methods for determining the amount of bsCOD in the influent will be described in Chap. 8 under wastewater characterization. The following assumptions are used to evaluate the stoichiometry of biological phosphorus removal: (1) 1.06 g acetate/g bsCOD will be produced as most of the COD fermented will be converted to VFAs due to the low cell yield of the fermentation process, (2) a cell yield of 0.30 g VSS/g acetate, and (3) a cell phosphorus content 0.3 g P/g VSS. Using these assumptions, about 10 g of bsCOD will be required to remove 1 g of phosphorus by the biological storage mechanism. Other bCOD removal in the activated-sludge system will result in additional phosphorus removal by normal cell synthesis.

Better performance for biological phosphorus removal systems is achieved when bsCOD or acetate is available at a steady rate. Periods of starvation or low bsCOD concentrations result in changes in the intracellular storage reserves of glycogen, PHB, and polyphosphates and rapidly lead to decreased phosphorus removal efficiency (Stephens and Stensel, 1998). The amount of phosphorus that can be removed from a wastewater is illustrated in Example 7–8.

EXAMPLE 7–8 Estimating the Amount of Phosphorus Removal Given the following influent wastewater characteristics and the corresponding biological process information, estimate the effluent phosphorus concentration.

Influent	Concentration, g/m³
COD	300
bCOD	200
bsCOD	50
Phosphorus	6

1. Heterotrophic synthesis yield, $Y = 0.40$ g VSS/g COD
2. Endogenous decay coefficient, $k_d = 0.08$ g VSS/g VSS·d

3. SRT = 5 d
4. Phosphorus content of PAOs = 0.30 g P/g VSS
5. Phosphorus content of other bacteria = 0.02 g P/g VSS
6. Clarifier effluent VSS concentration = 8 g/m^3

Solution

1. Determine phosphorus removed by PAOs due to the fermentation of the 50 g rbsCOD/m^3 in the wastewater influent.
   a. Determine biomass produced using Eq. (7–57) neglecting cell debris

$$\text{Biomass produced} = \left[\frac{Y}{1 + (k_d)\text{SRT}}\right]\text{bsCOD}$$

$$= \left\{\frac{(0.40\text{ g VSS/g COD})}{[1 + (0.08\text{ g/g·d})(5\text{ d})]}\right\}(50\text{ g bsCOD/m}^3) = 14.3\text{ g VSS/m}^3$$

   b. Determine the phosphorus removed

$$\text{P removed} = (0.30\text{ g P/g VSS})(14.3\text{ g VSS/m}^3) = 4.3\text{ g/m}^3$$

2. Determine phosphorus removed by heterotrophs from the conversion of colloidal and particulate bCOD.
   a. Determine the COD removed

$$\text{COD removed} = \text{bCOD} - \text{bsCOD} - 200 - 50\text{ g/m}^3 = 150\text{ g/m}^3$$

$$\text{Biomass produced from bpCOD} = \left[\frac{Y}{1 + (k_d)\text{SRT}}\right]\text{bpCOD}$$

$$= \left\{\frac{(0.40\text{ g VSS/g COD})}{[1 + (0.08\text{ g/g·d})(5\text{ d})]}\right\}150\text{ g bpCOD/m}^3 = 42.9\text{ g VSS/m}^3$$

   b. Determine the phosphorus removed

$$\text{P removed} = 0.02\text{ g P/g VSS} = 0.02(42.9) = 0.86\text{ g/m}^3$$

3. Determine total phosphorus removed and effluent phosphorus concentration.

$$\text{Total P removed} = 4.3 + 0.86 = 5.16\text{ g/m}^3$$

$$\text{Effluent soluble concentration} = 6.0 - 5.16 = 0.84\text{ g/m}^3$$

4. Estimate P content of effluent VSS.

$$\text{Average P content of effluent VSS} = \frac{(0.30\text{ g P/g VSS})(14.3\text{ g/m}^3) + (0.02\text{ g P/g VSS})(42.9\text{ g/m}^3)}{[(14.3 + 42.9)\text{ g/m}^3]}$$

$$= 0.09\text{ g P/g VSS}$$

$$\text{Phosphorus in effluent VSS} = 0.09(8\text{ g/m}^3) = 0.72\text{ g/m}^3$$

$$\text{Total effluent } P \text{ concentration} = 0.84 + 0.72 = 1.56\text{ g/m}^3$$

Growth Kinetics

Biological phosphorus growth kinetics are within the same order of magnitude of other heterotrophic bacteria. Mamais and Jenkins (1992) showed that biological phosphorus removal could be maintained in anaerobic/aerobic systems at SRTs greater than 2.5 d at 20°C. A maximum specific growth rate at 20°C is given as 0.95 g/g•d (Barker and Dold, 1997).

Environmental Factors

System performance is not affected by DO as long as the aerobic zone DO concentration is above 1.0 mg/L. At pH values below 6.5, phosphorus removal efficiency is greatly reduced (Sedlak, 1991).

In biological phosphorus removal systems, sufficient cations associated with polyphosphate storage must also be available. The recommended molar ratios of Mg, K, and Ca to phosphorus are 0.71, 0.50, and 0.25, respectively (Wentzel et al., 1989). Thus, for an influent soluble phosphorus concentration of 10 mg/L, 5.6, 6.3, and 3.2 mg/L of Mg, K, and Ca, respectively, would be required. The relative amounts of these cations associated with phosphate storage are 0.28, 0.26, and 0.09 mole/mole of phosphorus, respectively (Sedlak, 1991). Most municipal wastewaters have sufficient amounts of these inorganic elements, but care must be taken to assure sufficient amounts in industrial applications or laboratory experiments.

7–12 ANAEROBIC FERMENTATION AND OXIDATION

Anaerobic fermentation and oxidation processes are used primarily for the treatment of waste sludge (see Fig. 7–24) and high-strength organic wastes. However, applications for dilute waste streams have also been demonstrated and are becoming more common. Anaerobic fermentation processes are advantageous because of the lower

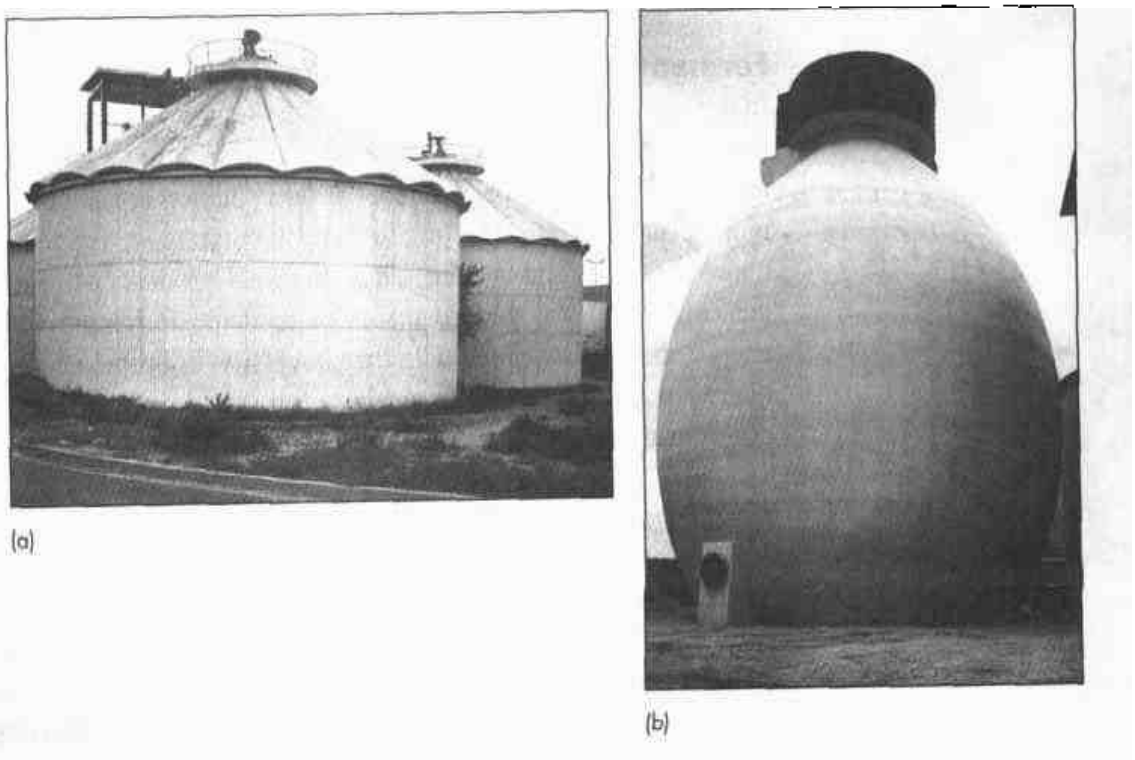


Figure 7–24
Views of anaerobic digesters. (a) Kuwait City, Kuwait and (b) egg-shaped digester at Okinawa, Japan.

biomass yields and because energy, in the form of methane, can be recovered from the biological conversion of organic substrates. Although most fermentation processes are operated in the mesophilic temperature range (30 to 35°C), there is increased interest in thermophilic fermentation alone or before mesophilic fermentation. The latter is termed temperature phased anaerobic digestion (TPAD) and is typically designed with a sludge SRT of 3 to 7 d in the first thermophilic phase at 50 to 60°C and 7 to 15 d in the final mesophilic phase (Han and Dague, 1997). Thermophilic anaerobic digestion processes, considered in Chap. 14, are used to accomplish high pathogen kill to produce *Class A biosolids*, which can be used for unrestricted reuse applications.

For treating high-strength industrial wastewaters, anaerobic treatment has been shown to provide a very cost-effective alternative to aerobic processes with savings in energy, nutrient addition, and reactor volume. Because the effluent quality is not as good as that obtained with aerobic treatment, anaerobic treatment is commonly used as a pretreatment step prior to discharge to a municipal collection system or is followed by an aerobic process. Suspended and attached growth anaerobic treatment process designs for liquid streams are presented in Chap. 10 and anaerobic digester designs for sludge treatment are presented in Chap. 14.

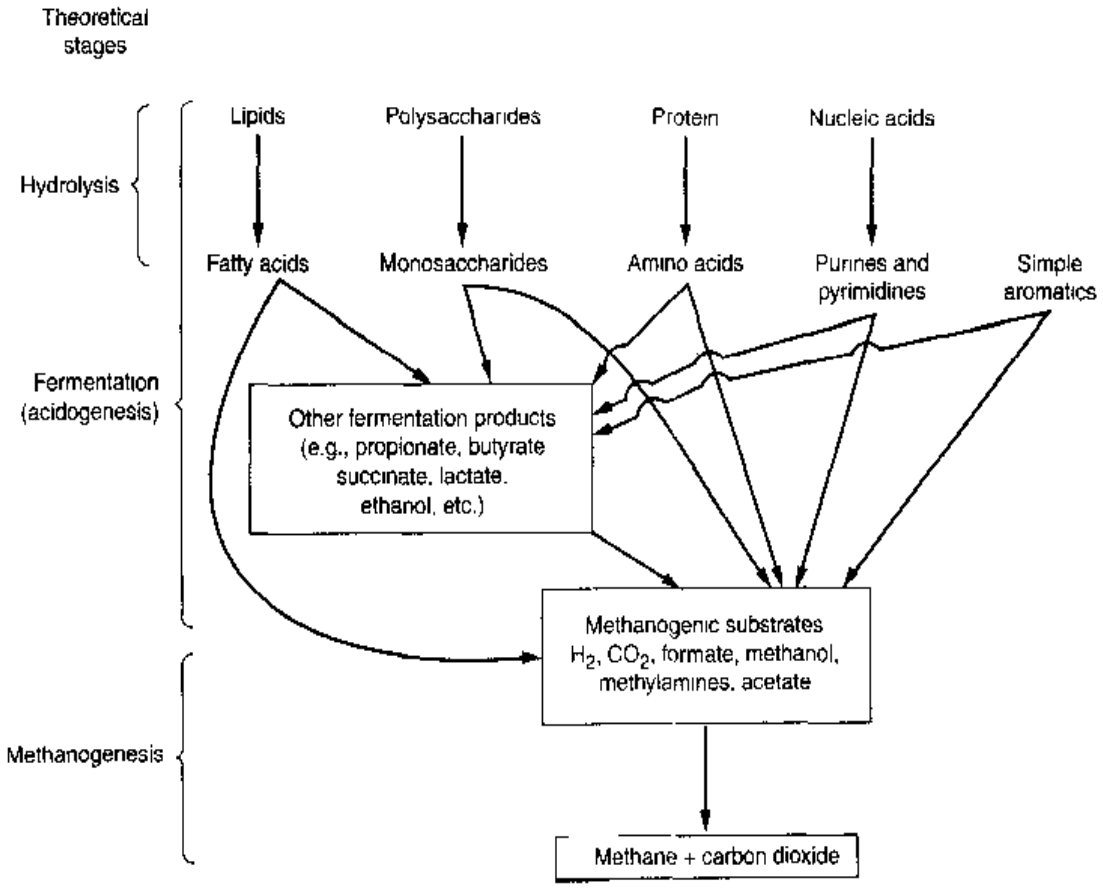
Process Description

Three basic steps are involved in the overall anaerobic oxidation of a waste: (1) hydrolysis, (2) fermentation (also known as acidogenesis), and (3) methanogenesis. The three steps are illustrated schematically on Fig. 7–25. The starting point on the schematic for a particular application depends on the nature of the waste to be processed.

Hydrolysis. The first step for most fermentation processes, in which particulate material is converted to soluble compounds that can then be hydrolyzed further to simple monomers that are used by bacteria that perform fermentation, is termed *hydrolysis*. For some industrial wastewaters, fermentation may be the first step in the anaerobic process.

Fermentation. The second step is *fermentation* (also referred to as *acidogenesis*). In the fermentation process, amino acids, sugars, and some fatty acids are degraded further, as shown on Fig. 7–25. Organic substrates serve as both the electron donors and acceptors. The principal products of fermentation are acetate, hydrogen, CO_2, and propionate and butyrate. The propionate and butyrate are fermented further to also produce hydrogen, CO_2, and acetate. Thus, the final products of fermentation (acetate, hydrogen, and CO_2) are the precursors of methane formation (methanogenesis). The free energy change associated with the conversion of propionate and butyrate to acetate and hydrogen requires that hydrogen be at low concentrations in the system ($H_2 < 10^{-4}$ atm), or the reaction will not proceed (McCarty and Smith, 1986).

Methanogenesis. The third step, *methanogenesis*, is carried out by a group of organisms known collectively as methanogens. Two groups of methanogenic organisms are involved in methane production. One group, termed *aceticlastic methanogens*, split acetate into methane and carbon dioxide. The second group, termed hydrogen-utilizing methanogens, use hydrogen as the electron donor and CO_2 as the electron acceptor to produce methane. Bacteria within anaerobic processes, termed *acetogens*, are also able to use



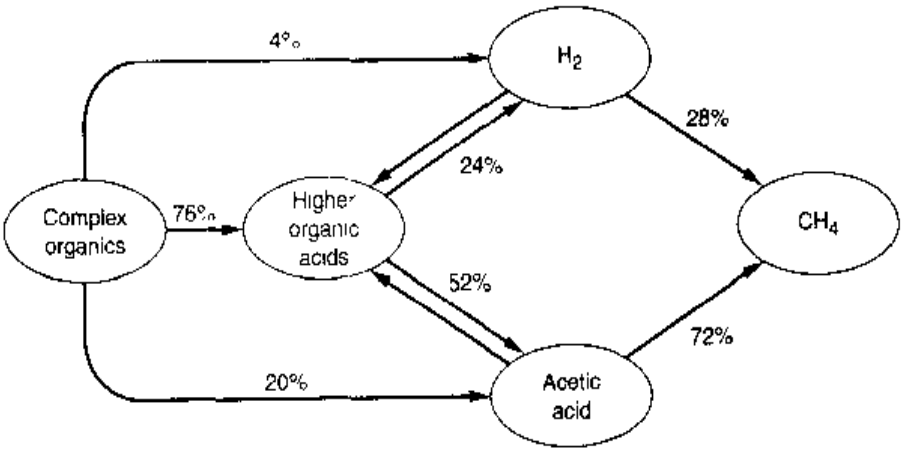


Figure 7–25

Anaerobic process schematic of hydrolysis, fermentation, and methanogenesis. *(Adapted from McCarty and Smith, 1991.)*

Figure 7–26

Carbon and hydrogen flow in anaerobic digestion process. *(Adapted from Jeris and McCarty, 1963 and McCarty, 1981.)*

CO_2 to oxidize hydrogen and form acetic acid. However, the acetic acid will be converted to methane, so the impact of this reaction is minor. As shown on Fig. 7–26, about 72 percent of the methane produced in anaerobic digestion is from acetate formation.

Microbiology

The group of nonmethanogenic microorganisms responsible for hydrolysis and fermentation consists of facultative and obligate anaerobic bacteria. Organisms isolated

from anaerobic digesters include *Clostridium* spp., *Peptococcus anaerobus, Bifidobacterium* spp., *Desulphovibrio* spp., *Corynebacterium* spp., *Lactobacillus, Actinomyces, Staphylococcus,* and *Escherichia coli.* Other physiological groups present include those producing proteolytic, lipolytic, ureolytic, or cellulytic enzymes.

The microorganisms responsible for methane production, classified as archaea, are strict obligate anaerobes. Many of the methanogenic organisms identified in anaerobic digesters are similar to those found in the stomachs of ruminant animals and in organic sediments taken from lakes and rivers. The principal genera of microorganisms that have been identified at mesophilic conditions include the rods (*Methanobacterium, Methanobacillus*) and spheres (*Methanococcus, Methanothrix,* and *Methanosarcina*).

Methanosarcina and *Methanothrix* (also termed *Methanosaeta*) are the only organisms able to use acetate to produce methane and carbon dioxide. The other organisms oxidize hydrogen with carbon dioxide as the electron acceptor to produce methane. The acetate-utilizing methanogens were also observed in thermophilic reactors (van Lier, 1996; Zinder and Koch, 1984; and Ahring, 1995). Some species of *Methanosarcina* were inhibited by temperature at 65°C, while others were not, but no inhibition of *Methanothrix* was shown. For hydrogen-utilizing methanogens at temperatures above 60°C, *Methanobacterium* was found to be very abundant.

Syntrophic Relationships in Fermentation. The methanogens and the acidogens form a syntrophic (mutually beneficial) relationship in which the methanogens convert fermentation end products such as hydrogen, formate, and acetate to methane and carbon dioxide. Because the methanogens are able to maintain an extremely low partial pressure of H_2, the equilibrium of the fermentation reactions is shifted toward the formation of more oxidized end products (e.g., formate and acetate). The utilization of the hydrogen produced by the acidogens and other anaerobes by the methanogens is termed *interspecies hydrogen transfer.* In effect, the methanogenic organisms serve as a hydrogen sink that allows the fermentation reactions to proceed. If process upsets occur and the methanogenic organisms do not utilize the hydrogen produced fast enough, the propionate and butyrate fermentation will be slowed with the accumulation of volatile fatty acids in the anaerobic reactor and a possible reduction in pH.

Nuisance Organisms. Nuisance organisms in anaerobic operations are the sulfate-reducing bacteria, which can be a problem when the wastewater contains significant concentrations of sulfate. These organisms can reduce sulfate to sulfide, which can be toxic to methanogenic bacteria at high enough concentrations. Where high sulfide concentrations occur, one solution is to add iron at controlled amounts to form iron sulfide precipitate. Sulfate-reducing bacteria, obligate anaerobes of the domain Bacteria, are morphologically diverse, but share the common characteristic of being able to use sulfate as an electron acceptor and are divided into one of two groups depending on whether they produce fatty acids or use acetate. Group I sulfate reducers can use a diverse array of organic compounds as their electron donor, oxidizing them to acetate and reducing sulfate to sulfide. A common genus found in anaerobic biochemical operations is *Desulfovibrio.* Group II sulfate reducers oxidize fatty acids, particularly acetate, to carbon dioxide, while reducing sulfate to sulfide. A bacteria commonly found in this group is in the genus *Desulfobacter.*

Stoichiometry of Anaerobic Fermentation and Oxidation

A limited number of substrates are used by the methanogenic organisms and reactions defined as CO_2, and methyl group type reactions are shown as follows (Madigan et al., 1997), involving the oxidation of hydrogen, formic acid, carbon monoxide, methanol, methylamine, and acetate, respectively.

$$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O \quad (7\text{–}111)$$

$$4HCOO^- + 4H^+ \rightarrow CH_4 + 3CO_2 + 2H_2O \quad (7\text{–}112)$$

$$4CO + 2H_2O \rightarrow CH_4 + 3CO_2 \quad (7\text{–}113)$$

$$4CH_3OH \rightarrow 3CH_4 + CO_2 + 2H_2O \quad (7\text{–}114)$$

$$4(CH_3)_3N + H_2O \rightarrow 9CH_4 + 3CO_2 + 6H_2O + 4NH_3 \quad (7\text{–}115)$$

$$CH_3COOH \rightarrow CH_4 + CO_2 \quad (7\text{–}116)$$

In the reaction for the aceticlastic methanogens as given by Eq. (7–116), the acetate is cleaved to form methane and carbon dioxide.

A COD balance can be used to account for the changes in COD during fermentation. Instead of oxygen accounting for the change in COD, the COD loss in the anaerobic reactor is accounted for by the methane production. By stoichiometry the COD equivalent of methane can be determined. The COD of methane is the amount of oxygen needed to oxidize methane to carbon dioxide and water.

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O \quad (7\text{–}117)$$

From the above, the COD per mole of methane is 2(32 g O_2/mole) = 64 g O_2/mole CH_4. The volume of methane per mole at standard conditions (0°C and 1 atm) is 22.414 L, so the CH_4 equivalent of COD converted under anaerobic conditions is 22.414/64 = 0.35 L CH_4/g COD.

EXAMPLE 7–9 Prediction of Methane Gas Production An anaerobic reactor, operated at 35°C, processes a wastewater stream with a flow of 3000 m^3/d and a bsCOD concentration of 5000 g/m^3. At 95 percent bsCOD removal and a net biomass synthesis yield of 0.04 g VSS/g COD used, what is the amount of methane produced in m^3/d?

Solution

1. Prepare a steady-state mass balance for COD to determine the amount of the influent COD converted to methane.
   a. The required steady-state mass balance is

$$\begin{array}{rcccccc} & \text{Influent} & & \text{portion of} & & \text{influent COD} & \text{influent COD} \\ 0 = & \text{COD} & - & \text{influent COD} & - & \text{converted to} & - \text{converted to} \\ & & & \text{in effluent} & & \text{cell tissue} & \text{methane} \end{array}$$

$$COD_{in} = COD_{eff} + COD_{VSS} + COD_{methane}$$

b. Determine the values of the individual mass balance terms.

COD_{in} = (5000 g/m^3)(3000 m^3/d) = 15,000,000 g/d

COD_{eff} = (1 − 0.95)(5000 g/m^3)(3000 m^3/d) = 750,000 g/d

COD_{VSS} = (1.42 g COD/g VSS)(0.04 g VSS/g COD)(0.95)(15,000,000 g/d)

= 809,400 g/d

c. Solve for the COD converted to methane.

$COD_{methane}$ = 15,000,000 − 750,000 − 809,400 = 13,440,600 g/d

2. Determine the amount of methane produced at 35°C.

a. Determine the volume of gas occupied by 1 mole of gas at 35°C.

$$V = \frac{nRT}{P}$$

$$V = \frac{(1 \text{ mole})(0.082057 \text{ atm·L/mole·K})[(273.15 + 35)\text{K}]}{1.0 \text{ atm}}$$

= 25.29 L

b. The CH_4 equivalent of COD converted under anaerobic conditions is (25.29 L/mole)/(64 g COD/mole CH_4) = 0.40 L CH_4/g COD.

c. Methane production

CH_4 production = (13,440,600 g COD/d)(0.40 L CH_4/g COD)(1 m^3/10^3 L)

= 5376 m^3/d

At 65 percent methane the total gas flow = (5376 m^3/d)/0.65

= 8271 m^3/d

Comment It is important to determine the volume occupied by the gas at the actual operating temperature.

Growth Kinetics

In anaerobic processes two rate-limiting concepts are important: (1) the hydrolysis conversion rate and (2) the soluble substrate utilization rate for fermentation and methanogenesis. The hydrolysis of colloidal and solid particles does not affect the process operation and stability but does affect the total amount of solids converted. In anaerobic digestion processes used for municipal waste sludges, greater than 30 days detention time is needed to approach full conversion of solids. The soluble substrate utilization kinetics are of great concern to develop a stable anaerobic process.

Because of the relatively low free energy change for anaerobic reactions, growth yield coefficients are considerably lower than the corresponding values for aerobic oxidation. Typical synthesis yield and endogenous decay coefficients for fermentation and

methanogenic anaerobic reactions are $Y = 0.10$ and 0.04 g VSS/g VSS and $k_d = 0.04$ and 0.02 g VSS/g VSS·d, respectively.

The process is more stable when the volatile fatty acid (VFA) concentrations approach a minimal level, which can be taken as an indication that a sufficient methanogenic population exists and sufficient time is available to minimize hydrogen and VFA concentrations. The rate-limiting step is the conversion of VFAs by the methanogenic organisms and not the fermentation of soluble substrates by the fermenting bacteria. Thus, the methanogenic growth kinetics are of most interest in anaerobic process designs. Appropriate system SRTs are selected based on kinetics and treatment goals. At 20, 25, and 35°C, the washout or SRT_{min} values for methanogenesis are 7.8, 5.9, and 3.2 d, respectively (Lawrence and McCarty, 1970). Thus, with a factor of safety of 5, design SRT values would be about 40, 30, and 15 d, respectively, for a suspended growth process. Safety factors higher than 5 have been used to provide a more stable process (Parker and Owen, 1986).

Environmental Factors

Anaerobic processes are sensitive to pH and inhibitory substances. A pH value near neutral is preferred and below 6.8 the methanogenic activity is inhibited. Because of the high CO_2 content in the gases developed in anaerobic processes (30 to 35 percent CO_2), a high alkalinity is needed to assure pH near neutrality. An alkalinity concentration in the range of 3000 to 5000 mg/L as $CaCO_3$ is often found. For sludge digestion sufficient alkalinity is produced by the breakdown of protein and amino acids to produce NH_3, which combines with CO_2 and H_2O to form alkalinity as $NH_4(HCO_3)$. For industrial wastewater applications, especially for waste containing mainly carbohydrates, it is necessary to add alkalinity for pH control. Substances inhibitory to anaerobic processes (e.g., NH_3, H_2S, and various other inorganic and organic compounds) are considered in Chap. 10.

7–13 BIOLOGICAL REMOVAL OF TOXIC AND RECALCITRANT ORGANIC COMPOUNDS

Most of the organic compounds in domestic wastewater and some in industrial wastewaters are of natural origin and can be degraded by common bacteria in aerobic or anaerobic processes. However, currently there are over 70,000 synthetic organic chemicals, termed *xenobiotic compounds*, in general use (Schwarzenbach et al., 1993). Unfortunately, some of these organic compounds pose unique problems in wastewater treatment, due to their resistance to biodegradation and potential toxicity to the environment and human health. Organic compounds that are difficult to treat in conventional biological treatment processes are termed *refractory*. In addition, there are naturally occurring substances, such as those found in petroleum products, that are of similar concern. Examples of petroleum compounds and synthetic organic compounds found in different types of wastewater are reported in Table 7–10.

Development of Biological Treatment Methods

Since the early 1970s, information and knowledge related to the biodegradation of toxic and refractory compounds has increased significantly, based on work with specific

Table 7-10
Examples of toxic and recalcitrant organic compounds found in wastewater[a]

Type of waste	Types of organic compounds
Petroleum	Alkanes, alkenes, polyaromatic hydrocarbons, monocyclic aromatics benzene, toluene, ethylbenzene, xylenes, naphthenes
Nonhalogenated solvents	Alcohols, ketones, esters, ethers, aromatic and aliphatic hydrocarbons, glycols, amines
Halogenated solvents	Chlorinated methanes—methylene chloride, chloroform, carbon tetrachloride; chlorinated ethenes—tetrachloroethene, trichloroethene; chlorinated ethanes—trichloroethane; chlorinated benzenes
Pesticides, including insecticides, herbicides, fungicides	Organochloride compounds, organophosphate compounds, carbamate esters, phenyl ethers, creosotes, chlorinated phenols
Munitions and explosives	Nitroaromatics, trinitrotoluene, nitramines, nitrate esters
Industrial intermediates	Phthalate esters, benzene, phenol, chlorobenzenes, chlorophenols, xylenes
Transformer and hydraulic fluids	Polychlorinated biphenyls
Production products	Dioxin, furans

[a] Adapted from Watts (1997)

industrial wastewaters (i.e., petrochemical, textile, pesticide, pulp and paper, and pharmaceutical industries). In addition, since the 1980s, significant progress has also been made on the biodegradation of organic substances found at hazardous waste sites. Work in both of these fields has expanded knowledge on the capabilities and limitations of biodegradation. With a few exceptions most organic compounds can be biodegraded eventually, but in some cases the rates may be slow, unique environmental conditions may be required (i.e., redox potential, pH, temperature), fungi may be needed instead of prokaryotes, or specific bacteria capable of degrading the xenobiotic compounds may be needed. For example, anaerobic degradation of polychlorinated biphenyls (PCB) occurred using bacteria seed from sediment in the Hudson River where PCB had accumulated over decades, but after 1.5 years of exposure in a laboratory anaerobic digester used to treat municipal wastewater plant sludge, bacteria could not be developed to degrade PCB (Ballapragada et al., 1998).

Importance of Specific Microorganisms. The ability to degrade toxic and recalcitrant compounds will depend primarily on the presence of appropriate microorganism(s) and acclimation time. In some cases, special seed sources are needed to provide the necessary microorganisms. Once the critical microorganism is present, long-term exposure to the organic compound may be needed to induce and sustain the enzymes and bacteria required for degradation. Acclimation times can vary from hours to weeks depending on the microorganism population and organic compound. Melcer et al. (1994) found that a period of 3 weeks was required before complete removal of dichlorobenzene (DCB) occurred in a municipal activated-sludge plant. They noted that

intermittent addition of DCB resulted in much lower treatment efficiencies. Without acclimation and no biodegradation, the DCB was removed from the activated-sludge aeration tank by volatilization as described in Chap. 5. Strand et al. (1999) showed that after 4 weeks of constant exposure to dinitrophenol in a laboratory activated-sludge process, seeded from a municipal wastewater plant, dinitrophenol degradation increased from 0 to 98 percent. When dinitrophenol was not added to the process, the ability to degrade dinitrophenol was eventually lost. Thus, it appears that a relatively constant supply of toxic and recalcitrant organic compounds can lead to better biodegradation performance than intermittent additions.

Biodegradation Pathways. The three principal types of degradation pathways that have been observed are (1) the compound serves as a growth substrate; (2) the organic compound provides an electron acceptor; and (3) the organic compound is degraded by cometabolic degradation. In cometabolic degradation, the compound that is degraded is not part of the microorganism's metabolism. Degradation of the compound is brought about by a nonspecific enzyme and provides no benefit to the cell growth. Complete biodegradation of toxic and recalcitrant organic compounds to harmless end products such as CO_2 and H_2O or methane may not always occur, and instead biotransformation to a different organic compound is possible. Care must be taken to determine if the organic compound produced is innocuous, or just as harmful as or more harmful than the initial compound.

Anaerobic Degradation

Many toxic and recalcitrant organic compounds are degraded under anaerobic conditions, with the compound serving as a growth substrate with fermentation and ultimate methane production. Typical examples include nonhalogenated aromatic and aliphatic compounds such as phenol, toluene, alcohols, and ketones. However, most chlorinated organic compounds are not attacked easily under anaerobic conditions and do not serve as growth substrates. Fortuitously, many of these compounds also serve as electron acceptors in anaerobic oxidation reduction reactions. Most of the work and application for anaerobic degradation of chlorinated organic compounds have been related to subsurface contamination of chlorinated solvents at hazardous waste sites (McCarty, 1999).

Examples of chlorinated compounds degraded under anaerobic conditions include tetrachloroethene, trichloroethene, carbon tetrachloride, trichlorobenzene, pentachlorophenol, chlorohydrocarbons, and PCBs. The chlorinated compound serves as the electron acceptor, and hydrogen produced from fermentation reactions provides the main electron donor. Hydrogen replaces chlorine in the molecule, and such reactions have generally been referred to as *anaerobic dehalogenation* or *anaerobic dechlorination*. For example, dechlorination of tetrachloroethene proceeds sequentially with a loss of chlorine in each step via trichloroethene to dichloroethene to vinyl chloride and finally to ethene.

As the number of chlorine molecules on the organic molecule decreases, the reactions tend to be slower and less complete. Dechlorination of tetrachloroethene, trichlorobenzene, and pentachlorophenol has been demonstrated in lab-scale anaerobic digesters (Ballapragada et al., 1998) treating municipal primary and secondary sludge. However, the reaction rates were slow with mono- and dichlorophenol and mono-I dichlorobenzenes remaining. Conversion of tetrachloroethene to vinyl chloride and

ethene occurred in the digesters after one year of acclimatization and constant exposure of the chloroethenes.

Aerobic Biodegradation

With proper environmental conditions, seed source, and acclimation time, a wide range of toxic and recalcitrant organic compounds have been found to serve as growth substrates for heterotrophic bacteria. Such compounds include phenol, benzene, toluene, polyaromatic hydrocarbons, pesticides, gasoline, alcohols, ketones, methylene chloride, vinyl chloride, munitions compounds, and chlorinated phenols. However, many chlorinated organic compounds cannot be attacked readily by aerobic heterotrophic bacteria and thus do not serve as growth substrates. Some of the lesser chlorinated compounds, such as dichloromethane, 1,2-dichloroethane, and vinyl chloride can be used as growth substrates by aerobic bacteria. Fortunately, a number of chlorinated organic compounds are degradable by cometabolic degradation. It should be noted that organic compounds that are saturated fully with chlorine are degraded only by anaerobic dechlorination (Stensel and Bielefeldt, 1997).

Chlorinated organic compounds that have been degraded by cometabolic degradation include trichloroethene, dichloroethene, vinyl chloride, chloroform, dichloromethane, and trichloroethane. Cometabolic degradation is possible by bacteria that produce nonspecific mono-oxygenase or dioxygenase enzymes. These enzymes mediate a reaction with oxygen and hydrogen and change the structure of the chlorinated compound. Bacteria that produce oxygenase enzymes oxidize certain substrates that induce the enzyme. Oxygenase-producing bacteria include methanotrophic bacteria that oxidize methane, a number of bacteria that can oxidize phenol or toluene, a number of bacteria that can oxidize propane, and nitrifying bacteria that oxidize ammonia to nitrite.

The reaction of the nonspecific oxygenase enzyme with the organic chlorinated compound typically produces an intermediate compound that is degraded by other aerobic heterotrophic bacteria in the biological consortia. Various reactor designs have been developed to apply this biological process for treatment of contaminated groundwater or vapor extraction gas streams (Lee et al., 2000). While such reactions are possible in municipal and industrial biological wastewater treatment processes, a large amount of the chlorinated organic compounds that may be present are more likely lost from the process by volatilization during aeration, because of their high volatility and the minimal potential for cometabolic bacteria to be present.

Abiotic Losses

Due to concerns about environmental and health effects of toxic and recalcitrant compounds, it is important to understand their fate and transport in biological treatment processes. For many toxic and recalcitrant organic compounds entering biological wastewater treatment processes, nonbiological or abiotic losses may be more significant than biodegradation. Abiotic losses include adsorption of the compound to the mixed-liquor solids in the reactor with subsequent transport out of the system by the waste sludge and volatilization with release of the compound to the surrounding atmosphere.

Losses Due to Adsorption. For certain compounds, removal by partitioning (i.e., adsorbing) onto the biomass can be more significant than biodegradation or volatilization. To describe solids partitioning, the Freundlich Isotherm model (see Sec. 4–8 in Chap. 4

and Sec. 11–7 in Chap. 11) is modified to a general linear equilibrium relationship ($n = 1$) for adsorption to solids at relatively low liquid organic concentrations:

$$q = K_p S \tag{7–118}$$

where q = g organic adsorbed/g adsorbent
K_p = partition coefficient, L/g
S = concentration of organic compound in liquid, g/L

Absorption of organic compounds in biological treatment processes has been observed to be relatively fast (Melcer et al., 1994), so that Eq. (7–118) can be used to describe the distribution of the compound between the solid biomass and liquid phases as a function of the partition coefficient K_p for the compound. The value for K_p depends on the hydrophobic nature of the compound and the adsorption characteristics of the solids. Solids with high carbon content and greater surface area result in higher K_p values. The following equation by Dobbs et al. (1989) can be used to obtain an estimate of the partition coefficient for wastewater treatment process solids as a function of the compound octanol-water partition coefficient K_{ow}:

$$\log K_p = 0.58 \log K_{ow} + 1.14 \tag{7–119}$$

where K_p = partition coefficient, L/kg
K_{ow} = octanol/water partition coefficient (dimensionless)

Octanol-water partition coefficient values have been developed for many organic compounds (Schwarzenbach et al., 1993; LaGrega et al., 2001). Octanol/water partition coefficients for selected compounds are given in Table 5–36 in Chap. 5. The test to determine K_{ow} involves measuring the concentration of the organic compound in an octanol/ water mixture after quiescent separation of the octanol layer above the water layer. Greater amounts of more hydrophobic compounds will be found in the octanol layer, and these compounds will have greater K_p values in solids/water mixtures. Ranges of K_p values for various types of compounds are shown in Table 7–11. Based on the information given in Table 7–11, benzopyrene and PCBs are more likely to be found on solids than in the liquid than compounds like benzene and trichloroethene, as

Table 7–11
Comparison of selected estimated partition coefficients (K_p) values for different types of organic compounds[a]

Organic compound	K_p, L/g
Benzene	0.23
Dinitrotoluene	0.29
Trichloroethene	0.33
Dieldrin	1.48
Phenanthrene	5.33
Pentachlorophenol	10.96
Polychlorinated biphenyl	43.87
Benzopyrene	45.15

[a] Adapted from LaGrega et al. (2001).

their K_p values are greater by a factor of about 150. Such high partition coefficients result in very low liquid concentrations, which minimize the amount of the organic compound lost by biodegradation and volatilization.

Using the equilibrium partition coefficient, the amount of organic compound removed by sludge wasting can be estimated from the ratio of the mass of organic compound adsorbed to the mass of solids wasted per day:

$$q = \frac{r_{ad}}{r_{X,w}} \tag{7-120}$$

where q = g organic compound adsorbed/g solids
r_{ad} = rate of organic compound absorbed daily, g/d
$r_{X,w}$ = rate of solids wasted daily, g/d

By substituting Eq. (7–118) for q and solving for r_{ad}, the amount of compound lost daily due to adsorption is

$$r_{ad} = -r_{X,w}K_pS \tag{7-121}$$

At steady state, the amount of solids wasted daily is related to the average SRT value for the activated-sludge system as given by Eq. (7–45):

$$r_{X,w} = \frac{X_T V}{\text{SRT}} \tag{7-122}$$

Substituting Eq. (7–122) into Eq. (7–121) yields the following expression for mass loss due to adsorption:

$$r_{ad} = -\frac{X_T V K_p S}{\text{SRT}} \tag{7-123}$$

Losses Due to Volatilization. The removal of volatile organic compounds due to aeration (volatilization) was discussed previously in Sec. 5–13 in Chap. 5 and is reviewed briefly here.

$$r_{sv} = -K_L a_s(S) \tag{7-124}$$

where r_{sv} = loss due to volatilization, mg/L·d
$K_L a_s$ = $K_L a$ of organic compound, d^{-1}
S = concentration of organic compound in liquid, mg/L

Modeling Biotic and Abiotic Losses

A number of models have been developed and evaluated that account for the fate of recalcitrant organic compounds in biological treatment processes (Melcer et al., 1995; Melcer et al., 1994; Monteith et al., 1995; Parker et al., 1993; Grady et al., 1997; and Lee et al., 1998*a*). In general, the models contain basic mechanisms and mass balances that account for the mass rate of the organic compound entering the treatment process, and leaving in the liquid effluent, by biodegradation, by volatilization, and by adsorption on waste solids.

In the following discussion, all of these mechanisms as discussed above are combined into a general model to describe the fate of specific compounds in a biological treatment process. The following steady-state mass balance (i.e., accumulation = 0) across a complete-mix activated-sludge process can be prepared to predict the fate of an organic compound subject to biotic and abiotic processes.

	organic		loss of organic		loss of organic		loss of organic		loss of organic
0 =	constituent in influent	−	constituent due to biodegradation	−	constituent due to sorption	−	constituent due to volatilization	−	constituent in effluent

$$QS_0 = r_{su} + r_{ad} + r_{sv} - QS \tag{7–125}$$

where QS_0 = mass of compound in wastewater influent, g/d
r_{su} = biodegradation rate, g/d
r_{ad} = solids adsorption rate, g/d
r_{sv} = volatilization rate, g/d
QS = mass of compound in wastewater effluent, g/d

Substituting the appropriate reaction terms for each component of the mass balance yields the following expression:

$$QS_0 = \left(\frac{1}{Y}\right)\frac{\mu_m S}{(K_s + S)}(X_s)(V) + \frac{X_T V K_p S}{\text{SRT}} + K_L a_s S V + QS \tag{7–126}$$

The fate of the compound in the influent wastewater as a function of the solids concentration, liquid concentration, τ, SRT, and rate terms is obtained by dividing Eq. (7–126) by Q:

$$S_0 = \left(\frac{1}{Y}\right)\frac{\mu_m S}{(K_s + S)}(X_s)\tau + K_p S X_T\left(\frac{\tau}{\text{SRT}}\right) + K_L a_s S(\tau) + S \tag{7–127}$$

Note in Eqs. (7–126) and (7–127), X_s is the biomass concentration capable of degrading the specific organic compound, and X_T is the total MLVSS concentration that includes all the biomass grown on various substrates plus the nonbiodegradable VSS. The value of X_s can be calculated as a function of the amount of substrate that is biodegraded and kinetic coefficients, and the system τ, and SRT. The following expression is used to calculate X_s at steady state for a complete-mixed reactor with consideration for losses of the substrate by volatilization and adsorption:

$$X_s = \frac{Y[(S_0 - S) - K_p S X_T(\tau/\text{SRT}) - K_L a_s S(\tau)]}{k_d(\tau) + (\tau/\text{SRT})} \tag{7–128}$$

For most cases where biodegradation is occurring and the loss is not overwhelming due to volatilization and/or solids adsorption, the liquid constituent concentration, based on Eq. (7–40), for a complete-mix reactor at steady state is given by

$$S = \frac{K_s[1 + (k_d)\text{SRT}]}{\text{SRT}(\mu_m - k_d) - 1} \tag{7–129}$$

For the other exceptional cases, Eq. (7–127) and (7–128) can be solved simultaneously.

The approach outlined above can be used to estimate the fate of an organic compound in a complete-mix activated-sludge reactor assuming steady-state conditions, a constant input of the organic constituent, and a fully acclimated culture. Predicting the fate of an organic constituent in an activated-sludge treatment process is illustrated in Example 7–10.

EXAMPLE 7–10 Predicting the Fate of Benzene in an Activated-Sludge Treatment Process
A complete-mix activated-sludge system is used to treat domestic wastewater, but receives a wastewater discharge containing benzene. Given the following information on the activated-sludge process design, and biotic and abiotic rate information for benzene, what is the effluent soluble benzene concentration and the relative amounts of benzene lost through biodegradation, sorption to solids, volatilization, and in the liquid effluent?

1. Influent benzene concentration, $S_o = 2.0$ g/m^3
2. System SRT = 6.0 d
3. Aeration tank $\tau = 0.25$ d
4. MLVSS concentration, $X_T = 2500$ g/m^3
5. $K_p = 0.234 \times 10^{-3}$ m^3/g
6. $K_L a_s = 3$/h = 72/d
7. $\mu_m = 2.0$ g VSS/g VSS·d
8. $K_s = 0.50$ g/m^3
9. $k_d = 0.10$ VSS/g VSS·d
10. $Y = 0.60$ g VSS/g benzene

Solution

1. Determine the liquid benzene concentration using Eq. (7–129).

$$S = \frac{(0.5\ \text{g/m}^3)[1 + (0.10\ \text{g VSS/g VSS·d})(6.0\ \text{d})]}{(6.0\ \text{d})[(2.0 - 0.10)\text{g VSS/g VSS·d}] - 1} = 0.077\ \text{g/m}^3$$

2. Determine concentration of biomass degrading benzene X_s from Eq. (7-128):

$$X_s = \frac{Y[(S_o - S) - K_p S X_T\,(\tau/\text{SRT}) - K_L a_s S(\tau)]}{k_d(\tau) + (\tau/\text{SRT})}$$

$$X_s = \frac{(0.60\ \text{g/g})\{[(2.0 - 0.077)\text{g/m}^3] - (0.234 \times 10^{-3}\ \text{m}^3\text{/g})(0.077\ \text{g/m}^3)(2500\ \text{g/m}^3)(0.25\ \text{d}/6.0\ \text{d}) - (72/\text{d})(0.077\ \text{g/m}^3)(0.25\ \text{d})\}}{(0.10\ \text{g/g·d})(0.25\ \text{d}) + (0.25\ \text{d}/6.0\ \text{d})}$$

$$= 4.83\ \text{g/m}^3$$

3. Determine the loss of benzene due to biodegradation [1st term in Eq. (7–127)]:

$$\left(\frac{1}{Y}\right)\frac{\mu_m(S)}{(K_s + S)}(X_v)\tau = \left[\frac{1}{(0.6\ \text{g/g})}\right]\left\{\frac{(2.0/\text{d})(0.077\ \text{g/m}^3)}{[(0.5 + 0.077)\ \text{g/m}^3]}\right\}(4.83\ \text{g/m}^3)(0.25\ \text{d})$$

$$= 0.537\ \text{g/m}^3$$

4. Determine the loss of benzene due to sorption [2nd term in Eq. (7–127)]:

$$\frac{K_p S(X_v)\tau}{\text{SRT}} = \frac{(0.234 \times 10^{-3}\ \text{m}^3/\text{g})(0.077\ \text{g/m}^3)(2500\ \text{g/m}^3)(0.25\ \text{d})}{6.0\ \text{d}}$$

$$= 0.0019\ \text{g/m}^3$$

5. Determine the loss of benzene due to volatilization [3rd term in Eq. (7–127)]:

$$(K_L a_v)(S)(\tau) = (72/\text{d})(0.077\ \text{g/m}^3)(0.25\ \text{d}) = 1.386\ \text{g/m}^3$$

6. Summarize the losses due to the various mechanisms.

Pathway	Influent fate, g/m³	Fraction of total
Effluent	0.077	0.039
Biodegradation	0.537	0.268
Sorption	0.002	0.001
Volatilization	1.386	0.692
Total	2.002[a]	1.000

[a]0.002 is due to round-off error.

a. For benzene, which is a volatile organic compound with a low solids partition coefficient, 69.2 percent of the influent benzene is transferred to the atmosphere. 26.8 percent is biodegraded, 3.9 percent remains dissolved in the liquid effluent, and 0.1 percent is sorbed onto the solids leaving the process.

b. The effect of the aeration system benzene $K_L a$ value on the relative amounts biodegraded or stripped to the atmosphere is illustrated in the following summary table:

		$K_L a$, h⁻¹			
Parameter	Unit	1.5	3.0	4.0	6.3
Effluent	g/m³	0.077	0.077	0.077	0.052
Effluent	%	3.9	3.9	3.9	2.6
Biodegraded	%	61.4	26.8	3.7	0.0
Volatilized	%	34.6	69.2	92.3	97.3

7–14 BIOLOGICAL REMOVAL OF HEAVY METALS

Metal removal in biological treatment processes is mainly by adsorption and complexation of the metals with the microorganisms. In addition, processes that result in transformations and precipitation of metals are possible. Microorganisms combine with metals and adsorb them to cell surfaces because of interactions between the metal ions and the negatively charged microbial surfaces. Metals may also be complexed by carboxyl groups found in microbial polysaccharides and other polymers, or absorbed by protein materials in the biological cell.

The removal of metals in biological processes has been found to fit adsorption characteristics displayed by the Freundlich isotherm model (see Sec. 11–7 in Chap. 11) (Mullen et al., 1989; Kunz et al., 1976). A significant amount of soluble metal removal has been observed in biological processes, with removals ranging from 50 to 98 percent depending on the initial metal concentration, the biological reactor solids concentrations, and system SRT. In anaerobic processes the reduction of sulfate to hydrogen sulfide can promote the precipitation of metal sulfides. A classic example is the addition of ferric or ferrous chloride to anaerobic digesters to remove sulfide toxicity by the formation of iron sulfide precipitates. The precipitation of heavy metals by hydrogen sulfide is discussed in Sec. 6–5 in Chap. 6.

PROBLEMS AND DISCUSSION TOPICS

7–1 Prepare a recipe for an inorganic medium to be used in a laboratory chemostat to grow 500, 1000, or 1200 mg VSS/d (value to be selected by instructor) of bacteria biomass, assuming that the chemical formula for the biomass can be described as $C_5H_7NO_2$. Determine the concentration of essential inorganic compounds as reported in Table 7-4 for a feed rate of 1 L/d. Assume that phosphorus is added as KH_2PO_4, sulfur as Na_2SO_4, nitrogen as NH_4Cl, and other cations associated with chloride.

7–2 Protein is a major component of bacterial enzymes. List the key cell components involved and the major steps that lead to protein production.

7–3 From the literature (e.g., *Journal of Applied and Environmental Microbiology*) identify the key physiological, metabolic characteristics, and phylogenetic classification of a bacteria that may have a role in biological wastewater treatment or toxic degradation. Cite a minimum of 3 references.

7–4 From the literature, describe an application using molecular biology (e.g., molecular probes or other methods) techniques that can be related to biological wastewater treatment. Cite a minimum of 3 references.

7–5 A 1-L sample contains 20, 28, or 36 g (value to be selected by instructor) of casein ($C_8H_{12}O_3N_2$). If 18 g of bacterial cell tissue ($C_5H_7NO_2$) is synthesized per lb of casein consumed, determine the amount of oxygen required to complete the oxidation of casein to end products and cell tissue. The end products of the oxidation are carbon dioxide (CO_2), ammonia (NH_3), and water. Assume that the nitrogen not incorporated in cell-tissue production will be converted to ammonia.

7–6 A complete-mix suspended growth reactor, without a clarifier and recycle, is used to treat a wastewater flow containing only soluble organic substances. The influent BOD and COD are as follows.

		Wastewater		
Influent	**Unit**	**A**	**B**	**C**
BOD	mg/L	200	180	220
COD	mg/L	450	450	480

If the effluent dissolved BOD concentration is 2 mg/L, and the effluent volatile suspended solids concentration is 100 mg/L, determine (wastewater to be selected by the instructor) (a) the observed yield in terms of g VSS/g BOD, g VSS/g COD, and g TSS/g BOD, (b) the effluent total sCOD concentration including nonbiodegradable dissolved COD, and (c) the fraction of the influent BOD that is oxidized to CO_2 and H_2O. Assume the biodegradable COD/BOD ratio is 1.6 and 1.42 g O_2 equivalent/g biomass.

7–7 An aerobic complete-mix reactor (no recycle) with a volume of 1000 L receives a 500 L/d wastewater flow and has an effluent soluble COD concentration of 10 mg/L. The reactor oxygen uptake rate is 10 mg/L·h. For one of the wastewaters with the characteristics given below (to be selected by instructor), determine: (a) the τ value for the reactor in days, (b) the oxygen used per day in (g/d), (c) the effluent volatile suspended solids concentration (assume biomass oxygen equivalent of 1.42 g O_2/g VSS), and (d) the observed yield in g VSS/g bsCOD removed.

		Wastewater		
Item	**Unit**	**A**	**B**	**C**
Influent sCOD	mg/L	1000	1800	600
Reactor oxygen uptake rate	mg/L·h	10	15	8

7–8 Using the half-reaction free energy values given in Table 7–7, calculate and compare the biomass yields (g VSS/g COD_r) for the degradation of methanol, carbohydrate mixture, or ethanol (constituent to be selected by instructor) with oxygen and nitrate as the electron acceptors. Assume ammonia is available for cell synthesis needs and 1.42 g O_2 equiv/g biomass.

7–9 Nitrate and sulfate are both available in an anaerobic laboratory chemostat with both nitrate-reducing and sulfate-reducing bacteria present. The chemostat is fed continuously a solution containing the electron acceptors in equal amounts, glucose, and a nutrient media. Which biological populations will remain after long-term operation? Explain.

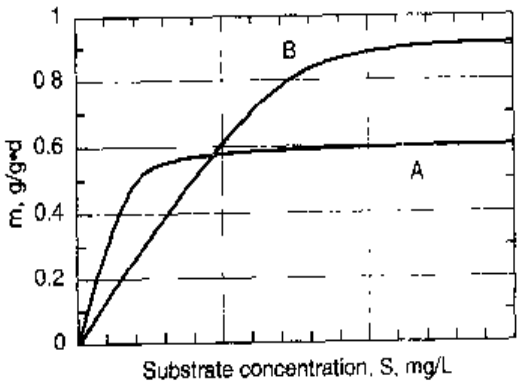
7–10 For Example 7-3, use the half reactions to write a balanced equation of acetate oxidation by methanogenic bacteria.

7–11 For the synthesis yield values given in Table 7–8 for organic compound degradation, what are the respective f_e and f_s values?

7–12 Compare the end products of organic compound degradation under the following conditions and discuss how the bacterial synthesis yields are affected by them: aerobic (oxygen as electron

acceptor), fermentation (organic compound as electron acceptor), and methanogenesis (CO_2 as electron acceptor).

7–13 If bacterial cells are of the coccus type with a diameter of 1, 1.2, or 1.5 μm and are 80 percent water with 90 percent of the dry weight as organic, determine (cell diameter to be selected by the instructor): (a) the volume and organic mass of one cell and (b) the number of cells present in one liter of a biomass suspension with a concentration of 100 mg VSS/L.



7–14 For aerobic bacteria with an assumed generation time of 20, 30, or 60 min (time to be selected by instructor), how many bacteria would be present after 12 hours, if 20 cells are present at time zero? Using the bacteria volume and mass from Problem 7–13 for a 1-μm diameter bacteria, what would be the dry weight of the bacteria after 12 hours in mg volatile suspended solids?

7–15 Consider a batch reaction with nitrifying bacteria in a chemostat. The initial concentration of nitrifying bacteria is 10 mg/L and the initial substrate concentration is 40 mg NH_4-N/L. The NH_4-N is oxidized to NO_3-N and the cell yield is 0.12 g VSS/g NH_4-N oxidized. Other kinetic coefficients related to substrate utilization and growth are one of the following selected by instructor:

		Wastewater		
Coefficient	**Unit**	**A**	**B**	**C**
μ_m	g VSS/g VSS·d	0.50	0.75	0.60
K_s	mg/L	0.50	0.50	0.75
k_d	g VSS/g VSS·d	0.01	0.08	0.04

What is the substrate and biomass concentration at 0.80 days? Plot the substrate and biomass concentration versus time up to 1.0 day. (Hint: one solution approach is to use a spreadsheet to solve for the biomass and substrate concentration at small time increments.)

7–16 Curves A and B represent the Monod kinetics for two different bacteria capable of degrading the same substrate. You are to operate a laboratory continuous flow CMAS reactor without recycle that is inoculated with bacteria A and B. In the first experiment (I) a high SRT is used (10 d or greater) and in the second (II) a very low SRT is used (about 1.1 d). Which bacteria will be dominant in experiments I and II? Explain why

7-17 A complete-mix aerobic reactor without solids recycle is used to treat a wastewater containing 100 mg/L phenol (C_6H_6O) at 20°C. Using the following kinetic coefficients (coefficient set A, B, or C to be selected by instructor) determine: (a) the minimal hydraulic retention time τ in days at which the biomass can be washed out faster than they can grow, (b) the minimum τ value at 10°C, assuming the temperature-activity coefficient θ is 1.07, (c) the effluent phenol and biomass concentration at a τ value of 4.0 d at 20°C, and (d) the amount of oxygen required in kg/d for a τ value of 4.0 d assuming a flow of 100 m^3/d. Plot the phenol and biomass concentration and the amount of oxygen required versus τ in days.

		Wastewater		
Coefficient	**Unit**	**A**	**B**	**C**
k	g phenol/g VSS-d	0.90	0.80	0.90
K_s	mg phenol/L	0.20	0.15	0.18
Y	g VSS/g phenol	0.45	0.45	0.40
k_d	g VSS/g VSS-d	0.10	0.08	0.06

7-18 Laboratory test reactors have been operated at different SRT values at steady state to obtain biological kinetic coefficients for a wastewater with soluble constituents only. The reactors are complete-mix and aerated with clarifiers and solids recycle. The τ value in all cases is 0.167 d and the SRT values were varied for the five tests. The influent and effluent soluble COD and reactor MLVSS concentrations are summarized as follows:

Test no.	**SRT, d**	**S_o, mg COD/L**	**S, mg COD/L**	**X, mg VSS/L**
1	3.1	400	10.0	3950
2	2.1	400	14.3	2865
3	1.6	400	21.0	2100
4	0.8	400	49.5	1050
5	0.6	400	101.6	660

From these results determine the values for the biokinetic coefficients, k, K_s, μ_m, Y, and k_d. (Note: calculate the solids production at each SRT.)

7-19 The following data were obtained using four bench-scale continuous-flow activated-sludge units to treat a food-processing waste. Using these data, determine Y and k_d.

	Parameter		
Unit	**X, g MLVSS/L**	**r_g, g MLVSS/L·d**	**U, g BOD_5/g MLVSS·d**
1	18.81	0.88	0.17
2	7.35	1.19	0.41
3	7.65	1.42	0.40
4	2.89	1.56	1.09

7–20 Using the data given below for three different complete-mix activated-sludge reactors, determine (reactor to be selected by instructor): (a) the system SRT, (b) how much oxygen is required in kg/d if the effluent soluble COD concentration = 5 mg/L, and (c) the oxygen uptake rate, expressed in mg/L·h, at steady state in the aeration tank.

		Reactor		
Item	**Unit**	**A**	**B**	**C**
Aeration tank MLVSS	mg/L	3000	3000	3000
Aeration tank volume	m^3	1000	1000	1000
Influent flow rate	m^3/d	5000	5000	5000
Waste sludge flow rate	m^3/d	59	45	65
Waste sludge VSS concentration	mg/L	8000	8000	8000
Influent soluble COD concentration	mg/L	400	400	400

7–21 A complete-mix activated-sludge process with secondary clarification and sludge recycle is used to treat a dairy wastewater at a flowrate of 1000 m^3/d with a degradable influent COD of 3000 mg/L and BOD of 1875 mg/L. The MLSS concentration is 2800, 3300, or 3500 mg/L (MLSS value to be selected by instructor), MLVSS/MLSS ratio is 0.80, effluent TSS concentration is 20 mg/L, τ is 24 hours, recycle MLSS concentration is 10,000 mg/L, and waste sludge flowrate from the recycle line is 85.5 m^3/d. Using the given information, determine: (a) the system SRT, the F/M ratio in g BOD/g MLVSS·d, and the volumetric BOD loading ($kg/m^3 \cdot d$), (b) the observed yield in terms of g TSS/BOD and g TSS/g COD, and (c) the synthesis yield, assuming that k_d = 0.10 g VSS/g VSS·d and f_d = 0.15 g VSS/g VSS.

7–22 A conventional activated-sludge plant is operated at SRT values of 8, 10, or 12 d (value to be selected by instructor). The reactor volume is 8000 m^3 and the MLSS concentration is 3000 mg/L. Determine (a) the sludge production rate, (b) the sludge wasting flowrate when wasting from the reactor, and (c) the sludge wasting flowrate when wasting from the recycle line. Assume that the concentration of suspended solids in the recycle is equal to 10,000 mg/L, and the solids loss in the secondary clarifier effluent is minor and can be neglected.

7–23 A complete-mix activated-sludge process with a clarifier and sludge recycle receives an influent wastewater flow of 2000 m^3/d and influent particulate concentration of 400, 500, or 600 mg VSS/L (value to be selected by instructor) that is entirely biodegradable. The volume of the activated-sludge reactor is 500 m^3. The biokinetic coefficients for particulate degradation (Eq. 7–20) are k_p = 2.2 g VSS/g biomass·d and K_s = 0.15 g VSS/g biomass. The yield and endogenous decay coefficients are 0.50 g biomass/g VSS and 0.10 g VSS/g VSS·d, respectively. Using the given information: (a) develop a steady-state mass balance for particulate removal in the activated-sludge system, (b) develop equations for the aeration tank particulate and biomass concentrations as a function of SRT (assume that the effluent flow contains no degradable particulates and particulates only leave the system via the waste sludge), (c) determine the biomass and particulate concentrations in the aeration tank at SRT values of 3, 5, and 10 d, and (d) determine the percent removal of particulates at 3, 5, and 10 d.

7–24 The following sets of kinetic coefficients (to be selected by instructor) are given for the treatment of a municipal wastewater with an influent degradable COD of 300 mg/L and influent nbVSS

concentration of 100 mg/L. Using these data and assuming the effluent degradable COD concentration is negligible compared to the amount of COD removed, prepare plots of (a) the observed yield (as g VSS/g COD) removed as a function of SRT and (b) the g oxygen used/g COD removed as a function of SRT. On the plot in Part (a) also show the fraction of the yield from cell debris and influent nbVSS.

Coefficient	Unit	Coefficient set A	B	C
Y	g VSS/g COD	0.40	0.40	0.35
k_d	g VSS/g VSS·d	0.10	0.08	0.12
f_d	g VSS/g VSS	0.10	0.15	0.15

7–25 Design a complete-mix activated sludge process with recycle to treat an industrial wastewater with one of the following characteristics (to be selected by instructor) at peak month conditions.

Item	Unit	Wastewater A	B	C
Flow	m^3/d	4000	4300	4000
BOD	mg/L	800	600	1000
nbVSS	mg/L	200	200	200
TKN	mg/L	30	30	40
Total phosphorus	mg/L	8	8	6
Temperature	°C	15	15	15

The relevant biokinetic coefficients and operating conditions are:

Y = 0.45 g VSS/g COD
k_d = 0.10 g VSS/g VSS·d
μ_m = 2.5 g VSS/g VSS·d
K_s = 20 mg COD/L
f_d = 0.10 g VSS/g VSS
bCOD = 1.6 (BOD)

SRT = 10 d
Return sludge = 8000 mg TSS/L
Aeration tank MLSS = 2500 mg/L
Clarifier effluent TSS = 15 mg/L

Using the given information and biokinetic coefficients, determine (a) the aeration tank volume (m^3), the amount of waste solids produced/day (kg/d), the oxygen requirement (kg/d), the aeration tank oxygen uptake rate (mg/L·h), the effluent soluble BOD concentration, the return sludge recycle ratio for the following design conditions, and the MLVSS to MLSS ratio, and (b) whether supplemental nitrogen or phosphorus is required and, if so, how much in mg/L? Assume the biomass contains 12 percent nitrogen and 2 percent phosphorus on a volatile suspended solids basis. Assume no nitrification occurs

7–26 For the same industrial wastewater application given in Problem 7–23, powdered activated carbon (PAC) is added to the influent at a dose of 50 mg/L to sorb potential toxic substances. The SRT is still held at 10 d. Determine the MLSS concentration, the MLVSS/MLSS ratio, and the total daily sludge production in kg TSS/d with the PAC addition.

7–27 A complete-mix activated-sludge system receives wastewater with one of the following characteristics (wastewater to be selected by instructor):

Item	Unit	Wastewater A	Wastewater B	Wastewater C
Flow	m^3/d	6000	6000	6000
Biodegradable COD	mg/L	300	400	500
Influent nbVSS	mg/L	100	100	150

The relevant design criteria are:

Flow = 6000 m^3/d
Biodegradable COD = 300 mg/L
Influent nbVSS = 100 mg/L

The following biokinetic coefficients can be assumed:

Y = 0.40 g VSS/g COD
k_d = 0.10 g VSS/g VSS·d
μ_m = 5.0 g VSS/g VSS·d
K_s = 20 mg COD/L

If the system aeration oxygen transfer capacity is 52 kg O_2/h, what maximum SRT can be used so that the oxygen requirements can be met by the existing oxygen transfer capacity?

7–28 The kinetics for substrate utilization can be described by a first-order relationship (Eq. 7–18) ($r_{su} = -kSX$). (a) Using the given first-order kinetic relationship instead of the Michaelis-Menten relationship for substrate utilization, derive a steady-state relationship that can be used to calculate the effluent soluble substrate concentration from a complete-mix suspended growth reactor. Verify that Eq. (7–43) can be used to determine the biomass (X) concentration. (b) For the following reactor conditions and biokinetic information, determine the SRT needed to provide an effluent soluble substrate concentration of 1.0 mg/L, and the biomass concentration.

S_0 = 500 mg/L COD
τ = 0.25 d
Y = 0.50 g VSS/g COD removed
k_d = 0.06, 0.10, or 0.12 g VSS/g VSS·d (to be selected by instructor)
$r_{su} = -kXS$, where k = 0.504 g/g·d

7–29 Consider a biofilm treating a liquid stream containing acetate and dissolved oxygen with a stagnant liquid layer above the biofilm. (a) Using the stoichiometric relationship developed for the biological degradation of acetate in Example 7–4, determine the maximum acetate concentration in the bulk liquid that can be satisfied before the aerobic degradation in the biofilm is limited by the surface flux rate of oxygen, where the bulk liquid DO concentration is 2.0, 3.0, or 4.0 mg/L (DO value to be selected by instructor). (b) Compare these results to the results of NH_4-N oxidation in Example 7–7. Why is the bulk liquid NH_4-N concentration so much lower at a DO concentration of 2.0 mg/L?

Given:

Acetate diffusivity coefficient = 0.9 cm^2/d
Oxygen diffusivity coefficient = 2.6 cm^2/d

7–30 An activated-sludge system treating domestic wastewater is operated at a solids retention time of 10 d with a mixed-liquor temperature of 18°C. For many weeks nitrification has occurred, with an effluent NH_4-N concentration reported at less than 1.0 mg/L. After some time, the nitrification performance declines with effluent NH_4-N concentrations exceeding 10 mg/L. As the city engineer you are requested to investigate the cause of the decline in performance and to make recommendations for actions that will get the discharge quality back in compliance. Describe possible causes for the decline in nitrification efficiency and how you would evaluate the problem.

7–31 Using the half-reactions from Table 7-7 calculate the oxygen equivalent of nitrite (g O_2/g NO_2-N), for biological reaction with nitrite as the electron acceptor instead of oxygen.

7–32 An anoxic suspended growth reactor is operated at an SRT of 5.0, 10.0, or 15.0 d (to be selected by instructor) and acetate is added as the electron donor. Given the following kinetic coefficients for acetate under nitrate reduction conditions, determine how much acetate is needed, in kg/d, to remove 20 mg/L of nitrate in a treatment flowrate of 4000 m^3/d.

Y = 0.3 g VSS/g COD removed
k_d = 0.08 g VSS/g VSS·d

7–33 Two complete-mix suspended growth laboratory reactors with sludge recycle fed the same synthetic wastewater are operated in parallel at the same aerobic SRT. One reactor has an anaerobic/aerobic sequence to promote biological phosphorus removal and the other is operated only with the aerobic portion. The influent flow contains 100, 200, or 300 mg/L acetate (as selected by instructor) for the organic carbon source. The phosphorus and volatile fraction contents of the two mixed liquors are as follows. The lower VSS/TSS ratio for the biological phosphorus removal reactor accounts for both polyphosphate and associated cation in the storage products.

Reactor	g P/g VSS	g VSS/g TSS
Aerobic only	0.015	0.85
Biological P removal	0.25	0.65

Using the following operating conditions and kinetic coefficients, how much phosphorus is removed from the influent for each system in mg/L, and what are the aerobic reactor MLVSS and MLSS concentrations? (Note: for this problem the coefficients are assumed equal for both types of organisms, but in practice they may be different).

Y = 0.40 g VSS/g COD
k_d = 0.10 g VSS/g VSS·d
SRT = 5 d
τ = 3 h
f_d = 0.10 g VSS/g VSS

7–34 A laboratory reactor is to be operated to study operating conditions that affect biological phosphorus removal. The influent phosphorus concentration will be 10, 20, or 30 mg/L (as selected by instructor). What minimum concentrations of magnesium, potassium, and calcium should be in the influent liquid?

7–35 An anaerobic treatment process is used to treat a flow of 500 m^3/d with an influent soluble COD concentration of 2000, 5000, or 9000 mg/L (value to be selected by instructor). The net biomass yield is 0.04 g VSS/g COD removed and 95 percent soluble COD removal occurs at a temperature

of 30°C. Assuming the gas contains 65 percent methane, calculate the total gas flow in m^3/d. What is the energy value of the gas produced in kJ/d? (The heat value of methane is 50.1 kJ/g at 30°C.)

7–36 Based on a review of the literature (cite a minimum of two references) explain the importance of the syntrophic relationship between methanogens and acid fermenters in an anaerobic process. What is the effect (increase, decrease, or remain the same) on the gas production rate, percent methane in the gas, volatile fatty acid concentration, and pH if an upset occurs to create an imbalance between fermenters and methanogens.

7–37 Modify equations 7-127, 7-128, and 7–129 based on using first-order kinetics for the substrate removal rate versus the Monod growth kinetic model, where: $r_{su} = -kSX$. The first-order model is often used to describe the biodegradation kinetics of a number of priority pollutants.

7–38 Assume a complete-mix reactor is to be used to treat a wastewater containing a priority pollutant with the following characteristics and other easily degradable organic compounds. The priority pollutant is not very volatile so that losses due to tripping can be ignored. Using the following information determine (a) the fate of the compound in terms of biodegradation losses, and removal in the system effluent and waste sludge, and (b) the values computed in Part (a) if the value for μ_m is 3 times higher.

Design data and coefficients:

System SRT (to be selected by instructor) 5, 10, or 15 d
Reactor MLVSS = 2000 mg/l.
Reactor τ = 0.25 d
Compound characteristics and biokinetic coefficients:
Influent concentration = 5.0 mg/l.
$k_p = 15 \times 10^{-3}$ m^3/g
μ_m = 2.0 g VSS/g VSS·d
K_s = 0.4 g/m^3
Y = 0.6 g VSS/g compound
k_d = 0.08 g VSS/g VSS·d

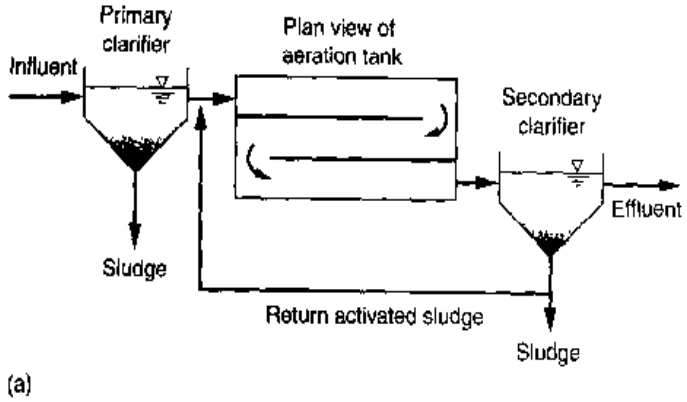
REFERENCES 880

The theory of biological wastewater treatment is presented and discussed in detail in Chap. 7. As noted in Chap. 7, biological treatment processes may be classified as aerobic and anaerobic suspended growth, attached growth, and various combinations thereof. The focus of this chapter is on suspended growth treatment processes as exemplified by the activated-sludge process for BOD and nitrification and for nitrogen and phosphorus removal. Attached growth and combined processes are discussed in Chap. 9, and other suspended and attached growth anaerobic processes are considered in Chap. 10. Included in this chapter are (1) general descriptions of the basic activated-sludge processes used to meet a wide range of treatment objectives, (2) a description of

key wastewater *characteristics* that affect activated-sludge process design, (3) fundamentals of process analysis and control, (4) processes for BOD removal and nitrification, (5) processes for nitrogen removal, (6) processes for phosphorus removal, (7) selection and design of physical facilities for activated-sludge processes, (8) aerated lagoons, (9) biological treatment with membrane separation, and (10) a review of activated-sludge modeling approaches. Stabilization ponds, i.e., non-aerated lagoons, are not covered in this text, as they are used mainly for small rural communities where sufficient land is available and discharge requirements may not be as stringent as in urban areas. For information about the design of stabilization ponds, see Metcalf & Eddy (1991), Reed et al. (1995), and Crites and Tchobanoglous (1998).

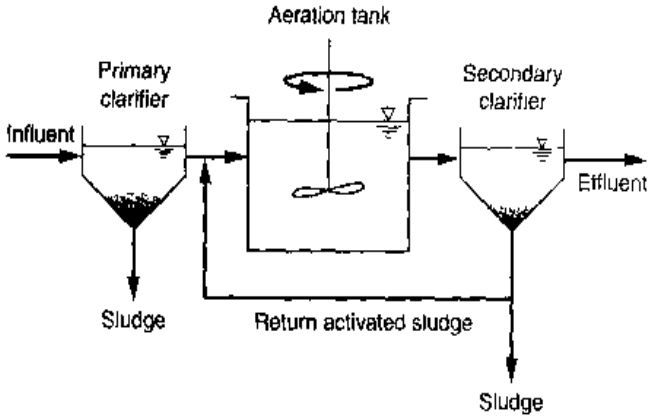
8–1 INTRODUCTION TO THE ACTIVATED-SLUDGE PROCESS



To provide a basis for the process designs presented in the subsequent sections of this chapter, it will be useful to consider (1) a brief summary of the historical development of the activated-sludge process, (2) a description of the basic process, (3) a brief review of the evolution of the activated-sludge process, and (4) an overview of recent process developments.

Historical Development

The activated-sludge process is now used routinely for biological treatment of municipal and industrial wastewaters. The antecedents of the activated-sludge process date back to the early 1880s to the work of Dr. Angus Smith, who investigated the aeration of wastewater in tanks and the hastening of the oxidation of the organic matter. The aeration of wastewater was studied subsequently by a number of investigators, and in 1910 Black and Phelps reported that a considerable reduction in putrescibility could be secured by forcing air into wastewater in basins. In experiments conducted at the Lawrence Experiment Station during 1912 and 1913 by Clark and Gage with aerated wastewater, growths of organisms could be cultivated in bottles and in tanks partially filled with roofing slate spaced about 25 mm (1 in) apart and would greatly increase the degree of purification obtained (Clark and Adams, 1914). The results of the work at the Lawrence Experiment Station were so striking that knowledge of them led Dr. G. J. Fowler of the University of Manchester, England to suggest experiments along similar lines be conducted at the Manchester Sewage Works where Ardern and Lockett carried out valuable research on the subject. During the course of their experiments, Ardern and Lockett found that the sludge played an important part in the results obtained by aeration, as announced in their paper of May 3, 1914 (Ardern and Lockett, 1914). The process was named *activated sludge* by Ardern and Lockett because it involved the production of an activated mass of microorganisms capable of aerobic stabilization of organic material in wastewater (Metcalf & Eddy, 1930).



Description of Basic Process

By definition, the basic activated-sludge treatment process, as illustrated on Fig. 8–1*a* and *b*, consists of the following three basic components: (1) a reactor in which the microorganisms responsible for treatment are kept in suspension and aerated; (2) liquid-solids separation, usually in a sedimentation tank; and (3) a recycle system for returning

D. Stensel.)*

solids removed from the liquid-solids separation unit back to the reactor. Numerous process configurations have evolved employing these components. An important feature of the activated-sludge process is the formation of flocculent settleable solids that can be removed by gravity settling in sedimentation tanks. In most cases, the activated-sludge process is employed in conjunction with physical and chemical processes that are used for the preliminary and primary treatment of wastewater, and posttreatment, including disinfection and possibly filtration.

Historically, most activated-sludge plants have received wastewaters that were pretreated by primary sedimentation, as shown on Fig. 8–1*a* and *b*. Primary sedimentation is most efficient at removing settleable solids, whereas the biological processes are essential for removing soluble, colloidal, and particulate (suspended) organic substances; for biological nitrification and denitrification; and for biological phosphorus removal. For applications such as treating wastewater from smaller-sized communities, primary treatment is often not used as more emphasis is placed on simpler and less operator-intensive treatment methods. Primary treatment is omitted frequently in areas of the world that have hot climates where odor problems from primary tanks and primary sludge can be significant. For these applications, various modifications of conventional activated-sludge processes are used, including sequencing batch reactors, oxidation ditch systems, aerated lagoons, or stabilization ponds.

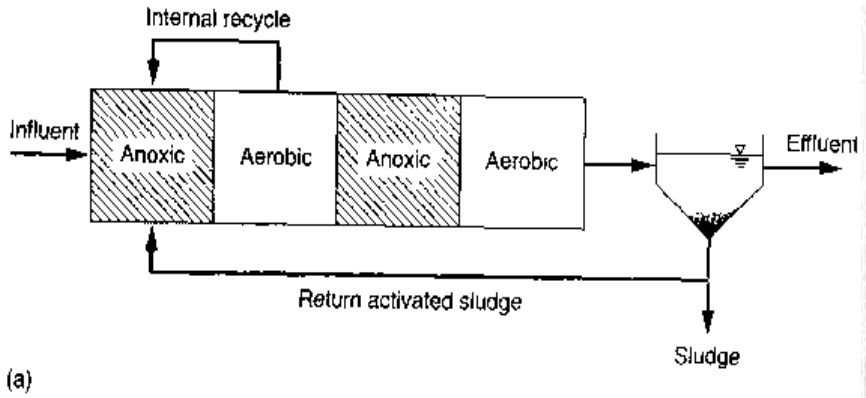
Evolution of the Activated-Sludge Process

A number of activated-sludge processes and design configurations have evolved since its early conception as a result of (1) engineering innovation in response to the need for higher-quality effluents from wastewater treatment plants; (2) technological advances in equipment, electronics, and process control; (3) increased understanding of microbial processes and fundamentals; and (4) the continual need to reduce capital and operating costs for municipalities and industries. With greater frequency, activated-sludge processes used today may incorporate nitrification, biological nitrogen removal, and/or biological phosphorus removal. These designs employ reactors in series, operated under aerobic, anoxic, and anaerobic conditions, and may use internal recycle pumps and piping. The general types of activated-sludge processes used (i.e., plug flow, complete mix, and sequencing batch reactor) are illustrated on Fig. 8–1.

Since the process came into common use in the early 1920s and up until the late 1970s, the type of activated-sludge process used most commonly was the one in which a plug-flow reactor with large length to width ratios (typically $> 10{:}1$) was used (see Fig. 8–1*a*). In considering the evolution of the activated-sludge process, it is important to note that the discharge of industrial wastes to domestic wastewater collection systems increased in the late 1960s. The use of a plug-flow process became problematic when industrial wastes were introduced because of the toxic effects of some of the discharges. The complete-mix reactor was developed, in part, because the larger volume allowed for greater dilution and thus mitigated the effects of toxic discharges. The more common type of activated-sludge process in the 1970s and early 1980s tended to be single-stage, complete-mix activated-sludge (CMAS) processes (see Fig. 8–1*b*), as advanced by McKinney (1962). In Europe, the CMAS process has not been adopted generally as ammonia standards have become increasingly stringent. For some nitrification applications, two-stage systems (each stage consisting of an aeration tank and clarifier) were used with the first stage designed for BOD removal, followed by a second stage for

nitrification. Other activated-sludge processes that have found application, with their dates of major interest in parentheses, include the oxidation ditch (1950s), contact stabilization (1950s), Krause process (1960s), pure oxygen activated sludge (1970s), Orbal process (1970s), deep shaft aeration (1970s), and sequencing batch reactor process (1980).

With the development of simple inexpensive program logic controllers (PLCs) and the availability of level sensors and automatically operated valves, the sequencing batch reactor (SBR) process (see Fig. 8–1*c*) became more widely used by the late 1970s, especially for smaller communities and industrial installations with intermittent flows. In recent years, however, SBRs are being used for large cities in some parts of the world. The SBR is a fill-and-draw type of reactor system involving a single complete-mix reactor in which all steps of the activated-sludge process occur. Mixed liquor remains in the reactor during all cycles, thereby eliminating the need for separate sedimentation tanks.



In comparing the plug-flow (Fig. 8–1*a*) and complete-mix activated-sludge (CMAS) (Fig. 8–1*b*) processes, the mixing regimes and tank geometry are quite different. In the CMAS process, the mixing of the tank contents is sufficient so that ideally the concentrations of the mixed-liquor constituents, soluble substances (i.e., COD, BOD, NH_4-N), and colloidal and suspended solids do not vary with location in the aeration basin. The plug-flow process involves relatively long, narrow aeration basins, so that the concentration of soluble substances and colloidal and suspended solids varies along the reactor length. Although process configurations employing long, narrow tanks are commonly referred to as plug-flow processes, in reality, true plug flow does not exist. Depending on the type of aeration system, back mixing of the mixed liquor can occur and, depending on the layout of the reactor and the system reaction kinetics, nominal plug flow may be described more appropriately by the series of complete-mix reactors as discussed in Chap. 4.

Activated-sludge process designs before and until the late 1970s generally involved the configurations shown on Fig. 8–1*a* and *b*. However, with interest in biological nutrient removal, staged reactor designs consisting of complete-mix reactors in series have been developed (see Fig. 8–2). Some of the stages are not aerated (anaerobic or anoxic stages) and internal recycle flows may be used. For nitrification, a staged aerobic reactor design may also be used to provide more efficient use of the total reactor volume than a single-stage CMAS process. A number of biological nutrient-removal configurations will be shown in subsequent sections of this chapter. Pilot-plant studies are sometimes used to evaluate and optimize biological nutrient-removal processes. A large pilot plant used by the city of New York for the investigation of alternative nitrogen-removal processes is shown on Fig. 8–3.

Recent Process Developments

As noted above, numerous modifications of the activated-sludge process have evolved in the last 10 to 20 years, aimed principally at effective and efficient removal of nitrogen and phosphorus. Nearly all of the various modifications are based on the same fundamental principles of biological treatment as described in Chap. 7. Many of the processes that are being used in full-scale operation are described in Secs. 8–4, 8–5, and 8–6; design examples for the processes most commonly used are also included.

Because of the development of improved membrane design, principally for water treatment applications, membrane technology has found increasing application for

enhanced solids separation for water reuse (see Chaps. 11 and 13), and more recently for use in suspended growth reactors for wastewater treatment. Membrane biological reactors (MBRs), which may change the look of wastewater-treatment facilities in the future, are discussed in Sec. 8–9.

Because the design and operation of the activated-sludge process is becoming more complex, computer modeling is an increasingly important tool to incorporate the large

number of components and reactions necessary to evaluate activated-sludge performance. The use of simulation models for suspended growth systems is discussed in Sec. 8–10.

8–2 WASTEWATER CHARACTERIZATION

Activated-sludge process design requires determining (1) the aeration basin volume, (2) the amount of sludge production, (3) the amount of oxygen needed, and (4) the effluent concentration of important parameters. To design an activated-sludge treatment process properly, characterization of the wastewater is perhaps the most critical step in the process. For biological nutrient-removal processes, wastewater characterization is essential for predicting performance. Wastewater characterization is an important element in the evaluation of existing facilities for optimizing performance and available treatment capacity. Flow characterization is also important including diurnal, seasonal, and wet-weather flow variations (see Chap. 3). Without comprehensive wastewater characterization, facilities may either be under- or overdesigned, resulting in inadequate or inefficient treatment.

Key Wastewater Constituents for Process Design

Wastewater characteristics of importance in the design of the activated-sludge process can be grouped into the following categories: carbonaceous substrates, nitrogenous compounds, phosphorus compounds, total and volatile suspended solids (TSS and VSS), and alkalinity. Typical wastewater constituents quantified for use in the design of wastewater treatment processes are reported in Table 8–1. While the constituents reported in Table 8–1 are sufficient for some designs, additional information is needed for biological nutrient-removal process designs or to evaluate the capacity of an existing system. A complete listing of wastewater components, with the nomenclature used in this chapter, is presented in Table 8–2. The terms presented in Table 8–2 are introduced, discussed, and applied in the following paragraphs. In the text of this chapter, the units of expression for constituent concentrations are given in mg/L. In the examples,

Table 8–1 Example of typical domestic wastewater characterization parameters and typical values

Component	Concentration, mg/L[a]
COD	430
BOD	190
TSS	210
VSS	160
TKN	40
NH_4-N	25
NO_3-N	0
Total phosphorus	7
Alkalinity	200 (as $CaCO_3$)

Table 8–2
Definition of terms used to characterize important wastewater constituents used for the analysis and design of biological wastewater treatment processes

Constituent[a,b]	Definition
BOD	
BOD	Total 5-d biochemical oxygen demand
sBOD	Soluble 5-d biochemical oxygen demand
UBOD	Ultimate biochemical oxygen demand
COD	
COD	Total chemical oxygen demand
bCOD	Biodegradable chemical oxygen demand
pCOD	Particulate chemical oxygen demand
sCOD	Soluble chemical oxygen demand
nbCOD	Nonbiodegradable chemical oxygen demand
rbCOD	Readily biodegradable chemical oxygen demand
rbsCOD	Readily biodegradable soluble chemical oxygen demand
sbCOD	Slowly biodegradable chemical oxygen demand
bpCOD	Biodegradable particulate chemical oxygen demand
nbpCOD	Nonbiodegradable particulate chemical oxygen demand
nbsCOD	Nonbiodegradable soluble chemical oxygen demand
Nitrogen	
TKN	Total Kjeldahl nitrogen
bTKN	Biodegradable total Kjeldahl nitrogen
sTKN	Soluble (filtered) total Kjeldahl nitrogen
ON	Organic nitrogen
bON	Biodegradable organic nitrogen
nbON	Nonbiodegradable organic nitrogen
pON	Particulate organic nitrogen
nbpON	Nonbiodegradable particulate organic nitrogen
sON	Soluble organic nitrogen
nbsON	Nonbiodegradable soluble organic nitrogen
Suspended Solids	
TSS	Total suspended solids
VSS	Volatile suspended solids
nbVSS	Nonbiodegradable volatile suspended solids
iTSS	Inert total suspended solids

[a] *Note:* b = biodegradable; i = inert; n = non; p = particulate; s = soluble.

[b] Measured constituent values, based on the terminology given in this table, will vary depending on the technique used to fractionate a particular constituent.

however, constituent concentrations are expressed as g/m^3 (which is equivalent to mg/L) for ease of use in process computations, thus eliminating one unit conversion step.

Carbonaceous Constituents. Carbonaceous constituents measured by BOD or COD analyses are critical to the activated-sludge process design. Higher concentrations of degradable COD or BOD result in (1) a larger aeration basin volume, (2) more oxygen transfer needs, and (3) greater sludge production. While the BOD has been the common parameter to characterize carbonaceous material in wastewater, COD is becoming more common and is the primary carbonaceous parameter used in most current comprehensive computer simulation design models. By using a COD mass balance, the fate of carbonaceous material between the amount oxidized and the amount incorporated into cell mass is followed more easily. The various forms of the COD in wastewater are shown on Fig. 8 -4 and defined in Table 8–2.

Unlike BOD, some portion of the COD is not biodegradable, so the COD is divided into *biodegradable* and *nonbiodegradable* concentrations. The next level of interest is how much of the COD in each of these categories is *dissolved* or *soluble*, and how much is *particulate*, comprised of colloidal and suspended solids. The *nonbiodegradable soluble COD* (nbsCOD) will be found in the activated-sludge effluent, and nonbiodegradable particulates will contribute to the total sludge production.

Because the *nonbiodegradable particulate COD* (nbpCOD) is organic material, it will also contribute to the VSS concentration of the wastewater and mixed liquor in the activated-sludge process, and is referred to here as the *nonbiodegradable volatile suspended solids* (nbVSS). The influent wastewater will also contain nonvolatile influent suspended solids that add to the MLSS concentration in the activated-sludge process. These solids are influent *inert TSS* (iTSS) and can be quantified by the difference in influent wastewater TSS and VSS concentrations. For biodegradable COD, understanding the fractions that are measured as soluble, soluble readily biodegradable COD (rbCOD), and particulate is extremely important for activated-sludge process design. The rbCOD portion is quickly assimilated by the biomass, while the particulate and colloidal COD must first be dissolved by extracellular enzymes and are thus assimilated at

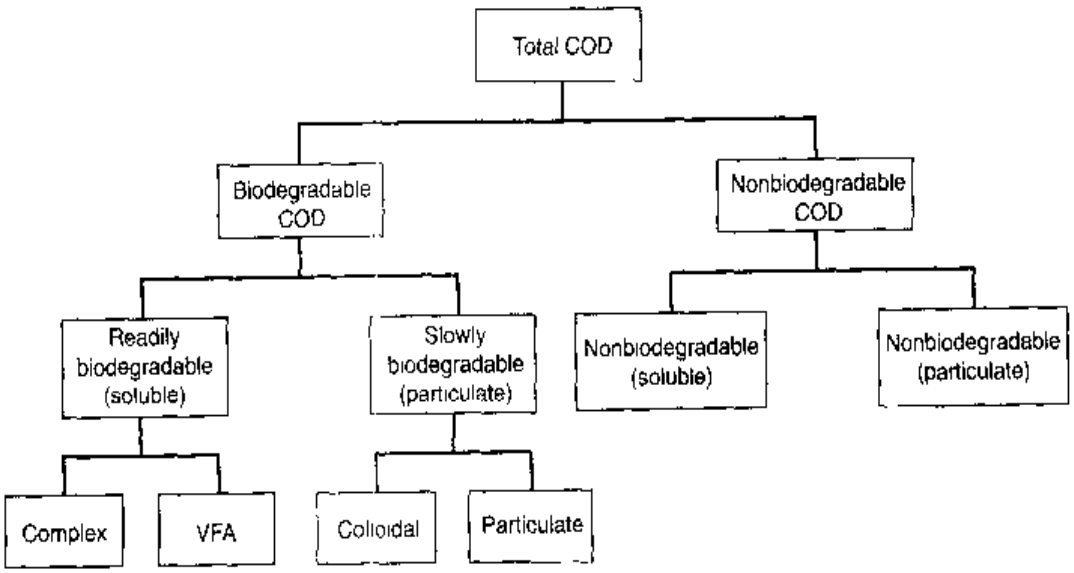

Figure 8–4

Fractionation of COD in wastewater. Information on the COD fractions is used in the detailed design of activated-sludge processes.

Table 8-3
Biological processes affected by readily biodegradable COD (rbCOD) concentration in influent wastewater

Process	Effect of rbCOD
Activated-sludge aeration	For plug flow or staged aeration zones, there will be a higher oxygen demand toward the front of the tank with a higher fraction of rbCOD in the influent COD
Biological nitrogen removal	For the preanoxic tank, there will be a higher denitrification rate with a higher fraction of rbCOD in the influent COD Can result in smaller anoxic tank volume
Biological phosphorus removal	Greater influent rbCOD concentration results in a greater amount of biological phosphorus removal
Activated-sludge selector	Higher fraction of rbCOD in influent COD provides more COD for floc-forming bacteria in the selector. Can have a greater impact on improving sludge volume index (SVI)

much slower rates [slowly biodegradable COD (sbCOD) on Fig. 8–4]. Filtration methods, such as a 0.45-μm filter, are used to determine the soluble COD (sCOD), the COD in the filtrate. The sCOD contains rbCOD, a small fraction of the colloidal COD, and nonbiodegradable soluble COD (nbsCOD). For domestic wastewater, the nbsCOD is equal to the soluble COD concentration of an activated-sludge process effluent ($sCOD_e$) when operated at an SRT $\geq$ 4 d. Special testing techniques, described on page 672, are used to find the "true" soluble rbsCOD.

The rbCOD fraction of the COD has a direct effect on the activated-sludge biological kinetics and process performance. Process applications where the rbCOD concentration affects the process design and performance are summarized in Table 8–3. For conventional plug-flow or staged aerobic activated-sludge reactors, more oxygen demand will be required toward the front of the aeration tank where there is a greater rbCOD concentration. The rbCOD concentration has a significant effect on the denitrification rate in preanoxic zones in biological nitrogen-removal processes, where it will be consumed before the aeration zone. The greater the amount of rbCOD, the faster will be the nitrate reduction rate. For biological phosphorus removal, the rbCOD can be quickly converted to acetate via fermentation in the anaerobic zone for uptake by the phosphorus-storing bacteria. The rbCOD concentration in the influent wastewater must be known to predict more accurately the performance of biological phosphorus removal.

A further step in the characterization of the influent COD is illustrated on Fig. 8–4. The rbCOD consists of complex soluble COD that can be fermented to volatile fatty acids (VFAs) in the influent wastewater. Wastewaters that are more septic, for example, from collection systems in warm climates with minimal slopes, will contain higher concentrations of VFAs.

BOD test data are necessary to obtain the total biodegradable COD (bCOD). Grady et al. (1999) point out that the bCOD/BOD ratio is greater than the ultimate BOD to BOD ratio (UBOD/BOD), because not all of the bCOD is oxidized in the BOD test. Some of the bCOD is converted into biomass, which can still remain as cell debris and active cells at the end of the long incubation time for the UBOD determination. For domestic wastewater with a measured UBOD/BOD ratio of 1.5, the bCOD/BOD ratio

may be 1.6 to 1.7 depending on the biomass yield and cell debris fraction. The bCOD/BOD can be estimated using the following equation, which is based on the fact that the bCOD consumed in the BOD test equals the oxygen consumed (UBOD) plus the oxygen equivalent of the remaining cell debris [bCOD = UBOD + $1.42f_d(Y_H)$bCOD] after long-term incubation:

$$\frac{\text{bCOD}}{\text{BOD}} = \frac{\text{UBOD/BOD}}{1.0 - 1.42f_d(Y_H)} \tag{8-1}$$

where f_d = fraction of cell mass remaining as cell debris, g/g
Y_H = synthesis yield coefficient for heterotrophic bacteria, g VSS/g COD used

For example, using values typical of domestic wastewater (UBOD/BOD = 1.5, f_d = 0.15, Y_H = 0.4), the bCOD/BOD ratio is 1.64.

Nitrogenous Constituents. The composition of nitrogen in wastewater is illustrated on Fig. 8–5. The total Kjeldahl nitrogen (TKN) is a measure of the sum of the ammonia and organic nitrogen. About 60 to 70 percent of the influent TKN concentration will be as NH_4-N, which is readily available for bacterial synthesis and nitrification. Organic nitrogen is present in both soluble and particulate forms, and some portion of each of these is nonbiodegradable. The particulate degradable organic nitrogen will be removed more slowly than the soluble degradable organic nitrogen because a hydrolysis reaction is necessary first. The nondegradable organic nitrogen is assumed to be about 6 percent of the nondegradable VSS as COD in the influent wastewater (Grady et al., 1999). The particulate nondegradable nitrogen will be captured in the activated-sludge floc and exit in the waste sludge, but the soluble nondegradable nitrogen will be found in the secondary clarifier effluent. The soluble nondegradable nitrogen contributes to the effluent total nitrogen concentration and is a small fraction of the influent wastewater TKN concentration (<3 percent). The soluble nondegradable organic nitrogen concentration in domestic wastewater typically ranges from 1 to 2 mg/L as N (Parkin and McCarty, 1981). There is also a possibility that some soluble nondegradable organic nitrogen may be produced from endogenous respiration. Further research

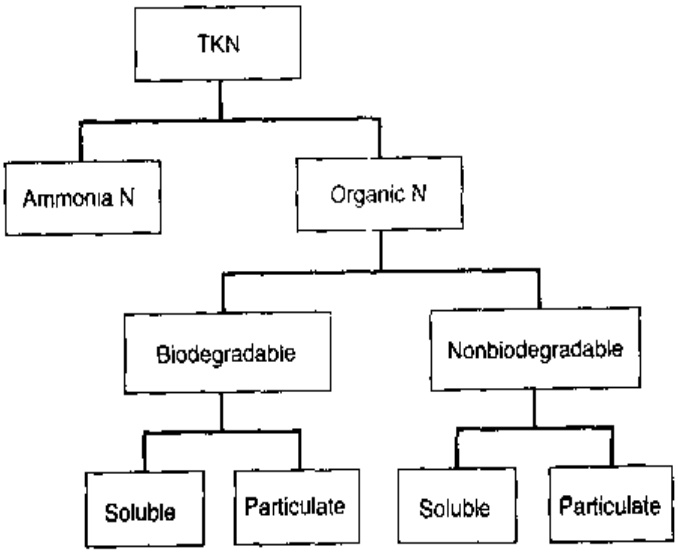

Figure 8–5
Fractionation of nitrogen in wastewater. Information on the nitrogen fractions is used in the detailed design of nitrification and denitrification processes.

is needed to understand fully the sources and factors affecting nondegradable organic nitrogen.

Alkalinity. Alkalinity concentration is an important wastewater characteristic that affects the performance of biological nitrification processes. Adequate alkalinity is needed to achieve complete nitrification. In some cases where a wastewater sample is not available, the total alkalinity of the wastewater may be estimated from information on the alkalinity of the potable water plus the alkalinity contributed through domestic use (see Table 3–16).

Measurement Methods for Wastewater Characterization

Special procedures are used to quantify the rbCOD, nbVSS, and soluble organic nitrogen (sON) and nonbiodegradable organic nitrogen (nbON) concentrations in wastewaters. Some of the methods and techniques used to quantify these constituents are discussed below.

Readily Biodegradable COD. The rbCOD concentration is either determined from a biological response or estimated by a physical separation technique. In the biological response method the oxygen uptake rate (OUR) is followed and recorded with time after mixing the wastewater sample with an acclimated activated-sludge sample. The wastewater may be preaerated so that upon contact with the activated sludge a high DO concentration is present to allow an immediate measurement of the OUR. The wastewater sample and activated sludge are mixed in a batch reactor with separate aeration and mixing. During mixing without aeration the DO concentration declines and is measured with a calibrated DO probe and meter with time to observe the OUR in mg/L·h. When the DO concentration decreases to about 3.0 mg/L, vigorous aeration is applied to elevate the DO concentration to 5 to 6 mg/L, so that another OUR measurement can begin.

An idealized example of the OUR response for a wastewater sample using an activated sludge containing nitrifying bacteria is shown on Fig. 8–6. The OUR versus time can be divided into four areas, which can be used to determine the oxygen consumed for the reaction indicated by the area. Area A is the oxygen used for rbCOD degradation,

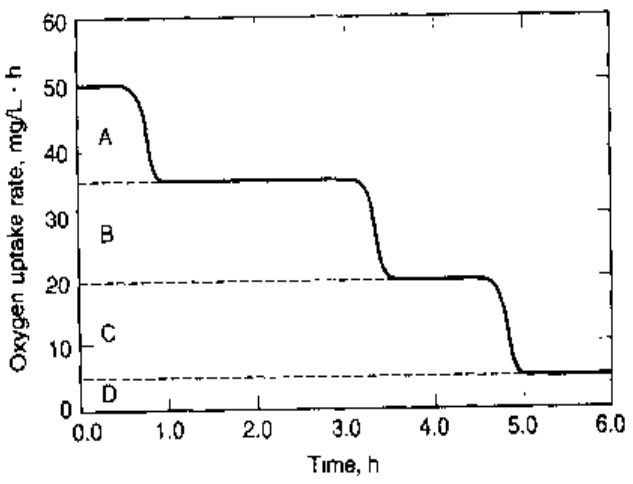

Figure 8–6

Idealized oxygen uptake rate (OUR) in aerobic batch test for a mixture of influent wastewater and activated-sludge mixed liquor. Area A represents rbCOD oxygen demand (*Barker and Dold, 1997*).

area B for zero-order nitrification, area C for particulate COD degradation, and area D for endogenous decay (Ekama et al., 1986). The rbCOD concentration is based on the amount of oxygen used in area A, and is calculated as follows by accounting for the fact that some of the rbCOD is used for cell synthesis:

$$\text{rbCOD} = \frac{O_A}{1 - Y_{H,COD}}\left(\frac{V_{AS} + V_{WW}}{V_{WW}}\right) \tag{8–2}$$

where O_A = oxygen consumed in area A, mg/L
$Y_{H,COD}$ = synthesis yield coefficient for heterotrophic bacteria, g cell COD/g COD used
V_{AS} = volume of activated sludge used in test, mL
V_{WW} = volume of wastewater sample, mL

A value of 0.67 for Y_H is recommended by Ekama et al. (1986).

The volume of activated sludge and wastewater may be selected by successive trials until a response is obtained that provides a satisfactory measurement area for the rbCOD degradation.

A common method used to estimate the rbCOD concentration is the floc/filtration method presented by Mamais et al. (1993) in an attempt to separate the *true* soluble COD in the wastewater sample. The method requires applying the floc/filtration procedure to both the wastewater sample and a secondary effluent sample or a settled supernatant sample after sufficient contact and aeration of the wastewater sample with activated sludge. The soluble COD measured in the secondary effluent sample is the nonbiodegradable soluble COD (nbsCOD) as the rbsCOD would be removed by the activated sludge process. The procedure is based on the assumption that suspended solids and colloidal material can be captured effectively and removed by flocculation with a zinc hydroxide precipitate to leave only truly dissolved organic material after filtration. The steps in the method for each sample are as follows: (1) 1 mL of a 100 g/L $ZnSO_4$ solution is added to 100 mL of sample with vigorous mixing for 1 min, (2) the pH is raised to about 10.5 using 6M (molar) NaOH, with 5 to 10 min of gentle mixing for floc formation, (3) the sample is settled for 10 to 20 min and the supernatant is withdrawn and filtered using a 0.45-μm membrane filter, and (4) the filtrate is analyzed for COD concentration. The difference in COD concentration between the wastewater and activated-sludge treated sample is the rbCOD.

The floc/filtration technique may not give the exact results as the rbCOD concentration determination by respirometry, but it provides a reasonable estimate. Floc/filtration is used widely at wastewater-treatment facilities because of its simplicity. As long as the selected procedure is compatible with the design models used to evaluate the activated-sludge process, a useful design approach is possible.

Nonbiodegradable Volatile Suspended Solids. The wastewater nonbiodegradable volatile suspended solids (nbVSS) concentration can be estimated from analyses for COD, sCOD, BOD, sBOD, and VSS concentration, and by assuming a constant COD/VSS ratio for both biodegradable and nonbiodegradable VSS:

$$\text{nbVSS} = \left[1 - \left(\frac{\text{bpCOD}}{\text{pCOD}}\right)\right]\text{VSS} \tag{8–3}$$

$$\frac{\text{bpCOD}}{\text{pCOD}} = \frac{(\text{bCOD}/\text{BOD})(\text{BOD} - \text{sBOD})}{\text{COD} - \text{sCOD}} \tag{8-4}$$

where bpCOD = concentration of biodegradable particulate COD, mg/L
pCOD = concentration of particulate COD, mg/L
sCOD = concentration of soluble COD in activated-sludge effluent, mg/L

Care must be taken in sample handling and analyses to obtain reliable nbVSS concentration data. A sufficient number of composite samples must be obtained to assure that the results are representative of the wastewater characteristics. Samples must be well mixed when taken for analyses, and for small sample volumes, the pipettes must have wide openings at the tip to better capture solids. When small sample volumes are used, for example, with the HACH COD analysis, treating the sample first in a high-speed blender is often done. Filtration through 0.45-μm membrane filters is recommended to obtain soluble samples for COD and BOD analyses.

Nitrogen Compounds. For the nitrogen compounds, the soluble organic nitrogen concentration is of interest from the standpoint of its effect on the effluent total nitrogen concentration. A filtered sample from the plant effluent or from a bench-scale treatability reactor can be used to determine the total effluent soluble organic nitrogen concentration by the difference between the TKN concentration of the filtered sample and the effluent NH_4-N concentration. The *nonbiodegradable soluble organic nitrogen* (nbsON) cannot be determined directly, but from a practical standpoint and considering the low concentration of effluent soluble organic nitrogen, the total effluent soluble organic nitrogen concentration usually provides sufficient information.

The *nonbiodegradable particulate organic nitrogen* (nbpON) can be estimated by an analysis of the influent VSS for organic nitrogen and the estimated amount of nbVSS. The fraction of nitrogen in the VSS is as follows:

$$f_N = \frac{(\text{TKN} - \text{sON} - \text{NH}_3 \text{ as N})}{\text{VSS}} \tag{8-5}$$

$$\text{nbpON} = f_N(\text{nbVSS}) \tag{8-6}$$

where f_N = fraction of organic nitrogen in VSS, g N/g VSS
TKN = total TKN concentration, mg/L
sON = soluble (i.e., filtered) organic nitrogen concentration, g/m^3
nbpON = nonbiodegradable particulate organic nitrogen concentration, g/m^3
Other terms as defined previously.

Summary Tabulation. In summary, the COD and nitrogen wastewater components can be tabulated as follows:

$$\text{COD} = \text{bCOD} + \text{nbCOD} \tag{8-7}$$

$$\text{bCOD} = \sim 1.6(\text{BOD}) \tag{8-8}$$

$$\text{nbCOD} = \text{sCODe} + \text{nbpCOD} \tag{8-9}$$

$$\text{bCOD} = \text{sbCOD} + \text{rbCOD} \tag{8-10}$$

$$TKN = NH_4\text{-}N + ON \tag{8-11}$$

$$ON = bON + nbON \tag{8-12}$$

$$nbON = nbsON + nbpON \tag{8-13}$$

where the terms are as defined in Table 8–2.

The application of the above equations in determining the characteristics of a wastewater is illustrated in Example 8–1.

EXAMPLE 8–1 Wastewater Characterization Evaluation Given the following wastewater characterization results, determine concentrations for the following:

1. bCOD (biodegradable COD)
2. nbpCOD (nonbiodegradable particulate COD)
3. sbCOD (slowly biodegradable COD)
4. nbVSS (nonbiodegradable VSS)
5. iTSS (inert TSS)
6. nbpON (nonbiodegradable particulate organic nitrogen)
7. Total degradable TKN

Influent wastewater characteristics:

Constituent	Concentration, mg/L
BOD	195
sBOD	94
COD	465
sCOD	170
rbCOD	80
TSS	220
VSS	200
TKN	40
NH_4-N	26
Alkalinity	200 (as $CaCO_3$)

Activated-sludge effluent:

Constituent	Concentration, mg/L
sCODe	30
sON	1.2

Solution

1. Determine biodegradable (bCOD) using Eq. (8–8).

$$bCOD = \sim 1.6(BOD)$$

$$= 1.6(195 \text{ mg/L}) = 312 \text{ mg/L}$$

2. Determine the nbpCOD.
   a. Determine the nbCOD using Eq. (8–7).

$$nbCOD = COD - bCOD$$

$$nbCOD = (465 - 312) \text{ mg/L} = 153 \text{ mg/L}$$

   b. Determine the nbpCOD using Eq. (8–9).

$$nbpCOD = nbCOD - sCODe$$

$$= (153 - 30) \text{ mg/L} = 123 \text{ mg/L}$$

3. Determine the sbCOD using Eq. (8–10).

$$sbCOD = bCOD - rbCOD$$

$$= (312 - 80) \text{ mg/L} = 232 \text{ mg/L}$$

4. Determine the nbVSS.
   a. Determine the bpCOD/pCOD ratio using Eq. (8–4).

$$\frac{bpCOD}{pCOD} = \frac{(bCOD/BOD)(BOD - sBOD)}{COD - sCOD}$$

$$\frac{bpCOD}{pCOD} = \frac{1.6(195 - 94) \text{ mg/L}}{(465 - 170) \text{ mg/L}} = 0.55$$

   b. Determine the nbVSS using Eq. (8–3).

$$nbVSS = \left[1 - \left(\frac{bpCOD}{pCOD}\right)\right]VSS$$

$$nbVSS = (1 - 0.55)(200 \text{ mg/L}) = 90 \text{ mg/L}$$

5. Determine the inert TSS.

$$iTSS = TSS - VSS = (220 - 200) \text{ mg/L} = 20 \text{ mg/L}$$

6. Determine the nbpON.
   a. Determine the organic N content of VSS using Eq. (8–5).

$$f_N = \frac{(TKN - sON - NH_4\text{-}N)}{VSS}$$

$$f_N = \frac{(40 - 1.2 - 26) \text{ mg/L}}{(200 \text{ mg/L})} = 0.064$$

b. Determine the nbpON using Eq. (8–6).

$$nbpON = f_N(nbVSS)$$

$$nbpON = 0.064(90\ mg/L) = 5.8\ mg/L$$

7. Determine total degradable TKN.

$$bTKN = TKN - nbpON - sON$$

$$= (40 - 5.8 - 1.2)\ mg/L$$

$$= 33\ mg/L$$

Recycle Flows and Loadings

The impact of recycle flows must also be quantified and included in defining the influent wastewater characteristics to the activated-sludge process. The possible sources of recycle flows include digester supernatant flows (if settling and decanting are practiced in the digestion operation), recycle of centrate or filtrate from solids dewatering equipment, backwash water from effluent filtration processes, and water from odor-control scrubbers. Depending on the source, a significant BOD, TSS, and NH_4-N load may be added to the influent wastewater. The levels of BOD and TSS concentrations possible for various solids processing unit operations are given in Table 14–49 in Chap. 14. Compared to untreated wastewater or primary clarifier effluent, the BOD/VSS ratio is often much lower for recycle streams. In addition, a significant NH_4-N load can be returned to the influent wastewater from anaerobic digestion-related processes. Concentrations of NH_4-N in the range of 1000 to 2000 mg/L are possible in centrate or filtrate from the dewatering of anaerobically digested solids. Thus, the ammonia load from a return flow of about one half percent of the influent flow can increase the influent TKN load to the activated-sludge process by 10 to 20 percent. The return solids load from effluent polishing filters can be estimated by a mass balance on solids removed across the filtration process, and thus released in the backwash water flow. In all cases, a mass balance for flow and important constituents, such as BOD, TSS/VSS, nitrogen compounds, and phosphorus should be done to account for all contributing flows and loads to the activated-sludge process.

8–3 FUNDAMENTALS OF PROCESS ANALYSIS AND CONTROL

The purpose of this section is to introduce (1) the basic considerations involved in process design, (2) process control measures, (3) operating problems associated with the activated-sludge process, and (4) activated-sludge selector processes. The information presented in this section is applied to the analysis and design of alternative activated-sludge processes in the remainder of this chapter. Many of the equations presented in this chapter were derived previously in Chap. 7 and are summarized in this section for convenient reference.

Process Design Considerations

In the design of the activated-sludge process, consideration must be given to (1) selection of the reactor type, (2) applicable kinetic relationships, (3) solids retention time and loading criteria to be used, (4) sludge production, (5), oxygen requirements and transfer, (6) nutrient requirements, (7) other chemical requirements, (8) settling characteristics of biosolids, (9) use of selectors, and (10) effluent characteristics.

Selection of Reactor Type. Important factors that must be considered in the selection of reactor types for the activated-sludge process include (1) the effects of reaction kinetics, (2) oxygen transfer requirements, (3) nature of the wastewater, (4) local environmental conditions, (5) presence of toxic or inhibitory substances in the influent wastewater, (6) costs, and (7) expansion to meet future treatment needs. Information on these factors is summarized in Table 8-4.

Kinetic Relationships. As developed in Chap. 7, kinetic relationships are used to determine biomass growth and substrate utilization, and to define process performance. Important kinetic relationships are summarized in Table 8-5. The derivation of these relationships may be found in Chap. 7.

Selection of Solids Retention Time and Loading Criteria. Certain design and operating parameters distinguish one activated-sludge process from another. The common parameters used are the solids retention time (SRT), the food to biomass (F/M) ratio (also known as food to microorganism ratio), and the volumetric organic loading rate. While the SRT is the basic design and operating parameter, the F/M ratio and volumetric loading rate provide values that are useful for comparison to historical data and typical observed operating conditions.

Solids Retention Time. The SRT, in effect, represents the average period of time during which the sludge has remained in the system. As presented previously in Chap. 7, SRT is the most critical parameter for activated-sludge design as SRT affects the treatment process performance, aeration tank volume, sludge production, and oxygen requirements. For BOD removal, SRT values may range from 3 to 5 d, depending on the mixed-liquor temperature. At 18 to 25°C an SRT value close to 3 d is desired where only BOD removal is required and to discourage nitrification and eliminate the associated oxygen demand. To limit nitrification, some activated-sludge plants have been operated at SRT values of 1 d or less. At 10°C, SRT values of 5 to 6 d are common for BOD removal only. Temperature and other factors that affect SRT in various treatment applications are summarized in Table 8-6.

Because nitrification is temperature-dependent, the design SRT for nitrification must be selected with caution as variable nitrification growth rates have been observed at different sites, presumably due to the presence of inhibitory substances (Barker and Dold, 1997; Fillos et al., 2000). For nitrification design, a safety factor is used to increase the SRT above that calculated based on nitrification kinetics and the required effluent NH_4-N concentration. A factor of safety is used for two reasons: (1) to allow flexibility for operational variations in controlling the SRT, and (2) to provide for additional nitrifying bacteria to handle peak TKN loadings. The influent TKN concentration

Table 8–4
General considerations for the selection of the type of suspended growth reactor

Factor	Description
Effect of reaction kinetics	The two types of reactors used commonly are the complete-mix and the plug-flow reactor. From a practical standpoint, the hydraulic detention times of many of the complete-mix and plug-flow reactors in actual use are about the same. The reason is that the designs for BOD removal are generally governed by an SRT sufficient to assure good settling properties and of a duration longer than that needed for BOD removal. For nitrification, the possible reaction kinetic benefits from using a staged-reactor or plug-flow system may be exploited, provided that the aeration equipment has a high enough oxygen transfer rate in first stage or at the front of a plug-flow tank to satisfy the demand from higher BOD removal and nitrification rates
Oxygen transfer requirements	Historically, in conventional plug-flow aeration systems, sufficient oxygen often could not be supplied at the beginning of the reactor to meet the demand. The inability to supply the needed oxygen led to development of the following modifications to the activated-sludge process: (1) tapered aeration in which an attempt was made to match the air supplied to the oxygen demand, (2) the step-feed process where the incoming wastewater is distributed along the length of the reactor (usually at quarter points), and (3) the complete-mix process where the air supplied uniformly matches or exceeds the oxygen demand. Most of the past oxygen transfer limitations have been overcome by better selection of process operational parameters and improvements in the design and application of aeration equipment
Nature of wastewater	The nature of the wastewater includes the overall characteristics of the wastewater as affected by contributions such as domestic wastewater, industrial discharges, and inflow/infiltration. Alkalinity and pH are important, particularly in the operation of nitrification processes (see Chap. 7). Because low pH values inhibit the growth of nitrifying organisms (and encourage the growth of filamentous organisms), pH adjustments may be required. Industrial waste discharges may also affect the pH in low-alkalinity wastewaters
Local environmental conditions	Temperature is an important environmental condition that affects treatment performance because changes in the wastewater temperature can affect the biological reaction rate. Temperature is especially important in nitrification design as the expected mixed-liquor temperature will affect the design SRT. Precipitation effects and groundwater infiltration are local factors that can affect both flowrates and constituent concentrations. High peak flowrates can cause the washout of solids in biological reactors
Toxic or inhibitory substances	For municipal wastewater treatment systems with a large number of industrial connections, a potential exists for receiving inhibitory substances that can depress biological nitrification rates. Where such potential exists, laboratory treatability studies are recommended to assess nitrification kinetics. If shock loads or toxic discharges are a design consideration, a complete-mix reactor can more easily withstand changing wastewater characteristics because the incoming wastewater is more or less uniformly dispersed with the reactor contents, as compared to a plug-flow reactor. The complete-mix process has been used in a number of installations to mitigate the impacts caused by shock loads and toxic discharges, especially from industrial installations
Cost	Construction and operating costs are very important considerations in selecting the type and size of reactor. Because the associated settling facilities are an integral part of the activated-sludge process, the selection of the reactor and the solids separation facilities must be considered as a unit
Future treatment needs	Potential future treatment needs can have an impact on present process selection. For example, if water reuse is anticipated in the future, the process selection should favor designs that can easily accommodate nitrogen removal and effluent filtration

Table 8–5
Summary of equations used in the analysis of suspended growth processes

Equation	Eq. No.	Definition of terms
$k_T = k_{20}\theta^{(T-20)}$	2–25	DO = dissolved oxygen, ML^{-3}
$r_{su} = -\dfrac{kXS}{K_s + S}$	7–12	F/M = food to microorganism ratio
$\mu_m = kY$	7–13	k = maximum rate of substrate utilization, T^{-1}
$r_{su} = \dfrac{\mu_m XS}{Y(K_s + S)}$	7–15	k_d = endogenous decay coefficient, T^{-1}
$r_g = Y\dfrac{kXS}{K_s + S} - k_d X$	7–22	k_{dn} = endogenous decay coefficient for nitrifying organisms, T^{-1}
$\mu = \dfrac{r_g}{X}$	7–23	k_T = reaction rate coefficient at temperature (T)
$\text{SRT} = \dfrac{VX}{(Q - Q_w)X_e + Q_w X_R}$	7–35	k_{20} = reaction rate coefficient at 20°C
$\text{SRT} = \dfrac{1}{\mu}$	7–37	K_n = half-velocity constant, ML^{-3}
$\dfrac{1}{\text{SRT}} = -\dfrac{YkS}{K_s + S} - k_d$	7–39	K'_o = oxygen inhibition coefficient, ML^{-3}
$S = \dfrac{K_s[1 + (k_d)\text{SRT}]}{\text{SRT}(Yk - k_d) - 1}$	7–40	K_s = half-velocity constant, ML^{-3}
$X = \left(\dfrac{\text{SRT}}{\tau}\right)\left[\dfrac{Y(S_o - S)}{1 + (k_d)\text{SRT}}\right]$	7–43	$K_{s\,NO_3}$ = half-velocity constant for nitrate limited reaction, ML^{-3}
$(X_{VSS})(V) = (P_{X,VSS})\text{SRT}$	7–54	L_{org} = volumetric organic loading rate, $ML^{-3}T^{-1}$
$(X_{TSS})(V) = (P_{X,TSS})\text{SRT}$	7–55	μ = specific growth rate, T^{-1}
$R_o = Q(S_o - S) - 1.42\,P_{X,bio}$	7–59	μ_m = maximum specific growth rate, T^{-1}
$F/M = \dfrac{QS_o}{VX}$	7–60	μ_n = specific growth rate for nitrification, T^{-1}
$L_{org} = \dfrac{(Q)(S_o)}{(V)}$	7–67	μ_{nm} = maximum specific growth rate of nitrifying bacteria, T^{-1}
$\text{SF} = \text{SRT}_{des}/\text{SRT}_{min}$	7–71	N = nitrogen concentration, ML^{-3}
$\mu_n = \left(\dfrac{\mu_{nm}N}{K_n + N}\right)\left(\dfrac{\text{DO}}{K_o + \text{DO}}\right) - k_{dn}$	7–93	η = ratio of substrate utilization rate with nitrate versus oxygen as the electron acceptor
$r_{su} = -\left(\dfrac{kXS}{K_s + S}\right)\left(\dfrac{NO_3}{K_{s,NO_3} + NO_3}\right)\left(\dfrac{K'_o}{K'_o + \text{DO}}\right)\eta$	7–110	P_X = solids, MT^{-1}
		Q = flowrate, L^3T^{-1}
		Q_w = waste sludge flowrate L^3T^{-1}
		R_o = oxygen, MT^{-1}
		r_g = net biomass production rate, $ML^{-3}T^{-1}$
		r_{su} = soluble substrate utilization rate, $ML^{-3}T^{-1}$
		S = concentration of growth-limiting substrate in solution, ML^{-3}
		SF = safety factor
		S_o = influent concentration, ML^{-3}
		SRT = solids retention time, T
		TSS = total suspended solids, M
		τ = hydraulic retention time (V/Q), T
		θ = temperature activity coefficient
		U = substrate utilization rate, T^{-1}
		V = volume, L^3
		VSS = volatile suspended solids, M
		X = biomass concentration, ML^{-3}
		X_e = concentration of biomass in the effluent, ML^{-3}
		X_R = concentration of biomass in the return line from clarifier, ML^{-3}
		Y = biomass yield, M of cell formed per M of substrate consumed

Note: Expressions for units are M = mass, L = length, and T = time.

Table 8–6
Typical minimum SRT ranges for activated-sludge treatment[a]

Treatment goal	SRT range, d	Factors affecting SRT
Removal of soluble BOD in domestic wastewater	1–2	Temperature
Conversion of particulate organics in domestic wastewater	2–4	Temperature
Develop flocculent biomass for treating domestic wastewater	1–3	Temperature
Develop flocculent biomass for treating industrial wastewater	3–5	Temperature/compounds
Provide complete nitrification	3–18	Temperature/compounds
Biological phosphorus removal	2–4	Temperature
Stabilization of activated sludge	20–40	Temperature
Degradation of xenobiotic compounds	5–50	Temperature/specific bacteria/compounds

[a]Adapted from Grady et al. (1999)

and mass loading can vary throughout the day (a peak to average TKN loading of 1.3 to 1.5 is not unusual, depending on plant size) and can also be affected by return flows from digested and dewatered biosolids processing. By increasing the design SRT, the inventory of nitrifying bacteria is increased to meet the NH_4-N concentration at the peak load so that the effluent NH_4-N concentration requirement is achieved.

Typically, the value of the factor of safety is equal to the peak/average TKN load. Because use of the peak/average TKN load is conservative, the NH_4-N concentration during the normal loading period will be lower with the net effect of a composite effluent NH_4-N concentration that is somewhat lower than the design goal. Dynamic simulation models can be used to optimize the design SRT value to meet target effluent NH_4-N concentrations, subject to changing influent flow and TKN concentrations (Barker and Dold, 1997). The steady-state solution approach described in Sec. 8–10 has resulted in reasonable designs.

Food to Microorganism Ratio. A process parameter commonly used to characterize process designs and operating conditions is the food to microorganism (biomass) ratio (*F/M*). Typical values for the BOD *F/M* ratio reported in the literature vary from 0.04 g substrate/g biomass·d for extended aeration processes to 1.0 g/g·d for high rate processes. The BOD *F/M* ratio is usually evaluated for systems that were designed based on SRT to provide a reference point to previous activated-sludge design and operating performance.

Volumetric Organic Loading Rate. The volumetric organic loading rate is defined as the amount of BOD or COD applied to the aeration tank volume per day. Organic loadings, expressed in kg BOD or COD/m^3·d, may vary from 0.3 to more than

3.0. While the mixed-liquor concentration, the *F/M* ratio, and the SRT (which may be considered an operating variable as well as a design parameter) are ignored when such empirical relationships are used, these relationships do have the merit of requiring a minimum aeration tank volume that has proved to be adequate for the treatment of domestic wastewater. These empirical parameters are not adequate for predicting effluent quality, however, when such relationships are used to design facilities for the treatment of wastewater containing industrial wastes or for biological nitrogen- and phosphorus-removal processes. Higher volumetric organic loadings generally result in higher required oxygen transfer rates per unit volume for the aeration system.

Sludge Production. The design of the sludge-handling and disposal/reuse facility depends on the prediction of sludge production for the activated-sludge process. If the sludge-handling facilities are undersized, then the treatment process performance may be compromised. Sludge will accumulate in the activated-sludge process if it cannot be processed fast enough by an undersized sludge-handling facility. Eventually, the sludge inventory capacity of the activated-sludge system will be exceeded and excess solids will exit in the secondary clarifier effluent, potentially violating discharge limits. The sludge production relative to the amount of BOD removed also affects the aeration tank size.

Two methods are used to determine sludge production. The first method is based on an estimate of an observed sludge production yield from published data from similar facilities, and the second is based on the actual activated-sludge process design in which wastewater characterization is done and the various sources of sludge production are considered and accounted for. The first method may be satisfactory for determining an initial activated-sludge process design and an estimated sludge production for a particular activated-sludge process. With the first method, the quantity of sludge produced daily (and thus wasted daily) can be estimated using Eq. (8–14). For a given wastewater, the Y_{obs} value will vary depending on whether the substrate is defined as BOD, bCOD, or COD.

$$P_{X,VSS} = Y_{obs}(Q)(S_o - S)(1\ kg/10^3\ g) \tag{8–14}$$

where $P_{X,VSS}$ = net waste activated sludge produced each day, kg VSS/d
Y_{obs} = observed yield, g VSS/g substrate removal
Q = influent flow, m^3/d
S_o = influent substrate concentration, mg/L
S = effluent substrate concentration, mg/L

Observed volatile suspended solids yield values, based on BOD, are illustrated on Fig. 8–7. The observed yield decreases as the SRT is increased due to biomass loss by more endogenous respiration. The yield is lower with increasing temperature as a result of a higher endogenous respiration rate at higher temperature. The yield is higher when no primary treatment is used, as more nbVSS remains in the influent wastewater. The temperature correction value θ for endogenous respiration [see Eq. (2–25) in Table 8–5] is 1.04 between 20 and 30°C, and 1.12 between 10 and 20°C. A θ value of 1.04 has been adopted in this text for the temperature effect on endogenous decay.

With sufficient wastewater characterization, a more accurate prediction of sludge production can be made. The following equation, based on Eq. (7–52) in Chap. 7,

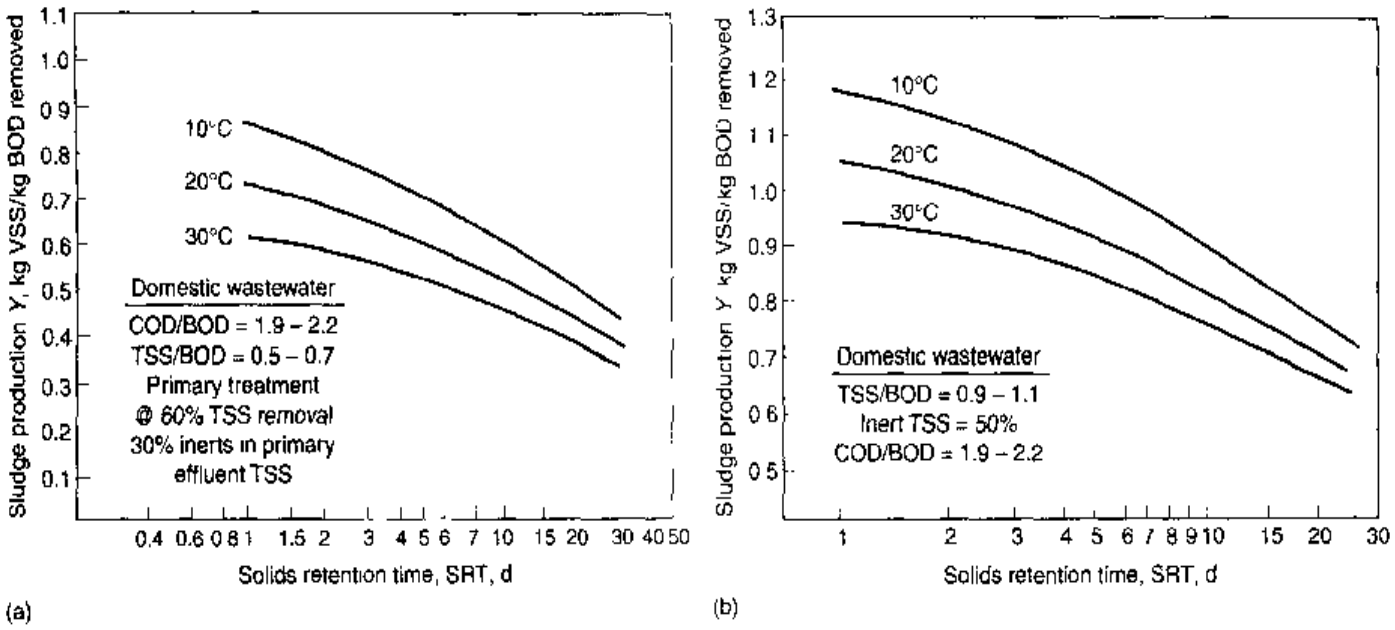

Figure 8–7

Net solids production vs. solids retention time (SRT) and temperature: (*a*) with primary treatment and (*b*) without primary treatment.

accounts for the heterotrophic biomass growth, cell debris from endogenous decay, nitrifying bacteria biomass, and nonbiodegradable volatile suspended solids and can be used to estimate sludge production.

$$P_{X,VSS} = \underbrace{\frac{QY(S_o - S)(1\ kg/10^3\ g)}{1 + (k_d)SRT}}_{\text{(A) Heterotrophic biomass}} + \underbrace{\frac{(f_d)(k_d)QY(S_o - S)SRT(1\ kg/10^3\ g)}{1 + (k_d)SRT}}_{\text{(B) Cell debris}}$$

$$+ \underbrace{\frac{QY_n(NO_x)(1\ kg/10^3\ g)}{1 + (k_{dn})SRT}}_{\text{(C) Nitrifying bacteria biomass}} + \underbrace{Q(nbVSS)(1\ kg/10^3\ g)}_{\text{(D) Nonbiodegradable VSS in influent}} \quad (8\text{–}15)$$

where NO_x = concentration of NH_4-N in the influent flow that is nitrified, mg/L
k_{dn} = endogenous decay coefficient for nitrifying organisms, g VSS/g VSS·d
Other terms as defined previously.

The total mass of dry solids wasted/day includes TSS and not just VSS. The TSS includes the VSS plus inorganic solids. Inorganic solids in the influent wastewater ($TSS_o - VSS_o$) contribute to inorganic solids and are an additional solids production term that must be added to Eq. (8–15). The biomass terms in Eq. (8–15) (A, B, and C) contain inorganic solids and the VSS fraction of the total biomass is about 0.85, based

on the cell composition given in Table 7–4. Thus, Eq. (8–15) is modified as follows to calculate the solids production in terms of TSS:

$$P_{X\,TSS} = \frac{A}{0.85} + \frac{B}{0.85} + \frac{C}{0.85} + D + Q(TSS_o - VSS_o) \qquad (8\text{–}16)$$

(b)
Inert TSS
in influent

where TSS_o = influent wastewater TSS concentration, mg/L
VSS_o = influent wastewater VSS concentration, mg/L

The daily mass of solids in the aeration tanks is determined from the SRT. The daily sludge production can be computed by Eqs. (7–54) and (7–55) in Table 8–5.

By selecting an appropriate MLSS concentration, the aeration volume can be determined using Eq. (7–55) in Table 8–5. Concentrations of MLSS generally in the range of 1200 to 4000 mg/L may be selected, but must be compatible with the sludge settling characteristics and clarifier design as discussed later in this section and in Sec. 8–7.

Oxygen Requirements. The oxygen required for the biodegradation of carbonaceous material is determined from a mass balance using the bCOD concentration of the wastewater treated and the amount of biomass wasted from the system per day. If all of the bCOD were oxidized to CO_2, H_2O, and NH_3, the oxygen demand would equal the bCOD concentration. However, bacteria oxidize a portion of the bCOD to provide energy and use the remaining portion of the bCOD for cell growth. Oxygen is also consumed for endogenous respiration, and the amount will depend on the system SRT. For a given SRT, a mass balance on the system can be done where the bCOD removal equals the oxygen used plus the biomass VSS remaining in terms of an oxygen equivalent. The oxygen requirements for BOD removal without nitrification can be computed using Eq. (7–59) in Table 8–5. As an approximation, for BOD removal only, the oxygen requirement will vary from 0.90 to 1.3 kg O_2/kg BOD removed for SRTs of 5 to 20 d, respectively (WEF, 1998).

When nitrification is included in the process, the total oxygen requirements will include the oxygen required for removal of carbonaceous material plus the oxygen required for ammonia and nitrite oxidation to nitrate (see Sec. 7–9 in Chap. 7) as follows:

$$R_o = Q(S_o - S) - 1.42P_{X,bio} + 4.33Q(NO_x) \qquad (8\text{–}17)$$

where R_o = total oxygen required, g/d
$P_{X,bio}$ = biomass as VSS wasted, g/d [parts A, B, and C of Eq. (8–15)]
Other terms as defined previously.

As shown in Eq. (8–17), NO_x is the amount of TKN oxidized to nitrate. A nitrogen mass balance for the system that accounts for the influent TKN, nitrogen removed for biomass synthesis, and unoxidized effluent nitrogen is done to determine NO_x. Unless a careful wastewater characterization study is done to determine the nonbiodegradable particulate and soluble nitrogen (nbpON and nbsON), these components are ignored. Ignoring these terms results in predicting a slightly higher NO_x concentration (5 to 15 percent) and a more conservative oxygen requirement estimate from Eq. (8–17). The

nitrogen mass balance, based on the assumption of 0.12 g N/g biomass ($C_5H_7NO_2$ for biomass), is as follows:

$$\begin{array}{lcccc} \text{Nitrogen} & = & \text{nitrogen in} & - & \text{nitrogen in} \quad \text{nitrogen in} \\ \text{oxidized} & & \text{influent} & & \text{effluent} \quad \text{cell tissue} \end{array}$$

$$Q(NO_x) = Q(TKN_o) \quad QN_e \quad - 0.12\,P_{x,bio}$$

$$NO_x = TKN - N_e - 0.12\,P_{x,bio}/Q \tag{8–18}$$

where NO_x = nitrogen oxidized, mg/L
TKN_o = influent TKN concentration, mg/L
N_e = effluent NH_4-N concentration, mg/L
Other terms as defined previously.

Equation (8–18) can be solved for the NO_x concentration by estimating the effluent NH_4-N concentration from the nitrification process design.

Nutrient Requirements. If a biological system is to function properly, nutrients must be available in adequate amounts. As discussed in Chaps. 2 and 7, the principal nutrients are nitrogen and phosphorus. Using the formula $C_5H_7NO_2$, for the composition of cell biomass, about 12.4 percent by weight of nitrogen will be required. The phosphorus requirement is usually assumed to be about one-fifth of the nitrogen value. These are typical values, not fixed quantities, because it has been shown that the percentage distribution of nitrogen and phosphorus in cell tissue varies with the system SRT and environmental conditions. The amount of nutrients required can be estimated based on the daily biomass production rate [terms A, B, and C in Eq. (8–15)]. It should be noted that nutrient limitations can occur when the concentrations of nitrogen and phosphorus are in the range of 0.1 to 0.3 mg/L. As a general rule, for SRT values greater than 7 d, about 5 g nitrogen and 1 g phosphorus will be required per 100 g of BOD to provide an excess of nutrients.

Other Chemical Requirements. In addition to the nutrient requirements, alkalinity is a major chemical requirement needed for nitrification. The amount of alkalinity required for nitrification, taking into account cell growth, is about 7.07 g $CaCO_3$/g NH_4-N [see Eq. (7–91) in Chap. 7]. In addition to the alkalinity required for nitrification, additional alkalinity must be available to maintain the pH in the range from 6.8 to 7.4. Typically the amount of residual alkalinity required to maintain pH near a neutral point (i.e., pH ~ 7) is between 70 and 80 mg/L as $CaCO_3$.

Mixed-Liquor Settling Characteristics. The settling characteristics of the mixed-liquor solids must be considered when designing the secondary clarifier for liquid-solids separation. Clarifier design must provide adequate clarification of the effluent and solids thickening for the activated-sludge solids. In the design of installations where sludge characteristics are not known, data from other installations must be assumed or experience of the designer with similar suspended growth processes must be utilized. Tests are available (as described below) to evaluate sludge settling or thickening characteristics, and techniques have been developed to apply these fundamental characteristics to clarifier design.

Two commonly used measures developed to quantify the settling characteristics of activated sludge are the sludge volume index (SVI) and the zone settling rate (WEF,

1998). The SVI is the volume of 1 g of sludge after 30 min of settling. The SVI is determined by placing a mixed-liquor sample in a 1- to 2-L cylinder and measuring the settled volume after 30 min and the corresponding sample MLSS concentration. The numerical value is computed using the following expression:

$$\text{SVI} = \frac{(\text{settled volume of sludge, mL/L})(10^3 \text{ mg/g})}{(\text{suspended solids, mg/L})} = \frac{\text{mL}}{\text{g}} \tag{8–19}$$

For example, a mixed-liquor sample with a 3000 mg/L TSS concentration that settles to a volume of 300 mL in 30 min in a 1-L cylinder would have an SVI of 100 mL/g. A value of 100 mL/g is considered a good settling sludge (SVI values below 100 are desired). SVI values above 150 are typically associated with filamentous growth (Parker et al., 2001).

Because the SVI test is empirical, it is subject to significant errors. For example, if sludge with a concentration of 10,000 mg/L did not settle at all after 30 min, the SVI value would be 100. To avoid erroneous results and to allow for a meaningful comparison of SVI results for different sludges, the diluted SVI (DSVI) test has been used (Jenkins et al., 1993). In Jenkins's analysis, the sludge sample is diluted with process effluent until the settled volume after 30 min is 250 mL/L or less. The standard SVI test is then followed with this sample.

Many SVI tests at wastewater treatment plants are done in a 2-L settleometer that has a larger diameter than 1- or 2-L graduated cylinders (see Fig. 8–8). To eliminate wall effects on solids settling in a small-diameter test apparatus, use of a slow-speed stirring device is encouraged (Wahlberg and Keinath, 1988). The test is called a stirred SVI when a stirring device is used (see Standard Methods, WEF, 1998). The stirred SVI test is used frequently in Europe.

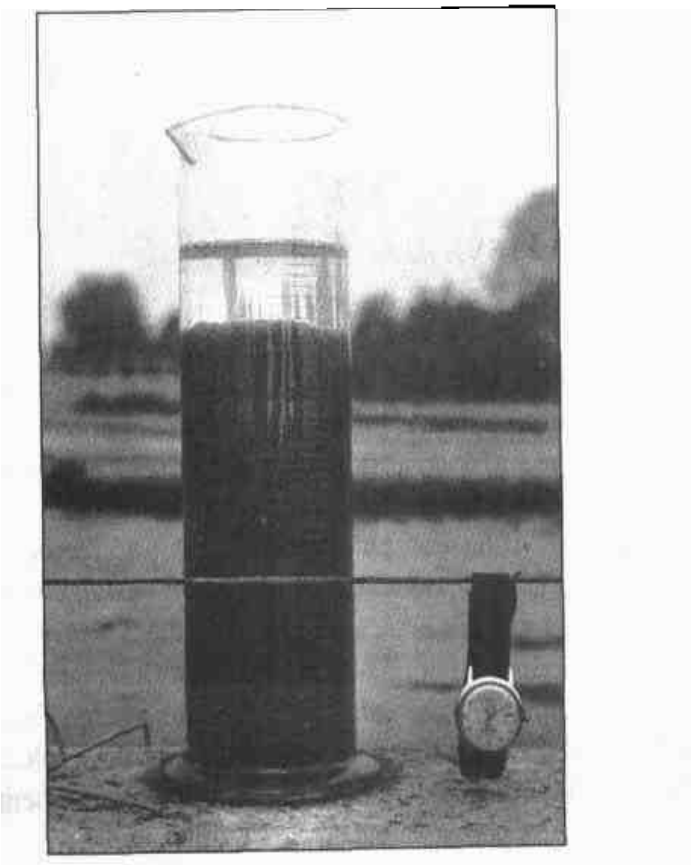

Figure 8–8
Field test for determining sludge volume index (SVI).

The secondary clarifier design has also been related to an expected zone settling velocity (ZSV). The ZSV can also be observed during SVI tests or can be measured in larger, taller cylinders. The ZSV is the settling velocity of the sludge/water interface at the beginning of the sludge settleability test (V_i), and the procedure is described in Standard Methods (WEF, 1998). The surface overflow rate, based on a zone settling velocity, is determined using the following expression:

$$OR = \frac{(V_i)(24)}{SF} \tag{8–20}$$

where OR = surface overflow rate, $m^3/m^2 \cdot d$
V_i = settling velocity of interface, m/h ($m^3/m^2 \cdot h$)
24 = conversion factor from m/h to m/d
SF = safety factor, typically 1.75 to 2.5

An advantage of this procedure is that the value for ZSV can be selected to account for the effect of higher MLSS concentrations. At higher MLSS concentrations, the value for V_i will decrease and the resulting clarifier surface area will increase. The V_i value can be estimated using the following equation (Wilson and Lee, 1982; Wilson, 1996):

$$V_i = V_{max} \exp(-K \times 10^{-6})X \tag{8–21}$$

where V_i = settling velocity of interface, m/h
V_{max} = maximum settling velocity of interface, typically 7 m/h
K = constant, typically 600 L/mg for activated-sludge mixed liquor with an SVI of 150
X = average MLSS concentration, mg/L

Correlations between V_i and the MLSS concentration have been developed with SVI as an additional parameter using data from several facilities (Daigger, 1995; Wahlberg, 1995). The results of the correlations are summarized by the following equations:

$$\ln (V_i) = 1.871 - (0.1646 + 0.001586\ SVI)\ X_T \tag{8–22}$$

$$\ln (V_i) = 2.028 - (0.1030 + 0.0025555\ DSVI)\ X_T \tag{8–23}$$

where DSVI = diluted SVI, mL/g
X_T = MLSS concentration, g/L

Secondary Clarification. Several approaches are used in the design of secondary clarification facilities. The approach used most commonly is to base the design on a consideration of the surface overflow rate and the solids loading rate. Because steady-state operations seldom occur due to fluctuations in wastewater flowrate, return activated-sludge flowrate, and MLSS concentrations, attention to the occurrence of peak events and use of safety factors [Eq. (8–20)] are important design considerations.

Typical surface overflow rates are given in Table 8–7. Overflow rates are based on wastewater flowrates instead of on the mixed-liquor flowrates because the overflow rate is equivalent to an upward flow velocity. The return sludge flow is drawn off the bottom of the tank and does not contribute to the upward flow velocity. Selection of a surface overflow rate is influenced by the target effluent requirements and the need to provide consistent process performance (see Chap. 15).

Table 8-7
Typical design information for secondary clarifiers for the activated-sludge process[a]

Type of treatment	Overflow rate				Solids loading				Depth, m[b]
	gal/ft²·d		m³/m²·d		lb/ft²·h		kg/m²·h		
	Average	Peak	Average	Peak	Average	Peak	Average	Peak	
Settling following air-activated sludge (excluding extended aeration)	400–700	1000–1600	16–28	40–64	0.8–1.2	1.6	4–6	8	3.5–6
Selectors, biological nutrient removal	400–700	1000–1600	16–28	40–64	1.0–1.5	1.8	5–8	9	3.5–6
Settling following oxygen-activated sludge	400–700	1000–1600	16–28	40–64	1.0–1.4	1.8	5–7	9	3.5–6
Settling following extended aeration	200–400	600–800	8–16	24–32	0.2–1.0	1.4	1 0–5	7	3.5–6
Settling for phosphorus removal; effluent concentration, mg/L									3.5–6
Total P = 2	600–800		24–32						
Total P = 1[c]	400–600		16–24						
Total P = 0.2–0.5[d]	300–500		12–20						

[a] Adapted in part from Kang (1987); WEF (1998).

[b] m × 3.2808 = ft.

[c] Occasional chemical addition required.

[d] Continuous chemical addition required for effluent polishing.

Note: Peak is a 2-h sustained peak.

The solids loading rate on an activated-sludge settling tank may be computed by dividing the total solids applied by the surface area of the tank.

$$\text{SLR} = \frac{(Q + Q_R)(X)}{A} \tag{8-24}$$

where SLR = solids loading rate
Q = influent flowrate, m^3/d
Q_R = return activated-sludge flowrate, m^3/d
X = MLSS concentration, mg/L
A = clarifier cross-sectional area, m^2

The commonly used units for SLR are kilograms per square meter per hour ($kg/m^2 \cdot h$) [pounds per square foot per hour ($lb/ft^2 \cdot h$)]. If peak flowrates are of short duration, average 24-h values may govern; if peaks are of long duration, peak values should be assumed to govern to prevent the solids from overflowing the tank.

In effect, the solids loading rate represents a characteristic value for the suspension under consideration. In a settling tank of fixed surface area, the effluent quality will deteriorate if the solids loading is increased beyond the characteristic value for the suspension. Typical solids loading values used for the design of biological systems are also given in Table 8–7. Higher rates should not be used for design without extensive experimental work covering all seasons and operating variables.

While the surface overflow rate has been the historical clarifier design parameter, the solids loading rate is considered by some to be the limiting parameter that affects the effluent concentration. Parker et al. (2001) have shown that with a proper hydraulic design and management of solids in the sedimentation tank, the overflow rate has little or no effect on the effluent quality over a wide range of overflow rates, and the design can be based on the solids loading rates. Wahlberg (1995) supports Parker's position and, based on the evaluation of secondary clarifier performance for a number of facilities, found no effect of using surface overflow rates up to 3.4 m/h.

Additional information for the physical design of solids separation facilities is given in Sec. 8–7.

Use of Selectors. Because solids separation is one of the most important aspects of biological wastewater treatment, a biological selector (a small contact tank) is often incorporated in the design to limit the growth of organisms that do not settle well. Selectors are naturally incorporated into the biological nitrogen- and phosphorus-removal processes described. For BOD removal only or BOD removal and nitrification processes, an appropriate selector design can be added before the activated-sludge aeration basin. Selector design concepts and design are discussed at the end of this section.

Effluent Characteristics. The major parameters of interest that determine the effluent quality from biological treatment processes consist of organic compounds, suspended solids, and nutrients as indicated by the following four constituents:

1. Soluble biodegradable organics
   a. Organics that escaped biological treatment

   b. Organics formed as intermediate products in the biological degradation of the waste
   c. Cellular components (result of cell death or lysis)
2. Suspended organic material
   a. Biomass produced during treatment that escaped separation in the final settling tank
   b. Colloidal organic solids in the plant influent that escaped treatment and separation
3. Nitrogen and phosphorus
   a. Contained in biomass in effluent suspended solids
   b. Soluble nitrogen as NH_4-N, NO_3-N, NO_2-N, and organic N
   c. Soluble orthophosphates
4. Nonbiodegradable organics
   a. Those originally present in the influent
   b. Byproducts of biological degradation

In a well-operating activated-sludge process treating domestic wastes with an SRT $\geq$ 4 d, the soluble carbonaceous BOD of a filtered sample is usually less than 3.0 mg/L. Although use of Eq. (7–40) may result in predicted effluent sBOD concentrations $<$ 1.0 mg/L, the practical sBOD measurement value appears to be in the range of 2 to 4 mg/L. With a proper secondary clarifier design and good settling sludge, the effluent suspended solids may be in the range of 5 to 15 mg/L. Assuming an sBOD of 3 mg/L, a VSS/TSS ratio of 0.85, and an effluent TSS of 10 mg/L, the final effluent BOD concentration, BOD_e, can be estimated as follows:

$$BOD_e = sBOD + \left(\frac{1\ g\ \overline{BOD}}{1.42\ g\ \overline{VSS}}\right)\left(\frac{0.85\ g\ \overline{VSS}}{g\ \overline{TSS}}\right)(TSS, mg/L) \qquad [8\text{–}25]$$

$$BOD_e = 3\ mg/L + (0.70)(0.85)(10\ mg/L)$$

$$BOD_e = 8.6\ mg/L$$

Process Control

To maintain high levels of treatment performance with the activated-sludge process under a wide range of operating conditions, special attention must be given to process control. The principal approaches to process control are (1) maintaining dissolved oxygen levels in the aeration tanks, (2) regulating the amount of return activated sludge (RAS), and (3) controlling the waste-activated sludge (WAS). The parameter used most commonly for controlling the activated-sludge process is SRT. The mixed-liquor suspended solids (MLSS) concentration may also be used as a control parameter. Return activated sludge is important in maintaining the MLSS concentration and controlling the sludge blanket level in the secondary clarifier. The waste activated-sludge flow from the recycle line is selected usually to maintain the desired SRT. Oxygen uptake rates (OURs) are also measured as a means of monitoring and controlling the activated-sludge process. Routine microscopic observations are important for monitoring the microbial characteristics and for early detection of changes that might negatively impact sludge settling and process performance.

Dissolved Oxygen Control. Theoretically, the amount of oxygen that must be transferred in the aeration tanks equals the amount of oxygen required by the microorganisms in the activated-sludge system to oxidize the organic material. In practice, the transfer efficiency of oxygen for gas to liquid is relatively low so that only a small amount of oxygen supplied is used by the microorganisms. When oxygen limits the growth of microorganisms, filamentous organisms may predominate and the settleability and quality of the activated sludge may be poor. In general, the dissolved oxygen concentration in the aeration tank should be maintained at about 1.5 to 2 mg/L in all areas of the aeration tank. Higher DO concentrations (>2.0 mg/L) may improve nitrification rates in reactors with high BOD loads. Values above 4 mg/L do not improve operations significantly, but increase the aeration costs considerably.

Return Activated-Sludge Control. The purpose of the return of activated sludge is to maintain a sufficient concentration of activated sludge in the aeration tank so that the required degree of treatment can be obtained in the time interval desired. The return of activated sludge from the final clarifier to the inlet of the aeration tank is the essential feature of the process. Ample return sludge pump capacity should be provided and is important to prevent the loss of sludge solids in the effluent. The solids form a sludge blanket in the bottom of the clarifier, which can vary in depth with flow and solids loadings variations to the clarifier. At transient peak flows, less time for sludge thickening is available so that the sludge blanket depth increases. Sufficient return sludge pumping capacity is needed, along with sufficient clarifier depth (3.7 to 5.5 m), to maintain the blanket below the effluent weirs. Return sludge pumping rates of 50 to 75 percent of the average design wastewater flowrate are typical, and the design average *capacity* is typically of 100 to 150 percent of the average design flowrate. Return sludge concentrations from secondary clarifiers range typically from 4000 to 12,000 mg/L (WEF, 1998).

Several techniques are used to calculate the desirable return sludge flowrate. Common control strategies for determining the return sludge flowrate are based on maintaining either a target MLSS level in the aeration tanks or a given sludge blanket depth in the final clarifiers. The most commonly used techniques to determine return sludge flowrate are (1) settleability, (2) sludge blanket level control, (3) secondary clarifier mass balance, and (4) aeration tank mass balance.

Settleability. Using the settleability test, the return sludge pumping rate is set so that the flowrate is approximately equal to the percentage ratio of the volume occupied by the settleable solids from the aeration tank effluent to the volume of the clarified liquid (supernatant) after settling for 30 min in a 1000-mL graduated cylinder. This ratio should not be less than 15 percent at any time. For example, if the settleable solids occupied a volume of 275 mL after 30 min of settling, the percentage volume would be equal to 38 percent [(275 mL / 725 mL) × 100]. If the plant flow were 2 m^3/s, the return sludge rate should be 0.38 × 2 m^3/s = 0.76 m^3/s.

Another settleability test method often used to control the rate of return sludge pumping is based on the sludge volume index (SVI). If the SVI is known, then the percentage of return sludge, in terms of the recirculation ratio (Q_r/Q) required to maintain a given percentage of mixed-liquor solids concentration in the aeration tank is

$$Q_r = 100/[(100/P_w\text{SVI}) - 1] \tag{8-26}$$

where Q_r = return activated-sludge flowrate, percent of influent flowrate
P_u = MLSS expressed as a percentage
SVI = as defined by Eq. (8–19)

For example, to maintain a mixed-liquor solids concentration of 0.30 percent (3000 mg/L), the percentage of sludge that must be returned when the sludge volume index is 100 is equal to $100/[(100/0.30 \times 100) - 1]$, or 43 percent.

Sludge Blanket Level. With the sludge blanket level control method, an optimum sludge blanket level is maintained in the clarifiers. The optimum level is determined by experience and is a balance between settling depth and sludge storage. The optimum depth of the sludge blanket usually ranges between 0.3 and 0.9 m (1 and 3 ft). The sludge blanket method of control requires considerable operator attention because of the diurnal flow and sludge production variations and changes in the settling characteristics of the sludge. Several methods are available to detect the sludge blanket levels, including withdrawing samples using air-lift pumps, gravity-flow tubes, portable sampling pumps, and core samplers, or using sludge-supernatant interface detectors.

Mass-Balance Analysis. The return sludge pumping rate may also be determined by making a mass-balance analysis around either the settling tank or the aeration tank. The appropriate limits for the two mass-balance analyses are illustrated on Fig. 8–9. Assuming the sludge-blanket level in the settling tank remains constant and that the solids in the effluent from the settling tank are negligible, the mass balance around the settling tank shown on Fig. 8–9*a* is as follows:

Accumulation = inflow − outflow

$$0 = X(Q + Q_R) - Q_R X_R - Q_w X_R - Q_e X_e \tag{8–27}$$

where X = mixed-liquor suspended solids, mg/L
Q = secondary influent flowrate, m^3/s
Q_R = return sludge flowrate, m^3/s
X_R = return activated-sludge suspended solids, mg/L

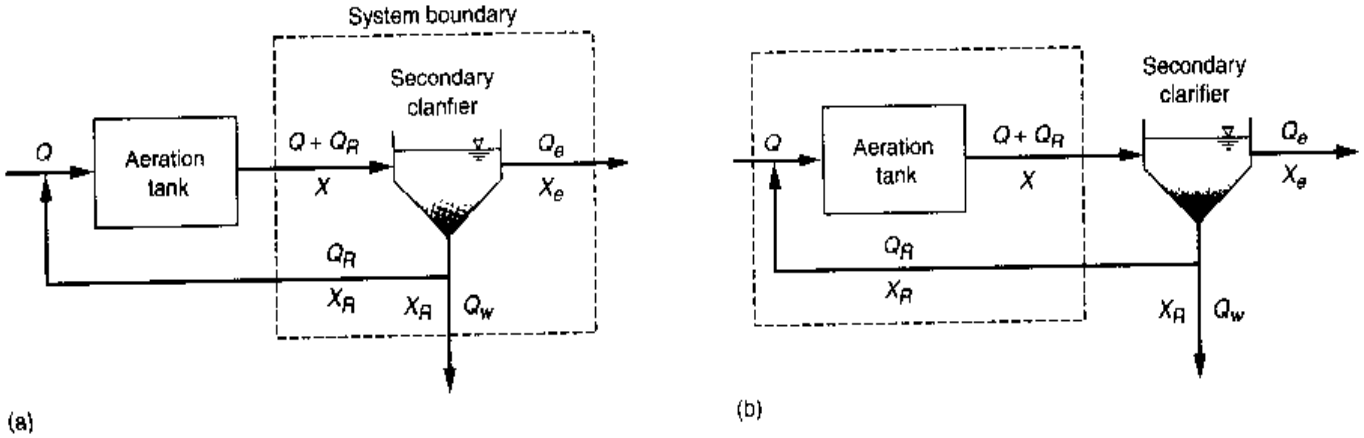

Figure 8–9

Definition sketch for suspended solids mass balances for return sludge control: (*a*) secondary clarifier mass balance and (*b*) aeration tank mass balance.

Q_w = waste activated-sludge flowrate, m³/s
Q_e = effluent flowrate, m³/s
X_e = effluent suspended solids, mg/L

Assuming X_e is negligible and that $Q_w X_R$ is related to the SRT [Eq. (7–35)], solving Eq. (8–27) for Q_R yields

$$Q_R = \frac{[XQ - (XV/\text{SRT})]}{X_R - X} \tag{8–28}$$

The recycle ratio ($Q_R/Q = R$) is then

$$R = \frac{1 - (\tau/\text{SRT})}{(X_R/X) - 1} \tag{8–29}$$

The required RAS pumping rate can also be estimated by performing a mass balance around the aeration tank (see Fig. 8–9*b*). The solids entering the tank will equal the solids leaving the tank if new cell growth can be considered negligible. Under conditions such as high organic loadings, this assumption may be incorrect. Solids enter the aeration tank in the return sludge and in the influent to the secondary process. However, if the influent solids are negligible compared to the MLSS, the mass balance around the aeration tank results in the following expression:

Accumulation = inflow − outflow

$$0 = X_R Q_R - X(Q + Q_R) \tag{8–30}$$

Solving for the return activated-sludge ratio R yields

$$Q_R/Q = R = \frac{X}{X_R - X} \tag{8–31}$$

Sludge Wasting. To maintain a given SRT, the excess activated sludge produced each day must be wasted. The most common practice is to waste sludge from the return sludge line because RAS is more concentrated and requires smaller waste sludge pumps. The waste sludge can be discharged to the primary sedimentation tanks for co-thickening, to thickening tanks, or to other sludge-thickening facilities. An alternative method of wasting sometimes used is withdrawing mixed liquor directly from the aeration tank or the aeration tank effluent pipe where the concentration of solids is uniform. The waste mixed liquor can then be discharged to a sludge-thickening tank or to the primary sedimentation tanks where it mixes and settles with the untreated primary sludge. The actual amount of liquid that must be pumped to achieve process control depends on the method used and the location from which the wasting is to be accomplished. Also, because the solids capture of the sludge processing facilities is not 100 percent, and some solids are returned, the actual wasting rate will be higher than the theoretically determined value. For example, if SRT is used for process control and wasting is from the return sludge line, the wasting rate can be computed by modifying the terms of Eq. (7–32) (see Table 8–5).

$$\text{SRT} = \frac{VX}{(Q_w X_R + Q_e X_e)} \tag{8–32}$$

where V = volume of the reactor, m^3
X = aeration tank mass concentration, mg/L
Q_w = waste sludge flowrate from the return sludge line, m^3/d
X_R = concentration of sludge in the return sludge line, mg/L
Q_e = effluent flowrate from secondary clarifier, m^3/d
X_e = effluent TSS concentration, mg/L

If it is assumed that the concentration of solids in the effluent from the settling tank is low, then Eq. (8–32) reduces to

$$\text{SRT} \approx \frac{VX}{Q_w X_R} \tag{8-33}$$

and

$$Q_w \approx \frac{VX}{(X_R)\text{SRT}} \tag{8-34}$$

To determine the waste flowrate using Eq. (8–34), the solids concentration in both the aeration tank and the return line must be measured.

If wasting is done from the aeration tank and the solids in the settled effluent are again neglected, then the rate of pumping can be estimated using the following relationship:

$$\text{SRT} = \frac{V}{Q_w} \tag{8-35}$$

or

$$Q_w = \frac{V}{\text{SRT}} \tag{8-36}$$

where Q_w = waste sludge flowrate from the aeration tank, m^3/d

Thus, the process may be controlled by daily wasting of a quantity of flow equal to the volume of the aeration tank divided by the SRT.

Oxygen Uptake Rates. Microorganisms in the activated-sludge process use oxygen as they consume the substrate. The rate at which they use oxygen, known as the *oxygen uptake rate* (OUR), is a measure of the biological activity and loading on the aeration tank. Values for the OUR are obtained by performing a series of DO measurements over a period of time, and the measured results are conventionally reported as mg O_2/L·min or mg O_2/L·h.

Oxygen uptake is most valuable for plant operations when combined with VSS data. The combination of OUR with MLVSS yields a value termed the specific oxygen uptake rate (SOUR) or respiration rate. The SOUR is a measure of the amount of oxygen used by microorganisms and is reported as mg O_2/g MLVSS·h. It has been shown that the mixed liquor SOUR and the final effluent COD can be correlated, thereby allowing predictions of final effluent quality to be made during transient loading conditions (Huang and Cheng, 1984). Changes in SOUR values may also be used to assess the presence of toxic or inhibitory substances in the influent wastewater.

Microscopic Observations. Routine microscopic observations provide valuable monitoring information about the condition of the microbial population in the activated-sludge process. Specific information gathered includes changes in floc size and density, the status of filamentous organism growth in the floc, the presence of *Nocardia* bacteria, and the type and abundance of higher life-forms such as protozoans and rotifers. Changes in these characteristics can provide an indication of changes in the wastewater characteristics or of an operational problem. Examples of the changes in predominance of microorganisms versus F/M ratio and SRT are shown on Fig. 8–10. A decrease in the protozoan population may be indicative of DO limitations, operation at a lower SRT, or inhibitory substances in the wastewater. Early detection of filamentous or *Nocardia* growth will allow time for corrective action to be taken to minimize potential problems associated with excessive growth of these organisms. Procedures may be followed to identify the specific type of filamentous organism, which may help identify an operating or design condition that encourages their growth (Jenkins et al., 1993).

Operational Problems

The most common problems encountered in the operation of an activated-sludge plant are bulking sludge, rising sludge, and *Nocardia* foam. Because few plants have escaped these problems, it is appropriate to discuss their nature and methods for their control.

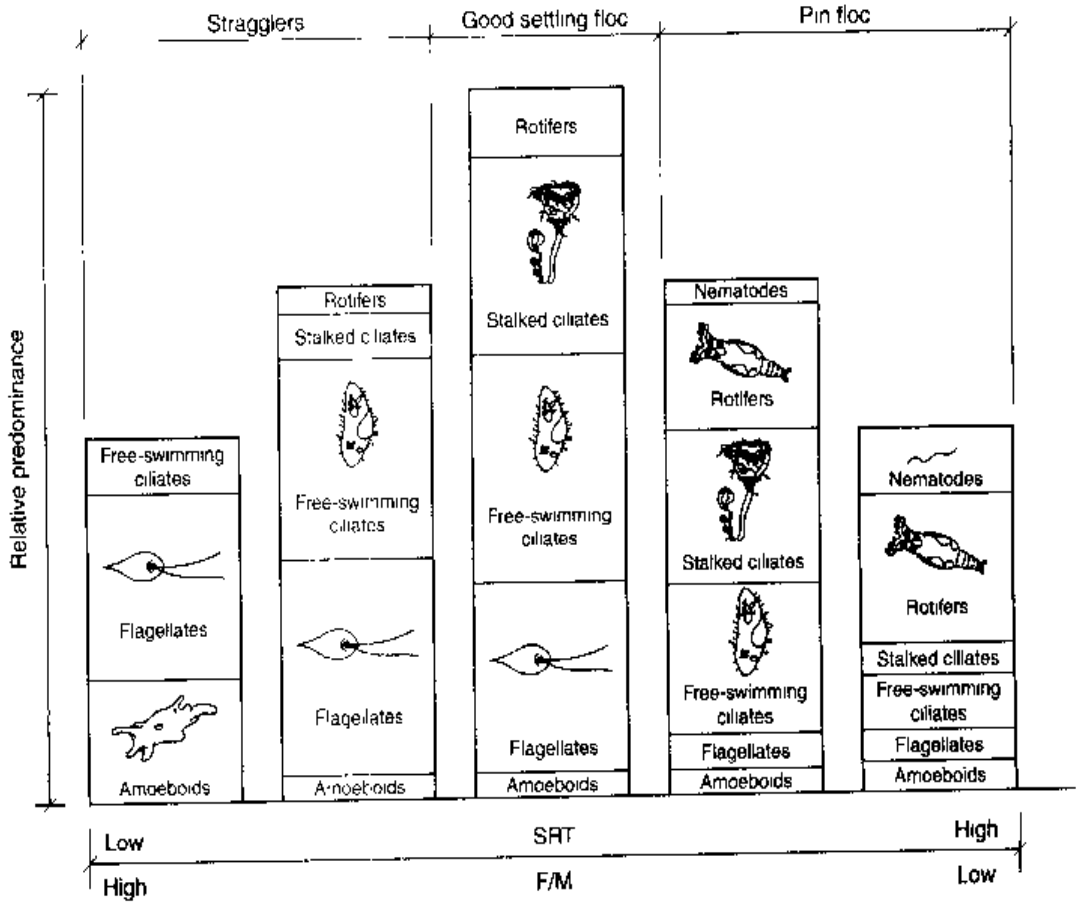

Figure 8–10
Relative predominance of microorganisms versus food to microorganisms (F/M) ratio and solids retention time (SRT). *(Adapted in part from WEF, 1996.)*

Bulking Sludge. In many cases MLSS with poor settling characteristics has developed into what is known as a *bulking sludge* condition, which defines a condition in the activated-sludge clarifier that can cause high effluent suspended solids and poor treatment performance. In a bulking sludge condition, the MLSS floc does not compact or settle well, and floc particles are discharged in the clarifier effluent. With good settling sludge, sludge levels may be as low as 10 to 30 cm at the bottom of the clarifier. In extreme bulking sludge conditions, the sludge blanket cannot be contained and large quantities of MLSS are carried into the system effluent, potentially resulting in violation of permit requirements, inadequate disinfection, and clogging of effluent filters.

Two principal types of sludge bulking problems have been identified. One type, *filamentous bulking*, is caused by the growth of filamentous organisms or organisms that can grow in a filamentous form under adverse conditions, and is the predominant form of bulking that occurs. The other type of bulking, *viscous bulking*, is caused by an excessive amount of extracellular biopolymer, which produces a sludge with a slimy, jellylike consistency (Wanner, 1994). As the biopolymers are hydrophilic, the activated sludge is highly water-retentive, and this condition is referred to as *hydrous bulking*. The resultant sludge has a low density with low settling velocities and poor compaction. Viscous bulking is usually found with nutrient-limited systems or in a very high loading condition with wastewater having a high amount of rbCOD.

Bulking sludge problems due to the growth of filamentous bacteria are more common. In filamentous growth, bacteria form filaments of single-cell organisms that attach end-to-end, and the filaments normally protrude out of the sludge floc. This structure, in contrast to the preferred dense floc with good settling properties, has an increased surface area to mass ratio, which results in poor settling. On Fig. 8–11, a good settling, dense nonfilamentous floc is contrasted to floc containing filamentous growth. Many types of filamentous bacteria exist, and means have been developed for the identification and classification of filamentous bacteria found commonly in activated-sludge systems (Eikelboom, 2000). The classification system is based on morphology (size and shape of cells, length and shape of filaments), staining responses, and cell inclusions. Common filamentous organisms are summarized in Table 8–8, along with the operating conditions that favor their growth. Sludge bulking can be caused by a variety of factors, including wastewater characteristics, design limitations, and operational issues. Individual items associated with each of these categories are identified in Table 8–9.

Activated-sludge reactor operating conditions (low DO, low F/M, and complete-mix operation) clearly have an effect on the development of filamentous populations. One of the kinetic features of filamentous organisms that relates to these conditions is that they are very competitive at low substrate concentrations whether it be organic substrates, DO, or nutrients. Thus, lightly loaded complete-mix activated-sludge systems or low DO (<0.5 mg/L) operating conditions provide an environment more favorable to filamentous bacteria than to the desired floc-forming bacteria.

Filamentous bacteria such as *Beggiatoa* and *Thiothrix* grow well on hydrogen sulfide and reduced substrates, respectively, that would be found in septic wastewaters (Wanner, 1994). When the influent wastewater contains fermentation products such as volatile fatty acids and reduced sulfur compounds (sulfides and thiosulfate), *Thiothrix* can proliferate. Prechlorination of the wastewaters has been done in some cases to prevent their growth. Besides causing bulking problems in activated-sludge systems, *Beggiatoa* and *Thiothrix*

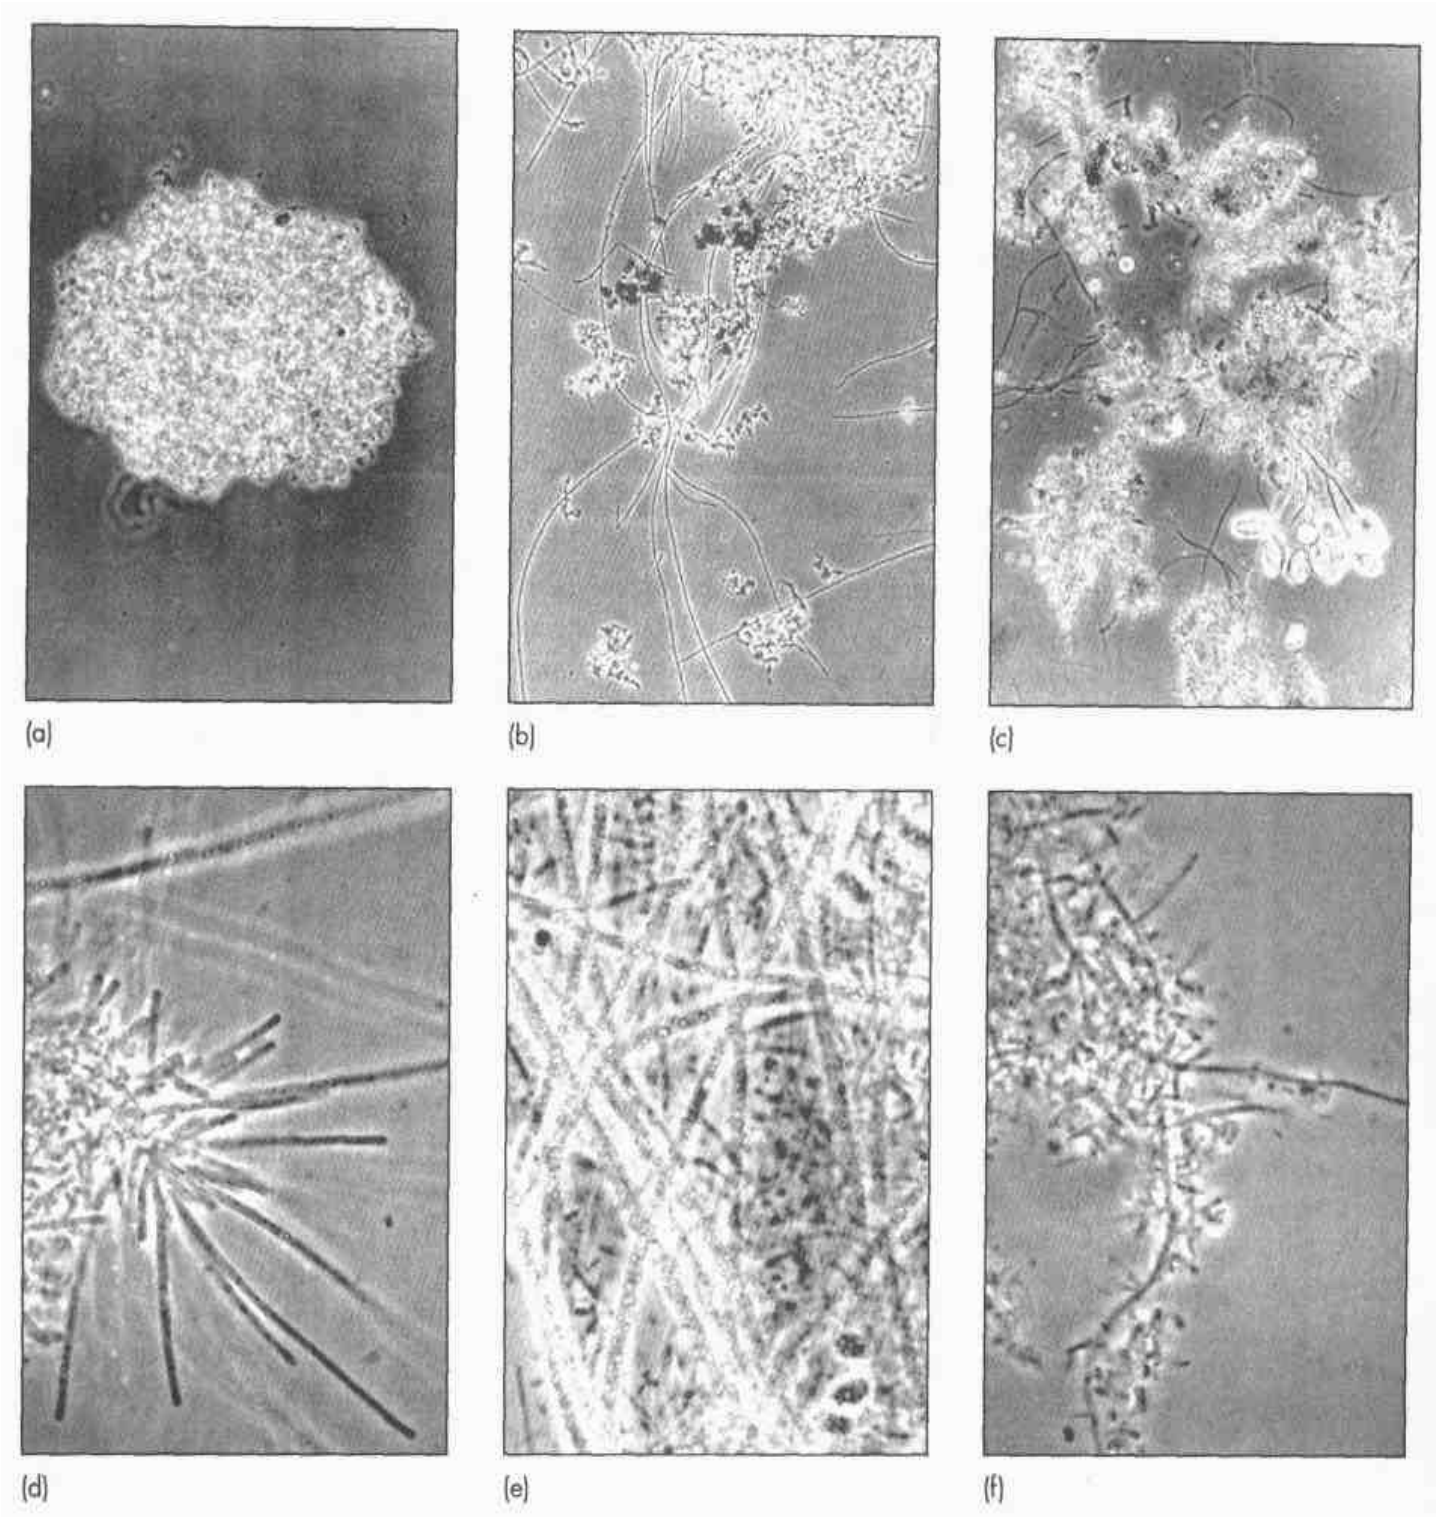

Figure 8–11

Table 8–8
Filamentous organisms found in activated sludge and associated process conditions[a]

Filament type identified	Cause of filament growth
Sphaerotilus natans, Halsicomenobacter hydrossis, Microthrix parvicella, type 1701	Low dissolved oxygen concentration
M. parvicella, types 0041, 0092, 0675, 1851	Low F/M
H. hydrossis, Nocardia spp., *Nostocoida limicola, S. natans, Thiothrix* spp., types 021N, 0914	Complete-mix reactor conditions
Beggiatoa, Thiothrix spp., types 021N, 0914	Septic wastewater/sulfide available
S. natans, Thiothrix spp., type 021N, possible *H. hydrossis,* types 0041, 0675	Nutrient deficiency
Fungi	Low pH, nutrient deficiency

[a] From Eikelboom (1975).

Table 8–9
Factors that affect sludge bulking

Factor	Description
Wastewater characteristics	Variations in flowrate
	Variations in composition
	pH
	Temperature
	Septicity
	Nutrient content
	Nature of waste components
Design limitations	Limited air supply
	Poor mixing
	Short circuiting (aeration tanks and clarifiers)
	Clarifier design (sludge collection and removal)
	Limited return sludge pumping capacity
Operational issues	Low dissolved oxygen
	Insufficient nutrients
	Low F/M
	Insufficient soluble BOD

can create problems in fixed-film systems, including trickling filters and rotating biological contactors.

In the control of bulking, where a number of variables are possible causes, a checklist of items to investigate is valuable. The following items are recommended: (1) wastewater characteristics, (2) dissolved oxygen content, (3) process loading, (4) return and waste sludge pumping rates, (5) internal plant overloading, and (6) clarifier operation. One of the first steps to be taken when sludge settling characteristics change is to view

the mixed liquor under the microscope to determine what type of microbial growth changes or floc structure changes can be related to the development of bulking sludge. A reasonable quality phase-contrast microscope with magnification up to 1000 times (oil immersion) is necessary to view the filamentous bacteria structure and size.

Wastewater Characteristics. The nature of the components found in wastewater or the absence of certain components, such as trace elements, can lead to the development of a bulked sludge (Wood and Tchobanoglous, 1975). If it is known that industrial wastes are being introduced into the system either intermittently or continuously, the quantity of nitrogen and phosphorus in the wastewater should be checked first, because limitations of both or either are known to favor bulking. Nutrient deficiency is a classic problem in the treatment of industrial wastewaters containing high levels of carbonaceous BOD. Wide fluctuations in pH are also known to be detrimental in plants of conventional design. Variations in organic waste loads due to batch-type operations can also lead to bulking and should be checked.

Dissolved Oxygen Concentration. Limited dissolved oxygen has been noted more frequently than any other cause of bulking. If the problem is due to limited oxygen, it can usually be confirmed by operating the aeration equipment at full capacity or by decreasing the system SRT, if possible, to reduce the oxygen demand. The aeration equipment should have adequate capacity to maintain at least 2 mg/L of dissolved oxygen in the aeration tank under normal loading conditions. If 2 mg/L of oxygen cannot be maintained, installation of improvements to the existing aeration system may be required.

Process Loading/Reactor Configuration. The aeration SRT should be checked to make sure that it is within the range of generally accepted values. In many cases, complete-mix systems with long SRTs and subsequent low F/M ratios experience filamentous growths. In such systems, the filamentous organisms are more competitive for substrate. Laboratory research and full-scale investigations have led to activated-sludge design configurations that provide conditions favoring the dominance of *floc-forming* bacteria over filamentous organisms (Jenkins et al., 1993). Reactors in series with various types of environmental conditions, i.e., aerobic, anoxic, and anaerobic, are generally used to augment or replace a complete-mix reactor. The series configurations are called selector processes because they provide conditions that cause selection of floc-forming bacteria in lieu of filamentous organisms as the dominant population. The selector process is discussed in greater detail later in this section.

Internal Plant Overloading. To avoid internal plant overloading, recycle loads should be controlled so they are not returned to the plant flow during times of peak hydraulic and organic loading. Examples of recycle loads are centrate or filtrate from sludge dewatering operations and supernatant from sludge digesters.

Clarifier Operation. The operating characteristics of the clarifier may also affect sludge settling characteristics. Poor settling is often a problem in center-feed circular tanks where sludge is removed from the tank directly under the point where the mixed liquor enters. Sludge may actually be retained in the tank for many hours rather than the

desired 30 min and cause localized septic conditions. If this is the case, then the design is at fault, and changes must be made in the inlet feed well and sludge withdrawal equipment.

Temporary Control Measures. In an emergency situation or while the aforementioned factors are being investigated, chlorine and hydrogen peroxide may be used to provide temporary help. Chlorination of return sludge has been practiced quite extensively as a means of controlling bulking. A typical design for a low (5 to 10 h) τ system uses 0.002 to 0.008 kg of chlorine per kg MLSS·d (Jenkins et al., 1993). Although chlorination is effective in controlling bulking caused by filamentous growths, it is ineffective when bulking is due to light floc containing bound water. Chlorination normally results in the production of a turbid effluent until such time as the sludge is free of the filamentous forms. Chlorination of a nitrifying sludge will also produce a turbid effluent because of the death of the nitrifying organisms. The use of chlorine also raises issues about the formation of trihalomethanes and other compounds with potential health and environmental effects. Hydrogen peroxide has also been used in the control of filamentous organisms in bulking sludge. Dosage of hydrogen peroxide and treatment time depend on the extent of the filamentous development.

Rising Sludge. Occasionally, sludge that has good settling characteristics will be observed to rise or float to the surface after a relatively short settling period. The most common cause of this phenomenon is denitrification, in which nitrites and nitrates in the wastewater are converted to nitrogen gas. As nitrogen gas is formed in the sludge layer, much of it is trapped in the sludge mass. If enough gas is formed, the sludge mass becomes buoyant and rises or floats to the surface. Rising sludge can be differentiated from bulking sludge by noting the presence of small gas bubbles attached to the floating solids and the presence of more floating sludge on the secondary clarifier surface. Rising sludge is common in short SRT systems, where the temperature encourages the initiation of nitrification, and the mixed liquor is very active due to the low sludge age.

Rising sludge problems may be overcome by (1) increasing the return activated-sludge withdrawal rate from the clarifier to reduce the detention time of the sludge in the clarifier, (2) decreasing the rate of flow of aeration liquor into the offending clarifier if the sludge depth cannot be reduced by increasing the return activated-sludge withdrawal rate, (3) where possible, increasing the speed of the sludge-collecting mechanism in the settling tanks, and (4) decreasing the SRT to bring the activated sludge out of nitrification. For warm climates where it is very difficult to operate at a low enough SRT to limit nitrification, an anoxic/aerobic process is preferred to denitrification to prevent rising sludge and to improve sludge settling characteristics.

Nocardia Foam. Two bacteria genera, *Nocardia* and *Microthrix parvicella*, are associated with extensive foaming in activated-sludge processes. These organisms have hydrophobic cell surfaces and attach to air bubbles, where they stabilize the bubbles to cause foam. The organisms can be found at high concentrations in the foam above the mixed liquor. Both types of bacteria can be identified under microscopic examination. *Nocardia* has a filamentous structure, and the filaments are very short and are contained within the floc particles. *Microthrix parvicella* has thin filaments extending from the floc particles. Foaming on an activated-sludge basin and a microscopic view of *Nocardia* are

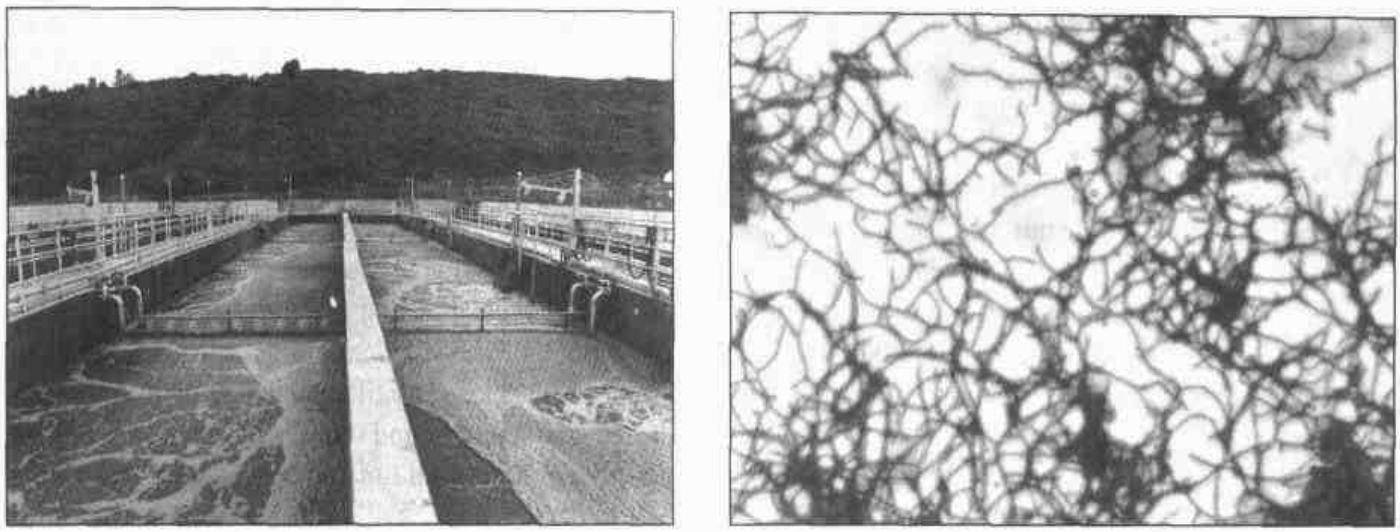

Figure 8–12

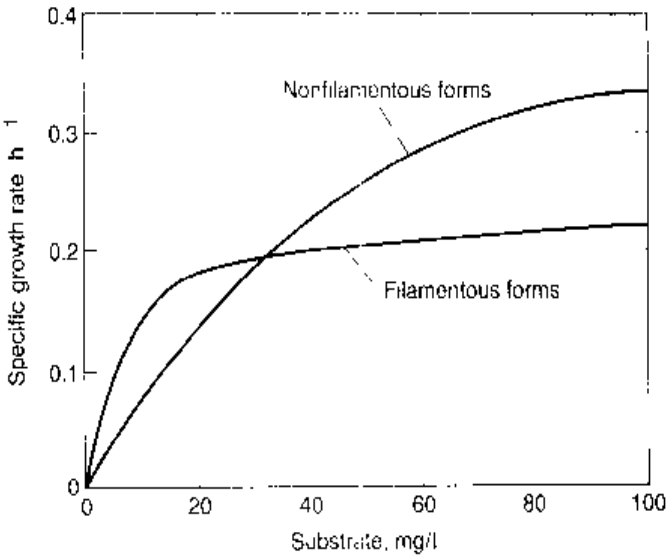
Nocardia foam: (a) example of foam on an aeration tank and (b) microscopic observation of gram-stained *Nocardia* filaments (Courtesy Dr. David Jenkins, University of California, Berkeley.)

shown on Fig. 8–12. The foam is thick, has a brown color, and can build up in thickness of 0.5 to 1 m.

The foam production can occur with both diffused and mechanical aeration but is more pronounced with diffused aeration and with higher air flowrates. Problems of *Nocardia* foaming in the activated sludge can also lead to foaming in anaerobic and aerobic digesters that receive the waste-activated sludge. *Nocardia* growth is common where surface scum is trapped in either the aeration basin or secondary clarifiers. Aeration basins that are baffled with flow from one cell to the next occurring under the baffles, instead of over the top, encourage *Nocardia* growth and foam collection.



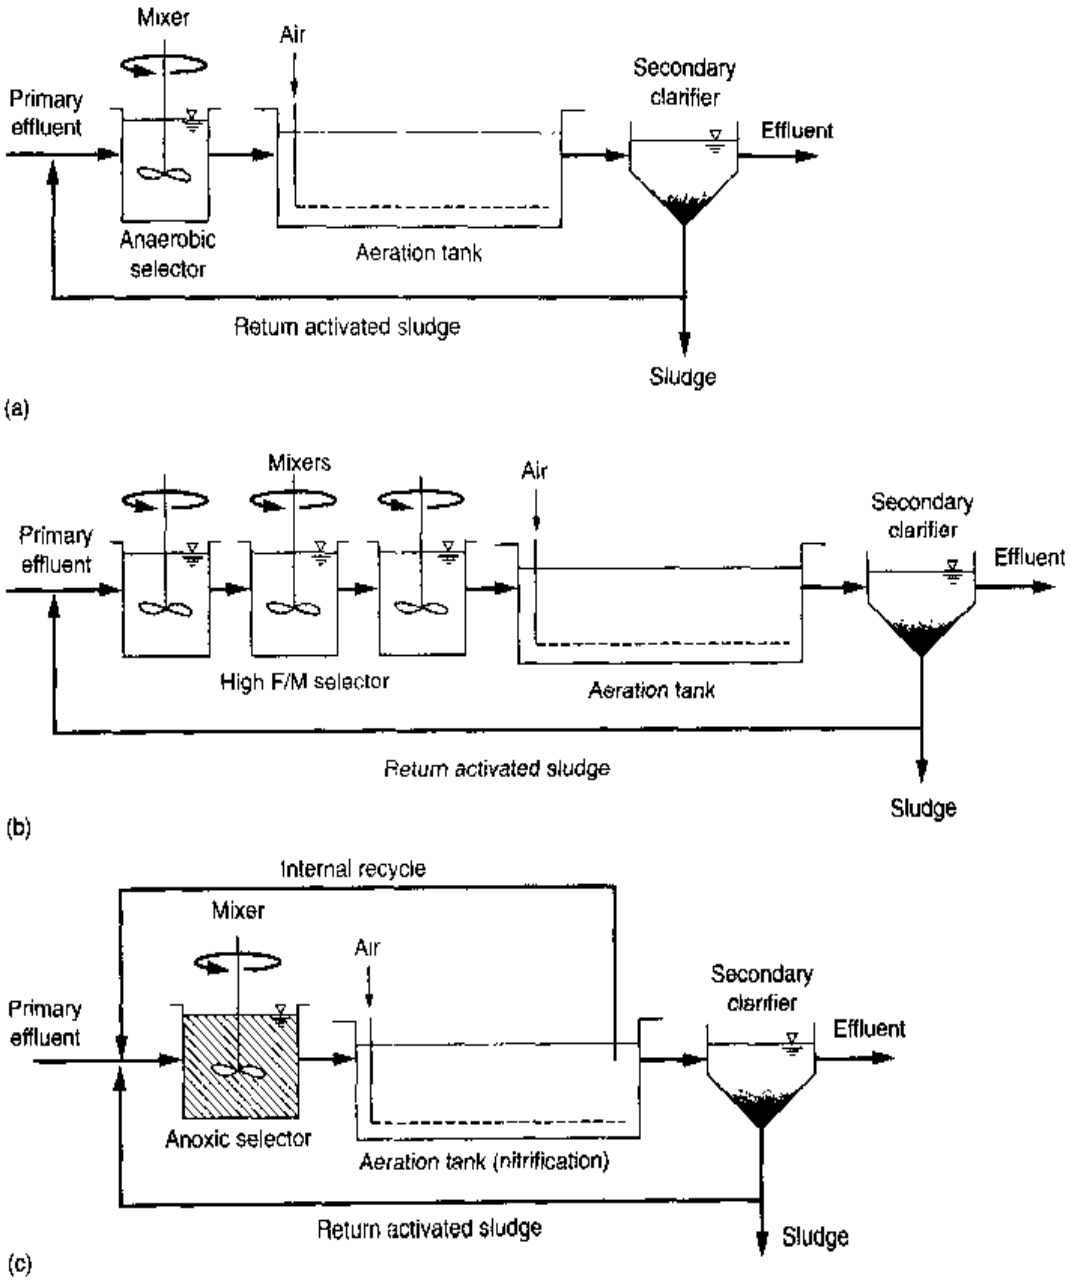
Methods that can be used to control *Nocardia* include (1) avoiding trapping foam in the secondary treatment process, (2) avoiding the recycle of skimmings into the secondary treatment process, and (3) using chlorine spray on the surface of the *Nocardia* foam. The use of a selector design may help to discourage *Nocardia* foaming, but significant foaming has been observed with anoxic/aerobic processes. The addition of a small concentration of cationic polymer has been used with some success for controlling *Nocardia* foaming (Shao et al., 1997). The presence of *Nocardia* has also been associated with the presence of *Nocardia-Microthrix* with fats and edible oils in wastewater. Reducing the oil and grease content from discharges to the collection system from restaurants, truck stops, and meatpacking facilities by effective degreasing processes can help control potential *Nocardia* problems.

Activated-Sludge Selector Processes

In the above discussion, problems caused by nuisance microorganisms in activated sludge were presented, including the effect of filamentous bacteria on sludge settling characteristics and the potential of sludge bulking when the filamentous bacteria are present in high numbers. Prior to the 1970s, filamentous bulking was considered an

Figure 8–13

Typical growth curve for filamentous and nonfilamentous organisms as a function of the substrate concentration.



inevitable consequence of activated-sludge treatment, but work by Chudoba et al. (1973) with staged versus complete-mix activated-sludge reactors led to the concept that reactor configuration designs, now termed *selectors*, could be used to control filamentous bulking and improve sludge-settling characteristics. Rensink (1974) has also introduced the relationship between the reactor configuration and bulking control.

The concept of a selector is the use of a specific bioreactor design that favors the growth of floc-forming bacteria instead of filamentous bacteria to provide an activated sludge with better settling and thickening properties. The high substrate concentration in the selector favors the growth of nonfilamentous organisms (see Fig. 8–13). A selector is a small tank (20 to 60 min contact time) or a series of tanks in which the incoming wastewater is mixed with return sludge under aerobic, anoxic, and anaerobic conditions. Various types of selectors are shown on Fig. 8–14. The selector reactor precedes the activated-sludge aeration tank and may be designed as a separate reaction stage for a complete-mix reactor (see Fig. 8- 14*a*) or as individual compartments in a plug-flow system (see Fig. 8–14*b* and *c*). Sequencing batch reactors may also be operated to employ the selector concept. The goal in the selector is to have most of the rbCOD consumed by the floc-forming bacteria. Because the particulate degradable COD decomposes at a much slower rate and will be present in the aeration tank, the rbCOD must be utilized for the benefit of the floc-forming bacteria. Selector designs are based on either kinetic or metabolic mechanisms (Albertson, 1987; Jenkins et al., 1993; and Wanner, 1994) and are described in the following paragraphs. The kinetics-based selector designs are called *high F/M selectors*, and the metabolic-based selectors are either anoxic or anaerobic processes.

Kinetics-Based Selector. Selector designs based on biokinetic mechanisms provide for reactor substrate concentrations that result in faster substrate uptake by the floc-forming bacteria. While filamentous bacteria are more efficient for substrate utilization at low substrate concentrations, the floc-forming bacteria have higher growth rates at high soluble substrate concentrations. A series of reactors at relatively low τ values (minutes) is used to provide high soluble substrate concentrations, in contrast to

Figure 8-14

Typical selector configurations: (a) anaerobic/aerobic, (b) high F/M, and (c) anoxic selector.

feeding influent wastewater to aeration tanks with τ values on the order of hours. For three reactors in series, the following COD F/M ratios, based on the influent flowrate and COD concentration, are recommended (Jenkins et al., 1993).

- First reactor, 12 g COD/g MLSS·d
- Second reactor, 6 g COD/g MLSS·d
- Third reactor, 3 g COD/g MLSS·d

The F/M ratio is calculated for the first reactor using the volume and MLSS concentration at that reactor and the influent wastewater flowrate and COD concentration. The F/M value shown for the second reactor includes the volume of the first and second reactor and the applied loading as the product of the influent flowrate and COD concentration.

Albertson (1987) recommended a similar approach based on a BOD F/M loading of 3 to 5 g BOD/g MLSS in the first reactor, with the second and third reactors being equal to and twice the first reactor volume, respectively. Albertson further notes that if the loading to the first reactor is too high (F/M > 8 g BOD/g MLSS·d), a viscous, nonfilamentous-type bulking can develop. The kinetic concept of a high F/M selector suggests that it be aerobic, and high DO concentrations are needed to maintain an aerobic floc (>6 to 8 mg/L). In many cases, such high DO concentrations are not practical or provided, and the staged selector design (described above) is operated at a low to zero DO concentration so that a metabolic selector mechanism is involved.

A sequencing batch reactor (SBR) can also act as a very effective high F/M selector, depending on the wastewater strength and feeding strategy. For high-strength wastewaters with a relatively large fraction of the SBR volume occupied by the influent wastewater, a high initial F/M ratio can occur. The subsequent reaction by the batch process is equal to that for a plug-flow reactor.

Metabolic-Based Selector. With biological nutrient-removal processes, improved sludge-settling characteristics, and, in many cases, minimal filamentous bacteria growth has been observed. The anoxic or anaerobic metabolic conditions used in these processes favor growth of the floc-forming bacteria. The filamentous bacteria cannot use nitrate or nitrite for an electron acceptor, thus yielding a significant advantage to denitrifying floc-forming bacteria. Similarly, the filamentous bacteria do not store polyphosphates and thus cannot consume acetate in the anaerobic contact zone in biological phosphorus-removal designs, giving an advantage for substrate uptake and growth to the phosphorus-storing bacteria. In some wastewater-treatment facilities (Seattle and San Francisco, for example), an anaerobic selector has been used before the aeration tank in low SRT activated-sludge systems designed for BOD removal, even though phosphorus removal is not required.

Where nitrification is used and phosphorus removal is not required, anoxic selectors (either the staged high F/M gradient or the single-stage designs) have been used. For the high F/M anoxic or anaerobic selectors, the resultant mixed-liquor SVI may be in the range of 65 to 90 mL/g, and for single-tank anoxic selectors, SVI values in the range of 100 to 120 mL/g are more commonly obtained.

The use of selector designs in activated sludge is more common because of the many advantages derived from the minimal investment in a relatively small reactor volume. By improving sludge settling, the activated-sludge treatment capacity may be increased, as higher MLSS concentrations are usually possible. The hydraulic capacity of the secondary clarifiers is also increased.

8–4 PROCESSES FOR BOD REMOVAL AND NITRIFICATION

Important considerations for the design of activated-sludge processes were presented in Sec. 8–3. The purpose of this section is to illustrate in detail the design procedure for three different activated-sludge processes. Following the design examples, detailed information is presented on the alternative processes used for BOD removal and nitrification,

typical process design parameters, and process selection considerations. Biological nitrogen and phosphorus removal can be incorporated into most of the processes used for BOD removal and nitrification, but because of additional design factors, nitrogen- and phosphorus-removal processes are covered separately in Secs. 8–5 and 8–6, respectively. Details for the selection and design of physical facilities may be found in Sec. 8–7.

Process Design Considerations

The fundamental principles of wastewater characterization, biological treatment, and process analysis were presented in Chap. 7 and in Secs. 8–2 and 8–3. For wastewater characterization, rbCOD and nbVSS are of greatest significance in process design. For BOD removal and nitrification processes, the rbCOD concentration is important for evaluating the oxygen demand profiles for plug-flow, staged, and batch-fed processes. The effect of nbVSS concentration in the influent will be significant in process sludge production and aeration volume requirements.

In the following paragraphs, three activated-sludge process design examples are provided to demonstrate application of these fundamental principles to BOD removal and nitrification processes. The examples are (1) a single-sludge complete-mix activated-sludge process without and with nitrification, (2) a sequencing batch reactor (SBR) with nitrification, and (3) a staged nitrification process. The types of computations presented are typically used for these three different types of processes. All of the elements shown for the BOD removal and nitrification process design can be applied to a BOD removal-only design by modifying the SRT and removing items that deal with nitrification. The design methodology presented is based fundamentally on using SRT and thus can be applied to the broad range of processes described at the end of this section.

For general design purposes, kinetic expressions used for design were summarized in Table 8–5. Kinetic coefficients for the removal of carbonaceous material (based on bCOD) by heterotrophic bacteria are given in Table 8–10. The μ_m and K_s values given

Table 8–10
Activated-sludge kinetic coefficients for heterotrophic bacteria at 20°C[a]

Coefficient	Unit	Range	Typical value
μ_m	g VSS/g VSS·d	3.0–13.2	6.0
K_s	g bCOD/m^3	5.0–40.0	20.0
Y	g VSS/g bCOD	0.30–0.50	0.40
k_d	g VSS/g VSS·d	0.06–0.20	0.12
f_d	Unitless	0.08–0.20	0.15
θ values			
μ_m	Unitless	1.03–1.08	1.07
k_d	Unitless	1.03–1.08	1.04
K_s	Unitless	1.00	1.00

in Table 8–10 are the default values recommended in the IAWPRC ASM 1 model (Henze et al., 1987*a*). The kinetic coefficients to be used for the design of nitrification with activated sludge are given in Table 8–11. Because reported nitrification kinetics cover a wide range, bench-scale or in-plant testing should be undertaken to evaluate site-specific nitrification kinetic values. Higher maximum specific growth rates than indicated in Table 8–11 could be found or testing could reveal lower reaction rates and a significant nitrification inhibition problem. Source control measures may be required to mitigate nitrification inhibition. Aeration tank volume requirements and SRT values are directly related to nitrification μ_m values.

Complete-Mix Activated-Sludge Process

A typical complete-mix activated-sludge (CMAS) process is shown on Fig. 8–15. Effluent from the primary sedimentation tank and recycled return activated sludge are introduced typically at several points in the reactor. Because the tank contents are thoroughly mixed, the organic load, oxygen demand, and substrate concentration are uniform throughout the entire aeration tank and the F/M ratio is low. Care should be taken to assure that the CMAS reactor is well mixed and that influent feed and effluent withdrawal points are selected to prevent short-circuiting of untreated or partially treated wastewater. The complete-mix reactor is usually configured in square, rectangular, or round shapes. Tank dimensions depend mainly on the size, type, and mixing pattern of the aeration equipment.

The computational approach used in the design of the activated-sludge process is given in Table 8–12 and makes use of the design equations presented in Chap. 7 and Secs. 8–2 and 8–3. The application of the design approach is presented in Example 8–2. The key design concepts are the selection of the design SRT, the selection of kinetic and stoichiometric coefficients, and application of appropriate mass balances.

(a)

(b)

Figure 8–15

Complete-mix activated-sludge process: (a) schematic diagram and (b) view of a typical complete-mix reactor.

Table 8–12
Computation approach for the design of the activated-sludge process for BOD removal and nitrification

1. Obtain influent wastewater characterization data
2. Determine the effluent requirements in terms of NH_4-N, TSS, and BOD concentrations
3. Select an appropriate nitrification safety factor for the design SRT based on expected peak/average TKN loadings Safety factors may vary from 1.3 to 2.0
4. Select the minimum DO concentration for the aeration basin mixed liquor. A minimum DO concentration of 2.0 mg/L is recommended for nitrification
5. Determine the nitrification maximum specific growth rate (μ_m) based on the aeration basin temperature and DO concentration, and determine K_n
6. Determine the net specific growth rate μ and SRT at this growth rate, to meet the effluent NH_4-N concentration
7. Obtain the design SRT by applying the safety factor to Step 6
8. Determine the biomass production
9. Perform a nitrogen balance to determine NO_x, the concentration of NH_4-N oxidized
10. Calculate the VSS mass and TSS mass for the aeration basin
11. Select a design MLSS concentration and determine the aeration basin volume and hydraulic residence time
12. Determine the overall sludge production and observed yield
13. Calculate the oxygen demand
14. Determine if alkalinity addition is needed
15. Design the secondary clarifier
16. Design the aeration oxygen transfer system
17. Summarize the final effluent quality
18. Prepare a design summary table

EXAMPLE 8–2 Complete-Mix Activated-Sludge Process Design for BOD Removal Only and for BOD Removal with Nitrification Design a complete-mix activated-sludge (CMAS) process to treat 22,464 m^3/d of primary effluent to (*a*) meet a BOD_e concentration less than 30 g/m^3 and (*b*) accomplish BOD removal and nitrification with an effluent NH_4-N concentration of 0.50 g/m^3 and BOD_e and $TSS_e \leq 15$ g/m^3. Compare the two design conditions in a summary table. The aeration basin mixed-liquor temperature is 12°C.

Note: Steps 2 through 8 cover condition (*a*), BOD removal only; and Steps 9 through 20 cover condition (*b*), BOD removal and nitrification. Clarifier design is discussed in Step 21.

The following wastewater characteristics and design conditions apply:

Wastewater characteristics:

Constituent	Concentration, g/m^3
BOD	140
sBOD	70
COD	300
sCOD	132
rbCOD	80
TSS	70
VSS	60
TKN	35
NH_4-N	25
TP	6
Alkalinity	140 as $CaCO_3$
bCOD/BOD ratio	1.6

Note: $g/m^3 = mg/L$.

Design conditions and assumptions:

1. Fine bubble ceramic diffusers with an aeration clean water O_2 transfer efficiency = 35%
2. Liquid depth for the aeration basin = 4.9 m
3. The point of air release for the ceramic diffusers is 0.5 m above the tank bottom
4. DO in aeration basin = 2.0 g/m^3
5. Site elevation is 500 m (pressure = 95.6 kPa)
6. Aeration α factor = 0.50 for BOD removal only and 0.65 for nitrification; $\beta = 0.95$ for both conditions, and diffuser fouling factor $F = 0.90$

7. Use kinetic coefficients given in Tables 8–10 and 8–11
8. SRT for BOD removal = 5 d
9. Design MLSS X_{TSS} concentration = 3000 g/m^3; values of 2000 to 3000 g/m^3 can be considered
10. TKN peak/average factor of safety FS = 1.5

Solution **Part A, BOD Removal without Nitrification**

1. Develop the wastewater characteristics needed for design.
   a. Find bCOD using Eq. (8–8).

   $$\text{bCOD} = 1.6(\text{BOD}) = 1.6(140\ \text{g/m}^3) = 224\ \text{g/m}^3$$

   b. Find nbCOD using Eq. (8–7).

   $$\text{nbCOD} = \text{COD} - \text{bCOD} = (300 - 224)\ \text{g/m}^3 = 76\ \text{g/m}^3$$

   c. Find effluent sCOD_e (assumed to be nonbiodegradable).

   $$\text{sCOD}_e = \text{sCOD} - 1.6\ \text{sBOD}$$
   $$= (132\ \text{g/m}^3) - (1.6)(70\ \text{g/m}^3) = 20\ \text{g/m}^3$$

   d. Find nbVSS using Eq. (8–4).

   $$\text{nbVSS} = (1 - \text{bpCOD/pCOD})\text{VSS}$$

   $$\frac{\text{bpCOD}}{\text{pCOD}} = \frac{(\text{bCOD/BOD})(\text{BOD} - \text{sBOD})}{\text{COD} - \text{sCOD}}$$

   $$\frac{\text{bpCOD}}{\text{pCOD}} = \frac{1.6(\text{BOD} - \text{sBOD})}{\text{COD} - \text{sCOD}} = \frac{1.6[(140 - 70)\ \text{g/m}^3]}{[(300 - 132)\ \text{g/m}^3]} = 0.67$$

   $$\text{nbVSS} = (1 - 0.67)(60\ \text{g VSS/m}^3) = 20\ \text{g/m}^3$$

   e. Find the iTSS.

   $$\text{iTSS} = \text{TSS} - \text{VSS}$$
   $$= (70 - 60)\ \text{g/m}^3 = 10\ \text{g/m}^3$$

2. Design suspended growth system for BOD removal only.
   a. Determine biomass production using parts A and B of Eq. (8–15).

   $$P_{X,\text{VSS}} = \frac{QY(S_o - S)}{1 + (k_d)\text{SRT}} + \frac{(f_d)(k_d)QY(S_o - S)\text{SRT}}{1 + (k_d)\text{SRT}}$$

   Define input data for above equation.

   $Q = 22{,}464\ \text{m}^3/\text{d}$

   $Y = 0.40$ g VSS/g bCOD (Table 8–10)

   $S_o = 224$ g bCOD/m^3 (see Step 1)

Determine S from Eq. (7–40) in Table 8–5. Note: $Yk = \mu_m$

$$S = \frac{K_s[1 + (k_d)\text{SRT}]}{\text{SRT}(\mu_m - k_d) - 1}$$

Use μ_m and k_d from Table 8–10.

$K_s = 20\ \text{g/m}^3$

$\mu_{m,T} = \mu_m\theta^{(T-20)}$

$\mu_{m,12^\circ\text{C}} = 6.0\ \text{g/g·d}(1.07)^{12-20} = 3.5\ \text{g/g·d}$

$k_{d,T} = k_{20}\theta^{(T-20)}$ Eq. (2–25)

$k_{d,12^\circ\text{C}} = (0.12\ \text{g/g·d})(1.04)^{12-20} = 0.088\ \text{g/g·d}$

$$S = \frac{(20\ \text{g/m}^3)[1 + (0.088\ \text{g/g·d})(5\ \text{d})]}{(5\ \text{d})[(3.5 - 0.088)\ \text{g/g·d} - 1]} = 1.8\ \text{g bCOD/m}^3$$

b. Substitute the above values in the expression given above and solve for $P_{X,\text{VSS}}$

$$P_{X,\text{VSS}} = \frac{(22{,}464\ \text{m}^3/\text{d})(0.40\ \text{g/g})[(224 - 1.8)\ \text{g/m}^3](1\ \text{kg}/10^3\ \text{g})}{[1 + (0.088\ \text{g/g·d})(5\ \text{d})]}$$

$$+ \frac{(0.15\text{g/g})(0.088\ \text{g/g·d})(0.40\ \text{g/g})(22{,}464\ \text{m}^3/\text{d})[(224 - 1.8)\ \text{g/m}^3](5\ \text{d})(1\ \text{kg}/10^3\ \text{g})}{[1 + (0.088\ \text{g/g·d})(5\ \text{d})]}$$

$$P_{X,\text{VSS}} = (1386.5 + 91.5)\ \text{kg/d} = 1478\ \text{kg VSS/d}$$

3. Determine the mass of VSS and TSS in the aeration basin. The mass of VSS and TSS can be determined using Eqs. (7–54) and (7–55) given in Table 8–5.

Mass $= P_X(\text{SRT})$

a. Determine $P_{X,\text{VSS}}$ and $P_{X,\text{TSS}}$ using Eqs. (8–15) and (8–16) including parts A, B, and D. Part C = 0 because there is no nitrification.

From Eq. (8–15), $P_{X,\text{VSS}}$ is:

$$P_{X,\text{VSS}} = 1478\ \text{kg/d} + Q(\text{nbVSS})$$

$$= 1478\ \text{kg/d} + (22{,}464\ \text{m}^3/\text{d})(20\ \text{g/m}^3)(1\ \text{kg}/10^3\ \text{g})$$

$$= (1478 + 449.3)\ \text{kg/d} = 1927.3\ \text{kg/d}$$

From Eq. (8–16), $P_{X,\text{TSS}}$ is

$$P_{X,\text{TSS}} = [(1478\ \text{kg/d})/0.85] + (449.3\ \text{kg/d}) + Q(\text{TSS}_o - \text{VSS}_o)$$

$$= 1738.8\ \text{kg/d} + 449.3\ \text{kg/d} + (22{,}464\ \text{m}^3/\text{d})(10\ \text{g/m}^3)(1\ \text{kg}/10^3\ \text{g})$$

$$= 2412.7\ \text{kg/d}$$

b. Calculate the mass of VSS and TSS in the aeration basin.

i. Mass of MLVSS using Eq. (7–54) in Table 8–5

$$(X_{VSS})(V) = (P_{X,VSS})\,SRT$$
$$= (1927.3\ kg/d)(5\ d) = 9637\ kg$$

ii. Mass of MLSS using Eq. (7–55) in Table 8–5

$$(X_{TSS})(V) = (P_{X,TSS})\,SRT$$
$$= (2412.7\ kg/d)(5.0\ d) = 12{,}064\ kg$$

4. Select a design MLSS mass concentration and determine the aeration tank volume and detention time using the TSS mass computed in Step 3.

a. Determine the aeration tank volume using the relationship from Step 3b.

$$(V)(X_{TSS}) = 25{,}405\ kg$$

At $X_{TSS} = 3000\ g/m^3$

$$V = \frac{(12{,}064\ kg)(10^3\ g/kg)}{(3000\ g/m^3)} = 4021\ m^3$$

b. Determine the aeration tank detention time.
Use 3 basins at 1340 m^3 each so that one of the basins can be taken off-line for a short period of time when maintenance of the aeration system is necessary.

$$\tau = \frac{V}{Q} = \frac{(4021\ m^3)(24\ h/d)}{(22{,}464\ m^3/d)} = 4.3\ h$$

c. Determine MLVSS.

$$\text{Fraction VSS} = \frac{9637\ kg\ VSS}{12{,}064\ kg\ TSS} = 0.80$$

$$MLVSS = 0.80(3000\ g/m^3) = 2400\ g/m^3$$

5. Determine F/M and BOD volumetric loading.

a. Determine F/M using Eq. (7–60) in Table 8–5.

$$F/M = \frac{QS_o}{XV} = \frac{kg\ BOD}{kg\ MLVSS \cdot d}$$
$$= \frac{(22{,}464\ m^3/d)(140\ g/m^3)}{(2400\ g/m^3)(4021\ m^3)} = 0.33\ g/g \cdot d = 0.33\ kg/kg \cdot d$$

b. Determine volumetric BOD loading

$$\text{BOD loading} = \frac{QS_o}{V} = \frac{kg\ BOD}{m^3 \cdot d}$$
$$= \frac{(22{,}464\ m^3/d)(140\ g/m^3)}{(4021\ m^3)(10^3\ g/kg)} = 0.78\ kg/m^3 \cdot d$$

6. Determine the observed yield based on TSS and VSS.
   a. Observed yield based on TSS

   Observed yield = g TSS/g bCOD = kg TSS/kg bCOD

   $P_{X,\text{TSS}} = 2412.7$ kg/d

   bCOD removed = $Q(S_o - S)$

   $= (22{,}464\ \text{m}^3/\text{d})[(224 - 1.8)\ \text{g/m}^3](1\ \text{kg}/10^3\ \text{g})$

   $= 4991.5$ kg/d

   $$Y_{\text{obs,TSS}} = \frac{(2412.7\ \text{kg/d})}{(4991.5\ \text{kg/d})} = \frac{0.48\ \text{kg TSS}}{\text{kg bCOD}} = \frac{0.48\ \text{g TSS}}{\text{g bCOD}}$$

   $$= \left(\frac{0.48\ \text{g TSS}}{\text{g bCOD}}\right)\left(\frac{1.6\ \text{g bCOD}}{\text{g BOD}}\right) = 0.77\ \text{g TSS/g BOD}$$

   b. Observed yield based on VSS

   $Y_{\text{obs,VSS}}$: VSS/TSS = 0.80 (see Step 4c)

   $$= \left(\frac{0.48\ \text{g TSS}}{\text{g bCOD}}\right)\left(\frac{0.80\ \text{g VSS}}{\text{g TSS}}\right)$$

   $= 0.38$ g VSS/g bCOD

   $$= \left(\frac{0.38\ \text{g VSS}}{\text{g bCOD}}\right)\left(\frac{1.6\ \text{g bCOD}}{\text{g BOD}}\right)$$

   $= 0.61$ g VSS/g BOD

7. Calculate the O_2 demand using Eq. (7–59) in Table 8–5.

   $R_o = Q(S_o - S) - 1.42\,P_{X,\text{bio}}$

   $= (22{,}464\ \text{m}^3/\text{d})[(224 - 1.8)\ \text{g/m}^3](1\ \text{kg}/10^3\ \text{g}) - 1.42(1478\ \text{kg/d})$

   $R_o = 4991.5\ \text{kg/d} - 2098.8\ \text{kg/d}$

   $= 2892.7\ \text{kg/d} = 120.5\ \text{kg/h}$

8. Fine bubble aeration design—determine air flowrate at average design flowrate using Eq. (5–55).

$$\text{AOTR} = \text{SOTR}\left(\frac{\beta C_{s,T,H} - C_L}{C_{s,20}}\right)(1.024^{T-20})(\alpha)(F)$$

where AOTR = actual oxygen transfer rate under field conditions, kg O_2/h
SOTR = standard oxygen transfer rate in tap water at 20°C and zero dissolved oxygen, kg O_2/h
Other terms as defined previously in Chap. 5.

a. Determine $C_{\bar{s},T,H}$, the average dissolved oxygen saturation concentration in clean water in aeration tank at temperature T and altitude H, using the following relationship from Eq. (5–55).

$$C_{\bar{s},T,H} = (C_{s,T,H})\frac{1}{2}\left(\frac{P_d}{P_{atm}} + \frac{O_t}{21}\right)$$

i. From Table D–1 (Appendix D), $C_{20} = 9.08$ mg/L and $C_{12} = 10.77$ mg/L

ii. Determine the relative pressure at elevation 500 m to correct the DO concentration for altitude.

From Appendix B

$$\frac{P_b}{P_a} = \exp\left[-\frac{g\,M(z_b - z_a)}{RT}\right]$$

$$= \exp\left\{-\frac{(9.81\ \text{m/s}^2)(28.97\ \text{kg/kg-mole})[(500 - 0)\ \text{m}]}{(8314\ \text{kg·m}^2/\text{s}^2\text{·kg-mole·K})[(273.15 + 12)\ \text{K}]}\right\} = 0.94$$

The oxygen concentration at 500 m and 12°C is

$$C_{s,T,H} = 10.77\ \text{mg/L} \times 0.94 = 10.12\ \text{mg/L}$$

iii. Determine atmospheric pressure in m of water at an elevation of 500 m and a temperature of 12°C (see Appendix B and C).

$$P_{atm,H} = \frac{(P_{atm,H}\ \text{kN/m}^3)}{(\gamma\ \text{kN/m}^3)} = \frac{(0.94)(101.325\ \text{kN/m}^2)}{(9.802\ \text{kN/m}^3)} = 9.72\ \text{m}$$

iv. Determine the oxygen concentration assuming the percent oxygen concentration leaving the aeration tank is 19%.

$$C_{\bar{s},1,H} = (C_{s,1,H})\left(\frac{1}{2}\right)\left(\frac{P_{atm,H} + P_{w,\text{Eff depth}}}{P_{atm,H}} + \frac{O_t}{21}\right)$$

$$= 10.12\ \text{mg/L}\left(\frac{1}{2}\right)\left[\frac{9.72\ \text{m} + (4.9 - 0.5)\ \text{m}}{9.72\ \text{m}} + \frac{19}{21}\right]$$

$$= 11.93\ \text{mg/L}$$

b. Determine the SOTR using $\alpha = 0.50$, $\beta = 0.95$, and diffuser fouling factor $F = 0.9$.

$$\text{SOTR} = \text{AOTR}\left[\frac{C_{s,20}}{\alpha F(\beta C_{s,T,H} - C)}\right](1.024^{20-T})$$

$$= \frac{(120.5\ \text{kg/h})(9.08\ \text{g/m}^3)(1.024)^{20-12}}{(0.50)(0.9)[(0.95)(11.93\ \text{g/m}^3) - 2.0\ \text{g/m}^3]} = 315\ \text{kg/h}$$

c. Determine the air flowrate.

$$\text{Air flowrate, kg/min} = \frac{(\text{SOTR kg/h})}{[(E)(60\ \text{min/h})(\text{kg O}_2/\text{m}^3\ \text{air})]}$$

Using the data given in Appendix B, the density of air at 12°C and a pressure of 95.2 kPa (0.94 × 101.325 kPa) is 1.1633 kg/m^3. The corresponding amount of oxygen by weight is 0.270 (0.2318 × 1.1633 kg/m^3). Thus, the required air flowrate is

$$\text{Air flowrate, m}^3\text{/min} = \frac{(315 \text{ kg/h})}{[(0.35)(60 \text{ min/h})(0.270 \text{ kg O}_2\text{/m}^3 \text{ air})]}$$

$$= 55.5 \text{ m}^3\text{/min}$$

Note: To continue the facilities design for secondary clarifiers for the BOD removal process, move to Step 21. For nitrification design, continue to Step 9.

Part B, BOD Removal and Nitrification

9. Perform the nitrification design following the same steps as for BOD removal except the design SRT must first be determined. Determine the specific growth rate μ_n for the nitrifying organisms using Eq. (7–93). The nitrification rate will control the design because the nitrifying organisms grow more slowly than the heterotrophic organisms that remove organic carbon.

$$\mu_n = \left(\frac{\mu_{n,m} N}{K_n + N}\right)\left(\frac{\text{DO}}{K_o + \text{DO}}\right) - k_{dn}$$

a. Find $\mu_{n,m}$ at $T = 12°\text{C}$.

$$\mu_{n,\,m,\,12°\text{C}} = (0.75 \text{ g/g·d})(1.07)^{12-20} = 0.44 \text{ g/g·d}$$

b. Find K_n, at $T = 12°\text{C}$.

$$K_{n,12°\text{C}} = (0.74 \text{ g/m}^3)(1.053)^{12-20} = 0.49 \text{ g/m}^3$$

c. Find k_{dn}, at $T = 12°\text{C}$.

$$k_{dn,\,12°\text{C}} = (0.08 \text{ g/g·d})(1.04)^{12-20} = 0.06 \text{ g/g·d}$$

d. Substitute the above and given values in Eq. (7–93) and solve for μ_n.

$$N = 0.50 \text{ g/m}^3, \text{DO} = 2.0 \text{ g/m}^3, K_o = 0.50 \text{ g/m}^3$$

$$\mu_n = \left\{\frac{(0.44 \text{ g/g·d})(0.50 \text{ g/m}^3)}{[(0.49 + 0.50) \text{ g/m}^3]}\right\}\left\{\frac{(2.0 \text{ g/m}^3)}{[(0.50 + 2.0) \text{ g/m}^3]}\right\} - (0.06 \text{ g/g·d})$$

$$= 0.12 \text{ g/g·d}$$

10. Determine the theoretical and design SRT.

a. Find theoretical SRT using Eq. (7–37) in Table 8–5.

$$\text{SRT} = \frac{1}{\mu_n} = \frac{1}{(0.12 \text{ g/g·d})} = 8.33 \text{ d}$$

b. Determine the design SRT using Eq. (7–71).

$$\text{FS} = \text{TKN peak/TKN average} = 1.5$$

$$\text{Design SRT} = (\text{FS})(\text{theoretical SRT})$$
$$= 1.5(8.33\text{ d}) = 12.5\text{ d}$$

11. Determine biomass production using Eq. (8–15), parts A, B, and C.

$$P_{X,\text{bio}} = \frac{QY(S_o - S)}{1 + (k_d)\text{SRT}} + \frac{(f_d)(k_d)Q(Y)(S_o - S)\text{SRT}}{1 + (k_d)\text{SRT}} + \frac{QY_n(\text{NO}_x)}{1 + (k_{dn})\text{SRT}}$$

a. Define input data for the above equation.

$Q = 22{,}464\text{ m}^3/\text{d}$

$Y = 0.40\text{ VSS/g bCOD}$

$S_o = 224\text{ g bCOD/m}^3$ (Step 1)

$k_d = 0.088\text{ g/g·d}$ (Step 2a)

$\mu_m = 3.5\text{ g/g·d}$ (Step 2a)

Determine S from Eq. (7–40) in Table 8–5.

$$S = \frac{K_s[1 + (k_d)\text{SRT}]}{\text{SRT}(\mu_m - k_d) - 1}$$

$$S = \frac{(20\text{ g/m}^3)[1 + (0.088\text{ g/g·d})(12.5\text{ d})]}{(12.5\text{ d})[(3.5 - 0.088)\text{ g/g·d}] - 1} = 1.0\text{ g bCOD/m}^3$$

$Y_n = 0.12\text{ g VSS/g NO}_x$ (Table 8–11)

$k_{dn,\,12°\text{C}} = 0.06\text{ g/g·d}$ (Step 9e)

Assume $\text{NO}_x \approx 80\%$ (TKN) as nitrogen balance cannot be done yet. The error in assuming that the $\text{NO}_x \approx 80\%$ (TKN) is small as the nitrifier VSS yield is a small fraction of total MLVSS concentration.

$\text{NO}_x \approx 0.80(35\text{ g/m}^3) = 28\text{ g/m}^3$

b. Substitute the above values in the expression given above and solve for $P_{X,\text{bio}}$.

$$P_{X,\text{bio}} = \frac{(22{,}464\text{ m}^3/\text{d})(0.40\text{ g/g})[(224 - 1.0)\text{g/m}^3](1\text{ kg}/10^3\text{ g})}{[1 + (0.088\text{ g/g·d})(12.5\text{ d})]}$$
$$+ \frac{(0.15\text{ g/g})(0.088\text{ g/g·d})(0.40\text{ g/g})(22{,}464\text{ m}^3/\text{d})[(224 - 1.0)\text{ g/m}^3](12.5\text{ d})(1\text{ kg}/10^3\text{ g})}{[1 + (0.088\text{ g/g·d})(12.5\text{ d})]}$$
$$+ \frac{(22{,}464\text{ m}^3/\text{d})(0.12\text{ g/g})(28\text{ g/m}^3)(1\text{ kg}/10^3\text{ g})}{[1 + (0.06\text{ g/g·d})(12.5\text{ d})]}$$

$$P_{X,\text{bio}} = 954.2\text{ kg/d} + 157.4\text{ kg/d} + 43.1\text{ kg/d}$$
$$= 1154.7\text{ kg VSS/d}$$

12. Determine the amount of nitrogen oxidized to nitrate. The amount of nitrogen oxidized to nitrate can be found by performing a nitrogen balance using Eq. (8–18).

$$NO_x = TKN - N_e - 0.12\,P_{X,bio}/Q$$
$$= 35.0\ g/m^3 - 0.50\ g/m^3$$
$$- (0.12\ g\ N/g\ VSS)(1154.7\ kg\ VSS/d)(10^3\ g/kg)/(22{,}464\ m^3/d)$$
$$= (35.0 - 0.50 - 6.2)\ g/m^3 = 28.3\ g/m^3$$

13. Determine the concentration and mass of VSS and TSS in the aeration basin.

Mass = P_X(SRT)

a. Calculate the concentration of VSS and TSS in the aeration basin
   i. $P_{X,VSS}$, use Eq. (8–15). Parts A, B, and C have already been calculated above as $P_{X,bio}$. Part D must be added to determine $P_{X,VSS}$.

$$P_{X,VSS} = 1154.7\ kg/d + Q(nbVSS)$$
$$= 1154.7\ kg/d + (22{,}464\ m^3/d)(20\ g/m^3)(1\ kg/10^3\ g)$$
$$= (1154.7 + 449.3)\ kg/d = 1604.0\ kg/d$$

   ii. $P_{X,TSS}$, use Eq. (8–16), with the term E added to account for inert influent TSS.

$$P_{X,TSS} = [(1154\ kg/d)/0.85] + (449.3\ kg/d) + Q(TSS_o - VSS_o)$$
$$= 1358.5\ kg/d + 449.3\ kg/d + (22{,}464\ m^3/d)(10\ g/m^3)(1\ kg/10^3\ g)$$
$$= 2032.4\ kg/d$$

b. Calculate the mass of VSS and TSS in the aeration basin using Eqs. (7–54) and (7–55) in Table 8–5.
   i. Mass of MLVSS

$$(X_{VSS})(V) = (P_{X,VSS})SRT$$
$$= (1604.0\ kg/d)(12.5\ d) = 20{,}050\ kg$$

   ii. Mass of MLSS

$$(X_{TSS})(V) = (P_{X,TSS})SRT$$
$$= (2032.4\ kg/d)(12.5\ d) = 25{,}405\ kg$$

14. Select a design MLSS mass concentration and determine the aeration tank volume and detention time using the TSS mass computed in Step 6.
   a. Determine the aeration tank volume using the relationship from Step 6b.

$$(V)(X_{TSS}) = 25{,}405\ kg$$

At MLSS = $3000\ g/m^3$

$$V = \frac{(24{,}405\ kg)(10^3\ g/kg)}{(3000\ g/m^3)}$$

$$V = 8468\ m^3$$

b. Determine the aeration tank detention time.
Use 3 basins at 2822 m^3 each so that 1/3 of the volume can be taken off-line when maintenance of the aeration system is necessary.

$$\tau = \frac{V}{Q} = \frac{(8466\ m^3)(24\ h/d)}{(22{,}464\ m^3/d)} = 9.0\ h$$

c. Determine MLVSS.

$$\text{Fraction VSS} = \frac{20{,}050\ kg\ VSS}{25{,}405\ kg\ TSS} = 0.79$$

$$MLVSS = 0.79(3000\ g/m^3) = 2370\ g/m^3$$

15. Determine F/M and BOD volumetric loading.
a. Determine F/M using Eq. (7–60).

$$F/M = \frac{QS_o}{XV} = \frac{g\ BOD}{g\ MLVSS{\cdot}d}$$

$$= \frac{(22{,}464\ m^3/d)(140\ g/m^3)}{(2370\ g/m^3)(8466\ m^3)} = 0.16\ g/g{\cdot}d$$

b. Determine volumetric BOD loading using Eq. (7–61).

$$L_{org} = \frac{QS_o}{V} = \frac{kg\ BOD}{m^3{\cdot}d}$$

$$= \frac{(22{,}464\ m^3/d)(140\ g/m^3)}{(10^3\ g/kg)(8466\ m^3)} = 0.37\ kg/m^3{\cdot}d$$

Note: Both the F/M and L_{org} loading are in the low- to mid-range of the design parameters given later in this chapter in Table 8–16.

16. Determine the observed yield based on TSS and VSS.

Observed yield = g TSS/g bCOD = kg TSS/kg bCOD

$P_{X,TSS} = 2032.4\ kg/d$

bCOD removed $= Q(S_o - S)$

$= (22{,}464\ m^3/d)[(224 - 1.0)\ g/m^3)](1\ kg/10^3\ g)$

$= 5009.5\ kg/d$

a. Observed yield based on TSS

$$Y_{obs,TSS} = \frac{(2032.4\ kg/d)}{(5009.5\ kg/d)} = \frac{0.41\ kg\ TSS}{kg\ bCOD} = \frac{0.41\ g\ TSS}{g\ bCOD}$$

$$= \left(\frac{0.41\ g\ TSS}{g\ bCOD}\right)\left(\frac{1.6\ g\ bCOD}{g\ BOD}\right) = 0.65\ g\ TSS/g\ BOD$$

b. Observed yield based on VSS

$Y_{obs,VSS}$: VSS/TSS = 0.80 (see Step 4c)

$$= \left(\frac{0.41 \text{ g TSS}}{\text{g bCOD}}\right)\left(\frac{0.80 \text{ g VSS}}{\text{g TSS}}\right)$$

$$= 0.328 \text{ g VSS/g bCOD}$$

$$= \left(\frac{0.328 \text{ g VSS}}{\text{g bCOD}}\right)\left(\frac{1.6 \text{ g bCOD}}{\text{g BOD}}\right)$$

$$= 0.52 \text{ g VSS/g BOD}$$

17. Calculate the O_2 demand using Eq. (8–17).

$$R_o = Q(S_o - S) - 1.42\,P_{X,bio} + 4.33\,Q(NO_x)$$

$$= (22{,}464 \text{ m}^3/\text{d})[(224 - 1.0) \text{ g/m}^3](1 \text{ kg}/10^3 \text{ g}) - 1.42(1154.7 \text{ kg/d})$$
$$+ (4.33 \text{ g O}_2/\text{g N})(22{,}464 \text{ m}^3/\text{d})(28.3 \text{ g/m}^3)(1 \text{ kg}/10^3 \text{ g})$$

R_o = 5009.5 kg/d − 1639.7 kg/d + 2752.7 kg/d

= 6122.5 kg/d = 255.1 kg/h

18. Fine bubble aeration design—determine air flowrate at average design flowrate (see procedure for Step 8).

a. Determine the SOTR using the values given in the problem statement: $\alpha = 0.65$, $\beta = 0.95$, and $F = 0.9$.

$$\text{SOTR} = \text{AOTR}\left[\frac{C_{s,20}}{\alpha F(\beta C_{s,f,H} - C)}\right](1.024^{20-T})$$

$$= \frac{(255.1 \text{ kg/h})(9.08 \text{ g/m}^3)(1.024)^{20-12}}{(0.65)(0.9)[(0.95)(11.93 \text{ g/m}^3) - 2.0 \text{ g/m}^3]} = 512.9 \text{ kg/h}$$

b. Determine the air flowrate.

$$\text{Air flowrate, m}^3/\text{min} = \frac{(512.9 \text{ kg/h})}{[(0.35)(60 \text{ min/h})(0.270 \text{ kg O}_2/\text{m}^3 \text{ air})]}$$

$$= 90.5 \text{ m}^3/\text{min}$$

19. Check alkalinity.

a. Prepare an alkalinity balance

Alkalinity to maintain pH ~ 7 = Influent Alk − Alk used + Alk to be added

Influent alkalinity: 140 g/m^3 as $CaCO_3$

Amount of nitrogen converted to nitrate: NO_x = 28.3 g/m^3 (see Step 5)

Alkalinity used for nitrification = (7.14 g $CaCO_3$/g NH_4-N)(28.3 g/m^3)

= 202.6 g/m^3 used as $CaCO_3$

b. Substitute known values and solve for alkalinity needed.
Residual alkalinity concentration needed to maintain pH in the range of 6.8–7.0 = 70 to 80 g/m^3 as $CaCO_3$; select 80 g/m^3

80 g/m^3 = Influent alk − alk used + alk to be added

80 g/m^3 = 140 g/m^3 − 202.6 g/m^3 + alk to be added

Alkalinity needed = 142.6 g/m^3 as $CaCO_3$

$$= (22{,}464\ m^3/d)(142.6\ g/m^3)(1\ kg/10^3 g)$$

$$= 3203\ kg/d\ as\ CaCO_3$$

c. Determine the alkalinity needed as sodium bicarbonate.
Sodium bicarbonate may be preferred over lime for alkalinity addition due to ease of handling and fewer scaling problems as compared to lime. The amount of $Na(HCO_3)$ needed is as follows:

Equivalent weight of $CaCO_3$ = 50 g/equivalent

Equivalent weight of $Na(HCO_3)$ = 84 g/equivalent

$$Na(HCO_3)\ needed = \frac{(3203\ kg/d\ CaCO_3)(84\ g\ NaHCO_3/eq)}{(50\ g\ CaCO_3/equivalent)}$$

$$= 5380\ kg/d\ NaHCO_3$$

20. Estimate effluent BOD using Eq. (8–25).

$$BOD = sBODe + \left(\frac{g\ BOD}{1.42\ g\ VSS}\right)\left(\frac{0.85\ g\ VSS}{g\ TSS}\right)(TSS, g/m^3)$$

Assume sBODe = 3.0 g/m^3

TSS = 10 g/m^3

$$BOD = 3.0\ g/m^3 + (0.70)(0.85)(10\ g/m^3)$$

$$= 8.95\ g/m^3$$

21. Secondary clarifier design (for both BOD removal and BOD removal and nitrification).

a. Define return sludge recycle ratio (see Fig. 8–9):

$Q_r X_r = (Q + Q_r)X$ (assume waste sludge mass is insignificant)

Q_r = RAS flowrate, m^3/d

X_r = return sludge mass concentration, g/m^3

RAS recycle ratio = $Q_r/Q = R$

$R X_r = (1 + R)X$

$$R = \frac{X}{X_r - X}$$

b. Determine size of clarifier.
Assume X_r = 8000 g/m^3 (moderate settling/thickening sludge; per Sec. 8–3 range is 4000 to 12,000 mg/L).

$$R = \frac{(3000\ \text{g/m}^3)}{[(8000 - 3000)\ \text{g/m}^3]} = 0.60$$

Assume a hydraulic application rate of 22 m^3/m^2·d at average flow for the secondary clarifier (see Table 8–7); the range is 16 to 28 m^3/m^2·d

$$\text{Area} = \frac{(22{,}464\ \text{m}^3/\text{d})}{(22\ \text{m}^3/\text{m}^2\cdot\text{d})} = 1021\ \text{m}^3$$

Use 3 clarifiers (1 for each aeration tank)

Area/clarifier = 312 m^2

Clarifier diameter = 20.8 m; use 20 m

c. Check solids loading.

$$\text{Solids loading} = \frac{\text{kg TSS applied}}{\text{m}^2\ \text{clarifier area}\cdot\text{h}}$$

$$\text{Solids loading} = \frac{(Q + Q_r)(\text{MLSS})}{A} = \frac{(1 + R)Q(\text{MLSS})}{A}$$

where A = area of clarifier, m^2 = $(\pi/4)(20\ \text{m})^2 \times 3 = 942\ \text{m}^2$

$$\text{Solids loading} = \frac{(1 + 0.6)(22{,}464\ \text{m}^3/\text{d})(3000\ \text{g/m}^3)(1\ \text{kg}/10^3\text{g})}{(942\ \text{m}^2)(24\ \text{h/d})}$$

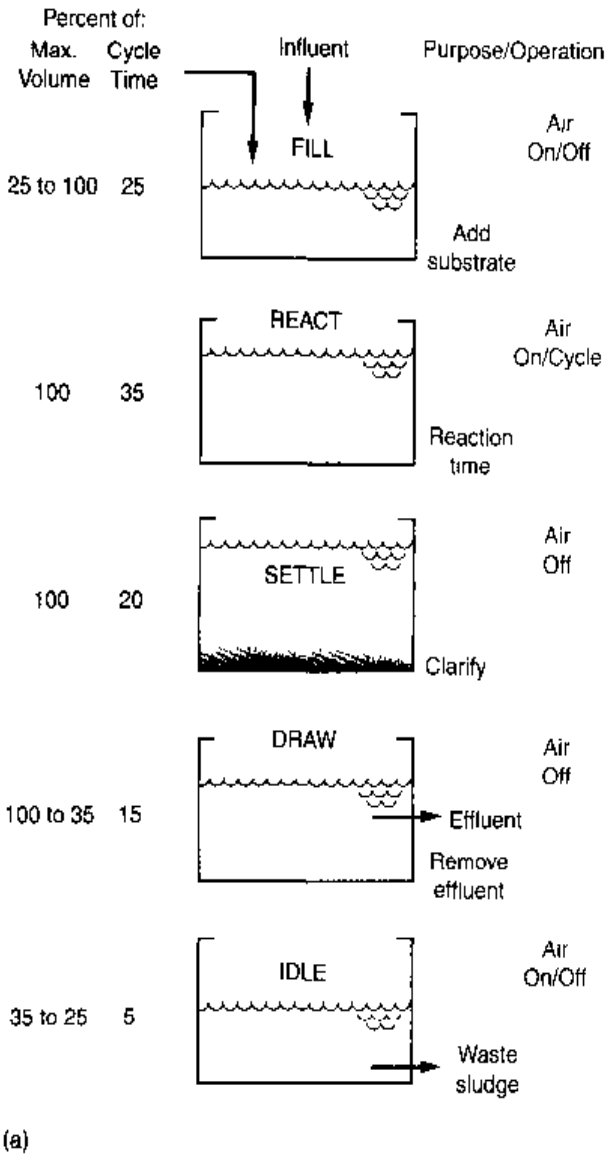
$$= 4.8\ \text{kg MLSS/m}^2\cdot\text{h}$$

(within acceptable range of solids loading of 4 to 6 kg/m^2·d given in Table 8–7)

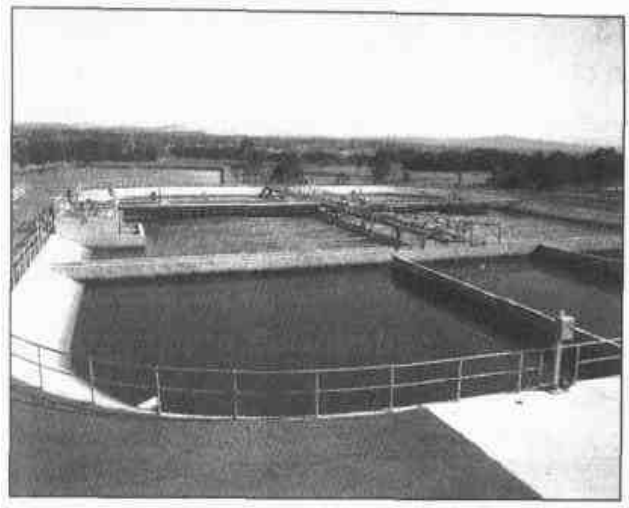
22. Prepare design summary.

Design parameter	Unit	BOD removal only (Part A)	BOD removal and nitrification (Part B)
Average wastewater flow	m^3/d	22,464	22,464
Average BOD load	kg/d	3145	3145
Average TKN load	kg/d	786	786
Aerobic SRT	d	5.0	12.5
Aeration tanks	Number	3	3
Aeration tank volume, ea	m^3	1340	2822
Hydraulic detention time, τ	h	4.3	9.0

(continued)



(*Continued*)



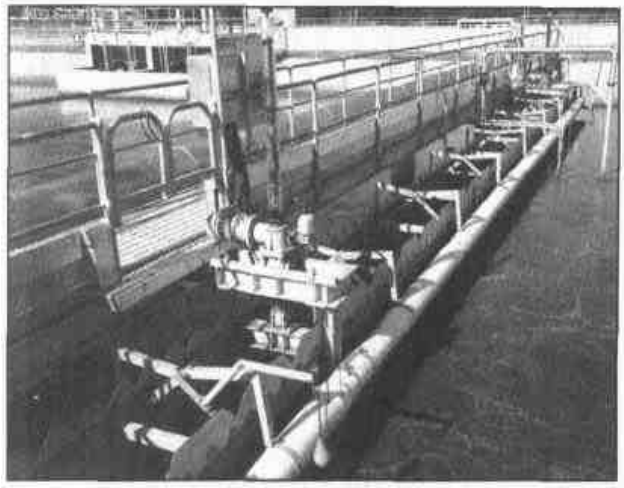
Design parameter	Unit	BOD removal only (Part A)	BOD removal and nitrification (Part B)
MLSS	g/m^3	3000	3000
MLVSS	g/m^3	2400	2370
F/M	g/g·d	0.33	0.16
BOD loading	kg BOD/m^3·d	0.78	0.37
Sludge production	kg/d	2413	2032
Observed yield	kg TSS/kg bCOD	0.77	0.65
	kg VSS/kg BOD	0.61	0.52
Oxygen required	kg/h	120.5	255.1
Air flowrate at average wastewater flow	sm^3/min	55.5	90.5
RAS ratio	Unitless	0.60	0.60
Clarifier hydraulic application rate	m^3/m^2-d	24	24
Clarifiers	Number	3	3
	Diameter, m	20	20
Alkalinity addition as $Na(HCO_3)$	kg/d	—	5380
Effluent BOD	g/m^3	<30	8.95
TSSe	g/m^3	<30	10
Effluent NH_4-N	g/m^3	28.8	≤0.5

Comment Examination of the biomass production components for the nitrification design shows that the cell debris and nitrifying bacteria amounts represent a small portion of the total biomass (13.6 and 3.7 percent, respectively). In Step 13, the contribution from nbVSS is significant, 22 percent of the TSS produced. In this example, the design procedure is described for an average wastewater flowrate. In actual design, computations must also be made for peak flow and load conditions.

Sequencing Batch Reactor Process

The sequencing batch reactor (SBR) process utilizes a fill-and-draw reactor with complete mixing during the batch reaction step (after filling) and where the subsequent steps of aeration and clarification occur in the same tank. All SBR systems have five steps in common, which are carried out in sequence as follows: (1) fill, (2) react (aeration), (3) settle (sedimentation/clarification), (4) draw (decant), and (5) idle. Each of these steps is illustrated on Fig. 8–16 and described in Table 8–13. For continuous-flow applications, at least two SBR tanks must be provided so that one tank receives flow

(b)



(c)

Figure 8-16

Sequencing batch reactor (SBR) activated-sludge process: (a) schematic diagram and (b) view of a typical SBR reactor and (c) view of movable weir used to decant contents of SBR reactor. Weir is located on the far side of the second dividing wall shown in (b). Photographs were taken in Australia.

while the other completes its treatment cycle. Several process modifications have been made in the times associated with each step to achieve nitrogen and phosphorus removal.

Sludge Wasting in SBRs. Sludge wasting is another important step in the SBR operation that greatly affects performance. Wasting is not included as one of the five basic process steps because there is no set time period within the cycle dedicated to wasting. The amount and frequency of sludge wasting is determined by performance requirements, as with a conventional continuous-flow system. In an SBR operation, sludge wasting usually occurs during the react phase so that a uniform discharge of solids (including fine material and large floc particles) occurs. A unique feature of the SBR system is that there is no need for a return activated-sludge (RAS) system.

Table 8-13 Description of operational steps for the sequencing batch reactor (SBR)

Operational step	Description
Fill	During the fill operation, volume and substrate (raw wastewater or primary effluent) are added to the reactor. The fill process typically allows the liquid level in the reactor to rise from 75% of capacity (at the end of the idle period) to 100%. When two tanks are used, the fill process may last about 50% of the full cycle time. During fill, the reactor may be mixed only or mixed and aerated to promote biological reactions with the influent wastewater
React	During the react period, the biomass consumes the substrate under controlled environmental conditions
Settle	Solids are allowed to separate from the liquid under quiescent conditions, resulting in a clarified supernatant that can be discharged as effluent
Decant	Clarified effluent is removed during the decant period. Many types of decanting mechanisms can be used, with the most popular being floating or adjustable weirs
Idle	An idle period is used in a multitank system to provide time for one reactor to complete its fill phase before switching to another unit. Because idle is not a necessary phase, it is sometimes omitted

Because both aeration and settling occur in the same chamber, no sludge is lost in the react step and none has to be returned to maintain the solids content in the aeration chamber. The SBR process can also be modified to operate in a continuous-flow mode, as discussed later in this chapter.

Application of Process Kinetics. During the react period, batch kinetics apply. The substrate concentration is much higher initially than would be present in a CMAS system, and the substrate decreases gradually as it is consumed by the biomass. The change in substrate concentration with time can be determined by starting with the substrate mass balance in Chap. 7 [Eq. (7-41)] for a continuous-flow complete-mix reactor:

$$\frac{dS}{dt}V = QS_o - QS + r_{su}V \tag{7-41}$$

where $r_{su} = -\dfrac{\mu_m XS}{Y(K_s + S)}$ (7-15)

Other terms as defined previously.

Because $Q = 0$ for the batch reaction, the substrate concentration is

$$\frac{dS}{dt} = -\frac{\mu_m XS}{Y(K_s + S)} \tag{8-37}$$

Integration of Eq. (8–37) with respect to time yields

$$K_s \ln \frac{S_o}{S_t} + (S_o - S_t) = X\left(\frac{\mu_m}{Y}\right)t \tag{8-38}$$

where S_o = initial substrate concentration at $t = 0$, mg/L
t = time, d
S_t = substrate concentration at time t, mg/L

The same kinetic expression applies for nitrification where $X = X_n$, the nitrifying bacteria concentration, $S = N$, the NH_4-N concentration, and the Monod model kinetic coefficients are substituted:

$$K_n \ln \frac{N_o}{N_t} + (N_o - N_t) = X_n\left(\frac{\mu_{mn}}{Y_n}\right)t \tag{8–39}$$

where N_o = NH_4-N concentration at $t = 0$, mg/L
N_t = NH_4-N concentration at time t, mg/L
X_n = nitrifying bacteria concentration, mg/L

The maximum specific growth rate for nitrifying bacteria is affected by the DO concentration [Eq. (7–93)], so this effect is included in Eq. (8–40) as follows:

$$K_n \ln \frac{N_o}{N_t} + (N_o - N_t) = X_n\left(\frac{\mu_{mn}}{Y_n}\right)\left(\frac{\text{DO}}{K_o + \text{DO}}\right)t \tag{8–40}$$

The above batch kinetic equations can be used to determine if the react period aeration time selected for SBR design is sufficient to provide the desired amount of degradation. An overall mass balance can be done first, assuming a certain amount of substrate is removed, to determine the biomass concentrations (X and X_n) for use in the equations. The time needed for dissolved BOD removal is relatively short (less than 1 h) due to the batch kinetics for treating domestic wastewater, resulting in a relatively low initial dissolved BOD concentration. For nitrification, SBR aerobic react times may range from 1.0 to 3.0 h (WEF, 1998). It should be noted that the SRTs for the SBR and continuous-flow activated-sludge processes are not comparable. At the same SRT, the SBR may be expected to be more efficient because of its batch kinetics, but the biomass may not be under aeration for a significant period of time so that the effective SRT is lower.

Because of the substrate concentration changes with time, the substrate utilization and oxygen demand rates change, progressing from high to low levels. The aeration system should be designed to reflect the changing requirements in oxygen demand. Additional descriptive material for the SBR process is provided in a later part of this section.

Process Design of SBRs. The following SBR design example requires selecting key design conditions and evaluating the results to determine if the design is appropriate. Because of the many design variables involved in an SBR design, an iterative approach is necessary in which key reactor design conditions are first assumed. A set of different design conditions can be evaluated by use of a spreadsheet analysis to determine the most optimal choice. The key design conditions selected are (1) the fraction of the tank contents removed during decanting and (2) the settle, decant, and aeration times. Because the fill volume equals the decant volume, the fraction of decant volume equals the fraction of the SBR tank volume used for the fill volume per cycle.

The design procedure for the SBR system is presented in Table 8–14 and illustrated in Example 8–3.

Table 8-14 Computation approach for the design of a sequencing batch reactor

1. Obtain influent wastewater characterization data, define effluent requirements, and define safety factors
2. Select the number of SBR tanks
3. Select the react/aeration, settling, and decant times. Determine the fill time and total time per cycle. Determine the number of cycles per day
4. From the total number of cycles per day, determine the fill volume per cycle
5. Select the MLSS concentration and determine the fill volume fraction relative to the total tank volume. Determine the decant depth. Using the computed depths, determine the SBR tank volume
6. Determine the SRT for the SBR process design developed
7. Determine the amount of TKN added that is nitrified
8. Calculate the nitrifier biomass concentration and determine if the aeration time selected is sufficient for the nitrification efficiency needed
9. Adjust the design as needed--additional iterations may be done
10. Determine the decant pumping rate
11. Determine the oxygen required and average transfer rate
12. Determine the amount of sludge production
13. Calculate the F/M and BOD volumetric loading
14. Evaluate alkalinity needs
15. Prepare design summary

EXAMPLE 8-3 Sequencing Batch Reactor Process Design Design a sequencing batch reactor process to treat a domestic wastewater with a flow of 7570 m^3/d with the following wastewater characteristics. The reactor mixed-liquor concentration at full volume is 3500 g/m^3 and the temperature is 12°C. The required effluent NH_4-N concentration = 0.50 g/m^3. Primary treatment is not used.

Wastewater characteristics:

Constituent	Concentration, g/m^3
BOD	220
sBOD	80
COD	485
sCOD	160
rbCOD	80
TSS	240

(continued)

(Continued)

Constituent	Concentration, g/m^3
VSS	220
TKN	35
NH_4-N	25
TP	6
Alkalinity	200 as $CaCO_3$
bCOD/BOD ratio	1.6

Note: g/m^3 = mg/L.

Design conditions and assumptions:

1. Use 2 tanks
2. Total liquid depth when full = 6 m
3. Decant depth = 30 percent of tank depth
4. SVI = 150 mL/g
5. $NO_x \approx 80$ percent of TKN
6. Use kinetic coefficients in Tables 8–10 and 8–11

Solution

1. Develop wastewater characteristics needed for process design.
   a. Determine bCOD using Eq. (8–8).

$$bCOD = 1.6(220\ g/m^3) = 352\ g/m^3$$

   b. Determine nbVSS concentration using Eq. (8–4).

$$\frac{bpCOD}{pCOD} = \frac{1.6[(220 - 80)\ g/m^3]}{[(485 - 160)\ g/m^3]} = 0.69$$

$$nbVSS = (1 - 0.69)(220\ g/m^3) = 68\ g/m^3$$

   c. Determine iTSS.

$$iTSS = TSS_0 - VSS_0$$
$$= (240 - 220)\ g/m^3 = 20\ g/m^3$$

2. Determine SBR operating cycle
   The total cycle time (T_c) consists of fill (t_F), react/aerate (t_A), settle (t_S), and decant (t_D). An idle time (t_I) can also be added. Thus, the total cycle time $T_c = t_F + t_A + t_S + t_D + t_I$. At least 2 tanks are needed so that when one tank is in the fill period t_F, the following cycles are occuring in the other tank: aeration t_A, settling t_S, and decant t_D cycles. Thus,

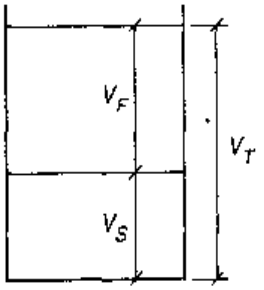
$$t_F = t_A + t_S + t_D$$

Select period times:

Assume: $t_A = 2.0$ h
$t_S = 0.50$ h
$t_D = 0.50$ h
$t_I = 0$

Then $t_F = 2.0 + 0.50 + 0.50 = 3.0$ h for each tank (Note: Some aeration may also be done in the fill period.)

Total cycle time $T_c = t_F + t_A + t_S + t_D = 6.0$ h



$$\text{Number of cycles/tank·d} = \frac{(24\text{ h/d})}{(6\text{ h/cycle})} = 4$$

$$\text{Total number of cycles/d} = (2\text{ tanks})\left[\frac{(4\text{ cycles/d})}{\text{tank}}\right]$$

$$= 8\text{ cycles/d}$$

$$\text{Fill volume/cycle} = \frac{(7570\text{ m}^3\text{/d})}{(8\text{ cycles/d})} = 946.3\text{ m}^3\text{/fill}$$

3. Determine fill fraction per cycle (V_F/V_T) allowed and compare to selected design value of 0.3.

a. Develop a mass balance based on solids in the reactor.

Mass of solids at full volume = Mass of settled solids

$V_T X = V_S X_S$

where V_T = total volume, m^3
X = MLSS concentration at full volume, g/m^3
V_S = settled volume after decant, m^3
X_S = MLSS concentration in settled volume, g/m^3

b. Solve mass balance and determine the fill fraction/cycle.

i. Estimate X_s based on an assumed SVI value of 150 mL/g.

$$X_s = \frac{(10^3\text{ mg/g})(10^3\text{ mL/L})}{(\text{SVI, mL/g})} = \frac{(10^3\text{ mg/g})(10^3\text{ mL/L})}{(150\text{ mL/g})}$$

$$= 6{,}666\text{ g/m}^3$$

$X = 3500\text{ g/m}^3$ (see problem statement)

ii. Determine the settled fraction.

$$\frac{V_S}{V_T} = \frac{X}{X_S} = \frac{(3500\ \text{g/m}^3)}{(6666\ \text{g/m}^3)} = 0.525$$

Provide 20 percent liquid above the sludge blanket so that solids are not removed by the decanting mechanism.

$$\frac{V_S}{V_T} = 1.2(0.525) = 0.63$$

iii. Determine the fill fraction.

$$V_F + V_S = V_T$$

where V_F = fill volume, m^3

$$\frac{V_F}{V_T} + \frac{V_S}{V_T} = 1.0$$

$$\frac{V_F}{V_T} = 1.0 - 0.63 = 0.37$$

Selected $V_F/V_T = 0.30$ is acceptable

4. Determine the overall hydraulic retention time τ.

Full liquid depth = 6.0 m

Decant depth = $0.3(6.0\ \text{m}) = 1.80\ \text{m}$

$$V_T = \frac{V_F/\text{tank}}{0.30} = \frac{(946.3\ \text{m}^3/\text{tank})}{0.30} = 3154\ \text{m}^3/\text{tank}$$

$$\text{Overall } \tau = \frac{2\ \text{tanks}\ (3154\ \text{m}^3/\text{tank})(24\ \text{h/d})}{(7570\ \text{m}^3/\text{d})} = 20\ \text{h}$$

5. Determine the SRT.

a. Use Eqs. (8–15), (8–16), and (7–58) to obtain a relationship that can be used to solve for ($P_{X,\text{TSS}}$) SRT.

$$(P_{X,\text{TSS}})\text{SRT} = \frac{QY(S_o - S)\text{SRT}}{[1 + (k_d)\text{SRT}](0.85)} + Q(\text{nbVSS})\text{SRT} + \frac{QY_n(\text{NO}_x)\text{SRT}}{[1 + (k_{dn})\text{SRT}](0.85)} + \frac{(f_d)(k_d)Q(Y)(S_o - S)\text{SRT}^2}{[1 + (k_d)\text{SRT}](0.85)} + Q(\text{TSS}_o - \text{VSS}_o)\text{SRT}$$

$$(P_{X,\text{TSS}})\text{SRT} = (V)(X_{\text{MLSS}}) = (3154\ \text{m}^3)(3500\ \text{g/m}^3)$$

$$= 11{,}039{,}000\ \text{g}$$

b. Develop input data to solve the above relationship for SRT:

nbVSS = 68 g/m^3 (from Step 1b)

Assume $S_o \approx S_o - S$

S_o = bCOD = 352 g/m^3 (Step 1a)

Q = (7570 m^3/d)/2 tanks = 3785 m^3/tank·d

iTSS$_o$ = TSS$_o$ − VSS$_o$ = (240 − 220) g/m^3 = 20 g/m^3 (Step 1c)

NO$_x$ = (0.80)(35 g TKN/m^3) = 28 g/m^3

Kinetic coefficients from Tables 8–10 and 8–11:

Y = 0.40 g VSS/g bCOD

$k_{d,\,12°C}$ = 0.12 g/g·d $(1.04)^{12-20}$ − 0.088 g/g·d

Y_n = 0.12 g VSS/g NO$_x$

$k_{dn,\,12°C}$ = 0.08 g/g·d $(1.04)^{12-20}$ = 0.06 g/g·d

f_d = 0.15 g/g

Substituting values and calculations for above equation yields

$$11{,}039{,}000\ \text{g} = \frac{(3785\ \text{m}^3/\text{d})(0.40\ \text{g VSS/g bCOD})(352\ \text{g/m}^3)(\text{SRT})}{[1 + (0.088\ \text{g/g·d})(\text{SRT})](0.85)}$$

$$+ (3785\ \text{m}^3/\text{d})(68\ \text{g/m}^3)(\text{SRT})$$

$$+ \frac{(3785\ \text{m}^3/\text{d})(0.12\ \text{g/g})(28\ \text{g/m}^3)(\text{SRT})}{[1 + (0.088\ \text{g/g·d})(\text{SRT})](0.85)}$$

$$+ \frac{(0.15\ \text{g/g})(0.088\ \text{g/g·d})(0.40\ \text{g VSS/g bCOD})(3785\ \text{m}^3/\text{d})(352\ \text{g/m}^3)(\text{SRT})^2}{[1 + (0.088\ \text{g/g·d})(\text{SRT})](0.85)}$$

$$+ (3785\ \text{m}^3/\text{d})(20\ \text{g/m}^3)(\text{SRT})$$

Solve for SRT (use spreadsheet with solver or solve by successive trials)

SRT = 17.0 d

6. Determine MLVSS concentration

a. Solve Eq. (7–54) (SRT = 17.0 d) ($S_o \approx S_o - S$)

$$(P_{X,\text{VSS}})\text{SRT} = V_T\,(X_{\text{MLVSS}})$$

$$(P_{X,\text{VSS}})\text{SRT} = \frac{Q(Y)(S_o - S)\text{SRT}}{1 + (k_d)\text{SRT}} + Q(\text{nbVSS})\text{SRT}$$

$$+ \frac{QY_n(\text{NO}_x)\text{SRT}}{1 + (k_{dn})\text{SRT}} + \frac{(f_d)(k_d)(Q)(Y)(S_o - S)(\text{SRT})^2}{1 + (k_d)\text{SRT}}$$

$$= \frac{(3785\ \text{m}^3/\text{d})(0.40\ \text{g VSS/g COD})(352\ \text{g/m}^3)(17.0\ \text{d})}{[1 + (0.088\ \text{g/g·d})(17.0\ \text{d})]} + (3785\ \text{m}^3/\text{d})(68\ \text{g/m}^3)(17.0\ \text{d})$$

$$+ \frac{(3785\ \text{m}^3/\text{d})(0.12\ \text{g VSS/g NO}_x)(28\ \text{g/m}^3)(17.0\ \text{d})}{[1 + (0.06\ \text{g/g·d})(17.0\ \text{d})]}$$

$$+ \frac{(0.15\ \text{g/g})(0.088\ \text{g/g·d})(0.40\ \text{g VSS/g COD})(3785\ \text{m}^3/\text{d})(352\ \text{g/m}^3)(17.0\ \text{d})^2}{[1 + (0.088\ \text{g/g·d})(17.0\ \text{d})]}$$

$$= V_T(X_{\text{MLVSS}})$$

$$V_T(X_{\text{MLVSS}}) = 8{,}926{,}716(\text{m}^3\text{·g/m}^3)$$

$$V_T = 3154\ \text{m}^3\ \text{(Step 4)}$$

$$V_T(X_{\text{MLVSS}}) = (3154\ \text{m}^3)(X_{\text{MLVSS}})$$

$$8{,}926{,}716(\text{m}^3\text{·g/m}^3) = (3154\ \text{m}^3)(X_{\text{MLVSS}})$$

$$X_{\text{MLVSS}} = 2830\ \text{g/m}^3$$

b. Determine the fraction of MLVSS.

$$\frac{X_{\text{MLVSS}}}{X_{\text{MLSS}}} = \frac{(2830\ \text{g/m}^3)}{(3500\ \text{g/m}^3)} = 0.81$$

7. Determine amount of NH_4-N oxidized (NO_x).
Nitrogen balance (Eq. 8–18)

$$NO_x = TKN_o - N_e - 0.12\,P_{X,\text{bio}}/Q$$

$$P_{X,\text{bio}} = [\text{Items A + B + C in Eq. (8–15)}]$$

$$P_{X,\text{bio}} = \frac{QY(S_o - S)}{1 + (k_d)\text{SRT}} + \frac{QY_n(\text{NO}_x)}{1 + (k_{dn})\text{SRT}} - \frac{(f_d)(k_d)QY(S_o - S)\text{SRT}}{1 + (k_d)\text{SRT}}$$

$$= \frac{(3785\ \text{m}^3/\text{d})(0.40\ \text{g VSS/g COD})(352\ \text{g/m}^3)}{[1 + (0.088\ \text{g/g·d})(17.0\ \text{d})]} + \frac{(3785\ \text{m}^3/\text{d})(0.12\ \text{g VSS/g NO}_x)(28\ \text{g/m}^3)}{[1 + (0.06\ \text{g/g·d})(17.0\ \text{d})]}$$

$$+ \frac{(0.15\ \text{g/g})(0.088\ \text{g/g·d})(3785\ \text{m}^3/\text{d})(0.40\ \text{gVSS/g COD})(352\ \text{g/m}^3)(17.0\ \text{d})}{[1 + (0.088\ \text{g/g·d})(17.0\ \text{d})]}$$

$$= 267{,}720\ \text{g/d} = 267.7\ \text{kg/d}$$

$$NO_x = 35.0 - 0.50 - \frac{(0.12)(267.7\ \text{kg/d})(10^3\ \text{g/kg})}{(3785\ \text{m}^3/\text{d})}$$

$$= (35.0 - 0.50 - 8.5)\ \text{g/m}^3$$

$$NO_x = 26.0\ \text{g/m}^3$$

8. Check the degree of nitrification to determine whether NH_4-N will be removed to a level of 0.50 g/m^3 in a 2-h aeration period.
   a. Determine the amount of oxidizable N available.

NO_x = 26.0 g/m^3 = NH_4-N in feed flow that can be oxidized

Oxidizable NH_4-N added/cycle:

$$V_F(NO_x) = 946.3 \text{ m}^3/\text{cycle } (26.0 \text{ g/m}^3)$$
$$= 24{,}604 \text{ g/fill}$$

NH_4-N remaining before fill = $V_S(N_e)$

N_e = 0.50 g/m^3 NH_4-N

$$V_S(N_e) = N_e(V - V_F)$$
$$= (0.50 \text{ g/m}^3)[(3154 - 946.3) \text{ m}^3]$$
$$= 1104 \text{ g}$$

Total oxidizable N at beginning of cycle = (24,604 + 1104) g = 25,708 g

$$\text{Initial concentration} = \frac{25{,}708 \text{ g}}{V_T} = \frac{25{,}708 \text{ g}}{3154 \text{ m}^3} = 8.15 \text{ g/m}^3 = N_o$$

   b. Determine the reaction time.
Using Eq. (8–40), the react time (aeration) after fill to achieve the desired NH_4-N concentration can be calculated. First, the nitrifier concentration must be determined.

$$K_n \ln \frac{N_o}{N_t} + (N_o - N_t) = X_n\left(\frac{\mu_{mn}}{Y_n}\right)\left(\frac{\text{DO}}{K_o + \text{DO}}\right)t$$

   i. Nitrifier concentration

$$X_n = \frac{Q(Y_n)(NO_x)\text{SRT}}{[1 + (k_d)\text{SRT}]V}$$
$$= \frac{(3785 \text{ m}^3/\text{d})(0.12 \text{ g VSS/g } NH_4\text{-N})(26.0 \text{ g/m}^3)(17.0 \text{ d})}{[1 + (0.06 \text{ g/g·d})(17.0 \text{ d})](3154 \text{ m}^3)}$$
$$= 31.5 \text{ g/m}^3$$

$$\mu_{m,12°C} = 0.75 \text{ g/g·d } (1.07)^{12-20} = 0.44 \text{ g/g·d}$$

$$K_{n,12°C} = 0.74 \text{ g/m}^3 \ (1.053)^{12-20} = 0.49 \text{ g/m}^3$$

$$K_o = 0.50 \text{ g/m}^3$$

ii. Determine the time for reaction.
Solve for t for $N_o = 8.15$ g/m^3, $N_e = 0.50$ g/m^3

$$0.49 \ln \left[\frac{(8.15 \text{ g/m}^3)}{(0.5 \text{ g/m}^3)}\right][(8.15 - 0.5) \text{ g/m}^3] = (31.5 \text{ g/m}^3)\left[\frac{(0.44 \text{ g/g·d})}{(0.12 \text{ g/g})}\right]\left(\frac{2.0}{0.5 + 2.0}\right)t$$

$t = 0.113$ days $= 2.7$ h

c. Determine the aeration time.

Required aeration time = 2.7 h

Aeration time selected was 2.0 h; therefore, aeration is required during part of the fill period

Fill time = 3.0 h

At least one half of the fill time should be used for mixing without aeration to provide a selector operation for SVI control.

$$\text{Total aeration time} = \frac{3.0}{2} + 2.0 = 3.5 \text{ h}$$

Thus, there is sufficient time for nitrification. Because the factor of safety for this design is quite low, other iterations can be done to develop a more conservative design, which would result in a larger volume (V_T) and longer SRT. The volume could be increased by making V_F/V_T smaller or by increasing the time for the react period.

9. Determine the decant pumping rate.

Decant volume = fill volume

$V_F = 946.3$ m^3

Decant time = 30 min

$$\text{Pumping rate} = \frac{946.3 \text{ m}^3}{30 \text{ min}} = 31.5 \frac{\text{m}^3}{\text{min}}$$

10. Determine oxygen required/tank using Eq. (8–17).

$$R_o = Q(S_o - S) - 1.42 P_{X,bio} + 4.33 Q(\text{NO}_x)$$

$$= (3785 \text{ m}^3/\text{d})(352 \text{ g/m}^3)(1 \text{ kg}/10^3 \text{ g}) - 1.42(267.7 \text{ kg/d}) + 4.33(26.0 \text{ g/m}^3)(3785 \text{ m}^3/\text{d})(1 \text{ kg}/10^3 \text{ g})$$

$$R_o = (1332 - 380 + 426) \text{ kg/d} = 1378 \text{ kg/d}$$

Aeration time/tank

Aeration time/cycle = 3.5 h
Number of cycles/d = 4
Total aeration time = 14 h/d

$$\text{Average oxygen transfer rate} = \frac{(1378 \text{ kg } O_2/\text{d})}{(14 \text{ h/d})} = 98.4 \text{ kg/h}$$

Note: The oxygen demand will be higher at the beginning of the aeration period so the aeration system oxygen transfer capacity must be higher than this average transfer rate. The oxygen transfer rate should be multiplied by a factor of 1.5 to 2.0 to provide sufficient oxygen transfer at the beginning of the cycle and to handle peak loads.

11. Determine sludge production using Eq. (7–55). (MLSS = X_{TSS})

$$P_{X,TSS} = \frac{(V)(\text{MLSS})}{\text{SRT}}$$

$$= \frac{(2 \text{ tanks})(3154 \text{ m}^3/\text{tank})(3500 \text{ g/m}^3)(1 \text{ kg}/10^3 \text{ g})}{17.0 \text{ d}}$$

$$= 1299 \text{ kg/d}$$

$$\text{bCOD removed} = (7570 \text{ m}^3/\text{d})(352 \text{ g/m}^3)(1 \text{ kg}/10^3 \text{ g})$$

$$= 2664 \text{ kg/d}$$

$$\text{BOD removed} = \frac{(2664 \text{ kg bCOD/d})}{(1.6 \text{ kg bCOD/kg BOD})} = 1665 \text{ kg/d}$$

$$\text{Observed yield, g TSS/g BOD} = \frac{1299}{1665} = \left(\frac{0.78 \text{ g TSS}}{\text{g BOD}}\right)$$

$$\text{Observed yield, g VSS/g BOD} = \left(\frac{0.78 \text{ g TSS}}{\text{g BOD}}\right)\left(\frac{0.81 \text{ g VSS}}{\text{g TSS}}\right)$$

$$= \frac{0.63 \text{ g VSS}}{\text{g BOD}}$$

$$\text{Observed yield, g TSS/g bCOD} = \frac{1299}{2664} = 0.49 \text{ g TSS/g bCOD}$$

Note: The observed yield is higher than the observed yield in the CMAS design example (Example 8–2) even though the SRT is higher in this design. Because no primary treatment is used, the wastewater has a higher nbVSS concentration. Also note that the endogenous decay coefficient was assumed as a constant regardless of whether the biomass was under aeration or nonaerobic conditions. During a large part of the nonaerated period, nitrates are present, and the endogenous decay coefficient may not be lower. The error introduced by the decay coefficient assumption has little effect on the reliability of the design.

12. Determine F/M and BOD volumetric loading
    a. F/M

$$\text{F/M} = \frac{\text{kg BOD}}{\text{kg MLVSS·d}} = \frac{QS_o}{XV}$$

$$= \frac{(3785\ \text{m}^3/\text{d})(220\ \text{g/m}^3)}{(2830\ \text{g/m}^3)(3154\ \text{m}^3)} = 0.09\ \text{g/g·d}$$

    b. BOD volumetric loading

$$L_{org} = \frac{\text{kg BOD}}{\text{m}^3\text{·d}} = \frac{QS_o}{V}$$

$$= \frac{(7570\ \text{m}^3/\text{d})(220\ \text{g/m}^3)}{(3154\ \text{m}^3)(10^3\ \text{g/kg})} = 0.53\ \text{kg/m}^3\text{·d}$$

13. Prepare a design summary for average conditions.

Design parameter	Unit	Value
Average flow	m^3/d	7570
Average BOD load	kg/d	1665
Average TKN load	kg/d	265
Number of tanks	Number	2
Fill time	h	3.0
React time	h	2.0
Total aeration time	h	3.5
Settle time	h	0.5
Decant time	h	0.5
Cycle time	h	6.0
Total SRT	d	17.0
Tank volume	m^3	3154
Fill volume/cycle	m^3	946.3
Fill volume/tank volume	Ratio	0.3
Decant depth	m	1.8
Tank depth	m	6.0
MLSS	g/m^3	3500
MLVSS	g/m^3	2830
F/M	g/g·d	0.09
Volumetric BOD load	$kg/m^3·d$	0.53
Decant pumping rate	m^3/min	31.5
Sludge production	kg/d	1299
Observed yield	kg VSS/kg BOD	0.63
	kg TSS/kg bCOD	0.49
Average oxygen required/tank	kg/d	1378
Total aeration time/d-tank	h	14
Average O_2 transfer rate	kg/h	98.4

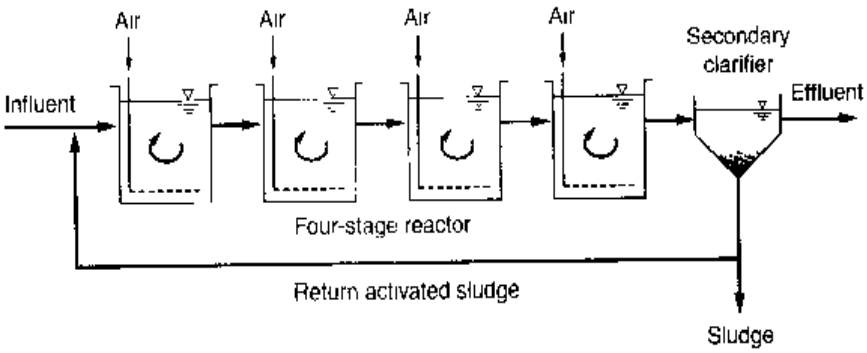
Staged Activated-Sludge Process

In the conventional plug-flow activated-sludge system, the tank hydraulics and mixing regime may result in two to four effective stages from the standpoint of biological kinetics. Activated-sludge processes can be designed with baffle walls to intentionally create a number of complete-mix activated-sludge zones operating in series (see Fig. 8–17). For the same reactor volume, reactors in series can provide greater treatment efficiency than a single complete-mix reactor, or provide a greater treatment capacity. As a consequence, staged activated-sludge process configurations are used at several full-scale installations.

Oxygen Demand in Staged Designs. The oxygen demand varies in staged complete-mix reactor designs and can be high enough in the first stage to challenge the volumetric oxygen transfer capability of aeration equipment. With high-density fine bubble aeration diffusers, such as membrane aeration panels described in Sec. 5–12 in Chap. 5, oxygen transfer rates of 100 to 150 mg/L·h are possible, with some manufacturers claiming higher rates. The changes in oxygen uptake rates (OURs) in each stage of a four-stage activated-sludge process (defined as a function of oxygen needed for nitrification, rbCOD removal, particulate degradable COD, and endogenous respiration) are depicted on Fig. 8–18. Most of the rbCOD will be consumed in the first stage, and the OUR for pCOD degradation will decrease from stage to stage as a function of the

Figure 8–17

Schematic diagram of a staged activated-sludge process.



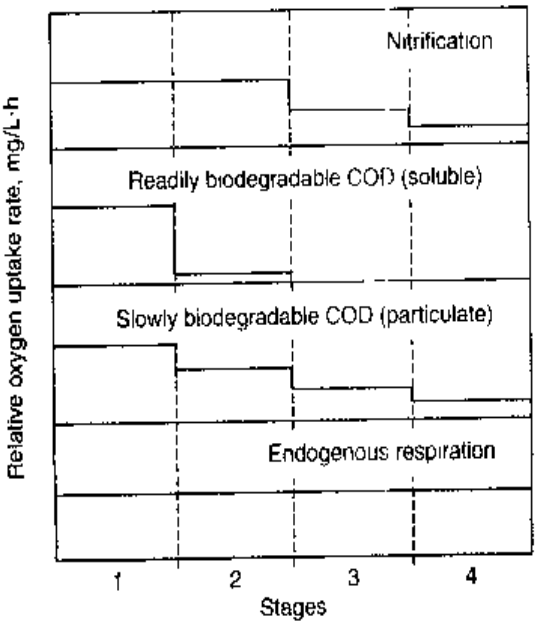


Figure 8–18

Changes in oxygen uptake rates for staged activated-sludge process.

degradation kinetics. Nitrification rates may be at a maximum zero-order kinetic rate for the first one to three stages due to higher NH_4-N concentrations in the early stages. Oxygen demand for endogenous respiration will be relatively constant from stage to stage.

The oxygen demand distribution may be estimated to determine the aeration design for staged processes. The percent of the total oxygen consumption may range from 40, 30, 20, and 10 percent, respectively, for a four-stage system. One design approach that can be used to obtain an estimate of the oxygen demand in a staged system is to calculate the total oxygen demand as would be done for a CMAS process, and then estimate the oxygen demand distribution with consideration to the various components described above. With proper selection of the type and placement of the diffusers and by providing an air supply system with DO control in each portion of the system, the air can be provided where needed. Generally, the approach outlined above is satisfactory because during the life of the process, the oxygen demand will vary across the tank as the load changes.

Use of Simulation Models. The other approach involves the use of simulation models, in which the kinetics and changes in constituent concentrations in each stage are taken into consideration. This approach will typically result in a more optimal design and can be used to assess the real capacity of a given activated-sludge design. The simulation approach involves solving a set of equations in each stage for each constituent, which includes rbCOD, pCOD, NH_3-N, endogenous respiration, and biomass concentration. Models also include phosphorus and the effect of biological phosphorus removal on design and performance. An example of such a comprehensive simulation model is presented at the end of this chapter.

The effect of using a staged system as compared to a single CMAS tank for nitrification is illustrated in Example 8–4.

EXAMPLE 8–4 Evaluation of Staged Reactors for Nitrification Compare the performance of a four-stage activated-sludge system with equal volumes per stage for nitrification to that for a single-stage system. The hydraulic retention time is 8 h for both systems, and the same SRT is used. The single-stage system is designed for an effluent NH_4-N concentration of 0.50 g/m^3 for the following conditions and using kinetic coefficients from Table 8–11.

Design conditions and assumptions:

Item	Unit	Value
Temperature	°C	18
μ_m	g/g·d	0.655
K_n	g NH_4-N /m^3	0.67
Y_n	g VSS/g NH_4-N	0.12
k_{dn}	g/g·d	0.074
Influent NH_4-N	g/m^3	30.0

(continued)

(*Continued*)

Item	Unit	Value
Effluent NH_4-N	g/m^3	0.50
DO	g/m^3	2.0
K_o	g/m^3	0.5
RAS recycle ratio	Unitless	0.5

Note: g/m^3 = mg/L.

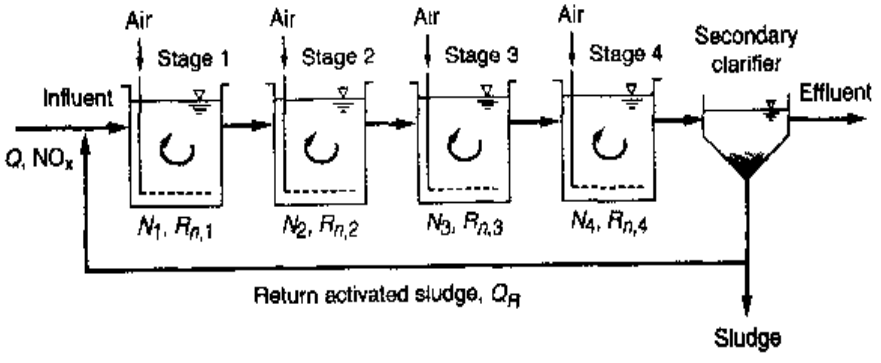
Solution

1. Determine the SRT value and the concentration of the nitrifying bacteria for a single-stage system, $\tau = 8$ h $= 0.33$ d, $N = 0.50$ g/m^3.
   a. Solve for the specific growth rate using Eq. (7–93) in Table 8–5.

$$\mu_n = \left(\frac{\mu_{nm} N}{K_n + N}\right)\left(\frac{\text{DO}}{K_o + \text{DO}}\right) - k_{dn}$$

$$= \left\{\frac{(0.655\ \text{g/g·d})(0.5\ \text{g/m}^3)}{[(0.67 + 0.50)\ \text{g/m}^3]}\right\}\left\{\frac{(2.0\ \text{g/m}^3)}{[(0.5 + 2.0)\ \text{g/m}^3]}\right\} = 0.074\ \text{g/g·d}$$

   b. Solve for SRT using Eq. (7–37).



$$\text{SRT} = \frac{1}{\mu_n} = \frac{1}{0.15\ \text{g/g·d}} = 6.7\ \text{d}$$

   c. Solve for the concentration of nitrifying bacteria using a modified form of Eq. (7–43).

$$X_n = \frac{(\text{SRT})Y_n(\text{NO}_x)}{\tau[1 + (k_d)\text{SRT}]}$$

$$= \frac{(6.7\ \text{d})(0.12\ \text{g/g})(30\ \text{g/m}^3)}{(0.33\ \text{d})[1 + (0.074\ \text{g/g·d})(6.7\ \text{d})]} = 48.9\ \text{g/m}^3$$

2. Perform nitrogen mass balances for a four-stage system shown on the following figure using equal volumes per stage. The total volume of the four-stage system is equal to the volume of the CMAS system, τ/stage $= 0.333$ d/4 $= 0.0833$ d/stage.

a. For Stage 1

Accumulation = in − out + generation

$$\frac{dN_1}{dt}V = Q(\mathrm{NO}_x) + Q_R N_4 - (Q + Q_R)N_1 - R_{n,1}V$$

The rate expression for nitrification, derived from Eq. (7–15), includes a correction for the DO concentration, and is given by

$$R_{n,1} = \left(\frac{\mu_m}{Y_n}\right)\left(\frac{N_1}{K_n + N_1}\right)\left(\frac{\mathrm{DO}}{K_o + \mathrm{DO}}\right)X_n$$

where Q = wastewater flowrate, m^3/d
NO_x = available influent NH_4-N = 30 g/m^3
Q_R = recycle flowrate from stage 4, m^3/d
Q/Q_R = 0.50
N_4 = NH_4-N concentration for stage 4, g/m^3
N_1 = NH_4-N concentration for stage 1, g/m^3
$R_{n,1}$ = nitrification rate for stage 1, $g/m^3 \cdot d$
X_n = nitrifying bacteria concentration, g/m^3

The nitrifying bacteria concentration is the same as that calculated for the CMAS system because the same amount of NH_4-N is removed and the system is at the same SRT.

At steady state $dN_1/dt = 0$, and

$$\mathrm{NO}_x + Q_R/QN_4 - (1 + Q_R/Q)/N_1 - R_{n,1}V/Q = 0$$

$$\mathrm{NO}_x + 0.5N_4 = 1.5N_1 + R_{n,1}(\tau)$$

where τ = 0.0833 d, detention time of stage 1
NO_x = 30 g/m^3

b. For Stage 2, use the same procedure as Stage 1.

$$V\frac{dN_2}{dt} = (Q + Q_R)N_1 - (Q + Q_R)N_2 - R_{n,2}V$$

$$1.5N_1 = 1.5N_2 + R_{n,2}(\tau)$$

c. For Stage 3

$$1.5N_2 = 1.5N_3 + R_{n,3}(\tau)$$

d. For Stage 4

$$1.5N_3 = 1.5N_4 + R_{n,4}(\tau)$$

3. $R_{n,i(i=1-4)}$ is a function of the NH_4-N concentration (N) in each stage:
For stage 1,

$$R_{n,1} = \left[\frac{(0.655\ \mathrm{g/g \cdot d})}{(0.12\ \mathrm{g\ VSS/g\ NH_4\text{-}N})}\right]\left\{\frac{\mathrm{N_1}}{[(0.67 + \mathrm{N_1})\ \mathrm{g/m^3}]}\right\}\left\{\frac{(2.0\ \mathrm{g/m^3})}{[(0.5 + 2.0)\ \mathrm{g/m^3}]}\right\}(48.9\ \mathrm{g/m^3})$$

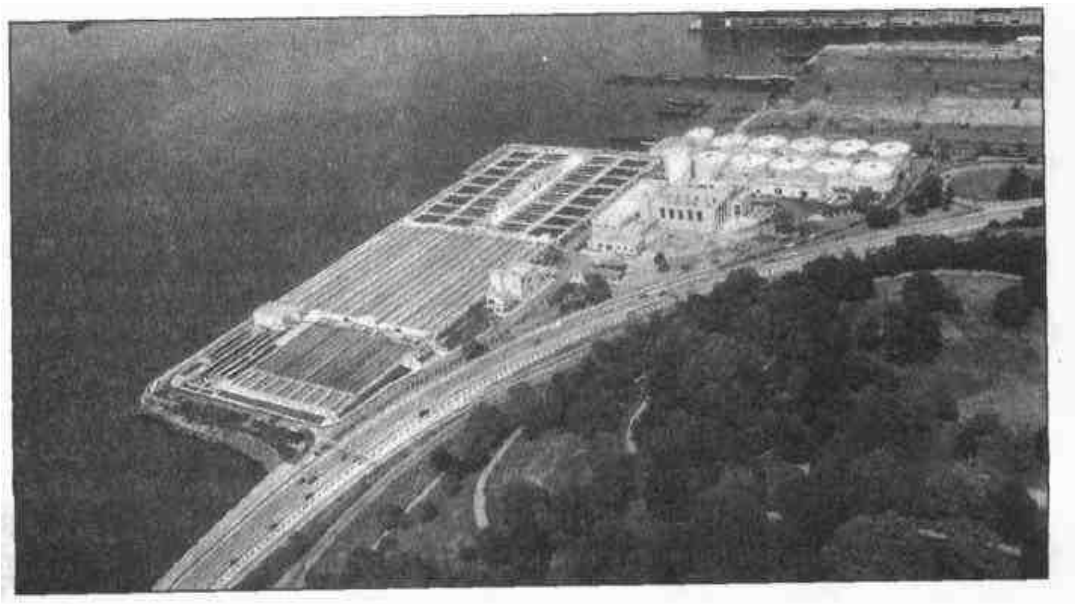
4. The above equations for the four stages are solved with a spreadsheet program starting with Stage 1. The value for N_4 is assumed and adjusted in iterative calculations. The following effluent NH_4-N concentrations are computed for each stage:

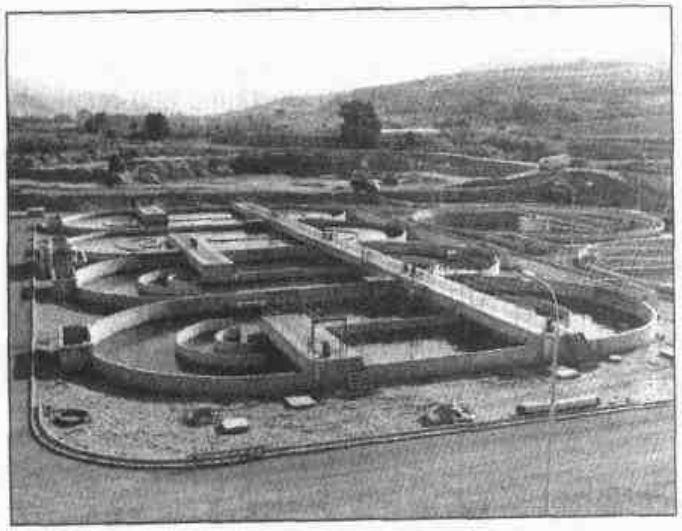
Stage	NH_4-N concentration, g/m³
1	12.2
2	4.7
3	0.50
4	0.03

5. Based on the above results, the same amount of nitrification that can be achieved theoretically with staging is 75 percent of the aeration tank volume required for a CMAS design.

Alternative Processes for BOD Removal and Nitrification

Over the last 30 years numerous activated-sludge processes have been developed for the removal of organic material (BOD) and for nitrification. Some of the processes are modifications or variations of basic processes that have evolved to meet different performance objectives. Descriptions and flowsheets are presented in Table 8–15 for representative processes used for BOD removal and nitrification. The processes are grouped according to the basic reactor configuration: plug-flow, complete-mix, and sequentially operated systems. A view of a large wastewater treatment plant using plug-flow reactors is shown on Fig. 8–19.





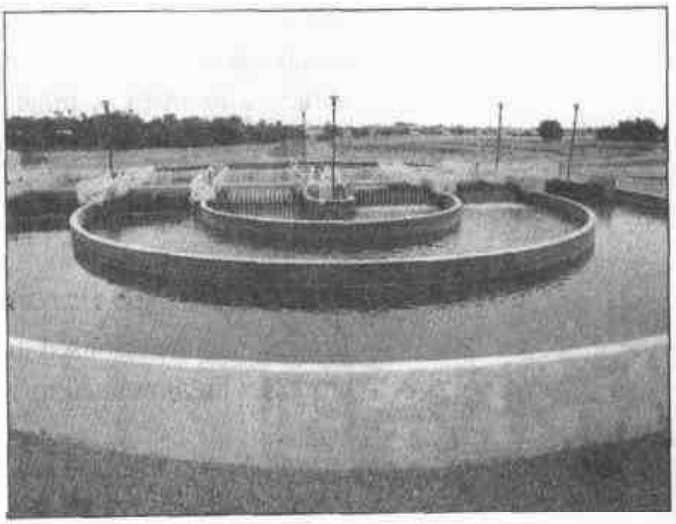


Figure 8–19
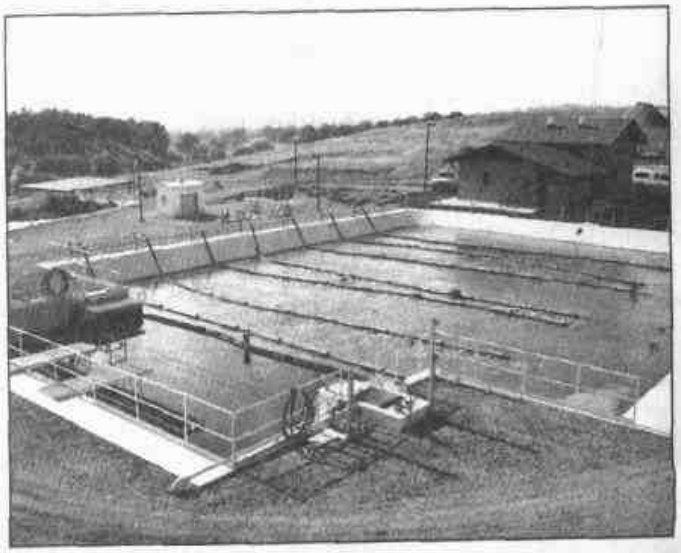
View of plug-flow reactors at Owls Head Wastewater Treatment Plant, New York. *(Courtesy of the New York City Department of Environmental Protection.)*

The processes differ in terms of their aeration configuration, aeration equipment design, solids retention time, operating mode, and ability to remove nitrogen, and some are proprietary. The high-rate aeration, contact stabilization, and high-purity oxygen processes are used primarily for BOD removal only, are designed for relatively short SRTs, and require less space than other processes. Where nitrification is not needed to meet treatment discharge limits, the three processes cited above are particularly attractive for large municipalities where space is limited. The conventional plug-flow, step-feed, and complete-mix processes are used for both BOD removal and nitrification and are applied over a wide range of SRTs, depending on the wastewater temperature and treatment needs. The Kraus process is seldom used, but it is included to show how oxidized nitrogen can be used to help BOD degradation in the first pass of a plug-flow aeration tank.



In contrast to the processes described above, conventional extended aeration, oxidation ditch, Orbal™, and Biolac™ processes represent a different approach to biological wastewater treatment (for the latter three, see Fig. 8–20). The processes employ a

(a)

(b)

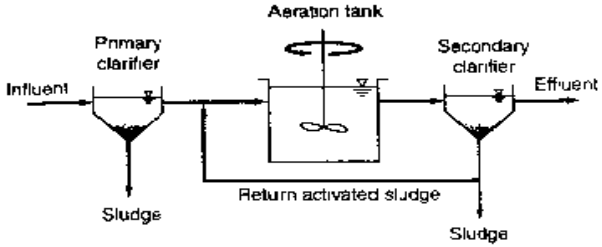
(c)

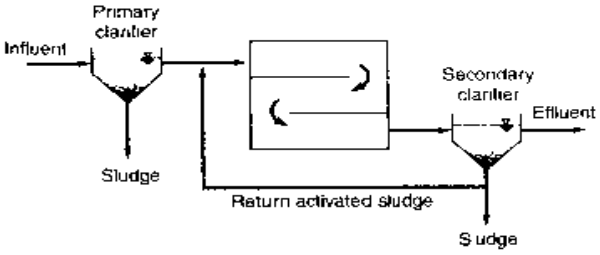
Figure 8–20

Views of alternative activated-sludge processes: (a) oxidation ditch with brush aerators, (b) Orbal™ process with disk aerators, and (c) Biolac™ process with contiguous clarifier.

much simpler system by generally eliminating primary treatment and anaerobic digestion from the overall treatment system. Larger aeration tanks with longer SRTs, usually exceeding 20 d, are used. The process approach is attractive for smaller communities where space is not an issue and less complex operation is preferred. The large aeration tank volume provides good equalization at high flow and loading occurrences, and a high-quality effluent is produced. With the exception of the conventional extended aeration process, the systems are operated usually to promote denitrification in addition to nitrification. The aeration and mixing of the channel-flow processes (oxidation ditch, Orbal™, and CCAS™) require much less energy for mixing than needed for aeration so that aeration equipment design is based on meeting oxygen requirements instead of tank mixing. Less energy is required in comparison to conventional extended aeration processes. In the past, the oxidation ditch and extended aeration processes were thought to need long SRTs to provide well-stabilized biosolids for reuse. However, with stricter regulations governing biosolids stabilization (see Chap. 14), separate aerobic digestion facilities are used to meet the requirements for reuse.

Several sequentially operated activated-sludge processes that do not use separate tanks for liquid-solids separation are also described in Table 8–15. The processes include the sequencing batch reactor, batch decant reactor, and the cycle activated-sludge system. Operation is based usually on long τ and SRT values. The processes are attractive to small communities because of the simplicity of operation and relatively low cost. Sequentially operated processes are also adaptable to nitrogen removal, as discussed in Sec. 8–5.

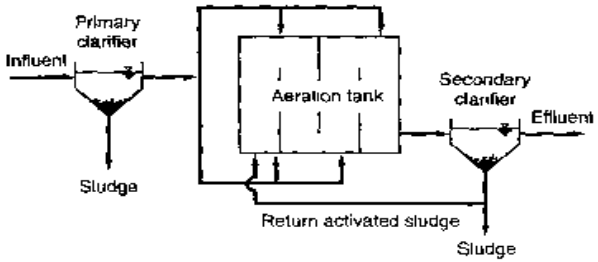


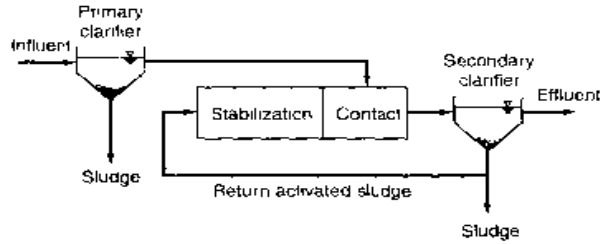


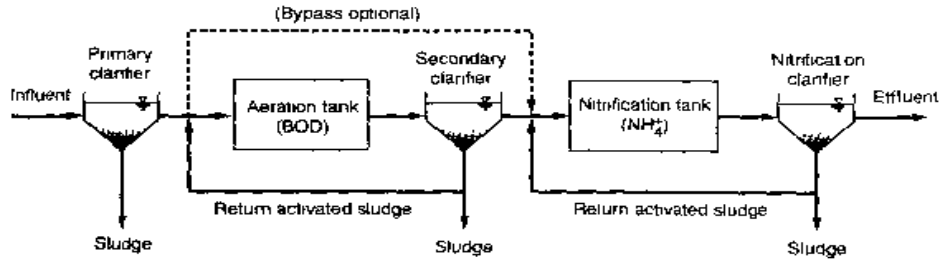
Process Design Parameters

Typical parameters used for the design and operation of various activated-sludge processes are presented in Table 8–16.

Process Selection Considerations

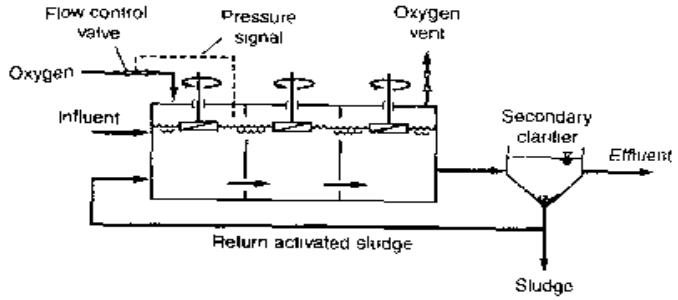






Selection of an activated-sludge process for BOD removal and nitrification is a function of many considerations including specific site constraints, compatibility with the existing process, compatibility with existing equipment, present and future treatment needs, level of capability of the operating staff, capital costs, and operating costs. Significant features and limitations of the various activated-sludge process alternatives that affect process selection in certain applications are summarized in Table 8–17.

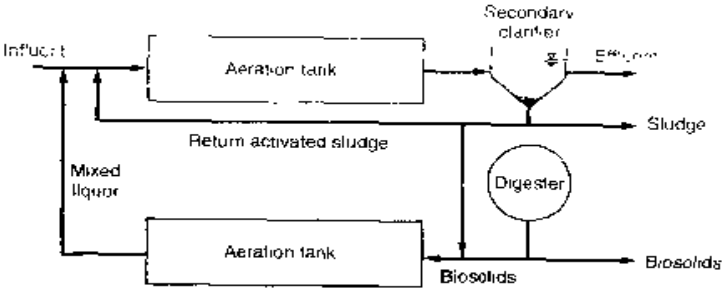
Table 8–15
Description of activated-sludge processes for BOD removal and nitrification



Process	Description
Complete-mix	
(a) Complete-mix activated-sludge (CMAS) 	The CMAS process is an application of the flow regime of a continuous-flow stirred-tank reactor. Settled wastewater and recycled activated sludge are introduced typically at several points in the aeration tank. The organic load on the aeration tank, MLSS concentration, and oxygen demand are uniform throughout the tank. An advantage of the CMAS process is the dilution of shock loads that occur in the treatment of industrial wastewaters. The CMAS process is relatively simple to operate but tends to have low organic substrate concentrations (i.e., low F/M ratios) that encourage the growth of filamentous bacteria, causing sludge bulking problems
Plug-flow	
(b) Conventional plug flow 	Settled wastewater and return activated sludge (RAS) enter the front end of the aeration tank and are mixed by diffused air or mechanical aeration. Typically, from 3 to 5 channels (passes) are used. In early designs, air application was generally uniform throughout the tank length, however, low DO concentrations usually occurred in the initial passes of the tank. In modern designs, the aeration system is designed to match the oxygen demand along the length of the tank by tapering the aeration rates, i.e., applying higher rates in the beginning and lower rates near the end of the tank. During the aeration period, adsorption, flocculation, and oxidation of organic matter occur. Activated-sludge solids are separated in a secondary settling tank
(c) High-rate aeration (see conventional plug flow)	High-rate aeration is a process modification in which low MLSS concentrations are combined with high volumetric BOD loadings. The high-rate system is characterized by short τ, high sludge recycle ratio, high F/M loading, and relatively low MLSS concentration. High-rate systems produce a lesser effluent quality, in terms of BOD and TSS concentration, as compared to conventional plug-flow or complete-mix systems. Because of the high loading used, more care must be taken to keep a stable operation. Adequate mixing and aeration are very important

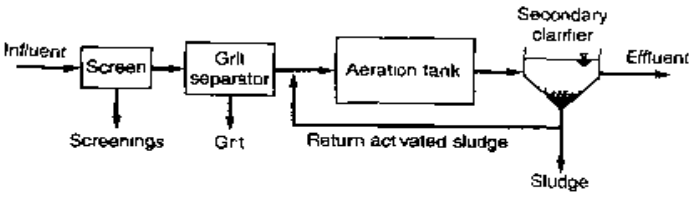
(continued)

Table 8–15 *(Continued)*



Process	Description
Plug-flow *(Continued)* (d) Step feed  	Step feed is a modification of the conventional plug-flow process in which the settled wastewater is introduced at 3 to 4 feed points in the aeration tank to equalize the F/M ratio, thus lowering peak oxygen demand. Generally, three or more parallel channels are used. Flexibility of operation is one of the important features of this process because the apportionment of the wastewater feed can be changed to suit operating conditions. The concentration of MLSS may be as high as 5000 to 9000 mg/L in the first pass, with lower concentrations in subsequent passes as more influent feed is added. The step-feed process has the capability of carrying a higher solids inventory, and thus a higher SRT for the same volume as a conventional plug-flow process. The step-feed process can also be operated in the contact-stabilization mode by feeding only the last pass, and high wet-weather flows can be bypassed to the last pass so that the solids load to the secondary clarifier can be minimized
(e) Contact stabilization  	Contact stabilization uses two seporate tanks or compartments for the treatment of the wastewater and stabilization of the activated sludge. The stabilized activated sludge is mixed with the influent (either raw or settled) wastewater in a contact zone. The contact zone detention time is relatively short (30 to 60 min), and the MLSS concentration in the contact zone is lower than that in the stabilization zone. Rapid removal of soluble BOD occurs in the contact zone, and colloidal and particulate organics are captured in the activated-sludge floc for degradation later in the stabilization zone. In the stabilization zone, return activated sludge (RAS) is aerated and the detention time is in the order of 1 to 2 h to maintain a sufficient SRT for sludge stabilization. Because the MLSS concentration is so much higher in the stabilization zone, the contact-stabilization process requires much less aeration volume than complete-mix or conventional plug-flow processes for the same SRT. The process was developed for BOD removal, and the short contact time limits the amount of soluble BOD degraded and NH_4-N oxidation
(f) Two-sludge  	The two-sludge process is a two-stage system using high-rate activated sludge for BOD removal followed by a second stage for nitrification, which is operated at a longer SRT. A portion of the wastewater influent may be bypassed around the first stage to provide BOD and suspended solids for the nitrification process and promote flocculation and solids capture in secondary clarification. The main reason to separate the BOD removal stage from the nitrogen removal stage is to treat toxic substances in the first stage, and thus protect the more sensitive nitrifying bacteria. With better industrial pretreatment programs in place today, BOD removal and nitrification are done more commonly in a single-sludge process

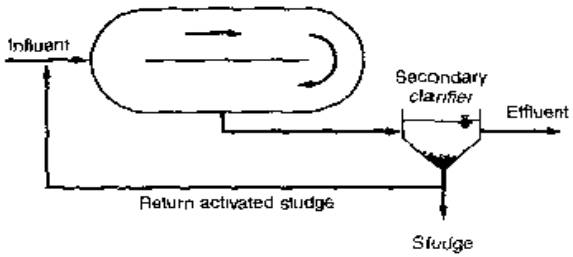
(g) High-purity oxygen

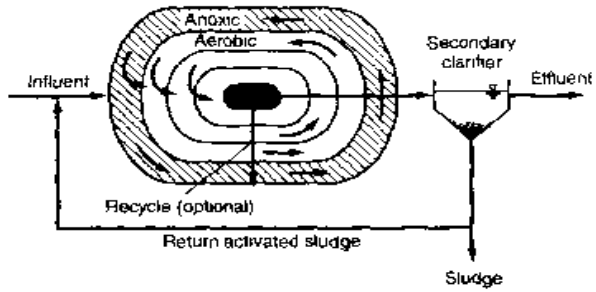


A staged enclosed reactor is used in the high-purity oxygen activated-sludge process (McWhirter, 1978). Three or four stages are generally used and the influent wastewater, RAS, and high-purity oxygen are added to the first stage. The headspace gas and mixed liquor flow concurrently from stage to stage. The oxygen partial pressure in the headspace may range from 40 to 60 percent in the first stage to 20 percent in the last stage. At high oxygen partial pressure, higher volumetric oxygen transfer rates are possible so that pure oxygen systems can have a higher MLSS concentration and operate at a shorter τ and higher volumetric organic loadings than conventional processes. The rate of oxygen addition is about 2 to 3 times greater than that by conventional aeration systems. Onsite oxygen generation equipment is needed to provide the pure oxygen gas for the process, making the process operation more complex than conventional activated-sludge processes. Nitrification ability is limited with the high-purity oxygen processes due to the accumulation of carbon dioxide in the gas headspace, which causes low pH in the mixed liquor (less than 6.5). Major advantages for pure oxygen systems are the reduced space requirement and greatly reduced quantities of off-gas if odor control and VOC control are required

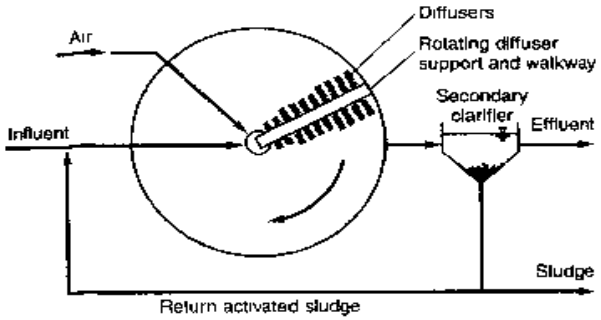
(h) Kraus process

The Kraus process is a variation of the step aeration process used to treat nitrogen deficient industrial wastewater. Digester supernatant is added as a food source to a portion of the return sludge in a separate aeration tank designed to nitrify. The resulting mixed liquor is then added to the main plug-flow aeration system. Besides providing nitrogen, nitrate is available to serve as an electron acceptor in the event of oxygen limitations





(i) Conventional extended aeration



The extended aeration process is similar to the conventional plug-flow process except that it operates in the endogenous respiration phase of the growth curve, which requires a low organic loading and long aeration time. Because of the long SRTs (20 to 30 d) and τ's on the order of 24 h, aeration equipment design is controlled by mixing needs and not oxygen demand. The process is used extensively for preengineered plants for small communities. Generally, primary clarification is not used. Secondary clarifiers are designed at lower hydraulic loading rates than conventional activated-sludge clarifiers to better handle large flowrate variations typical of small communities. Although the biosolids are well stabilized, additional biosolids stabilization is required to permit beneficial reuse (see Chap. 14)

(continued)

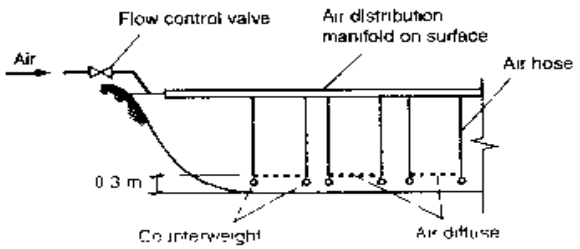


Table 8-15 *(Continued)*

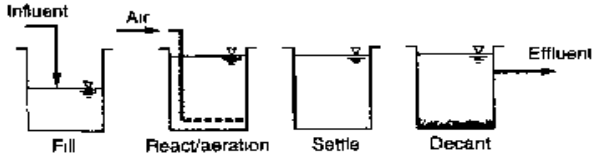
Process	Description
Extended aeration	
(j) Oxidation ditch 	The oxidation ditch consists of a ring- or oval-shaped channel equipped with mechanical aeration and mixing devices. Screened wastewater enters the channel and is combined with the return activated sludge. The tank configuration and aeration and mixing devices promote unidirectional channel flow, so that the energy used for aeration is sufficient to provide mixing in a system with a relatively long hydraulic retention time. The aeration/mixing method used creates a velocity from 0.25–0.30 m/s (0.8–1.0 ft/s) in the channel, which is sufficient to keep the activated sludge in suspension. At these channel velocities, the mixed liquor completes a tank circulation in 5–15 min, and the magnitude of the channel flow is such that it can dilute the influent wastewater flow by a factor of 20–30. As a result, the process kinetics approach that of a complete-mix reactor, but with plug flow along the channels. As the wastewater leaves the aeration zone, the DO concentration decreases and denitrification may occur. Brush-type or surface-type mechanical aerators are used for mixing and aeration (see Sec. 5–12 in Chap. 5). Secondary sedimentation tanks are used for most applications, and in some cases intrachannel clarifiers have been used
(k) Orbal™ 	The Orbal™ process is a variation of the oxidation ditch and uses a series of concentric channels within the same structure. Wastewater enters the larger outer channel and mixed liquor flows typically toward the center of the structure through at least two more channels before entering an internal clarifier or a distribution box. Disk aerators mounted on a horizontal shaft provide aeration. Channel depths range up to 4.3 m (14 ft). One version of the Orbal design (Bionutre™) limits the aeration rate in the first channel so that both nitrification and denitrification (anoxic condition) occur

(l) Countercurrent aeration system (CCAS™)



(m) Biolac™ process

Sequentially operated systems

(n) Sequencing batch reactor (SBR)

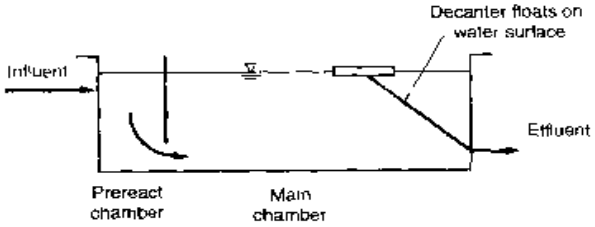
In the CCAS process, a unique aeration system is employed in which air diffusers are mounted at the bottom of a revolving bridge in a circular aeration tank. Because of the circulating motion of the bridge, which is moving faster than the aeration tank contents, fine bubbles are dispersed in a sweeping motion behind the traveling bridge. When the air is turned off, the movement of the diffusers creates enough mixing energy to keep the tank contents in suspension. The process is operated at a DO ranging from 0.7 to 1.0 mg/L. The low DO concentration is sufficient for nitrification at the long SRT, while allowing anoxic conditions to develop to promote denitrification. The system is normally designed with extended aeration SRTs

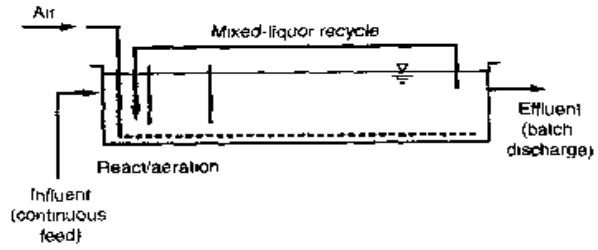
Biolac is a proprietary process that combines long solids retention times with submerged aeration in earthen basins. Fine bubble membrane diffusers are attached to floating aeration chains that are moved across the basin by the air released from the diffusers. Aeration basins are typically 2.4 to 4.6 m (8 to 15 ft) deep. The process can be designed for nitrification since the SRT ranges from 40 to 70 d. The F/M ratio ranges from 0.04 to 0.1 and the MLSS range is from 1500 to 5000 mg/L. A variation of the standard process, known as the "wave oxidation modification," allows biological nitrification and denitrification to occur simultaneously by using timers to cycle the air flowrate to each aeration chain. Either an internal or external clarifier can be used

The SBR is a fill-and-draw type of reactor system involving a single complete-mix reactor in which all steps of the activated-sludge process occur. For municipal wastewater treatment with continuous flow, at least 2 basins are used so that one basin is in the fill mode while the other goes through react, solids settling, and effluent withdrawal. An SBR goes through a number of cycles per day; a typical cycle may consist of 3-h fill, 2-h aeration, 0.5-h settle, and 0.5-h for withdrawal of supernatant. An idle step may also be included to provide flexibility at high flows. Mixed liquor remains in the reactor during all cycles, thereby eliminating the need for separate secondary sedimentation tanks. Decanting of supernatant is accomplished by either fixed or floating decanter mechanisms. The τ's for SBRs generally range from 18 to 30 h, based on influent flowrate and tank volume used. Aeration may be accomplished by jet aerators or coarse bubble diffusers with submerged mixers (see Sec. 5–12 in Chap. 5). Separate mixing provides operating flexibility and is useful during the fill period for anoxic operation. Sludge wasting occurs normally during the aeration period

(*continued*)

Table 8–15 (*Continued*)





Process	Description
(o) Batch decant reactor, intermittent cycle extended aeration system (ICEAS™)  	The ICEAS process, developed in Australia, is another type of SBR process used for treating flowrates up to 500,000 m^3/d. Influent wastewater is fed continuously through the same cycles of react, settle, and decant as in an SBR. The influent is fed into one side of a baffled chamber (a prereact zone) so the flow does not disturb the mixed liquor during the settling and decant period. Wastewater flows continuously through openings at the bottom of the baffle wall and into the main react zone where BOD and nitrification occur. After aeration and settling, separated liquid is removed by an automated, time-controlled decant mechanism. Sludge wasting is also accomplished during this phase
(p) Cyclic activated-sludge system (CAAS™)  	The CAAS process uses three baffled zones in an approximate volumetric proportion of 1:2:20, and mixed liquor is recycled from Zone 3 to Zone 1. Nitrification occurs because of the long SRTs used. Nitrate reduction is claimed to occur at significant levels in the sludge blanket during the settle and decant periods, as well as in the aeration period by operation at low DO concentrations. As in the ICEAS process, the influent wastewater is fed continuously while the effluent is removed on a batch basis

Table 8–16
Typical design parameters for commonly used activated-sludge processes[a]

Process name	Type of reactor	SRT, d	F/M kg BOD/kg MLVSS·d	Volumetric loading		MLSS, mg/L	Total τ, h	RAS, % of influent[e]
				lb BOD/ 1000 ft³·d	kg BOD/ m³·d			
High-rate aeration	Plug flow	0.5–2	1.5–2.0	75–150	1.2–2.4	200–1000	1.5–3	100–150
Contact stabilization	Plug flow	5–10	0.2–0.6	60–75	1.0–1.3	1000–3000[b] 6000–10000[c]	0.5–1[b] 2–4[c]	50–150
High-purity oxygen	Plug flow	1–4	0.5–1.0	80–200	1.3–3.2	2000–5000	1–3	25–50
Conventional plug flow	Plug flow	3–15	0.2–0.4	20–40	0 3–0.7	1000–3000	4–8	25–75[f]
Step feed	Plug flow	3–15	0.2–0.4	40–60	0.7–1.0	1500–4000	3–5	25–75
Complete mix	CMAS	3–15	0.2–0.6	20–100	0.3–1.6	1500–4000	3–5	25–100[f]
Extended aeration	Plug flow	20–40	0.04–0.10	5–15	0.1–0.3	2000–5000	20–30	50–150

Table 8-17
Advantages and limitations of activated-sludge processes for BOD removal and nitrification

Process	Advantages	Limitations
Complete mix	Common, proven process Adaptable to many types of wastewater Large dilution capacity for shock and toxic loads Uniform oxygen demand Design is relatively uncomplicated Suitable for all types of aeration equipment	Susceptible to filamentous sludge bulking
Conventional plug flow	Proven process May achieve a somewhat higher level of ammonia removal than the complete-mix process Adaptable to many operating schemes including step-feed, selector design, and anoxic/aerobic processes	Design and operation for tapered aeration is more complex May be difficult to match oxygen supply to oxygen demand in first pass
High rate	Requires less aeration tank volume than conventional plug flow Uses less aeration energy	Less stable operation; produces lower-quality effluent Not suitable for nitrification Sludge production is higher High peak flows can disrupt operation by washing out MLSS
Contact stabilization	Requires smaller aeration volume Handles wet-weather flows without loss of MLSS	Has little or no nitrification capability Operation somewhat more complex
Step feed	Distributes load to provide more uniform oxygen demand Peak wet-weather flows can be bypassed to the last pass to minimize high clarifier solids loading Flexible operation Adaptable to many operating schemes including anoxic/aerobic processes	More complex operation Flow split is not usually measured or known accurately More complicated design for process and aeration system
Extended aeration	High-quality effluent possible Relatively uncomplicated design and operation Capable of treating shock/toxic loads Well-stabilized sludge; low biosolids production	Aeration energy use is high Relatively large aeration tanks Adaptable mostly to small plants
High-purity oxygen	Requires relatively small aeration tank volume Emits less VOC and off-gas volume Generally produces good settling sludge Operation and DO control are relatively uncomplicated Adaptable to many types of wastewater	Limited capability for nitrification More complex equipment to install, operate, and maintain *Nocardia* foaming High peak flows can disrupt operation by washing out MLSS

(continued)

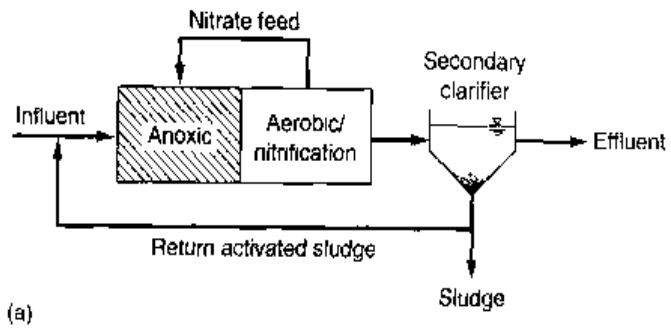
Table 8–17 (*Continued*)

Process	Advantages	Limitations
Oxidation ditch	Highly reliable process; simple operation	Large structure, greater space requirement
	Capable of treating shock/toxic loads without affecting effluent quality	Low F/M bulking is possible
	Economical process for small plants	Some oxidation ditch process modifications are proprietary and license fees may be required
	Uses less energy than extended aeration	Requires more aeration energy than conventional CMAS and plug-flow treatment
	Adaptable to nutrient removal	Plant capacity expansion is more difficult
	High-quality effluent possible	
	Well-stabilized sludge; low biosolids production	
Sequencing batch reactor	Process is simplified; final clarifiers and RAS pumping are not required	Process control more complicated
	Compact facility	High peak flows can disrupt operation unless accounted for in design
	Operation is flexible; nutrient removal can be accomplished by operational changes	Batch discharge may require equalization prior to filtration and disinfection
	Can be operated as a selector process to minimize sludge bulking potential	Higher maintenance skills required for instruments, monitoring devices, and automatic valves
	Quiescent settling enhances solids separation (low effluent SS)	Some designs use less efficient aeration devices
	Applicable for a variety of plant sizes	
Countercurrent aeration	High-quality effluent possible	Fine screening is required to prevent diffuser fouling
	Oxygen transfer efficiencies are higher than conventional aeration systems	Process is proprietary
	Well-stabilized sludge; low biosolids production	Significant downtime of aeration unit for maintenance will affect plant performance
	Process design can be modified to accommodate nutrient removal	Good operator skills required

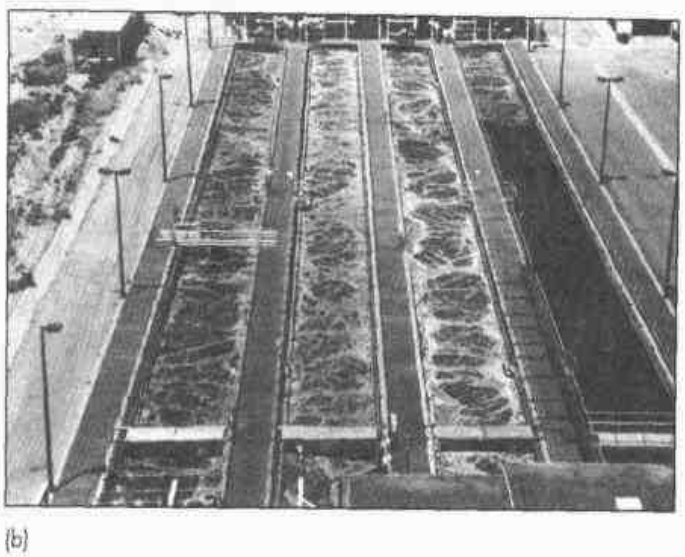
8–5 PROCESSES FOR BIOLOGICAL NITROGEN REMOVAL

Nitrogen removal is often required before discharging treated wastewater to sensitive water bodies (to prevent eutrophication), or for groundwater recharge or other reuse applications. Nitrogen removal can be either an integral part of the biological treatment system or an add-on process to an existing treatment plant. The purpose of this section, as in the previous section, is to illustrate in detail the design procedure for processes used to remove the nitrogen from wastewater biologically. However, before considering the design examples, it is appropriate to present an overview of the biological nitrogen-removal process and design issues for the anoxic/aerobic process. Following the discussion of design issues, design examples are provided for (1) the anoxic/aerobic process, (2) step-feed anoxic/aerobic process, (3) intermittent aeration, (4) a sequencing batch reactor, and (5) postanoxic denitrification with methanol addition. Descriptions and flow

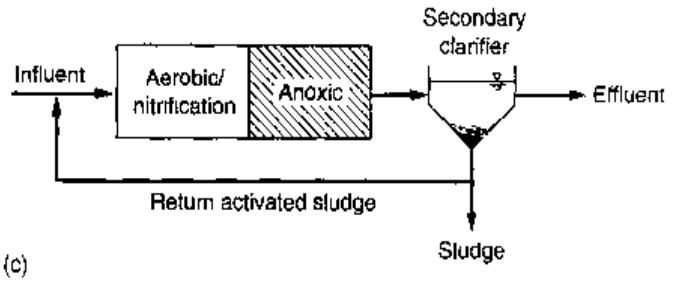
diagrams for several alternative processes for nitrogen removal, typical process design parameters, and process selection considerations are presented following the design examples.



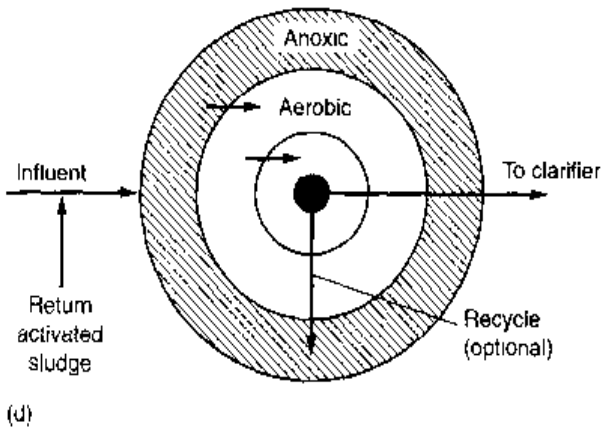
Overview of Biological Nitrogen-Removal Processes



All of the biological nitrogen-removal processes include an aerobic zone in which biological nitrification occurs. Some anoxic volume or time must also be included to provide biological denitrification to complete the objective of total nitrogen removal by both NH_4-N oxidation and NO_3-N and NO_2-N reduction to nitrogen gas. As discussed in Sec. 7–10 in Chap. 7, nitrate reduction requires an electron donor, which can be supplied in the form of influent wastewater BOD, by endogenous respiration, or an external carbon source.

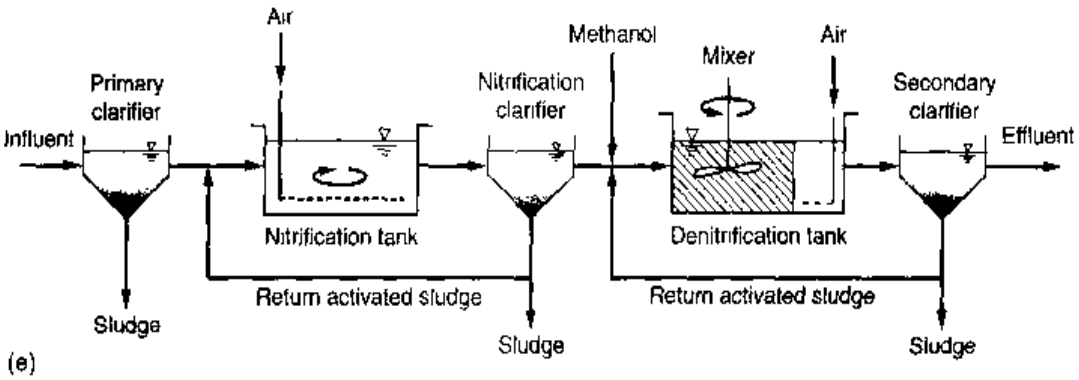


The types of suspended growth biological nitrogen-removal processes can be categorized as (1) single-sludge or (2) two-sludge. The term "single-sludge" means only one solids separation device (normally a secondary clarifier) is used in the process (see Fig. 8–21*a*, *c*, and *d*). The activated-sludge tank may be divided into different zones of anoxic and aerobic conditions and mixed liquor may be pumped from one zone to another (internal recycle), but the liquid-solids separation occurs only once. In the two-sludge system, the most common system consists of an aerobic process (for nitrification) followed by an anoxic process (for denitrification), each with its own clarifier, thus producing two sludges (see Fig. 8–21*e*). For postanoxic denitrification, an organic substrate, usually methanol, must be added to create a biological demand for the nitrate. Because single-sludge systems are used more often, they are discussed in more detail in the following paragraphs. The two-sludge system is discussed briefly later in this section.



Single-Sludge Biological Nitrogen-Removal Processes

The single-sludge biological nitrogen-removal processes are grouped according to whether the anoxic zone is located before, after, or within the aerobic nitrification zone. These three possibilities, illustrated on Fig. 8–21*a*, *c*, and *d*, are termed (1) preanoxic, where initial contact of the wastewater and return activated sludge is in an anoxic zone; (2) postanoxic, where the anoxic zone follows the aerobic zone; or (3) simultaneous nitrification-denitrification (SNdN) processes where both nitrification and denitrification occur in the same tank. In the preanoxic configuration (see Fig. 8–21*a*), nitrate produced in the aerobic zone is recycled to the preanoxic compartment. The rate of denitrification is affected by the rbCOD concentration in the influent wastewater, the MLSS concentration, and temperature. Postanoxic designs (Fig. 8–21*c*) may be operated with or without an exogenous carbon source. Without an exogenous source, postanoxic processes depend on the endogenous respiration of the activated sludge to provide electron donor for nitrate consumption in lieu of oxygen. The denitrification rate is much slower, by a factor of 3 to 8, compared to preanoxic applications that use influent wastewater BOD for the electron donor. A long detention time would be required in this type of postanoxic tank to achieve high nitrate-removal efficiency. Single-tank designs have also been used in which nitrification and denitrification occur simultaneously. The simultaneous nitrification-denitrification (SNdN) applications require DO control or other types of control methods to assure that both nitrification and denitrification occur in a single tank.



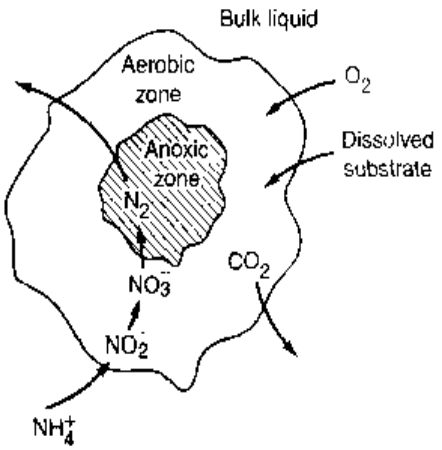


Figure 8–21

Schematic diagrams of four basic nitrogen-removal process configurations and a view of a typical reactor: (*a*) preanoxic, (*b*) view of plug-flow activated-sludge reactor used for nitrogen removal (the right-hand channel without aeration is the preanoxic section), (*c*) postanoxic, (*d*) simultaneous nitrification/denitrification, and (*e*) two stage nitrification-denitrification (also known as two-sludge).

Figure 8-22

Diagram of an activated-sludge particle showing aerobic and anoxic zones.

A significant amount of nitrogen removal has been observed in single-sludge activated-sludge systems without distinctive separate anoxic zones. Van Huyssteen et al. (1990) reported significant nitrogen loss in a nitrification aeration basin mixed and aerated by surface mechanical aerators. Significant nitrogen loss can occur in reactors, such as the oxidation ditch or similar process (see Fig. 8–21*d*) that have long hydraulic retention times. The combination of both nitrification and denitrification may be explained by two possible mechanisms.

First, regions of low DO or zero DO concentration may be present within the basin as a function of the mixing regime. Van Huyssteen et al. (1990) opined that as the mixed liquor traveled away from the surface mechanical aerators, the DO was depleted, creating conditions more favorable for anoxic reactions. Second, activated-sludge floc can contain both aerobic and anoxic zones, as illustrated in a simplified view of a biological floc on Fig. 8–22. Dissolved oxygen and dissolved substrates outside of the floc diffuse into the aerobic zone, and, depending on the DO concentration and concentrations of ammonia and bCOD, oxygen may be depleted at significant rates within the floc so that the DO cannot penetrate the entire floc depth. Nitrate produced by nitrification in the aerobic zone can diffuse into the inner anoxic zone along with substrate so that denitrification occurs within the floc depth. The existence of anoxic zones within the biological floc has been supported by Stenstrom and Song (1991), in which they showed that nitrification rates were related not only to bulk liquid DO concentration but also to the amount of BOD present. At higher soluble BOD concentrations, higher oxygen uptake rates occurred, and lower nitrification rates were observed for the same bulk liquid DO concentration, suggesting that the aerobic zone of the activated-sludge floc was decreased.

Nitrification and denitrification rates should both be at less than optimal levels for simultaneous nitrification/denitrification (SNdN) processes. Only a portion of the biomass is used for each of these reactions. In addition, the nitrification rate is lower due to the low DO concentration, and the denitrification rate is lower due to substrate consumption in the aerobic portion of the floc. However, systems with very long detention times, such as oxidation ditches, have sufficient volume to accommodate lower rates for both nitrification and denitrification.

Of the three basic process configurations, the preanoxic nitrification/denitrification process (Fig. 8–21*a*) is used most often because of (1) the relative ease of retrofit to

existing plants, (2) the benefits of the selector operation for control of bulking sludge, (3) the production of alkalinity before the nitrification step, and (4) the ability to convert an existing biological treatment system to nitrogen removal with relatively short to moderate basin detention times. Most of the nitrogen-removal processes can incorporate biological phosphorus removal, as discussed in Sec. 8–6. Design issues and design examples for commonly used biological nitrogen-removal processes are presented below. The fundamental design concepts that are exemplified can be of use in evaluating other types of suspended growth biological nitrogen-removal processes.

Process Design Considerations

In Sec. 8–4, the process design was based on the fundamental principles presented in Chap. 7 and Secs. 8–2 and 8–3 for BOD removal and nitrification. In this section, an additional treatment step is considered, i.e., denitrification, and information is presented that is specific to the nitrogen-removal process.

Anoxic/Aerobic Reactor Design Considerations. In the anoxic/aerobic process (Fig. 8–21*a*) nitrate is fed to the anoxic reactor from nitrate in the return activated-sludge flow and by pumping mixed liquor from the aerobic zone. In step-feed anoxic/aerobic processes, nitrate will be fed to the anoxic zone by flow of mixed liquor from a previous nitrification step. The electron donor is provided by the influent wastewater fed to these preanoxic zones. Key design parameters that affect the amount of nitrogen removed are (1) anoxic zone detention time, (2) mixed-liquor volatile suspended solids (MLVSS) concentration, (3) internal recycle rate and return sludge flow, (4) influent BOD or biodegradable COD (bCOD) concentration, (5) the readily biodegradable COD (rbCOD) fraction, and (6) temperature (Randall et al., 1992). The influent rbCOD concentration has a significant effect on the denitrification rate in the anoxic zone. Wastewaters with the same influent bCOD, but with a higher fraction of rbCOD, will undergo higher denitrification rates in the anoxic zone. Anoxic zones have been designed as single-stage or a series of complete mix tanks with equal or different detention times. Typical power requirements for mechanical mixing in the anoxic zone range from 8 to 13 kW/10^3 m^3 (0.3 to 0.5 hp/10^3 ft^3).

Two design approaches are used to design the anoxic zone volume and to determine the amount of nitrogen removal. One is a desktop design approach that employs mass balances for nitrogen and a commonly used design parameter, the specific denitrification rate (SDNR) in g NO_3-N reduced/g MLVSS·d. More recently, comprehensive mechanistic simulation models have been developed that can relate denitrification rates to fundamental biokinetics, wastewater characteristics, activated-sludge tank volumes and configurations, and SRT.

Most simulation models are based on the ASM1 model developed by a committee under the International Association of Water Pollution Research Control (IAWPRC). The ASM1 model is now referred to as the IWA (International Water Association) model to account for the organization name change. The model is developed around a basic activated-sludge model that can be used to describe biomass growth rates, and follows the fate of degradable COD and nitrogen (in both soluble and particulate forms) for systems that have both aerobic and anoxic treatment zones (Grady et al., 1986).

An ASM2 version of the model incorporates biological phosphorus removal as well as nitrogen removal (Barker and Dold, 1997). In these models, nitrate is consumed by

heterotrophic biomass under anoxic conditions during the consumption of either rbCOD or short-chain volatile fatty acids. The rbCOD substrate consumed in the anoxic reactor is from the influent wastewater plus that produced in the reactor by hydrolysis of influent pCOD and released biomass material due to cell lyses. A general description of the ASM1 model is included in Sec. 8–10.

Anoxic Tank Design Using the Specific Denitrification Rate. The desktop design approach is based on using a specific denitrification rate (SDNR), which is the nitrate reduction rate in the anoxic tank normalized to the MLSS concentration. The amount of nitrate removed in the anoxic tank is described by Eq. (8–41).

$$NO_r = (V_{nox})(SDNR)(MLVSS) \tag{8-41}$$

where NO_r = nitrate removed, g/d
V_{nox} = anoxic tank volume, m^3
SDNR = specific denitrification rate, g NO_3-N /g MLVSS·d
MLVSS = mixed liquor volatile suspended solids concentration, mg/L

Values of SDNR observed for preanoxic tanks in full-scale installations have ranged from 0.04 to 0.42 g NO_3-N/g MLVSS·d (Burdick et al., 1982; Henze, 1991; Bradstreet and Johnson, 1994; Reardon et al., 1996; Hong et al., 1997; and Murakami and Babcock, 1998). For postanoxic denitrification without an exogenous carbon source, observed SDNRs have ranged from 0.01 to 0.04 g N/g MLVSS·d.

Based on observed denitrification rates in pilot-plant and full-scale plants, empirical relationships have been developed that relate SDNR to the BOD or COD F/M ratio for the preanoxic tank (U.S. EPA, 1993). One commonly used relationship is described as (Burdick et al., 1982; U.S. EPA, 1993)

$$SDNR = 0.03(F/M) + 0.029 \tag{8-42}$$

where F/M = g BOD applied/g MLVSS·d in the anoxic tank

The above relationship was based on data collected for anoxic/aerobic processes at mixed-liquor temperatures in the range of 20 to 25°C. A conservative SDNR estimate can be made using Eq. (8–42) because the MLVSS in the systems evaluated contained a relatively low active biomass fraction and the wastewater had a relatively low rbCOD concentration. Such empirical relationships as described above are limited in application because the SDNR depends on a number of factors that are site- and design-specific, including the fraction of active biomass in the mixed liquor, rbCOD concentration in the anoxic zone, and temperature. The above factors are affected by the size of the anoxic zone, influent wastewater rbCOD and nbVSS concentrations, and design SRT. Thus, these empirical relationships can provide only a rough estimate of the SDNR.

Design SDNR values at 20°C are presented on Fig. 8–23. The values are generally applicable and can be used for wastewaters with different fractions of rbCOD (rbCOD/bCOD) and inert nonbiodegradable volatile solids. On Fig. 8–23, the F/M_b ratio and $SDNR_b$ values are based only on the active heterotrophic biomass concentration in the mixed liquor, so that the rates can be applicable to many situations regardless of the amount of nondegradable solids in the mixed liquor and the SRT. The F/M_b

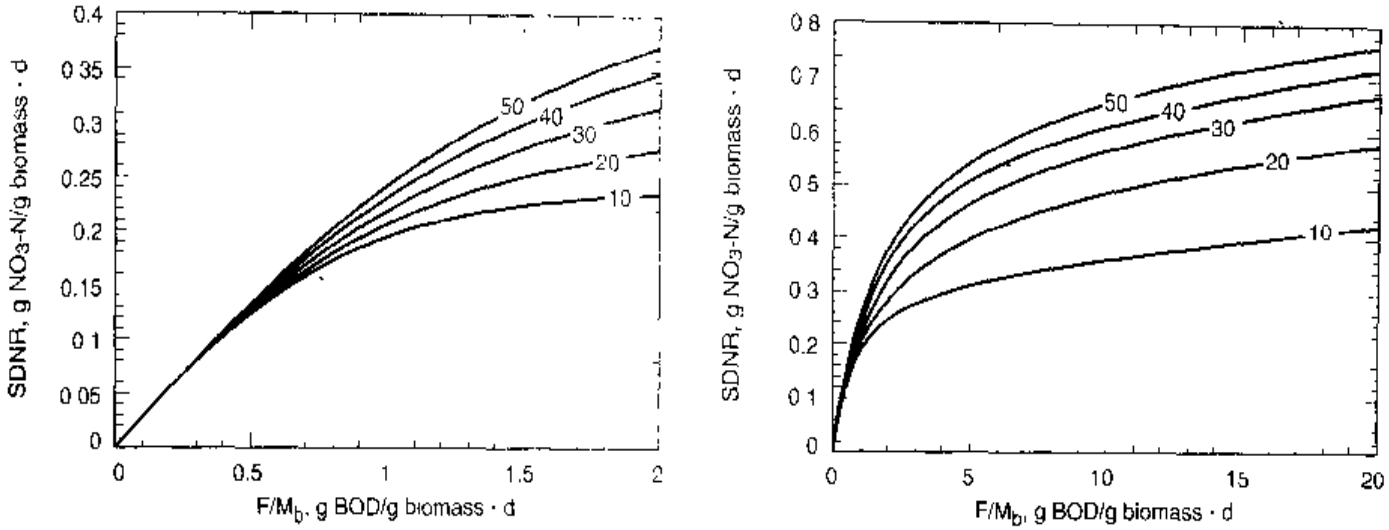

Figure 8–23

Plot of specific denitrification rates ($SDNR_b$) based on biomass concentration at 20°C versus food to biomass (F/M_b) ratio for various percentages of rbCOD relative to the biodegradable COD of the influent wastewater.

ratio is defined as a function of the BOD loading to the anoxic volume and active heterotrophic biomass concentration, as follows:

$$F/M_b = \frac{QS_o}{(V_{anx})X_b} \tag{8-43}$$

where F/M_b = BOD F/M ratio based on active biomass concentration, g BOD/g biomass·d
Q = influent flowrate, m^3/d
S_o = influent BOD concentration, mg/L
V_{anx} = anoxic volume, m^3
X_b = anoxic zone biomass concentration, mg/L

The curves shown on Fig. 8-23 are based on the results of model simulations of biomass, NO_3-N, rbCOD, and pbCOD mass balances in the anoxic tank. For lower anoxic τ values, the F/M_b is higher, which resulted in greater rbCOD concentrations in the anoxic zone and thus a higher biological reaction rate and SDNR. Internal recycle rates from the aerobic zone and temperature effects were accounted for. The biokinetic coefficients used in the model simulation are summarized in Table 8–18 and are model parameter default values from the ASM1 model (Grady et al., 1986) along with the rbCOD kinetics under anoxic conditions observed by Stensel and Horne (2000) from testing at different municipal wastewater-treatment facilities. The design procedure using $SDNR_b$ values from Fig. 8–23 requires calculating the active biomass VSS concentration in the mixed liquor using the procedure presented previously in Example 8–2. By using the calculated biomass concentration, the effects of SRT are accounted for in the design procedure. The BOD F/M_b ratio on Fig. 8–23 is also based on the active biomass VSS concentration.

Table 8-18
Biokinetic coefficient values used in model simulation to develop $SDNR_b$ design curves

Kinetic coefficient parameter	Unit	Value
Yield, Y	g VSS/g COD	0.40
Endogenous decay, k_d	g VSS/g biomass·d	0.15
Cell debris, f_d	g VSS/g VSS	0.10
Maximum specific growth rate, μ_m	g VSS/g VSS·d	3.2
Half-velocity, K_s	g/m^3	9.0
Particulate hydrolysis maximum specific rate constant, K_h	g VSS/g biomass·d	2.8
Hydrolysis half-velocity constant, K_x	g VSS/g VSS	0.15
COD of biomass	g COD/g VSS	1.42
Fraction of denitrifying bacteria, η	g VSS/g VSS	0.50

For multiple-staged anoxic reactors, the F/M_b ratio [Eq. (8–43)] is calculated using the volume of the stage for which the SDNR is calculated plus the volume of the previous stage(s). At high F/M_b ratios shown on Fig. 8–23, the SDNR reaches a maximum saturated rate, as the rbCOD concentration will be very high in the anoxic reactor. The maximum saturation rate will only be experienced for high F/M_b anoxic selector designs where the first anoxic zones have detention times of less than 10 to 20 min. For long anoxic detention times (in the order of 3 to 6 h), $SDNR_b$ values will be found at the lower F/M_b ratios.

The design procedure requires correcting the SDNR values from Fig. 8–23 for temperature and internal recycle ratios. The temperature correction is made by using the following expression:

$$SDNR_T = SDNR_{20}\theta^{T-20} \tag{8-44}$$

where θ = temperature coefficient (1.026)
T = temperature, °C

The SDNR in the preanoxic tank is affected by the internal recycle rate, often defined as an internal recycle (IR) ratio. The IR ratio is the recycle flowrate divided by the influent wastewater flowrate. At higher IR ratios, the influent rbCOD is diluted more in the anoxic reactor by mixed liquor from the aerobic reactor, resulting in a lower denitrification rate. The corrections to the SDNR for designs with internal recycle corrections greater than 1.0 are shown below. The SDNR value can be interpolated from the values listed. If the F/M is less than or equal to 1.0, no correction is required.

$$\text{IR} = 2 \qquad SNDR_{adj} = SDNR_{IR1} - 0.0166 \ln (F/M_b) - 0.0078 \tag{8-45}$$

$$\text{IR} = 3\text{–}4 \qquad SDNR_{adj} = SDNR_{IR1} - 0.029 \ln (F/M_b) - 0.012 \tag{8-46}$$

where $SDNR_{adj}$ = SDNR adjusted for the effect of internal recycle
$SDNR_{IR1}$ = SDNR value at internal recycle ratio = 1
F/M_b = BOD F/M ratio based on anoxic zone volume and active biomass concentration, g/g·d

Anoxic/Aerobic Process Design Procedure. The design procedure for an anoxic/aerobic process is presented in Table 8–19. The influent wastewater rbCOD fraction is a critical design parameter. and if unknown, a conservative value in the range of 15 to 25 percent of the total bCOD can be used. After defining the wastewater characteristics, the initial design step requires designing the aerobic reactor for nitrification similar to the procedure illustrated in Sec. 8–4. The aerobic volume is based on using an aerobic SRT for nitrification, and only the aerobic basin volume and mixed liquor are used to compute the sludge wasting for that SRT. The total process SRT will be longer when the mixed liquor and the volume of the anoxic reactor are included. The aeration oxygen requirement will be less than that for the nitrification-only design as nitrate will be used to consume some of the influent bCOD in the preanoxic zone.

A mass balance on nitrogen must be done to determine (1) how much nitrate is produced in the aeration zone. and (2) what the internal recycle ratio must be to meet the desired effluent nitrate concentration. The mass balance accounts for the nitrate produced in the aerobic zone. The amount of nitrate produced in the aerobic zone is based on the influent flowrate and nitrogen concentration, the amount consumed for cell synthesis,

Table 8–19
Computation approach for anoxic/aerobic process design

1. Establish wastewater flowrates and characteristics, including the rbCOD concentration, and effluent requirements
2. Follow the procedure outlined in Table 8–12 for the aerobic zone for a nitrification process with the exception that Steps 13–18 are done after the anoxic reactor design
3. Determine the biomass concentration in the mixed liquor from the nitrification design
4. Determine the internal recycle (IR) ratio, using the NO_x value determined in Step 9 of the nitrification design and desired effluent NO_3-N concentration
5. Calculate the amount of nitrate fed to the anoxic tank. The design is based on the assumption that essentially all of the nitrate fed to the anoxic zone will be reduced. A low nitrate concentration of 0.1 to 0.3 mg/L may remain, depending on the design, because the nitrate limits the denitrification reaction rate at only very low concentrations
6. Select the anoxic volume and configuration; single-stage or multiple-stage reactors
7. Calculate the F/M_b based on the biomass concentration determined for the mixed liquor in the nitrification design
8. Use Fig. 8–23 and appropriate corrections for temperature and IR ratio to obtain the $SDNR_b$ for the anoxic basin(s)
9. Using the $SDNR_b$ biomass concentration, and anoxic volume, compute the amount of nitrate removed in the anoxic basin(s). Compare the amount of removal required to remove all of the nitrate in the recycle streams fed to the anoxic zone
10. Repeat the anoxic zone design steps as necessary to obtain a satisfactory design
11. Calculate the oxygen demand
12. Determine if alkalinity addition is needed
13. Design the secondary clarifier
14. Design the aeration oxygen transfer system
15. Summarize the final effluent quality
16. Prepare a design summary table

and the effluent NH_3-N and soluble organic nitrogen concentrations. As a conservative design approach, all of the influent TKN is assumed to be biodegradable and the effluent soluble organic nitrogen concentration is ignored. The nitrate produced is contained in the total flow leaving the aerobic zone, which includes internal recycle, RAS, and effluent flows. The mass balance is expressed as

kg/d of nitrate produced in aerobic zone = nitrate in effluent + nitrate in internal recycle + nitrate in return activated sludge (RAS)

$$Q\,NO_x = N_e(Q + IR\,Q + R\,Q) \tag{8-47}$$

$$IR = \frac{NO_x}{N_e} - 1.0 - R \tag{8-48}$$

where IR = internal recycle ratio (internal recycle flowrate/influent flowrate)
R = RAS recycle ratio (RAS flowrate/influent flowrate)
NO_x = nitrate produced in aeration zone as a concentration relative to influent flow, mg NO_3-N/L
N_e = effluent NO_3-N concentration, mg/L

The effect of the IR ratio on the effluent NO_3-N concentration for a given amount of nitrate produced (NO_x) and for a RAS recycle ratio of 0.50 is illustrated on Fig. 8–24. A greater IR ratio is needed to produce the same effluent NO_3-N concentration when more NO_x is produced in the aerobic zone. To meet a standard of 10 mg TN/L or less, a design effluent NO_3-N concentration of 5 to 7 mg/L should be used. (Note: Selection of design values based on the variability in wastewater treatment plant performance is discussed in Chap. 15.) An internal recycle ratio in the range of 3 to 4 is typical, but ratios in the range of 2 to 3 are also applied for wastewaters with a lower influent wastewater TKN concentration. Recycle ratios above 4 are generally not warranted, as the incremental removal of NO_3-N is low and more DO is recycled from the aeration zone into the anoxic zone.

The amount of DO fed to the anoxic zone due to the internal recycle flow from the aerobic zone must be minimized because the oxygen will consume rbCOD, leaving less

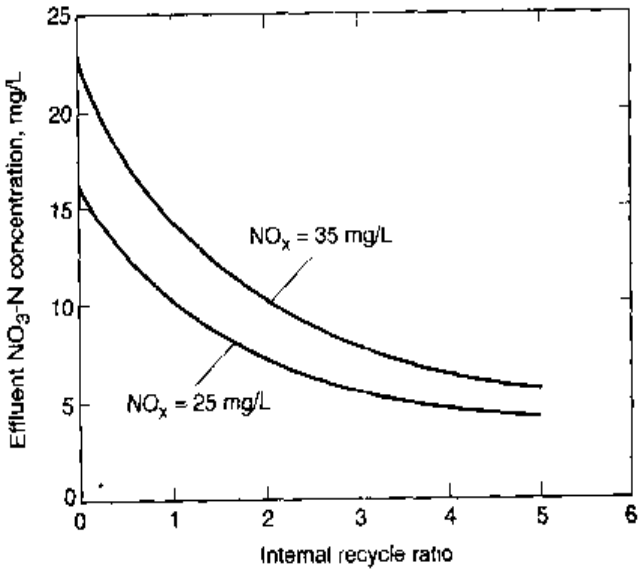

Figure 8–24
Effect of internal recirculation rate on effluent nitrate concentration (RAS ratio = 0.5) for an anoxic/aerobic process.

available for NO_3 reduction. In some designs, sections of the aerobic zone are baffled with DO control so that the DO concentration in the recycle can be controlled and minimized. Care must also be taken to ensure that the influent wastewater is not overly aerated when passing through the plant en route to the anoxic tank.

Single-Sludge Simultaneous Nitrification Denitrification (SNdN) Processes. Both high levels of nitrification and denitrification have been reported for oxidation ditch systems operated with low DO concentrations (0.10 to 0.40 mg/L) and with relatively long τ and SRT values (Rittman and Langeland, 1985; Trivedi and Heinen, 2000). The low DO concentration will result in lower nitrification rates, as the activated-sludge floc will be only partially aerobic. Thus, only a portion of the nitrifying bacteria contained in the floc will be active. In addition, as shown in Chap. 7, nitrification rates are lower at low DO concentrations. Denitrification occurs in the anoxic zones established within the floc particles due to oxygen depletion, with the result that simultaneous nitrification and denitrification takes place. The nitrification and denitrification rates are a function of the reaction kinetics, floc size, floc density, floc structure, rbCOD loading, and bulk liquid DO concentration. Because of the complex physical factors, the nitrification and denitrification rates cannot be predicted accurately with present models. Basic modifications to the Monod growth model, however, can be used to estimate the effects of a low DO concentration on nitrification and denitrification rates and system performance.

Nitrification specific growth rates are shown as a function of DO concentration as described in Eq. (7–93) (see also Table 8–5 for definition of terms):

$$\mu_n = \left(\frac{\mu_{nm} N}{K_N + N}\right)\left(\frac{\text{DO}}{K_o + \text{DO}}\right) - k_{dn} \qquad (7\text{–}93)$$

As the nitrification SRT is the inverse of the specific growth rate μ_n, Eq. (7–93) can be used to calculate required design SRT values as a function of NH_4-N and DO concentrations for a CMAS system. The effect of DO concentration on the design SRT is shown on Fig. 8–25 for an effluent NH_4-N concentration of 1.0 mg/L at 20°C using the kinetic coefficient values for nitrification given in Table 8–11. No safety factor is used for these

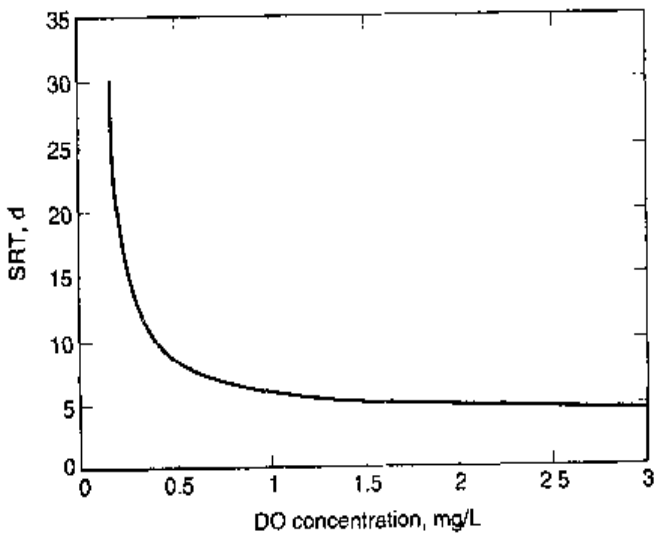

Figure 8–25
Effect of DO concentration on SRT required to achieve effluent NH_4-N concentration of 1.0 mg/L at 20°C in a CMAS system based on kinetic coefficients in Table 8–11 and K_o = 0.5 mg/L.

calculations. The actual SRT value used for design would be higher depending on the safety factor selected for a specific system. The nitrification rate at 0.2 mg/L DO concentration is 24 percent of the rate at a 2.0 mg/L concentration based on the calculated SRT values of 19.9 and 4.7 d, respectively.

With many oxidation ditch systems operated at SRT values of 20 to 30 d, the ability to produce complete nitrification at low DO is apparent. The exact nitrification rate at low DO concentrations is site-specific, and determines the K_o value that can be used in Eq. (7–93) to describe the reaction.

The rate of nitrate reduction can be related to the rate of substrate utilization given by Eq. (7–110) (also see Table 8–5 for definition of terms) as follows:

$$r_{su} = -\left(\frac{kXS}{K_s + S}\right)\left(\frac{NO_3}{K_{s,NO_3} + NO_3}\right)\left(\frac{K'_o}{K'_o + DO}\right)(\eta) \qquad (7\text{–}110)$$

The nitrate utilization rate can be related to the substrate utilization rate shown in Eq. (7–110) by the following procedure that first relates it to an oxygen utilization rate. The oxygen utilization rate (r_o) is derived from Eq.(7–59) by dividing the equation by the reactor volume. The oxygen utilization rate is the difference between the substrate utilization rate and the biomass growth rate on a COD basis as follows:

$$r_o = -r_{su} - 1.42r_g \qquad (8\text{–}49)$$

Substituting Eq. (7–21) for r_g in Eq. (8–49) yields

$$r_o = -(1 - 1.42Y)r_{su} + 1.42k_dX \qquad (8\text{–}50)$$

where r_o = oxygen utilization rate, g/m^3·d
r_{su} = substrate utilization rate, g/m^3·d
r_g = net biomass growth rate, g/m^3·d

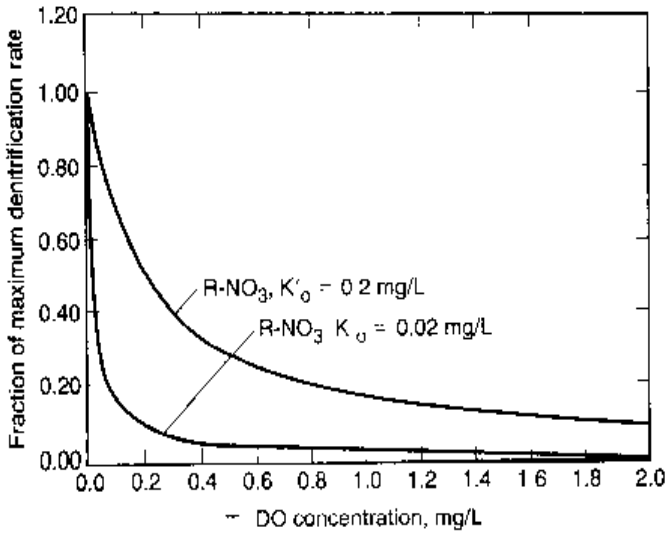
Using 2.86 g O_2 equivalent/g NO_3-N [from Eqs. (7–98) and (7–99)], the nitrate reduction rate (r_{NO_3}) is

$$r_{NO_3} = r_o/2.86 \qquad (8\text{–}51)$$

where r_{NO_3} = NO_3-N reduction rate, g/m^3·d

By accounting for the fraction of biomass that can use nitrate (η), r_{NO_3} is

$$r_{NO_3} = -\left(\frac{1 - 1.42Y}{2.86}\right)r_{su} + \left(\frac{1.42}{2.86}\right)k_dX\eta \qquad (8\text{–}52)$$



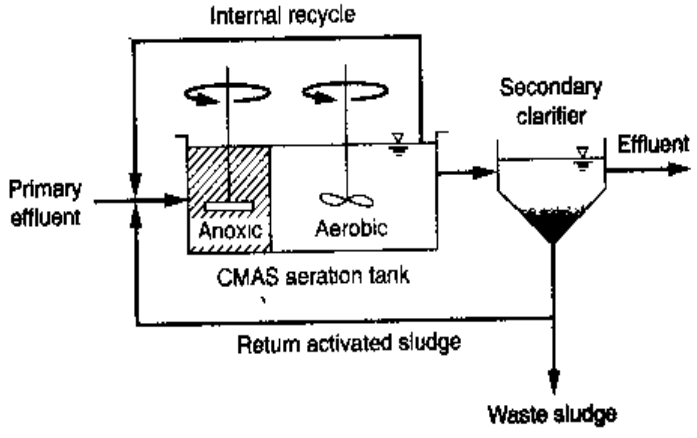
Substituting Eq. (7–110) into Eq. (8–52) to account for the effect of the nitrate and DO concentration on substrate utilization under denitrifying conditions yields

$$r_{NO_3} = \left(\frac{1 - 1.42Y}{2.86}\right)\left(\frac{kXS}{K_s + S}\right)\left(\frac{NO_3}{K_{s,NO_3} + NO_3}\right)\left(\frac{K'_o}{K'_o + DO}\right)(\eta) + \left(\frac{NO_3}{K_{s,NO_3} + NO_3}\right)\left(\frac{K'_o}{K'_o + DO}\right)\left(\frac{1.42}{2.86}\right)k_dX\eta \qquad (8\text{–}53)$$

Equation (8–53) is a general expression for the rate of nitrate reduction in an anoxic reactor. The nitrate reduction rate as shown by Eq. (8–53) is a function of the rbCOD,

Figure 8–26

Effect of mixed-liquor DO concentration on maximum denitrification rates (R-NO_3).



NO_3-N, DO, and biomass concentrations, as well as the various biokinetic coefficients. The DO inhibition coefficient K_o' is difficult to estimate and will be site-specific depending on the floc size and structure. The effect of DO concentration on the denitrification rate is shown on Fig. 8–26 for K_o' values of 0.02 and 0.2 mg/L. At a DO concentration of 0.2 mg/L, the denitrification rate may be 10 to 50 percent of its maximum rate. For long SRT systems with τ values in the range of 18 to 30 h, sufficient time may be available for high nitrate-removal efficiency, even though the rate is somewhat inhibited by having DO present at low concentrations.

Anoxic/Aerobic Process Design

An example of an anoxic/aerobic activated-sludge process using a complete-mix reactor for nitrogen removal is presented in Example 8–5.

EXAMPLE 8–5 Anoxic/Aerobic Process Design Design a preanoxic basin for the CMAS nitrification system process described in Example 8–2 to produce an effluent NO_3-N concentration of 6.0 g/m^3. A process schematic flow diagram is shown below. The design condition is based on the following information from Example 8–2.

Wastewater characteristics:

Constituent	Concentration, g/m³
BOD	140
bCOD	224
rbCOD	80
NO_x	28.3
TP	6
Alkalinity	140 as $CaCO_3$

Design conditions:

Parameter	Unit	Value
Influent flowrate	m³/d	22,464
Temperature	°C	12
MLSS	g/m³	3000
MLVSS	g/m³	2370
Aerobic SRT	d	12.5
Aeration basin volume	m³	8466
Mixing energy	kW/10³ m³	10
RAS ratio	Unitless	0.6
R_o	kg/h	255

Note: g/m³ = mg/L.

Assumptions:

1. Nitrate concentration in RAS = 6 g/m³.
2. Use the same coefficients as the nitrification process design.
3. Mixing energy for anoxic reactor = 10 kW/10³ m³.

Solution

1. Determine the active biomass concentration using Eq. (7–43) and substituting V/Q for τ.

$$X_b = \left[\frac{Q(\text{SRT})}{V}\right]\left[\frac{Y(S_o - S)}{1 + (k_d)\text{SRT}}\right]$$

where $S_o - S \approx S_o$

$$X_b = \frac{(22{,}464\ \text{m}^3/\text{d})(12.5\ \text{d})(0.40\ \text{g VSS/g COD})(224\ \text{g bCOD/m}^3)}{[1 + (0.088\ \text{g/g·d})(12.5\ \text{d})](8466\ \text{m}^3)}$$

$$= 1415\ \text{g/m}^3$$

2. Determine the IR ratio using Eq. (8–48).

   Aerobic tank NO_3-N concentration $= N_e = 6.0\ g/m^3$

   $$IR = \frac{NO_x}{N_e} - 1.0 - R = \frac{(28.3\ g/m^3)}{(6\ g/m^3)} - 1.0 - 0.60 = 3.1$$

3. Determine the amount of NO_3-N fed to the anoxic tank.

   Flowrate to anoxic tank $= IR\,Q + RQ$

   $$= 3.1(22{,}464\ m^3/d) + 0.60(22{,}464\ m^3/d)$$

   $$= 83{,}117\ m^3/d$$

   NO_x feed $= (83{,}117\ m^3/d)(6.0\ g/m^3) = 498{,}700\ g/d$

4. Determine the anoxic volume.
   As a first approximation, use a detention time $= 2.5$ h

   $$\tau = \frac{2.5\ h}{(24\ h/d)} = 0.104\ d$$

   $$V_{nox} = \tau \times Q = 0.104\ d\ (22{,}464\ m^3/d) = 2336\ m^3$$

5. Determine F/M_b using Eq. (8–43).

   $$F/M_b = \frac{QS_o}{V_{nox}(X_b)} = \frac{(22{,}464\ m^3/d)(140\ g\ BOD/m^3)}{(2336\ m^3)(1415\ g/m^3)} = 0.95\ g/g{\cdot}d$$

6. Determine the SDNR using the curve with an F/M_b range of 0 to 2 given on Fig. 8–23.

   Fraction of rbCOD $=$ rbCOD/bCOD $= (80\ g/m^3)(224\ g/m^3) = 0.36 = 36\%$

   From Fig. 8–23, $SDNR_b = 0.22\ g/g{\cdot}d$ at 20°C

   Apply temperature correction using Eq. (8–44):

   $$SDNR_{12} = 0.22(1.026)^{12-20} = 0.18\ g/g{\cdot}d$$

7. Determine the amount of NO_3-N that can be reduced using Eq. (8–41).
   a. Check NO_x based on $\tau = 2.5$ h.

      $NO_x = (V_{nox})(SDNR)(MLVSS, biomass)$

      $= (2336\ m^3)(0.18\ g/g{\cdot}d)(1415\ g/m^3) = 592{,}206\ g/d$

      Comparing 592,206 g/d versus 498,700 g/d, there is about 20% excess nitrate-removal capacity. Thus, $t = 2.5$ h is acceptable but a lower detention time may be used.

b. Evaluate new value for τ.
Select new τ. If the same SDNR is used, $\tau = 2.5$ h/1.2 $\approx$ 2.0 h, but SDNR will be higher due to higher F/M ratio for smaller anoxic reactor. Therefore, try $\tau = 1.5$ h.

$$V_{nox} = (1.5 \text{ h}/24 \text{ h/d})(22{,}464 \text{ m}^3/\text{d}) = 1404 \text{ m}^3$$

$$\text{F/M}_b = \frac{QS_o}{V_{nox}(X_b)} = \frac{(22{,}464 \text{ m}^3/\text{d})(140 \text{ g BOD/m}^3)}{(1404 \text{ m}^3)(1415 \text{ g/m}^3)} = 1.58 \text{ g/g·d}$$

c. Determine new SDNR values.
Using Fig. 8–23, for SDNR at 20°C, rbCOD fraction = 0.36

$$\text{SDNR}_{20} = 0.31 \text{ g/g·d}$$

$$\text{SDNR}_{12} = 0.31(1.026)^{[12-20]} = 0.25 \text{ g/g·d}$$

d. Determine the amount of nitrate that can be reduced [Eq. (8–41)].

$$\text{NO}_r = (0.25 \text{ g/g·d})(1404 \text{ m}^3)(1415 \text{ g/m}^3) = 501{,}541 \text{ g/d}$$

Capacity ratio = 501,541/498,700 = 1.01; therefore, $\tau = 1.5$ h is acceptable.

e. Compare the computed value to conventional observed SDNR values, based on MLSS.

$$\text{SDNR (MLSS)} = (0.25)(X_b/X_T)$$
$$= (0.25)(1415/3000) = 0.12 \text{ g/g·d}$$

The computed value is in the range of reported SDNR values (0.04 to 0.42 g/g·d).

8. Go to nitrification step in design and determine net oxygen required.

R_o (without denitrification) = 255 kg/h (See Step 17, Example 8–2)

The amount of oxygen supplied by nitrate reduction is as follows:

$$\text{Oxygen credit} = \left(\frac{2.86 \text{ g O}_2}{\text{g NO}_3\text{-N}}\right)[(28.3 - 6.0) \text{ g/m}^3]\left(\frac{22{,}464 \text{ m}^3}{\text{d}}\right)\left(\frac{1 \text{ kg}}{10^3 \text{ g}}\right)$$
$$= 1433 \text{ kg/d} = 59.7 \text{ kg/h}$$

Net O_2 required = R_o = (255 − 59.7) kg/h = 195.3 kg/h

Note the required aeration rate will decrease in proportion to a lower R_o. The oxygen required can be reduced by 23.4 percent.

9. Check alkalinity.
   a. Prepare an alkalinity mass balance.
   Alk to be added to maintain pH ~ 7 = Influent Alk − Alk used + Alk produced
      i. Influent alkalinity = 140 g/m^3 as $CaCO_3$
      ii. Alkalinity used = 7.14 (28.3 g NO_3-N/m^3) = 202.1 g/m^3
      iii. Alkalinity produced = 3.57 [(28.3 − 6) g/m^3] = 79.6 g/m^3
      iv. Alkalinity needed to maintain neutral pH = 80 g/m^3 as $CaCO_3$

b. Solve the above expression for Alk to be added.

Alk to be added = (80 − 140 + 202.1 − 79.6) g/m^3

= 62.5 g/m^3 as $CaCO_3$

Mass of alkalinity needed = (62.5 g/m^3)(22,464 m^3/d)(1 kg/10^3 g)

= 1404 kg/d as $CaCO_3$

c. Compare to alkalinity needed for nitrification only.
For the nitrification only design, the alkalinity needed was 3203 kg/d

Alkalinity savings = 3203 − 1404 = 1799 kg/d

10. Determine anoxic zone mixing energy.

Mixing energy = 10 kW/10^3 m^3 (given)

Volume = 1404 m^3

Power = (1404 m^3)(10 kW/10^3 m^3) = 14 kW total

11. Prepare summary of anoxic design.

Item	Unit	Value
Effluent NO_3 N	g/m^3	6.0
Internal recycle ratio	Unitless	3.1
RAS recycle ratio	Unitless	0.6
Anoxic volume	m^3	1404
MLSS	g/m^3	3000
Overall SDNR	g NO_3-N/g MLSS·d	0.13
Detention time	h	2.5
Mixing power	kW	14
Alkalinity required	kg/d as $CaCO_3$	1393

Comment In the above design example, computations are based on an average design condition. In actual design, allowances should be provided for peak flows and loads or a safety factor should be included, as discussed in Chap. 3.

Step-Feed Anoxic/Aerobic Process Design

Step feed for nitrogen removal is similar to the step-feed process described in Sec. 8–4 for BOD and nitrification. For nitrogen removal, wastewater is introduced at several feed points (see Fig. 8–27). In most cases, where a step-feed process is in place for BOD removal and nitrification, it will be relatively easy to upgrade it to a step-feed anoxic/aerobic biological nitrogen-removal process. For such applications the influent

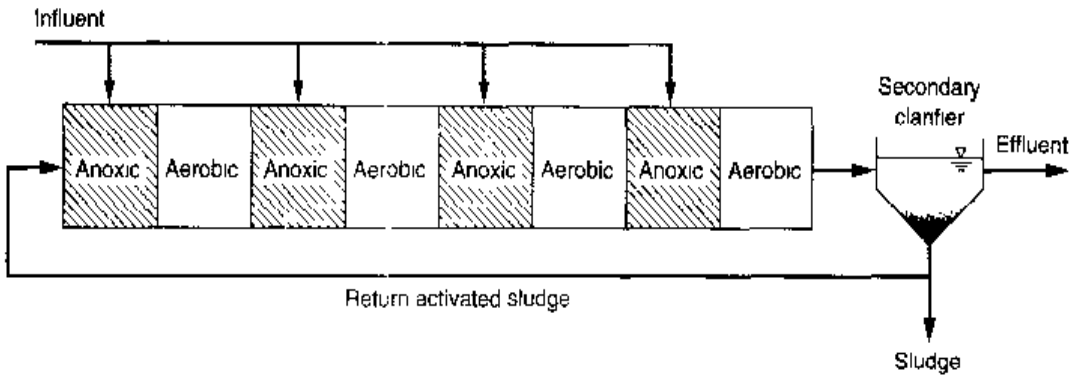


Figure 8–27
Schematic diagram of a step-feed biological nitrogen-removal process.

feed points and volumes of the individual channels in the reactor (passes) are already determined. The tank layout is generally symmetrical and the volume in each pass is equal. For a new tank design, it is possible to use a nonsymmetrical step-feed design where the feed split is somewhat equal, but the volume of each pass increases as the mixed-liquor concentration decreases from the first to last pass. The nonsymmetrical design approach may utilize the tank volumes more efficiently by using a similar F/M ratio for each pass.

The variables involved in the design of a step-feed biological nitrogen-removal process for an existing basin are (1) the flow distribution between passes, (2) the relative split between anoxic and aerobic volumes, and (3) the final pass MLSS concentration. The selection of the final pass MLSS concentration is normally based on using an acceptable solids loading for the secondary clarifier. As will be shown in the following design example, the selection of the final pass MLSS concentration, the RAS ratio, the influent flow split, and wastewater characteristics determine the system SRT. With the known SRT value, the biomass and nitrifying bacteria concentration in the mixed liquor can be determined, which can then be used to determine the nitrification and denitrification capacity of the system. The process design procedure involves successive iterations with varying anoxic/aerobic volumes and flow splits evaluated to find the most satisfactory design. Design of a step-feed biological nitrogen-removal process is presented in Example 8–6.

EXAMPLE 8–6 Step-Feed Biological Nitrogen-Removal Process Design Determine the amount of nitrification and nitrate removal in a four-pass step-feed biological nitrogen-removal process (see Fig. 8–27), using the same influent flowrate, wastewater characteristics, and temperature as was used in Example 8–2.

Design conditions and assumptions:

1. The flowrate is 22,464 m^3/d
2. The step-feed aeration tank is divided into four equal passes, with equal volumes used for the anoxic and aerobic zones
3. The flow split to each pass is 0.10, 0.40, 0.30, and 0.20 of the influent flow, for passes 1 through 4, respectively
4. MLSS concentration in the final aerobic zone is 3000 mg/L (same as in Example 8–2)

5. RAS recycle ratio (Q_{RAS}/Q) is 0.6
6. Anoxic volume is 20% of the total reactor volume
7. Total aeration tank volume is 9870 m^3 (from Examples 8–2 and 8–5. Anoxic and aeration tank volumes are 1404 and 8466 m^3, respectively)
8. Aeration tank DO = 2.0 g/m^3
9. Temperature = 12°C
10. Effluent NH_4-N = 0.5 g/m^3

Wastewater characteristics:

Constituent	Concentration, g/m^3
BOD	140
rbCOD	80
bCOD	224
nbVSS	20
TKN	35
TSS_o-VSS_o	10

Note: g/m^3 = mg/L.

Kinetic coefficients from Tables 8–10 and 8–11 and adjust for temperature

Heterotrophs:

$$Y = 0.40 \text{ g VSS/g bCOD}$$

$$k_{d,\,12°C} = 0.12 \text{ g/g·d } (1.04)^{12-20} = 0.088 \text{ g/g·d}$$

$$f_d = 0.15 \text{ g/g}$$

Nitrifiers:

$$Y_n = 0.12 \text{ g VSS/g } NO_x$$

$$k_{dn,\,12°C} = 0.08 \text{ g/g·d } (1.04)^{12-20} = 0.06 \text{ g/g·d}$$

$$\mu_{m,\,12°C} = 0.75 \text{ g/g·d } (1.07)^{12-20} = 0.44 \text{ g/g·d}$$

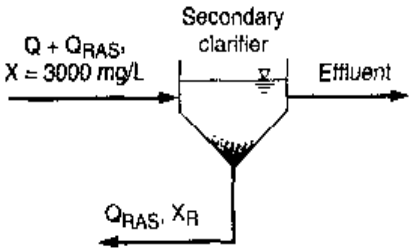
$$K_{n,\,12°C} = 0.74 \text{ g/m}^3 \ (1.053)^{12-20} = 0.49 \text{ g/m}^3$$

$$K_o = 0.50 \text{ g/m}^3$$

Solution

1. Determine the aeration and anoxic zone volumes. Anoxic volume is 20% of total volume per problem statement.

V = total volume = 9870 m^3



Anoxic volume = 0.20(9870 m^3) = 1974 m^3

Aerobic volume = $0.80(9870\ m^3) = 7896\ m^3$

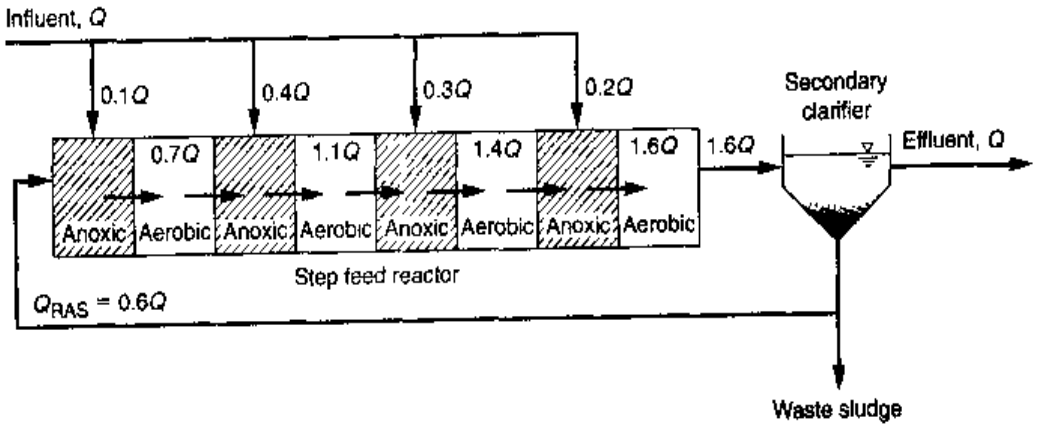
Anoxic volume/pass = $(1974\ m^3)/4 = 493.5\ m^3$

Aerobic volume/pass = $(7896\ m^3)/4 = 1974\ m^3$

2. Determine RAS concentration.

Perform a solids balance (neglect the effluent TSS because it is not significant for the clarifier solids balance).

$Q_{RAS} = 0.6\,Q$ (recycle ratio from problem statement)



The solids balance is

$$(Q + 0.6\,Q)\,3000\ g/m^3 = 0.6\,Q\,X_R$$

$$X_R = \frac{(Q + 0.6\,Q)(3000\ g/m^3)}{0.6\,Q}$$

$$X_R = (1.6\,Q/0.6\,Q)(3000\ g/m^3) = 8000\ g/m^3$$

3. Determine MLSS concentration in each pass (see figure below)

a. Pass 1 mass balance

Solids in = solids out (Note: solids production for a single pass is negligible)

$$0.10\,Q(0) + (Q_{RAS})(8000\ g/m^3) = (RAS + 0.1\,Q)X_1$$

$$0.1\,Q(0) + (0.6\,Q)(8000\ \text{g/m}^3) = (0.6\,Q + 0.1\,Q)X_1$$

$$X_1 = (8000\ \text{g/m}^3)(0.6/0.7) = 6860\ \text{g/m}^3$$

b. Pass 2 mass balance

$$(0.7\,Q)X_1 + 0.4\,Q(0) = 1.1\,QX_2$$

$$X_2 = (0.7/1.1)X_1 = (0.7/1.1)6860\ \text{g/m}^3$$

$$= 4365\ \text{g/m}^3$$

c. Pass 3 and 4 are calculated similarly

d. Summary of MLSS concentrations and volumes:

Pass	MLSS, g/m³	Anoxic volume, m³	Aerobic volume, m³
1	6860	493.5	1974
2	4365	493.5	1974
3	3430	493.5	1974
4	3000	493.5	1974

4. Perform solids balance on system and determine aerobic SRT.

a. Solids balance

$$\Sigma X_i V_i = (P_{x,\text{TSS}})(\text{SRT})$$

$$\Sigma X_i V_i = X_1V_1 + X_2V_2 + X_3V_3 + X_4V_4$$

$$= [(6860 + 4365 + 3430 + 3000)\ \text{g/m}^3](1974\ \text{m}^3)(1\ \text{kg}/10^3\ \text{g})$$

$$= 34{,}851\ \text{kg}$$

b. Apply Eq. (8–16) assuming $NO_x \sim 0.80$ TKN.

MLSS components = biomass + cell debris + nitrifiers + nbVSS + inorganic inerts

$$(\text{SRT})(P_{X,\text{TSS}}) = \frac{QY(S_o - S)\text{SRT}}{[1 + (k_d)\text{SRT}](0.85)(10^3\ \text{g/kg})} + \frac{f_d(k_d)QY(S_o - S)(\text{SRT})^2}{[1 + (k_d)\text{SRT}](0.85)(10^3\ \text{g/kg})}$$

$$+ \frac{QY_n(\text{NO}_x)\text{SRT}}{[1 + (k_{dn})\text{SRT}](0.85)(10^3\ \text{g/kg})} + \frac{Q(\text{nbVSS})\text{SRT}}{(10^3\ \text{g/kg})}$$

$$+ \frac{Q(\text{TSS}_o - \text{VSS}_o)\text{SRT}}{(10^3\ \text{g/kg})}$$

$$\text{NO}_x = 0.80(35\ \text{g/m}^3) = 28\ \text{g/m}^3$$

c. Solve for SRT.
Substituting wastewater and coefficient values yields

$$34{,}851\ \text{kg} = \frac{(22{,}464\ \text{m}^3/\text{d})(0.40\ \text{g/g})(224\ \text{g/m}^3)\text{SRT}}{[1 + (0.088\ \text{g/g·d})\text{SRT}](0.85)(10^3\ \text{g/kg})}$$

$$+ \frac{(0.15\ \text{g/g})(0.088\ \text{g/g·d})(0.40\ \text{g/g})(22{,}464\ \text{m}^3/\text{d})(224\ \text{g/m}^3)(\text{SRT})^2}{[1 + (0.088\ \text{g/g·d})\text{SRT}](0.85)(10^3\ \text{g/kg})}$$

$$+ \frac{(22{,}464\ \text{m}^3/\text{d})(0.12\ \text{g/g})(28\ \text{g/m}^3)(\text{SRT})}{[1 + (0.06\ \text{g/g·d})\text{SRT}](0.85)(10^3\ \text{g/kg})}$$

$$+ \frac{(22{,}464\ \text{m}^3/\text{d})(20\ \text{g/m}^3)\text{SRT}}{(10^3\ \text{g/kg})}$$

$$+ \frac{(22{,}464\ \text{m}^3/\text{d})(10\ \text{g/m}^3)\text{SRT}}{(10^3\ \text{g/kg})}$$

$$34{,}851\ \text{kg} = \frac{2367\ \text{SRT}}{1 + 0.088\ \text{SRT}} + \frac{31.2\ \text{SRT}^2}{1 + 0.088\ \text{SRT}}$$

$$+ \frac{88.8\ \text{SRT}}{1 + 0.06\ \text{SRT}} + 449\ \text{SRT} + 224.6\ \text{SRT}$$

Solve using spreadsheet solver function or by successive iterations, SRT = 19.2 d.

Compare to Example 8–2. In Example 8–2, aerobic volume = 8466 m^3 and SRT = 12.5 d. For step feed, aerobic volume = 7896 m^3 and SRT = 19.2 d. The lower volume and higher SRT is due to the higher MLSS concentrations in the early passes.

5. Determine the composition of the MLSS and MLVSS using the above solution in Step 4 for MLSS and SRT = 19.2 d. The results of the calculation of the MLVSS components are summarized in the following table:

Item	MLVSS, kg	Fraction of total MLVSS	MLSS, kg
Biomass	14,362	0.53	16,827
Cell debris	3,635	0.13	4,276
Nitrifiers	673	0.0247	792
nbVSS	8,620	0.32	8,620
Inert inorganics			4,312
Total	27,290		34,897

a. Fraction of biomass solids (from above table)
Thus, MLVSS/MLSS = 27,290/34,897 = 0.78

Biomass = 0.53(MLVSS)

Nitrifiers = 0.0247(MLVSS)

b. Nitrogen for nitrifier growth
With biomass and cell debris calculated, the NO_x for nitrifier growth is calculated as follows:

Daily biomass + debris production = (14,362 + 3635) kg = 17,997 kg

Daily wasting = 17,997 kg/19.2 d SRT = 937.3 kg/d

N used for synthesis = (0.12 g N/g VSS biomass) (937.3 kg/d)

= 112.5 kg/d

Based on influent flow the N synthesis is

$$\text{N synthesis} = \frac{(112.5\ \text{kg/d})(10^3\ \text{g/kg})}{(22{,}464\ \text{m}^3\text{/d})} = 5.0\ \text{g/m}^3$$

$$NO_x = TKN - N_{syn} - (NH_4\text{-}N)_e$$

$$= (35 - 5.0 - 0.5)\ \text{g/m}^3 = 29.5\ \text{g/m}^3$$

c. Nitrifier mass fraction correction

$$\text{Mass nitrifiers} = \frac{QY_n(NO_x)\text{SRT}}{[1 + (k_{dn})\text{SRT}]}$$

$$= \frac{(22{,}464\ \text{m}^3\text{/d})(0.12\ \text{g/g})(29.5\ \text{g/m}^3)(19.2\ \text{d})}{[1 + (0.06\ \text{g/g·d})(19.2\ \text{d})](10^3\ \text{g/kg})} = 709\ \text{kg VSS}$$

Corrected MLVSS = (27,290 − 673 + 709) kg = 27,326 kg

Nitrifiers as fraction of MLVSS = 709/27,326 = 0.0259 (as compared to 0.0247)

d. Summary Table
Based on the above data, prepare a summary table of biomass and nitrifier concentrations in each pass using ratios from above.

Pass	MLSS, g/m³	MLVSS, kg/d	Nitrifiers, g VSS/m³	Biomass, g VSS/ m³
1	6860	5350	140	2823
2	4365	3405	88	1796
3	3430	2675	70	1411
4	3000	2340	61	1234

6. Evaluate nitrification rate in each pass and compare to NH_4-N fed to stage.
   a. Develop equations for nitrification rate.
   The nitrification rate (R_n) in each stage is a function of the specific growth rate from ammonia oxidation and nitrifier concentration as follows:

$$R_n, \text{ g/d} = \left(\frac{\mu_m X_n}{Y_n}\right)V$$

For growth only related to substrate utilization [Eq. (7–93) in Table 8–5]

$$\mu_m = \left(\frac{\mu_{n,m} N}{K_n + N}\right)\left(\frac{\text{DO}}{K_o + \text{DO}}\right)$$

Substituting Eq. (7–93) into the above

$$R_n = \left(\frac{\mu_{n,m}}{Y_n}\right)\left(\frac{N}{K_n + N}\right)\left(\frac{\text{DO}}{K_o + \text{DO}}\right)X_n V$$

As indicated in the nitrogen mass balance for each pass, the rate of oxidizable nitrogen fed to the pass equals the nitrification rate plus the rate of ammonia nitrogen leaving the pass. The nitrogen entering the pass is related to the influent feed rate of available nitrogen (NO_x) to that pass and the rate of influent nitrogen from a previous pass. Before proceeding with the mass balance, prepare a flowrate summary.

   b. Prepare flowrate summary and mass balances.

Pass	Flowrate from previous reactor	Influent flowrate	Total flowrate
1	0.6 Q	0.1 Q	0.7 Q
2	0.7 Q	0.4 Q	1.1 Q
3	1.1 Q	0.3 Q	1.4 Q
4	1.4 Q	0.2 Q	1.6 Q

The balances for passes 1 and 2 are shown for steady state:

Pass 1 (recycle NH_4-N) = last pass (pass 4) NH_4-N

Rate of influent N = rate of effluent N + nitrification rate

$$\text{RAS } Q N_4 + 0.1\, Q\, \text{NO}_x = 0.7\, Q N_1 + R_{n,1}$$

$$0.6\, Q N_4 + 0.1\, Q\, \text{NO}_x = 0.7\, Q N_1 + R_{n,1}$$

$$R_{n,1} = \left(\frac{\mu_{n,m}}{Y_n}\right)\left(\frac{N_1}{K_n + N_1}\right)\left(\frac{\text{DO}}{K_o + \text{DO}}\right)X_{n,1} V$$

Pass 2

$$0.7\,Q\,N_1 + 0.4\,Q\,\mathrm{NO}_x = 1.1\,Q\,\mathrm{N}_2 + R_{n,2}$$

$$R_{n,2} = \left(\frac{\mu_{n,m}}{Y_n}\right)\left(\frac{N_2}{K_n + N_2}\right)\left(\frac{\mathrm{DO}}{K_o + \mathrm{DO}}\right)X_{n,2}V$$

c. Solve for nitrification rate in each stage.
Thus, N_1, N_2, N_3, and N_4 are solved for each stage using $\mathrm{NO}_x = 29.5$ g/m^3 (determined earlier). The value for N_4 is assumed to solve pass 1 and then the final solution is reached by iteration until the value for N_4 equals the value used to solve pass 1. A spreadsheet program with a solver function can assist in the solution. Using the coefficients shown for the design condition, the solution is summarized below.

d. Summary of step-feed solution for NH_4-N per pass:

Pass	Nitrifiers, g/m^3	Influent flowrate, m^3/d	RAS or flow from previous pass, m^3/d	NH_4-N, g/m^3	R_n, g/d
1	140	2246	13,478	0.05	69,389
2	89	8986	15,724	0.48	254,028
3	70	6739	24,710	0.46	196,129
4	61	4493	31,449	0.31	135,963

Sufficient volume exists to provide an effluent NH_4-N concentration of 0.5 g/m^3 or less for each pass. Excess volume is available in pass 1 and pass 4 for an effluent NH_4-N concentration of 0.5 g/m^3.

7. Determine the amount of nitrate removal in the anoxic zones and effluent NO_3-N concentration.
The amount of nitrate fed to each anoxic zone for passes 2, 3, and 4 equals the nitrification rate (g/d) in the previous pass plus the nitrate not removed in the previous anoxic zones. For the first anoxic zone, the nitrate feed is equal to the effluent NO_3-N concentration times the RAS flowrate. For the solution, the first step is to determine the denitrification capacity for each anoxic stage by calculating the F/M_b per pass and using Fig. 8–23 to obtain the SDNR as follows:

a. Calculate F/M_b from Eq. (8–43).

$$\mathrm{F/M_b} = \frac{Q\,S_o}{(V_{max})(X_b)} \quad [\text{from previous computation, } X_b = 0.53(\mathrm{MLSS})]$$

b. Obtain SDNR_b from Fig. 8–23.

$$\text{Rate of COD degradability} = \frac{\mathrm{rbCOD}}{\mathrm{bCOD}} = \frac{(80\ \mathrm{g/m^3})}{(224\ \mathrm{g/m^3})} = 0.36(\simeq 40\%)$$

c. Use Eq. (8–44) for temperature correction.

$$SDNR_{12} = SDNR_{20}(1.026)^{12-20} = SDNR_{20}(0.814)$$

d. NO_3-N removed = $(SDNR_b)(V_{nox})X_b$

Pass	X_b, g/m³	Influent flowrate, m³/d	Anoxic volume, m³	F/M_b	$SDNR_{12}$, g/g·d
1	2729	2246	493	0.23[a]	0.05[b]
2	1736	8986	493	1.47	0.26
3	1364	6739	493	1.40	0.24
4	1193	4493	493	1.07	0.20

Sample calculation for pass 1:

[a] $F/M_b = \dfrac{(2346\ m^3/d)(140\ g/m^3)}{(2729\ g/m^3)(493\ m^3)} = 0.23\ g/g{\cdot}d$

[b] From Fig. 8–23, SDNR = 0.06 g/g·d

$SDNR_{12} = 0.06\ (1.026)^{12-20} = 0.05$

NO_3-N removed = (0.05 g/g·d)(2729 g/m³)(493 m³) = 67,269 g/d.

Using the SDNR from the above for each pass, the amount of NO_3-N removed is tabulated below.

Pass	NO_3 removal capacity, g/d
1	67,269
2	222,520
3	161,388
4	117,269

8. Nitrate balance and effluent NO_3-N concentration.

a. Develop equations for nitrate mass balance.

A nitrate balance for each pass is done to determine how much nitrate remains after the anoxic reactor and the effluent nitrate nitrogen concentration. The nitrogen remaining after each reactor is

$$\begin{array}{lcll} NO_3\text{-N influent} & & \text{pass anoxic} & NO_3\text{-N} \\ \text{from RAS or} & - & \text{removal} & = \text{remaining after} \\ \text{previous pass} & & \text{capacity} & \text{anoxic reactor} \end{array}$$

If there is a negative value for NO_3-N remaining because of excess anoxic NO_3-N removal capacity, then a value of zero is assigned [see column (3) in the following table].

The effluent NO_3-N concentration from each pass is then:

$$\begin{array}{c}\text{NO}_3\text{-N remaining} \\ \text{after anoxic}\end{array} - \begin{array}{c}\text{NO}_3\text{-N produced} \\ \text{in the pass}\end{array} = \begin{array}{c}\text{effluent} \\ \text{NO}_3\text{-N}\end{array}$$

b. Prepare table to solve mass balance for each stage.
The NO_3-N balance is illustrated in the following table.

Pass	Total NO_3-N to pass, g/d	Anoxic removal capacity, g/d[a]	NO_3-N remaining after anoxic, g/d[b] (1) − (2)	NO_3-N produced (R_n) in pass, g/d[c]	Effluent NO_3-N, g/d (3) + (4)
	(1)	(2)	(3)	(4)	(5)
1	115,299	67,269	48,030	69,589	117,619
2	117,619	222,520	0	254,028	254,028
3	254,028	161,388	92,640	196,129	288,769
4	288,769	117,269	171,500	135,963	307,483
				Effluent NO_3-N = 8.6 g/m^3	

[a] Source of influent nitrate: for pass 1, RAS; other passes, column (6)

[b] From Step 8

[c] From Step 6.

c. Determine effluent NO_3-N concentration.
The nitrate fed to pass 1 from RAS is calculated as follows:

$$\text{NO}_3\text{-N to pass 1} = (Q_{RAS})N_e$$

where N_e = effluent NO_3-N concentration, g/m^3

The value for N_e is obtained using the effluent NO_3-N shown in column (5) for pass 4:

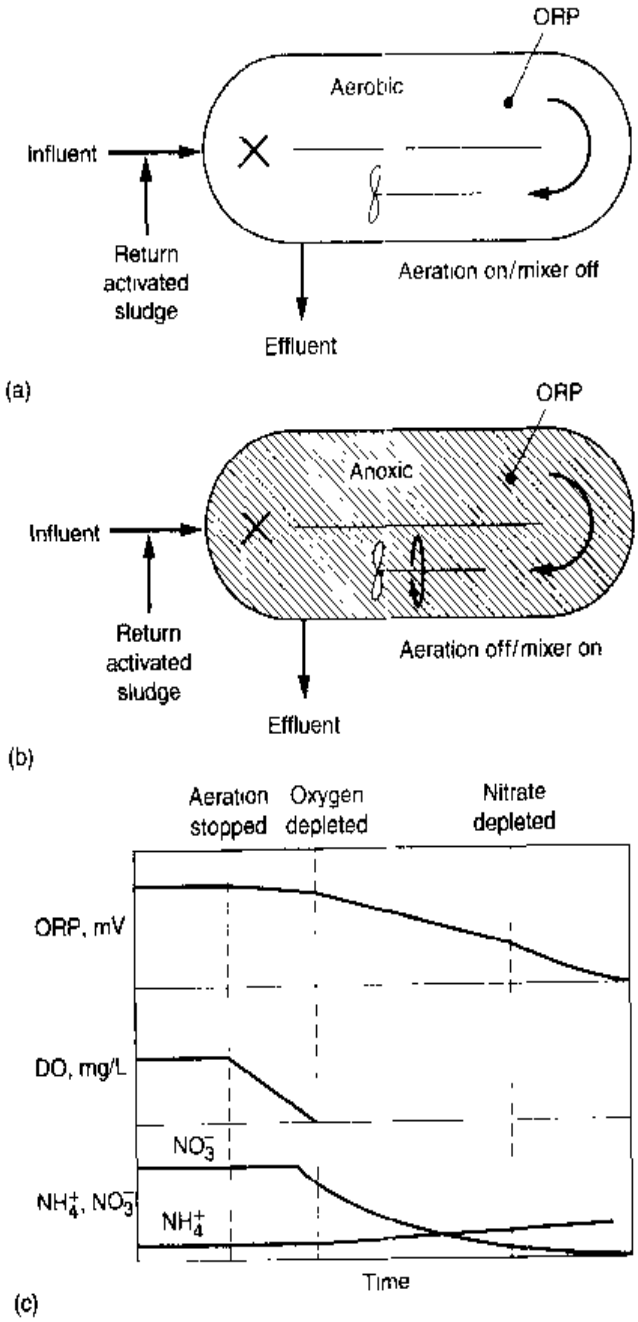
$$(Q + Q_{RAS})N_e = \text{pass 4 effluent NO}_3\text{-N (g/d)}$$

$$N_e = (307{,}483 \text{ g/d})/(Q + 0.6\,Q)$$

$$N_e = (307{,}483 \text{ g/d})/(1.6)(22{,}464 \text{ m}^3\text{/d}) = 8.6 \text{ g/m}^3$$

Initially, assume an effluent concentration, e.g., 10 g/m^3, to calculate the amount of NO_3-N fed to pass 1. Using the spreadsheet, perform successive iterations until the calculated effluent NO_3-N equals the trial.

9. Reevaluate design.
Note that some excess capacity is available and is not realized in the initial passes of the symmetrical step-feed design. Different influent flow splits may be used to reduce the effluent nitrate concentration, the anoxic and aerobic volumes can be changed, the anoxic zone may be staged, and the MLSS concentration may be increased. A spreadsheet model is necessary to evaluate various design changes.



Intermittent Aeration Process Design

Long SRT systems, such as oxidation ditch processes, may employ intermittent aeration to accomplish both nitrification and denitrification in a single tank. During the aeration-off period, the aeration tank operates essentially as an anoxic reactor as nitrate is used in lieu of DO for BOD removal. During the anoxic period, the tank operation is similar to a preanoxic tank because influent BOD is added continuously to drive the denitrification reaction.

Operation of an oxidation ditch using intermittent aeration is shown on Fig. 8–28. Intermittent aeration systems typically are operated with SRT values in the range of 18 to 40 d and hydraulic detention times in excess of 16 h. During the anoxic reaction

Figure 8–28

Operation of a Nitrox™ oxidation ditch process using intermittent aeration: (*a*) aerobic conditions, (*b*) anoxic conditions, and (*c*) variations in ORP, DO, ammonia, and nitrate.

period (Fig. 8–28*b*), aeration is stopped, a submerged mixer is turned on, and nitrate is used as the electron acceptor. The reactor is operated as a complete-mix activated-sludge anoxic process. During the anoxic period, DO and nitrate are depleted and the ammonia concentration increases (see Fig. 8–28*c*). The time for the anoxic and aerobic periods is important in determining the system's treatment performance.

The anoxic/aerobic cycle times may be adjusted manually as part of the system operation to optimize the process performance. Alternatively, a patented process, Nitrox™, uses an oxidation-reduction potential (ORP) measurement to control the intermittent operation. The ORP response during an aeration-off period is shown on Fig. 8–28*c*. As the DO concentrations decline, the ORP value decreases. When the NO_3-N is depleted, a dramatic decline in the ORP value occurs. The ORP decline is called the *ORP knee* and can be identified by calculating the ORP slope with time. In the Nitrox™ process, the ORP values are logged onto a computer, which is programmed to turn on the aeration based on the changing slope of the ORP. The aeration-off periods are selected to occur during different times of the day; the more ideal time is when the influent BOD concentration is high so that nitrate reduction occurs at a faster rate. The process behaves much like an anoxic selector as improved SVIs have been reported (Stensel et al., 1995).

Reported plant performance data for intermittent aeration processes indicate effluent NO_3-N concentrations range from 3.0 to 4.8 mg/L. The processes are also predicted to produce effluent total nitrogen (TN) concentrations <8.0 mg/L (U.S. EPA, 1993). The relatively long τ values used provide sufficient dilution to minimize the effluent NH_4-N concentrations during the OFF period. A sufficiently long SRT is also needed to provide enough nitrification capacity to allow the aeration system to be operated intermittently.

Because of the long SRT and τ, the denitrification kinetics are related to the overall degradation of bCOD, pbCOD, and endogenous decay and are not as strongly influenced by the rbCOD fraction as for the preanoxic denitrification application with the relatively short τ. During the complete-mix anoxic period in an intermittent oxidation ditch operation or in the anoxic zone of a continuously aerated oxidation ditch, the specific denitrification rate is affected by both the endogenous respiration rate and the bCOD in the influent wastewater as continuous feeding occurs. The average specific denitrification rate, which includes these effects, can be estimated by the following equation [based on Stensel (1981) and modified to account for the rate as a function of active heterotrophic biomass]:

$$SDNR_b = \frac{0.175A_n}{(Y_{net})\overline{SRT}} \tag{8–54}$$

where $SDNR_b$ = specific denitrification rate relative to heterotrophic biomass concentration, g NO_3-N/g biomass·d
A_n = net oxygen utilization coefficient, g O_2/g bCOD removed
Y_{net} = net yield for heterotrophic biomass, g VSS/g bCOD
0.175 = based on 2.86 g O_2 equivalent/g NO_3-N and the assumption that only 50% of heterotrophic biomass can use nitrate in place of oxygen

For a complete-mix activated-sludge reactor, A_n and Y_{net} are determined as follows (Stensel, 1981):

$$A_n = 1.0 - 1.42Y + \frac{1.42(k_d)(Y)\text{SRT}}{1 + (k_d)\text{SRT}} \tag{8–55}$$

$$Y_{net} = \frac{Y}{1 + (k_d)\text{SRT}} \tag{8–56}$$

The $SDNR_b$ in Eq. (8–54) is relative to the biomass concentration that is a portion of the MLVSS concentration. Thus, the design procedure used to determine the amount of nitrate removed in the anoxic period during intermittent aeration incorporates some of the elements of the computational steps for anoxic/aerobic design described in Table 8–19. In Step 3 of Table 8–19, the heterotrophic biomass concentration has to be determined. As detailed in Step 9, the biomass concentration, $SDNR_b$, anoxic volume, and anoxic time are used to determine the amount of nitrate nitrogen removed. Use of the above equations is illustrated in Example 8–7.

EXAMPLE 8–7 Determine Oxidation Ditch Intermittent Aeration Cycle Time for Nitrogen Removal Determine what fraction of the time an oxidation ditch system must be operated as an anoxic reactor for an intermittent aeration process to produce an effluent NO_3-N concentration of 7 g/m^3, based on the following design conditions.

Design conditions:

Oxidation ditch volume	= 8700 m^3
SRT	= 25 d
MLSS	= 3500 g/m^3
MLVSS	= 2500 g/m^3
Fraction of biomass	= 0.40 g biomass/g MLVSS
Temperature	= 15°C
Y, k_d	= values given in Table 8–10
Influent flowrate	= 7570 m^3/d
Nitrate concentration in oxidation ditch	= 27 g/m^3 based on influent flowrate

Note: g/m^3 = mg/L.

Solution

1. Determine the SDNR.
   a. Obtain Y and k_d from Table 8–10 and correct k_d for temperature [Eq. (2–25)].

      Y = 0.4 g VSS/g bCOD

      $k_{d,20}$ = 0.12 g/g·d

$$k_{d,15} = k_{d,20}(1.04)^{15-20}$$
$$= 0.12(1.04)^{15-20} = 0.099 \text{ g/g·d}$$

b. Using Eq. (8–55), determine A_n.

$$A_n = 1.0 - 1.42(0.4) + \frac{1.42(0.099 \text{ g/g·d})(0.40 \text{ g/g})(25 \text{ d})}{[1 + (0.099 \text{ g/g·d})(25 \text{ d})]}$$
$$= 0.84 \text{ g } O_2\text{/g bCOD}$$

c. Using Eq. (8–56) determine Y_{net}.

$$Y_{net} = \frac{Y}{1 + (k_d)\text{SRT}}$$
$$= \frac{0.4}{1 + (0.099 \text{ g/g·d})(25 \text{ d})} = 0.18 \text{ g VSS/g bCOD}$$

d. Using Eq. (8–54), determine SDNR_b.

$$\text{SDNR}_b = \frac{0.175\, A_n}{(Y_{net})\,\text{SRT}}$$
$$\text{SDNR}_b = \frac{0.175(0.84 \text{ g } O_2\text{/g bCOD})}{(0.18 \text{ g VSS/g bCOD})(25 \text{ d})} = \frac{0.033 \text{ g } NO_3\text{-N}}{\text{g biomass·d}}$$

2. Determine biomass concentration in the mixed liquor.

$$X_b = (2500 \text{ g/m}^3 \text{ MLVSS})\left(\frac{0.40 \text{ g biomass}}{\text{g MLVSS}}\right)$$
$$= 1000 \text{ g/m}^3 \text{ biomass}$$

3. Determine amount of NO_3-N removal needed in g/d.

Nitrate removed concentration $(NO_r) = (27.0 - 7.0) \text{ g/m}^3 = 20 \text{ g/m}^3$

$NO_r = (7570 \text{ m}^3\text{/d})\ (20 \text{ g/m}^3)$
$= 151{,}400 \text{ g/d}$

4. Determine NO_3-N removal rate under anoxic reaction time.

Anoxic $NO_r = (\text{SDNR}_b)(X_b)(V)$
$= (0.033 \text{ g } NO_3\text{-N/g biomass·d})(1000 \text{ g/m}^3)(8700 \text{ m}^3)$
$= 287{,}100 \text{ g/d}$

5. Determine anoxic time needed per day.

$$\text{Anoxic time} = \frac{(151{,}400 \text{ g/d})(24 \text{ h/d})}{(287{,}100 \text{ g/d})} = 12.7 \text{ h}$$

Fraction of day = 12.7 h/24 h = 0.52

The computed value is within the range of values reported for the anoxic fraction for cyclic aeration process as given in U.S. EPA (1993). The actual time may be less or the amount of nitrogen removal may be greater due to denitrification within the floc during low DO aeration and in the secondary clarifier. By knowing the approximate amount of time needed for the anoxic conditions, the aerobic SRT available for nitrification can be estimated.

Postanoxic Endogenous Denitrification

Postanoxic denitrification can be done in separate tanks within the same single-sludge system following nitrification, as first proposed by Wuhrmann (1964). The Bardenpho process is a good example of this application. After nitrification, the rbCOD is fully depleted and, depending upon the system SRT, most of the pbCOD is likely to be depleted. Thus, the electron donor that creates the demand for nitrate reduction is mainly from activated-sludge endogenous respiration. Observed SDNRs have ranged from 0.01 to 0.04 g NO_3-N/g MLVSS under endogenous respiration (U.S. EPA, 1993; Stensel et al., 1995). The endogenous oxygen equivalent utilization rate under anoxic conditions has been found to be about 50 percent of that under aerobic conditions (Randall et al., 1992; Wuhrmann, 1964). Based on the cited references, the SDNR under endogenous conditions ($SDNR_b$) can be calculated from the endogenous decay rate as follows:

$$SDNR_b = \frac{1.42k_d}{2.86}\eta = 0.5(k_d)(\eta) \qquad (8\text{–}57)$$

where 1.42 = g O_2/g biomass VSS
2.86 = g O_2 equivalent/g NO_3-N
η = fraction of biomass that can use NO_3-N in place of O_2 as an electron acceptor
k_d = biomass endogenous decay coefficient, g VSS/g VSS biomass·d

The values for k_d at 20°C and the temperature correction coefficient are shown in Table 8–10. As discussed previously, the $SDNR_b$ is based on the biomass concentration. As shown in Chap. 7, the fraction of biomass from the MLVSS reaction declines as the SRT increases, so the SDNR value based on the MLVSS concentration would decrease with increasing SRT.

The endogenous respiration SDNR value at 20°C as a function of SRT has also been described by the following empirical relationship (Burdick et al., 1982), in which the SDNR is based on the total MLVSS concentration:

$$SDNR_{MLVSS} = 0.12(SRT)^{-0.706} \qquad (8\text{–}58)$$

where $SDNR_{MLVSS}$ = g NO_3-N/g MLVSS·d

A temperature correction value (θ) of 1.08 is recommended for use with Eq. (8–58) (U.S. EPA, 1993).

Sequencing Batch Reactor Process Analysis

In the SBR process and other batch decant processes (see Figs. 8–1*c* and 8–16*b* and *c*) nitrate removal can be accomplished by three methods: (1) nitrate reduction by using a mixed nonaerated fill period, (2) cycling aeration On/Off during the react period, and (3) operating at a low DO concentration to encourage SNdN. Under cyclic aeration conditions, Eq. (8–51) may also be useful to estimate the SDNR because the nitrate-reduction activity is driven mainly by endogenous respiration. Denitrification during a mixed nonaerated fill period provides the most efficient means of nitrate removal and also provides a selector operation to prevent filamentous sludge bulking. Most of the nitrate produced during the previous aerobic cycle remains in the SBR tank because the decant volume is only 20 to 30 percent of the total tank volume. The mass of nitrate remaining after decant can be reduced during the fill period if sufficient BOD and time are available. The following example is used to illustrate how to estimate the amount of nitrate removed during a mixed fill period for an SBR reactor.

EXAMPLE 8–8 Determine Nitrate Removal During the Fill Period in an SBR Process Determine how much nitrate may be removed during a mixed, unaerated fill period in an SBR for the following design conditions. Assume the following design conditions apply.

Design conditions:

Number of tanks	2
Flow/tank, m^3/d	3785
Cycle times, h	
Fill	4.0
Aerate	3.0
Settle	0.5
Decant	0.5
Fill volume fraction, V_F/V_T	0.3
Influent BOD, g/m^3	200
Influent bCOD, g/m^3	320
Influent rbCOD, g/m^3	60
Influent TKN, g/m^3	35
Effluent NH_4-N, g/m^3	0.5
SRT, d	20
Temperature, °C	16

Note g/m^3 = mg/L.

Use kinetic coefficients from Table 8–10.

Solution

1. Determine tank volume.

   Cycle time = 4.0 + 3.0 + 0.50 + 0.50 = 8.0 h

$$\text{Cycles/day} = \frac{(24\text{ h/d})}{(8\text{ h/cycle})} = 3\text{ cycles/d}$$

$$\text{Fill volume/cycle} = \frac{(3785\text{ m}^3\text{/d})}{3\text{ cycles}} = 1261.7\text{ m}^3\text{/fill cycle}$$

$$V_F/V_T = 0.30$$

$$V_T = \frac{1261.7\text{ m}^3}{0.30} = 4206\text{ m}^3$$

2. Determine nitrate produced (NO_x).
   a. Determine heterotrophic biomass produced.
   Determine heterotrophic biomass production including cell debris to estimate the nitrogen used for synthesis using Eq. (8–15). (Biomass produced from nitrification can be ignored, as it represents a small fraction of the biomass.)

$$P_X = \frac{Q(Y)(S_o - S)}{1 + (k_d)\text{SRT}} + \frac{f_d(k_d)Y(Q)(S_o - S)\text{SRT}}{1 + (k_d)\text{SRT}}$$

   i. Use coefficients from Table 8–10 and adjust k_d for temperature.

$$k_d = 0.12(1.04)^{16-20} = 0.103\text{ g/g·d}$$

$$Y = 0.40\text{ g VSS/g bCOD}$$

$$f_d = 0.15$$

   Assume $S_o - S \approx S_o$.
   ii. Substitute and solve for P_X.

$$P_X = \frac{(3785\text{ m}^3\text{/d})(0.40\text{ g/g})(320\text{ g/m}^3)}{[1 + (0.103\text{ g/g·d})(20\text{ d})](10^3\text{ g/kg})}$$

$$+ \frac{(0.15\text{ g/g})(0.103\text{ g/g·d})(0.40\text{ g/g})(3785\text{ m}^3\text{/d})(320\text{ g/m}^3)(20\text{ d})}{[1 + (0.103\text{ g/g·d})(20\text{ d})](10^3\text{ g/kg})}$$

$$= (158.3 + 48.9)\text{ kg/d} = 207.2\text{ kg/d}$$

   b. Determine N synthesis.

$$NO_x = \text{TKN} - N_{syn} - (NH_4\text{-N})_e$$

$$N_{syn} = 0.12(P_X) = 0.12(207.2\text{ kg/d}) = 24.9\text{ kg/d}$$

$$N_{syn} = \frac{(24.9\text{ kg/d})(10^3\text{ g/kg})}{(3785\text{ m}^3\text{/d})} = 6.6\text{ g/m}^3$$

$$\text{Effluent } NH_4\text{-N} = 0.5\text{ g/m}^3$$

$$NO_x\text{ produced} = (35.0 - 6.6 - 0.5)\text{ g/m}^3 = 27.9\text{ g/m}^3$$

3. Determine amount of nitrate left in SBR mixed liquor after decant.
Assume: NO_3-N ≈ 0 before aeration period, which means that all of the nitrate remaining in the SBR in the liquid volume after decanting is removed by denitrification during the mixing and unaerated fill period.

a. Prepare nitrogen balance.

$$NO_x = TKN - N_{syn} - (NH_4\text{-}N)_e$$

$$NO_x = (35.0 - 6.6 - 0.5)\ g/m^3 = 27.9\ g/m^3$$

b. Determine NO_x produced per cycle.

$$g\ NO_x \text{ produced per cycle} = 27.9\ g/m^3\ (1261.7\ m^3/fill)$$

$$= 35{,}201\ g\ NO_x/fill$$

NO_3-N concentration at end of aeration with tank full: ($V = 4206\ m^3$)

$$= \frac{35{,}201\ g}{4206\ m^3} = 8.4\ g/m^3$$

Effluent NO_3-N = $8.4\ g/m^3$ based on all NO_3-N that is produced in the aeration period is removed by denitrification during the unaerated fill period.

c. Determine nitrate remaining in SBR.

Volume remaining after decant: $0.70(4206\ m^3) = 2944\ m^3$

NO_3-N present = $8.4\ g/m^3$ (V_s) = $(8.4\ g/m^3)(2944\ m^3) = 24{,}729\ g$

4. Determine $SDNR_b$ in fill period.

Active biomass concentration (from Step 2aii, biomass = 158.3 kg/d)

$$X_b = \frac{(\text{biomass})(\text{SRT})}{V_T} = \frac{(158.3\ kg/d)(20\ d)(10^3\ g/kg)}{4206\ m^3}$$

$= 753\ g/m^3$ at full volume

a. Determine F/M_b ratio in fill period.

Biomass in system = $(753\ g/m^3)(4206\ m^3) = 3167\ kg$

BOD feed rate = $Q_F S_o$

$$Q_F = \frac{V_F}{t_F} = (1261.7\ m^3/4\ h)(24\ h/d)$$

$$= 7570\ m^3/d$$

$$Q_F S_o = (7570\ m^3/d)\ (200\ g/m^3\ BOD)(1\ kg/10^3\ g)$$

$$= 1514\ kg/d$$

$$F/M_b = \frac{(1514\ kg/d)}{3167\ kg} = 0.48\ g/g{\cdot}d$$

b. Determine the $SDNR_b$.

Fraction rbCOD = $(60\ g/m^3)/(320\ g/m^3) = 0.19$

From Fig. 8–23 (FM_b range of 0 to 2.0) at $F/M_b = 0.48$

$SDNR_b = 0.12\ g/g{\cdot}d$ at 20°C

At 16°C, $SDNR_{16} = SDNR_{20}\,\theta^{16-20}$; $\theta = 1.026$

$= 0.108\ g/g{\cdot}d$

5. Determine NO_3-N removal capacity during the fill period.

$NO_x = (SDNR_b)(X_b)(V_T)$ [Note: $(X_b)(V_T)$ = biomass in system]

$= (0.108\ g/g{\cdot}d)(753\ g/m^3)(4206\ m^3)$

$= 342{,}049\ g/d$

Fill time = 4 h

$$NO_x \text{ at 4 h} = \frac{(342{,}049\ g/d)(4\ h)}{(24\ h/d)} = 57{,}008\ g$$

NO_3-N available from Step 3 = 24,729 g

Therefore, all of NO_3-N can be removed in the fill period.

Note: V_F/V_T controls effluent NO_3-N concentration.

Postanoxic Denitrification with an External Carbon Source

The biological nitrogen-removal processes discussed thus far in this text are single-sludge suspended growth processes with the electron donor for denitrification provided by BOD in the wastewater (e.g., preanoxic condition) or from mainly endogenous decay of the activated sludge (postanoxic). Prior to the late 1970s or early 1980s, the principal approach for nitrate removal was to add a process (either suspended growth or attached growth) after nitrification. Nitrification/denitrification using suspended growth processes is also termed the *two-sludge* process. Because only a negligible amount of BOD remains in the nitrified effluent, an external carbon source has to be added to supply the energy for the nitrifying organisms. In this section, postanoxic denitrification using a suspended growth process is considered. Attached growth denitrification is discussed in Chap. 9.

For postanoxic denitrification, nitrified influent is fed to a mixed anoxic tank along with an external carbon source, which is commonly methanol (see Fig. 8–21*e*). Suffi-

cient detention time and SRT are needed to consume the methanol with NO_3-N as the electron acceptor and to assure good floc settling and thickening characteristics. An SRT of at least 5 d is normally used. The anoxic tank is followed by a short aeration time of 10 to 20 min to release nitrogen gas bubbles from the mixed liquor to promote maximum suspended solids removal in the final clarifier. As in any suspended growth process, wasting of excess sludge is necessary.

The postanoxic suspended growth process can be designed in a similar manner to an activated-sludge process, with the electron donor being the growth substrate. The NO_3-N that must be removed serves as the electron acceptor in lieu of dissolved oxygen. Nitrate limits only the process kinetics at very low concentrations (less than 0.30 mg/L); thus, the process design is based on methanol degradation kinetics. The process is designed on a complete-mix activated-sludge (CMAS) process, using bCOD kinetic expressions from Table 8–5 to describe the methanol consumption and biomass growth. The nitrate consumption is treated in a manner similar to supplying oxygen for an aerobic CMAS process. Because the process and the organic substrate used are so well defined, in contrast to the preanoxic processes using wastewater BOD, the SDNR design approach is not appropriate.

Typical values for the biological kinetic coefficients, based on methanol addition, are summarized in Table 8–20, and a design example using the kinetic coefficients given in Table 8–20 is presented in Example 8–9. The design process procedure is outlined as follows.

1. Determine the amount of NO_3-N to be reduced.
2. Select the anoxic tank SRT.
3. Calculate the anoxic tank residual methanol concentration based on design SRT and kinetic coefficients.
4. Determine the methanol dose based on the amount of nitrate to be removed and the amount of dissolved oxygen in the influent wastewater to be consumed.
5. Calculate the total solids production.
6. Determine the anoxic tank volume based on the solids production and SRT.
7. Select a detention time for the postaeration tank prior to clarification.

Table 8–20
Denitrification kinetic coefficients with methanol as the growth substrate at 10°C and 20°C[a]

Parameter	Unit	Temperature, °C	
		10	20
Synthesis yield, Y	g VSS/g bCOD	0.17	0.18
Endogenous decay, k_d	g VSS/g VSS·d	0.04	0.05
Maximum specific growth rate, μ_m	g VSS/g VSS·d	0.52	1.86
Maximum specific substrate utilization rate, k	g bCOD/g VSS·d	3.1	10.3
Half-velocity, K_s	g/m^3	12.6	9.1

[a] Adapted from Stensel et al. (1973).

EXAMPLE 8–9 Suspended Growth Postanoxic Denitrification Process Given the following nitrified effluent flow and characteristics, design a postanoxic suspended growth system (see Fig. 8–21*e*) to achieve an effluent NO_3-N concentration of 2.0 g/m^3. Using the given data and assumptions, determine (1) the required methanol dose, (2) the anoxic volume and detention time, and (3) the waste sludge production.

Wastewater characteristics:

Item	Unit	Value
Flowrate	m^3/d	4000
NO_3-N	g/m^3	25
TSS	g/m^3	20
Temperature	°C	15

Note: g/m^3 = mg/L.

Design assumptions:

1. Use the following denitrification kinetic coefficients based on the kinetic data given in Table 8–20.

   Design denitrification kinetics at 15°C (interpolated)

   Y = 0.18 g VSS/g bCOD used

   k_d = 0.05 g VSS/g VSS·d

   k = 6.7 g bCOD/g VSS·d

   K_s = 10.9 g/m^3
2. MLSS = 2000 mg/L.
3. Feed TSS is not significantly degraded (and the BOD from the nitrification reactor is negligible).
4. Methanol exiting the anoxic zone is degraded in the aerobic zone.
5. SRT = 5 d for one anoxic tank.
6. Aeration period following denitrification = 15 min.
7. Clarifier overflow rate = 24 m/d (m^3/m^2·d).

Solution

1. Determine the residual concentration of methanol in the effluent from the anoxic zone based on process kinetics using Eq. (7–40) in Table 8–5.

$$S = \frac{K_s[1 + (k_d)\text{SRT}]}{\text{SRT}(Yk - k_d) - 1}$$

where S = residual methanol concentration as bCOD

Substitute known values and solve for S.

$$S = \frac{(10.9\ \text{g/m}^3)[1 + (0.05\ \text{g/g·d})(5\ \text{d})]}{(5\ \text{d})[(0.18\ \text{g/g})(6.7\ \text{g/g·d}) - 0.05\ \text{g/g·d}] - 1} = 2.9\ \text{g/m}^3\ \text{as bCOD}$$

2. Determine the required methanol dose.
   a. Determine the methanol required for NO_3-N reduction.

$$NO_3\text{-N reduced} = (25.0 - 2.0)\ g/m^3 = 23.0\ g/m^3$$

bCOD/NO_3-N ratio, Eq. (7–108)

$$\frac{bCOD}{NO_3\text{-N}} = \frac{2.86}{1 - 1.42Y_n}$$

The value of Y_n can be determined using Eq. (7–103).

$$Y_n = \frac{Y}{[1 + (k_d)SRT]} = \frac{(0.18\ g\ VSS/g\ bCOD)}{[1 + (0.05\ g/g{\cdot}d)(5\ d)]} = 0.144\ g\ VSS/g\ bCOD$$

Thus,

$$\frac{bCOD}{NO_3\text{-N}} = \frac{2.86}{1 - 1.42(0.144)} = 3.6\ g/g$$

   b. Determine the total methanol required, which is comprised of the amount needed for NO_3-N reduction and the residual bCOD from the anoxic reactor.

Methanol dose (as COD)

$$= (3.6\ g/g\ NO_3\text{-N})(23\ g/m^3) + 2.9\ g/m^3$$

$$= 85.7\ g/m^3\ \text{as COD}$$

$$\text{Methanol dose} = \frac{(85.7\ g\ COD/m^3)}{(1.5\ g\ COD/g\ CH_3OH)} = 57.1\ g\ CH_3OH/m^3$$

$$\text{Daily methanol consumption} = (57.1\ g/m^3)(4000\ m^3/d)(1\ kg/10^3\ g)$$
$$= 228.5\ kg/d$$

3. Determine solids production based on Eqs. (7–52) and (7–53):

$$P_{X,TSS} = \frac{QY(S_o - S)}{[1 + (k_d)SRT](0.85)} + \frac{f_d(k_d)QY(S_o - S)SRT}{[1 + (k_d)SRT](0.85)} + Q(TSS_o)$$

Assume $S_o - S \approx S_o$.

$$P_{X,TSS} = \frac{(4000\ m^3/d)(0.18\ g/g)(85.7\ g/m^3)}{[1 + (0.05\ g/g{\cdot}d)(5\ d)](0.85)}$$
$$+ \frac{0.15(0.05)(4000\ m^3/d)(0.18\ g/g)(85.7\ g/m^3)(5\ d)}{[1 + (0.05\ g/g{\cdot}d)(5\ d)](0.85)}$$
$$+ (4000\ m^3/d)(20\ g/m^3)$$
$$= 58{,}074\ g/d + 2178\ g/d + 80{,}000\ g/d$$
$$= 140{,}252\ g/d$$

4. Determine the volume of the anoxic reactor using Eq. (7–55).

$$(\text{MLSS})V = (P_{X,\text{TSS}})\text{SRT}$$

$$\text{At MLSS} = 2000 \text{ g/m}^3$$

$$V = \frac{(140{,}252 \text{ g/d})(5 \text{ d})}{(2000 \text{ g/m}^3)} = 350.6 \text{ m}^3$$

$$\tau = \frac{V}{Q} = \frac{(350.6 \text{ m}^3)(24 \text{ h/d})}{(4000 \text{ m}^3/\text{d})} = 2.1 \text{ h}$$

5. Use a detention time in the aeration zone = 15 min = 0.25 h
6. Determine the size of the clarifier.

Use hydraulic application rate = 24 $\text{m}^3/\text{m}^2\cdot\text{d}$ (given)

$$\text{Clarifier area} = \frac{(4000 \text{ m}^3/\text{d})}{(24 \text{ m}^3/\text{m}^2\cdot\text{d})} = 166.7 \text{ m}^2$$

Use two clarifiers:

Area/clarifier = 83.3 m^2

Clarifier diameter = 10.3 m

Round diameter to nearest 0.5 m, thus,

Clarifier diameter = 10.5 m.

Nitrogen Removal in Anaerobic Digestion Recycle Streams

Recycle flows from dewatering of anaerobically digested solids contain high NH_4-N concentrations (>1000 mg/L) that can increase wastewater influent load by 15 to 20 percent. The recycle steam is also characterized by relatively high temperature and pH. A sidestream treatment process termed the *Sharon*™ (single-reactor high-activity ammonia removal over nitrite) process has been developed at Delft University of Technology in the Netherlands to remove nitrogen biologically from digester recycle in a relatively short detention time reactor (Hellinga et al., 1998). The process takes advantage of the effect of high temperature on nitrification kinetics that favor more rapid growth of ammonia-oxidizing bacteria over nitrite-oxidizing bacteria. A complete-mix reactor without solids recycle is operated with intermittent aeration for nitrification and denitrification. The BOD in the anaerobic recycle stream is low compared to the NH_4-N concentration, so for nitrite reduction, methanol is added during the anoxic period to provide an electron donor. In a bench-scale study, 80 to 85 percent nitrogen removal has been reported for an operation having a temperature of 35°C, 1.5 d SRT, 80 min of aeration, and 40 min of anoxic contacting. The *Sharon*™ process can also be operated without the anoxic step and methanol addition to produce a nitrite-rich recycle stream that can be fed to a preanoxic zone or to the plant headworks.

Alternative Process Configurations for Biological Nitrogen Removal

A variety of activated-sludge process configurations are used to accomplish biological nitrogen removal. Representative process schematics and descriptions for biological nitrogen-removal processes are given in Table 8–21.

Process Design Parameters

Typical parameters used for the design and operation of various biological nitrogen-removal processes are presented in Table 8–22.

Process Selection Considerations

The selection of a specific process for biological nitrogen removal will depend on site-specific conditions, existing processes and equipment, and treatment needs. The advantage and limitations of the processes commonly used and their treatment capability in terms of effluent total nitrogen concentrations are summarized in Table 8–23.

The MLE process is one of the most common methods used for biological nitrogen removal, and can be adapted easily to existing activated-sludge facilities. The amount of nitrate removal is limited by the practical levels of internal recycle to the preanoxic zone, and the process is used more generally to achieve effluent total nitrogen concentrations between 5 and 10 mg/L. Dissolved oxygen control should be used in the zone from which the recycle stream is taken to limit the amount of DO fed to the anoxic zone.

The step-feed process is also applicable for meeting effluent total nitrogen concentrations of less than 10 mg/L. However, it is theoretically possible to achieve lower effluent nitrogen total concentrations (ranging from less than 3 to 5 mg/L) with step-feed BNR using internal recycle, such as in the MLE process, for the last pass of the anoxic-aerobic step-feed process. As in the MLE process, the DO concentration from the aerobic zone must be controlled to minimize dissolved oxygen addition to the anoxic zone. In the case of the step-feed process, more DO control points are required. Influent flow splitting measurement and control are necessary to optimize the step-feed reactor volume for nitrogen removal.

The sequencing batch reactor process provides a high degree of flexibility for nitrogen removal. Mixing during the fill period provides an opportunity for anoxic conditions for nitrate removal. During the aeration react period, the DO concentration may be cycled to provide anoxic operating periods. The batch decant reactor designs are slightly less flexible than the SBR processes because they depend on internal recycle like the MLE for a major portion of the nitrate removal.

Bio-denitro™, Nitrox™, and the oxidation ditch with DO control are all processes with large reactor volumes for nitrogen removal, and represent various methods for optimizing biological nitrogen removal in oxidation ditch systems. Very low effluent total nitrogen concentrations (less than 5 mg/L) have been reported for the Bio-denitro™ process. The Nitrox™ process is generally limited to effluent total nitrogen concentrations of 5 to 8 mg/L. During the aeration "off period" in the Nitrox™ process, ammonia accumulates in the oxidation ditch, resulting in higher effluent NH_4-N concentrations from the process. The effluent NH_4-N and total nitrogen concentration is dependent on

the total reactor volume and influent nitrogen concentrations. Higher influent TKN concentrations can result in higher effluent ammonia concentrations.

The Bardenpho process and postanoxic processes with methanol addition have demonstrated the ability to achieve less than 3 mg/L total nitrogen. The second anoxic zone of the Bardenpho process has a very low denitrification rate, resulting in less efficient reactor volume utilization. The addition of methanol to the second anoxic zone reduces the reactor volume requirements.

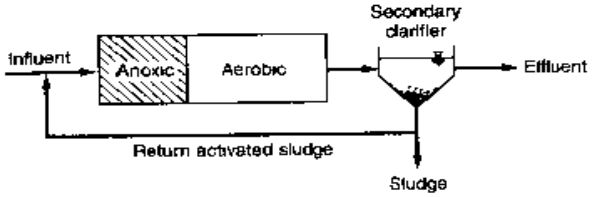
The SNdN processes, such as the Orbal™ and Sym-Bio™ NADH control process, require large reactor volumes and some operator attention and skill. However, depending on the operating conditions, these processes have been shown to be capable of producing very low effluent total nitrogen concentrations.

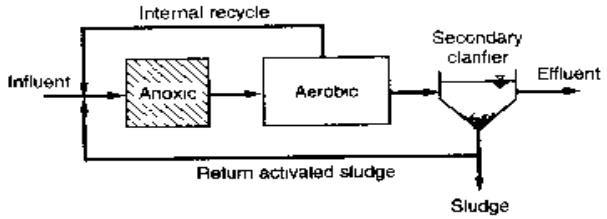
Besides removing nitrogen, the preanoxic and SNdN processes have additional advantages over the postanoxic processes. By removing nitrate before or during the nitrification step, the alkalinity produced by denitrification is made available to offset the alkalinity depleted by nitrification. Because 3.57 g of alkalinity (as $CaCO_3$) are produced per g NO_3-N oxidized, and 7.14 g alkalinity (as $CaCO_3$) are used per g NH_4-N oxidized, almost half of the alkalinity used for nitrification can be provided by preanoxic or SNdN processes. The recovery of alkalinity is very important for wastewaters that have low alkalinity. In some applications, alkalinity may have to be added in the form of lime or sodium hydroxide, at significant cost, to maintain an acceptable pH for the nitrification process.

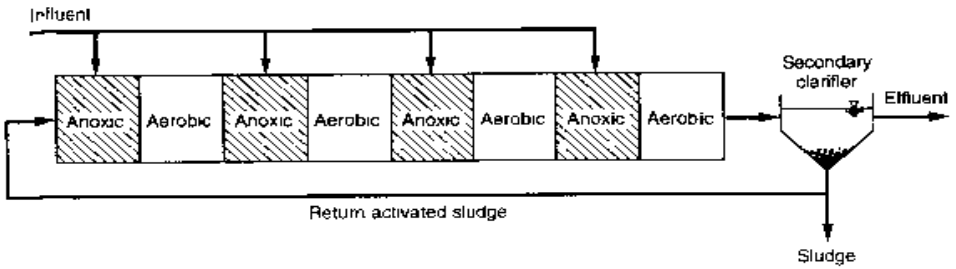
Other advantages of these processes include aeration energy savings and the ability to produce a sludge that settles well. By using nitrate to oxidize influent BOD, the preanoxic and SNdN processes require less oxygen for aeration compared to postanoxic processes. Greater energy savings can be achieved with the SNdN processes as compared to the preanoxic processes, because they are operated at a lower DO concentration. By operating at a lower DO concentration, the DO gradient is larger, which results in more efficient oxygen transfer during aeration. Internal recycle pumping is also eliminated, which accounts for further energy reduction.

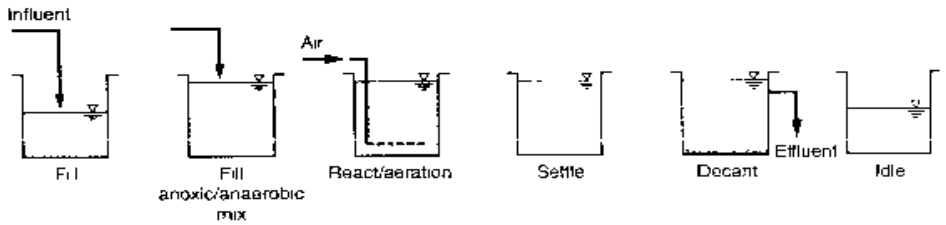
The postanoxic suspended growth process with methanol addition lacks the benefits of the preanoxic process, i.e., energy savings, alkalinity production, and filamentous bulking control, and has higher operating cost because of the purchase of methanol. The selection of the postanoxic suspended growth process is driven mainly by the site layout, existing reactor configuration, and equipment considerations.

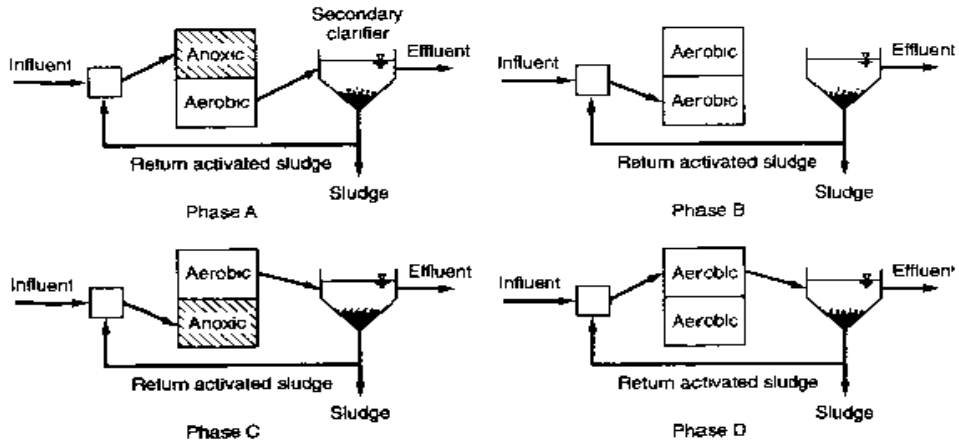
Table 8–21
Description of suspended growth processes for nitrogen removal

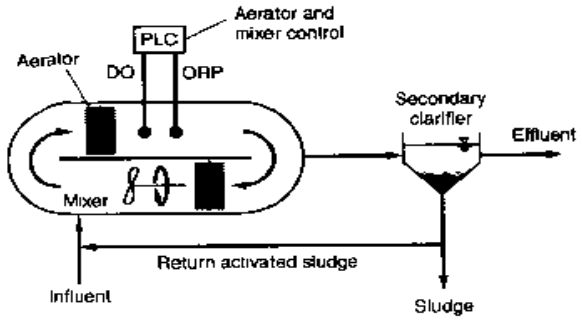








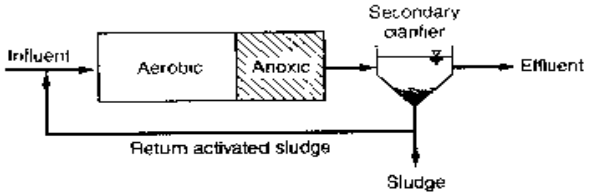




Process	Description
Preanoxic (a) Ludzack-Ettinger  (b) Modified Ludzack-Ettinger (MLE)  	The first concept of a preanoxic BNR was an anoxic-aerobic operating sequence by Ludzack and Ettinger (1962). The influent wastewater was fed to an anoxic zone, which was followed by an aerobic zone. The process relies on the nitrate formed in the aerobic zone being returned via the RAS to the anoxic zone. Because the only nitrate fed to the anoxic zone is that in the RAS, denitrification is limited greatly by the RAS recycle ratio. However, more recently, this process has been used with increased RAS recycle rates to prevent rising sludge in the secondary clarifiers due to denitrification One of the most commonly used BNR processes is the modified Ludzack-Ettinger (MLE) process. Barnard (1973) improved on the original Ludzack-Ettinger design by providing the internal recycle to feed more nitrate to the anoxic zone directly from the aerobic zone. Both the denitrification rate and overall nitrogen-removal efficiency are increased. The internal recycle flow ratio (recycle flowrate divided by influent flowrate) typically ranges from 2 to 4. With sufficient influent BOD and anoxic contact time, these recycle ratios result in an average effluent NO_3-N concentration from 4 to 7 mg/L when treating domestic wastewater. The MLE process is very adaptable to existing activated-sludge facilities and can easily meet a common effluent standard of <10mg/L total nitrogen. A BOD/TKN ratio of 4:1 in the influent wastewater is usually sufficient for effective nitrate reduction by preanoxic processes. Typical anoxic tank detention times for the MLE process range from 2 to 4 h, but when the anoxic zone is divided into 3 to 4 stages in series, denitrification kinetic rates are increased and the total detention time needed may then be 50 to 70 percent of the single-stage design. Another modification of the MLE process, termed "eMLE," uses an additional set of anoxic/aeration basins to enhance nutrient removal *(continued)*

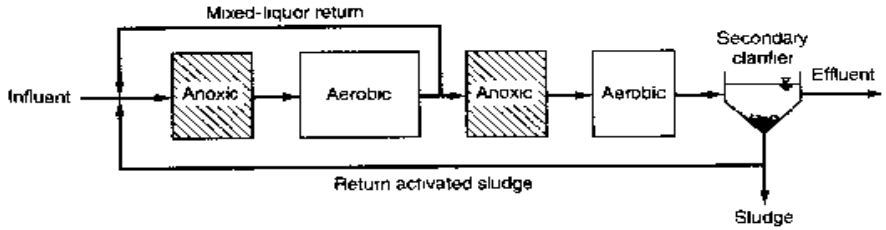
Table 8–21 (*Continued*)

Process	Description
Preanoxic (*Continued*) (c) Step feed  	Preanoxic zones can also be used in a step-feed BNR process. Because step-feed BNR processes are usually adapted to existing multiple-poss full-scale tanks, symmetrical anoxic/aerobic stages are generally used. However, nonsymmetrical designs with smaller initial anoxic/aerobic stages can take better advantage of the higher MLSS concentration in the early stages, due to less RAS dilution, resulting in greater treatment capacity. A possible influent flow splitting percent distribution for a 4-pass system is 15:35:30:20. The final flow portion to the last anoxic/aerobic zone is critical as the nitrate produced in the aerobic zone from that flow will not be reduced, and will thus determine the final effluent NO_3-N concentration. Effluent NO_3-N concentrations of less than 8 mg/L are possible
(d) Sequencing batch reactor (SBR)  	The SBR system (see Table 8–15) also employs preanoxic denitrification using BOD in the influent wastewater. Mixing is used during the fill period to contact the mixed liquor with the influent wastewater. For many domestic applications, depending on the wastewater strength, sufficient BOD and fill time are available to remove almost all of the nitrate remaining in the mixed liquor after the settle and decant steps. Some nitrate removal also occurs during the nonaerated settle and decant periods Separate mixing provides operating flexibility and is useful for anoxic operation during the aeration period, as well as anaerobic or anoxic contacting during the fill period. Mixing without aeration during the fill period is effective in improving sludge-settling properties in addition to nitrogen removal. Many facilities have reported effluent NO_3-N concentrations of less than 5 mg/L.
(e) Bio-denitro™  	The Bio-denitro™ process has also been referred to as a phased-isolation oxidation ditch technology. The process was developed in Denmark for nitrogen removal and has been installed in over 75 full-scale facilities producing effluent total nitrogen concentrations of less than 8 mg/L (Stensel and Coleman, 2000). The technology uses at least two oxidation ditches in a series configuration in which the operating sequence of the ditches and operation of the aeration and anoxic zones is varied. Submerged mixers are installed in the ditches so that for some operating phases, the basin is only mixed and not aerated. The basin continues to receive influent wastewater and operates as a preanoxic zone. Similar to the SBR operation, nitrate is available from a previous aerobic nitrification operation. Besides denitrification in the preanoxic zones, nitrate reduction is also possible during the aerobic operation depending on the DO concentration level. A typical duration for phases A, B, C, and D is 1.5, 0.5, 1.5, and 0.5 h, respectively



(f) Nitrox™

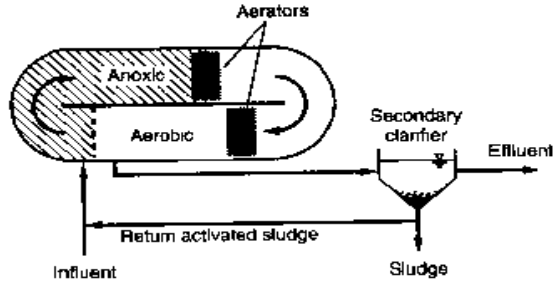
In the Nitrox™ process, the oxidation ditch operation is switched from an aerobic to an anoxic operating condition by turning off the aeration and operating a submerged mixer to maintain channel velocity. The process depends on the use of oxidation-reduction potential (ORP) control to (1) determine when the nitrate is depleted during the anoxic operation and (2) restart aeration. At selected times, the aerators are turned off and the mixer is turned on. When the nitrate is depleted in the aeration OFF period, the ORP drops dramatically. The ORP data is interpreted by a PC, which starts the aeration. A typical operating condition for the Nitrox™ process is to turn the aerators off at least twice per day, usually in the morning when the load is increasing and then in the early evening hours (Stensel and Coleman, 2000). The off-time for the nitrate depletion usually lasts 3 to 5 h depending on the plant load and amount of nitrate in the oxidation ditch. Effluent NO_3-N concentrations of less than 8 mg/L and NH_4-N concentrations ranging from 1.0 to 1.5 mg/L have been reported

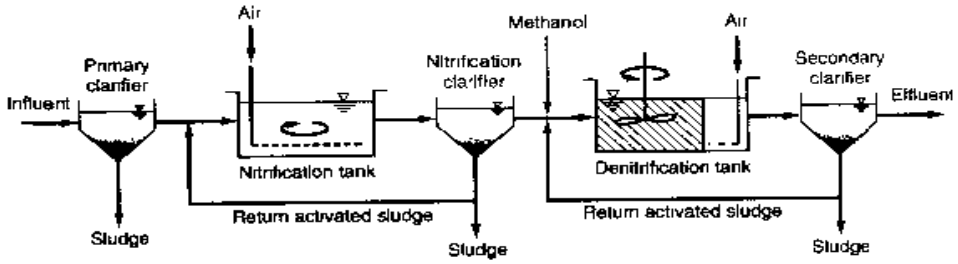


Postanoxic

(g) Single-sludge

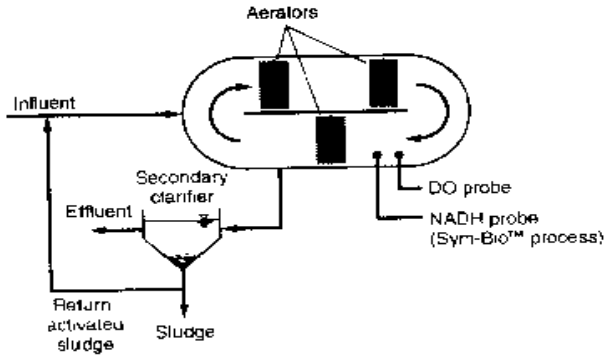
In the single-sludge process (developed by Wuhrmann), nitrogen removal was accomplished in the activated-sludge process by adding a mixed anoxic tank after aerobic nitrification. To achieve high nitrate-removal efficiency, a long detention time is required in the postanoxic tank because the denitrification rate is proportional to the endogenous respiration rate in the mixed liquor





(h) Bardenpho (4-stage)

Both preanoxic and postanoxic denitrification are incorporated in the Bardenpho process, which was developed and applied at full-scale facilities in South Africa in the mid-1970s, before making its way to the United States in1978. The detention time of the postanoxic stage is about the same as or larger than that used for the preanoxic zone. In the postanoxic zone, the NO_3-N concentration leaving the aeration zone is typically reduced from about 5 to 7 mg/L to less than 3 mg/L. During pilot-plant testing with higher-strength wastewaters, Barnard (1974) found that biological phosphorus removal occurred as well as nitrogen removal, hence the basis for the process name (the name comes from the first three letters of the inventor's name, Barnard; denitrification; and phosphorus)



(*continued*)

Table 8-21 (*Continued*)

Process	Description
Postanoxic (*Continued*) (i) Oxidation ditch  	Depending on the aeration design and length of the oxidation ditch channel, anoxic denitrification zones can be established in oxidation ditches to accomplish biological nitrogen removal in a single tank. An aerobic zone exists after the aerator, and as the mixed liquor flows down the channel away from the aerator, the DO concentration decreases due to oxygen uptake by the biomass. At a point where the DO is depleted, an anoxic zone is created in the ditch channel and the nitrate will be used for endogenous respiration activity by the mixed liquor. Most of the readily degradable BOD had been consumed previously in the aerobic zone. Because of the large tank volumes and long SRTs used in oxidation ditch processes, sufficient capacity is available to accommodate nitrification and denitrification zones. DO control is necessary, however, to maintain a sufficient anoxic zone volume to allow for significant nitrogen removal
(j) Two-stage (two-sludge) with an external carbon source  	An approach that was most popular in the 1970s and is occasionally used today is a postanoxic design with exogenous external carbon addition, usually methanol. The activated-sludge anoxic zone (1 to 3 h) is mixed and a short aeration time (<30 min) follows to strip nitrogen gas bubbles from the floc and to provide aerobic conditions to improve liquid-solids separation in the clarifier. Methanol is a commonly used substrate because it is more effective than other substrates for denitrification in terms of cost per unit of nitrate removed. Though its absolute cost may be higher than glucose or acetate, methanol is less expensive overall because it has a relatively low biomass yield. The lower yield means that a greater portion of the methanol is oxidized to result in a higher ratio of nitrate used per g of substrate provided. Typical ratios of methanol to nitrate removal are 3.0 to 4.0 g/g depending on the amount of DO in the influent wastewater and the anoxic system SRT. Longer SRT designs have greater amounts of biomass oxidized by endogenous respiration, which consumes nitrate, and thus the influent methanol to nitrate ratio can be lower. The use of methanol requires special storage and monitoring precautions as it is a flammable substance. Because methanol is flammable, other substrates, such as acetate, have been considered. Attached growth denitrification reactors with methanol addition have also been used for postanoxic nitrogen removal (see Chap. 9)

Simultaneous nitrification/denitrification

(k) Low DO oxidation ditch

Oxidation ditches that have sufficient volume available are able to accommodate both nitrification and denitrification at lower rates under low DO conditions. An oxidation ditch may be used to maintain DO concentrations below 0.5 mg/L with manual or automated DO control. Where multiple aerators are used, for example, with brush aerators, a low to zero DO is maintained throughout the channel. Besides DO control, other methods may be used, and one such method using NADH measurement is the Sym-Bio™ process.

The Sym-Bio™ process uses both a DO probe and an NADH probe to control simultaneous nitrification/denitrification (Trivedi and Heinen, 2000). The bacteria content of the reduced form of coenzyme nicotinamide adenine dinucleotide (NADH) is measured by the emitted fluorescence after exposed to ultraviolet light emission by the NADH probe. NADH plays a significant role in bacteria reactions that involve the transfer of hydrogen. Under more reduced conditions, the ratio of NADH/NAD will increase in the bacteria cell. The NADH probe can be used to accomplish SNdN by (1) monitoring the changes in NADH in the activated sludge and (2) controlling the operation of activated-sludge systems operated at low to zero DO concentrations. The process involves a series of steps; the DO is lowered and when the NADH/NAD ratio reaches a set value, the DO is increased to a higher level for a predetermined time. Effluent NO_3-N and NH_4-N concentrations of less than 3.0 and 1.0 mg/L, respectively, have been achieved

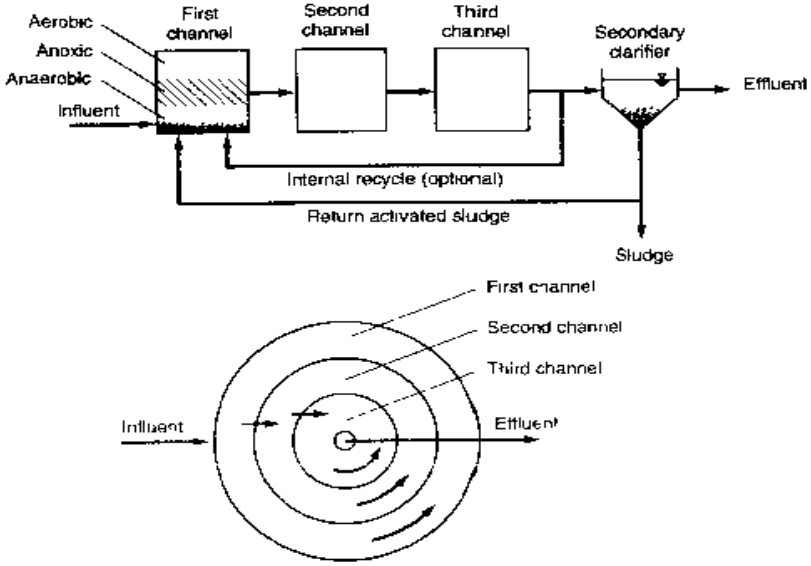
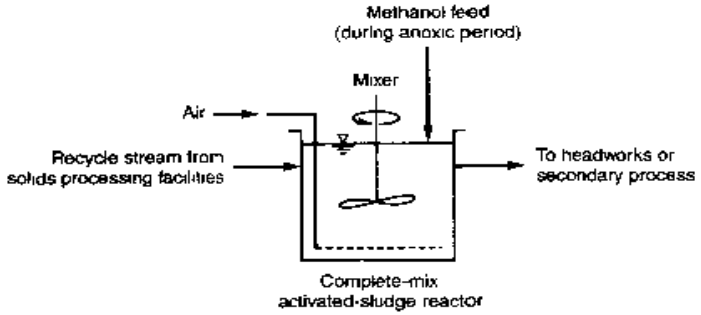
Table 8–21 (*Continued*)





Process	Description
Simultaneous nitrification/denitrification (*Continued*) (l) Orbal™ 	The channels in the Orbal process are operated in series with a zero to low DO (<0.3 mg/L) concentration in the first channel, a 0.5 to 1.5 mg/L DO concentration in the second channel, and a higher DO concentration (2 to 3 mg/L) in the third channel. The first channel receives the influent wastewater and return activated sludge and generally contains about one-half the total basin volume. Volumes of the second and third channels are about one-third and one-sixth of the total basin volumes, respectively. Recycle of mixed liquor from the inner loop to the outer loop allows denitrification of nitrates resulting from nitrification in the inner channels. Variations of the process include operation with and without internal recycle flow (Bionutre™ process) from the third channel to the first channel. An oxygen supply rate of about 50% of the estimated design requirement has been recommended to support SNdN in the first zone
Nitrogen removal from digested sludge processing recycle flows (m) Sharon (single-reactor high-activity ammonia removal over nitrite) 	A sidestream treatment process, the Sharon process, has been developed at Delft University of Technology in the Netherlands to remove nitrogen biologically from recycle flows from dewatering of anaerobically digested solids (Hellinga et al. 1998). The recycle stream is also characterized by a relatively high temperature and high pH. The process takes advantage of high-temperature effects on nitrification kinetics, which favors more rapid growth of ammonia-oxidizing bacteria and inhibition of nitrite-oxidizing bacteria. A short residence time (1 to 2 d) is then used to favor mainly nitrite production with an on/off aeration operation that provides an anoxic operating period to reduce nitrite. Methanol is added during the anoxic period to provide an electron donor for nitrite reduction. Alternatively, the nitrite stream can be returned to the headworks to provide an electron acceptor for odor control

Table 8-22
Typical design parameters for commonly used nitrogen-removal processes

Design parameter/ process	SRT, d[a]	MLSS, mg/L	τ, h			RAS, % of influent	Internal recycle, % of influent
			Total	Anoxic zone	Aerobic zone		
MLE	7–20	3000–4000	5–15	1–3	4–12	50–100	100–200
SBR	10–30	3000–5000	20–30	Variable	Variable		
Bardenpho (4-stage)	10–20	3000–4000	8–20	1–3 (1st stage)	4–12 (2nd stage)	50–100	200–400
				2–4 (3rd stage)	0.5–1 (4th stage)		
Oxidation ditch	20–30	2000–4000	18–30	Variable	Variable	50–100	
Bio-denitro™	20–40	3000–4000	20–30	Variable	Variable	50–100	
Orbal™	10–30	2000–4000	10–20	6–10	3–6 (1st stage)	50–100	Optional
					2–3 (2nd stage)

Table 8-23
Advantages and limitations of nitrogen-removal processes

Process	Advantages	Limitations
Preanoxic—general	Saves energy; BOD is removed before aerobic zone	
	Alkalinity is produced before nitrification	
	Design includes an SVI selector	
MLE	Very adaptable to existing activated-sludge processes	Nitrogen-removal capability is a function of internal recycle
	5 to 8 mg/L TN is achievable	Potential *Nocardia* growth problem
		DO control is required before recycle
Step feed	Adaptable to existing step-feed activated-sludge processes	Nitrogen-removal capability is a function of flow distribution
	With internal recycle in last pass, nitrogen concentrations less than 5 mg/L are possible	More complex operation than MLE; requires flow split control to optimize operation
	5 to 8 mg/L TN is achievable	Potential *Nocardia* growth problem
		Requires DO control in each aeration zone

(continued)

Table 8-23 (*Continued*)

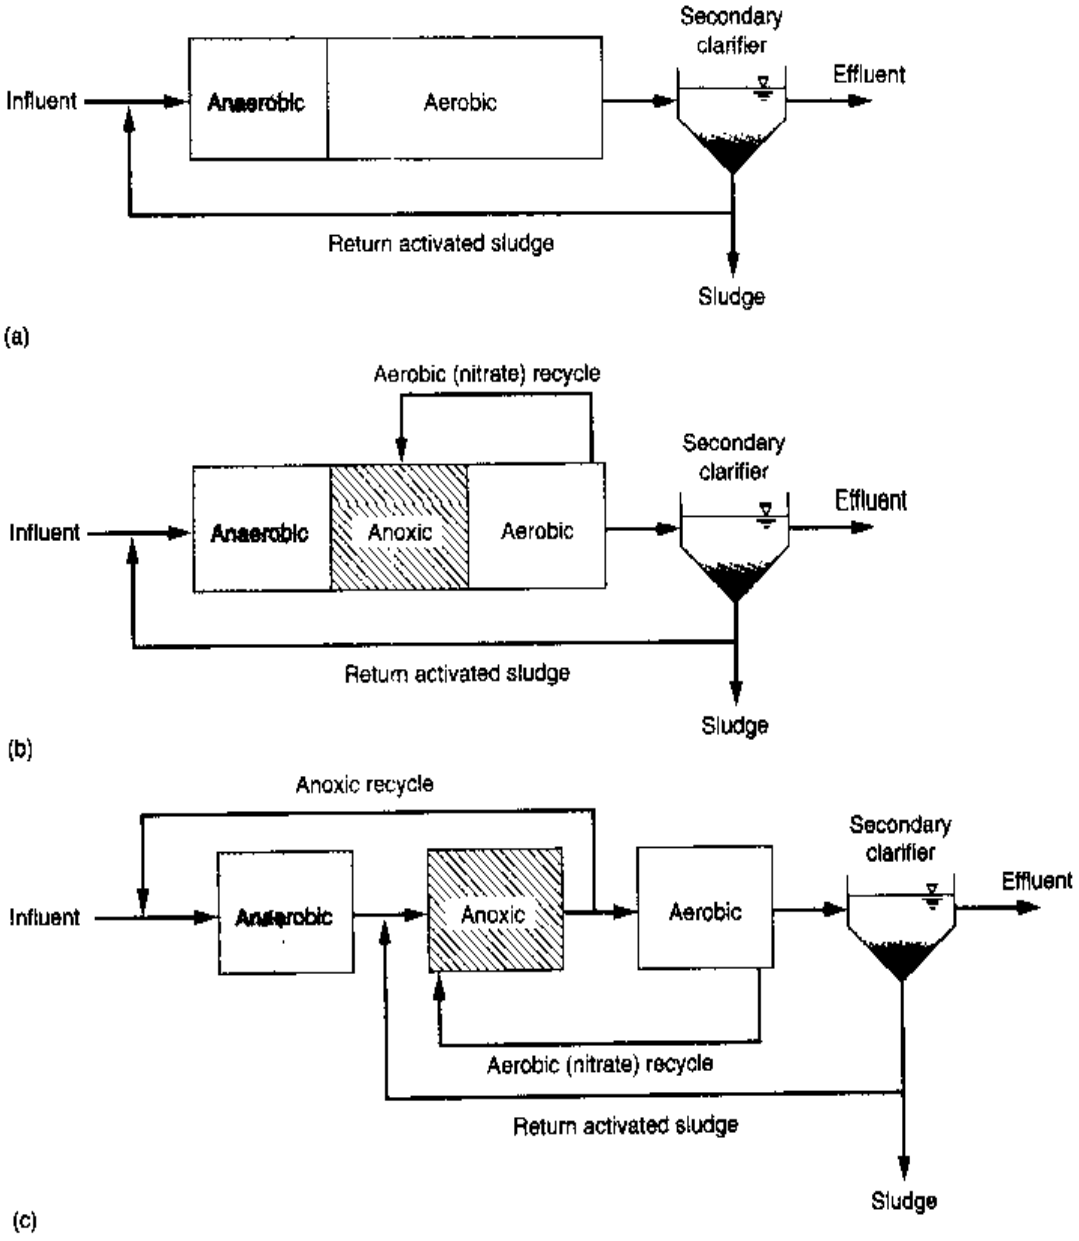
Process	Advantages	Limitations
Sequencing batch reactor	Process is flexible and easy to operate	Redundant units are required for operational reliability unless aeration system can be maintained without draining the aeration tank
	Mixed-liquor solids cannot be washed out by hydraulic surges because flow equalization is provided	More complex process design
	Quiescent settling provides low effluent TSS concentration	Effluent quality depends upon reliable decanting facility
	5 to 8 mg/L TN is achievable	May need effluent equalization of batch discharge before filtration and disinfection
Batch decant	5 to 8 mg/L TN is achievable	Less flexible to operate than SBR
	Mixed-liquor solids cannot be washed out by hydraulic surges	Effluent quality depends upon reliable decanting facility
Bio-denitro™	5 to 8 mg/L TN is achievable	Complex system to operate
	Large reactor volume is resistant to shock loads	Two oxidation ditch reactors are required; increases construction cost
Nitrox™	Large reactor volume is resistant to shock loads	Nitrogen-removal capability is limited by higher influent TKN concentrations
	Easy and economical to upgrade existing oxidation ditch processes	Process is susceptible to ammonia bleed-through
	Provides SVI control	Performance is affected by influent variations
Bardenpho (4-stage)	Capable of achieving effluent nitrogen levels less than 3 mg/L	Large reactor volumes required
		Second anoxic tank has low efficiency
Oxidation ditch	Large reactor volume is resistant to load variations without affecting effluent quality significantly	Nitrogen-removal capability is related to skills of operating staff and control methods
	Has good capacity for nitrogen removal; less than 10 mg/L effluent TN is possible	
Postanoxic with carbon addition	Capable of achieving effluent nitrogen levels less than 3 mg/L	Higher operating cost due to purchase of methanol
	May be combined with effluent filtration	Methanol feed control required
Simultaneous nitrification/ denitrification	Low effluent nitrogen level possible (3 mg/L lower limit)	Large reactor volume; skilled operation also required
	Significant energy savings possible	Process control system required
	Process may be incorporated into existing facilities without new construction	
	SVI control enhanced	
	Produces alkalinity	

8–6 PROCESSES FOR BIOLOGICAL PHOSPHORUS REMOVAL

Over the past 20 years, several biological suspended growth process configurations have been used to accomplish biological phosphorus removal, and they all include the basic steps of an anaerobic zone followed by an aerobic zone. Barnard (1974) was the first to clarify the need for anaerobic contacting between activated sludge and influent wastewater before aerobic degradation to accomplish biological phosphorus removal. Other modifications of the basic process include (1) combining the anaerobic/aerobic sequence with various biological nitrogen-removal designs, (2) recycling mixed liquor to the anaerobic zone from a downstream anoxic zone instead of only from the secondary clarifier underflow, (3) adding volatile fatty acids to the anaerobic zone as either acetate or a liquid stream from a fermentation reactor processing primary clarifier sludge, and (4) using multiple-staged anaerobic and aerobic reactors.

The alternating exposure to anaerobic conditions can be accomplished in the main biological treatment process, or "mainstream," or in the return sludge stream, or "sidestream." Several mainstream biological phosphorus-removal processes and one sidestream process, Phostrip™, are described in this section. Also included in this section are process design considerations, process control, analysis of biological phosphorus-removal performance, design parameters, and process selection considerations. The first "mainstream" biological phosphorus-removal process that was included with biological nitrogen removal is the Bardenpho process at Palmetto, FL, shown on Fig. 8–2*b*.

Biological Phosphorus-Removal Processes



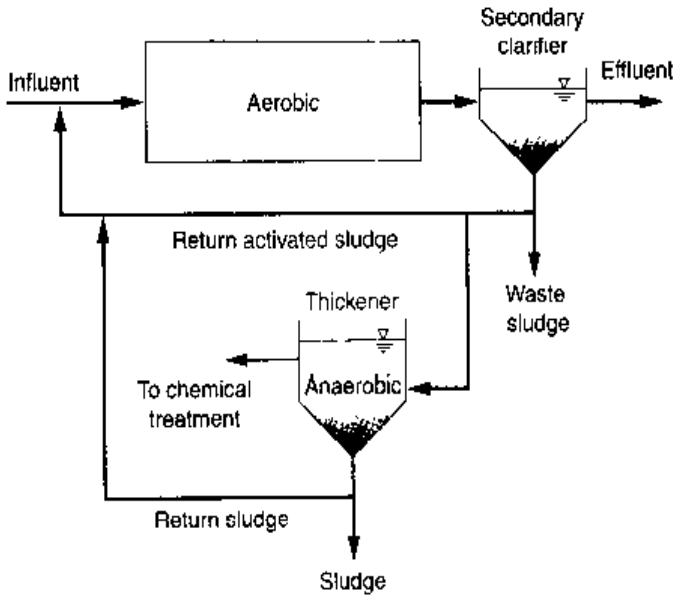
Three biological phosphorus-removal (BPR) configurations that are more commonly used are shown on Fig. 8–29. Barnard (1975) used the term *Phoredox* to represent any process with an anaerobic/aerobic sequence to promote BPR. Since then, other process names have evolved to designate specific process configurations, such as the A/O™ (anaerobic/aerobic only) or A^2O™ (anaerobic/anoxic/aerobic) processes. The A/O™ process is similar to the Phoredox process and was patented and marketed by Air Products and Chemicals, Inc., as well as the A^2O™ process.

The main difference between the Phoredox (A/O) process and the A^2O processes shown on Fig. 8–29*a* and *b* is that nitrification does not occur in the Phoredox (A/O) process. Low operating SRTs are used to prevent the initiation of nitrification. Desirable SRT values range from 2 to 3 d at 20°C and 4 to 5 d at 10°C for biological phosphorus removal to occur without nitrification (Grady et al., 1999). For applications where nitrification is needed to meet discharge requirements, the process must also include biological denitrification to prevent excessive amounts of nitrate from entering the anaerobic reactor by way of the RAS recycle. Heterotrophic bacteria will use nitrate to consume rbCOD in the anaerobic zone, which then leaves less rbCOD available for phosphorus-storing bacteria, thus decreasing the biological phosphorus-removal treatment efficiency.

The A^2O and UCT (University of Cape Town) processes are two basic types of mainstream systems used for nitrate removal with BPR. In the A^2O process, the return activated-sludge (RAS) recycle, which contains nitrate, is directed to the anaerobic

Figure 8–29

Typical mainstream biological phosphorus-removal processes: (*a*) Phoredox (A/O), (*b*) A^2O, and (*c*) University of Cape Town (UCT).



zone (see Fig. 8–29*b*). In the UCT process (see Fig. 8–29*c*), the RAS recycle is directed instead to an anoxic zone, and the mixed-liquor recycle to the anaerobic zone is drawn following the anoxic zone where the nitrate concentration is minimal. The UCT and similar processes (see later discussion in this section) are used generally for relatively weak wastewaters where the addition of nitrate would have a significant effect on the BPR performance.

The PhoStrip™ process combines biological and chemical processes for phosphorus removal. A portion of phosphorus-rich return activated sludge is diverted to an anaerobic stripping tank where phosphorus is released in solution (see Fig. 8–30). The phosphorus-rich stripper supernatant is then precipitated with lime and the stripped biomass is returned to the aeration tank. In the PhoStrip process, phosphorus-removal efficiency depends less on the influent rbCOD concentrations than for other biological phosphorus-removal processes (WEF, 1998).

Figure 8–30

PhoStrip sidestream biological treatment process for the removal of phosphorus.

Process Design Considerations

The process design considerations for BPR processes include (1) wastewater characteristics, (2) anaerobic contact time, (3) SRT, (4) waste sludge processing method, and (5) chemical addition capability. The reaction kinetics for BOD removal, nitrification, and denitrification are similar to those discussed in Secs. 8–4 and 8–5.

Wastewater Characteristics. Wastewater characterization, including rbCOD measurements, is essential to evaluate fully the design and performance of BPR systems. Biological phosphorus removal is initiated in the anaerobic zone where acetate (and propionate) is taken up by phosphorus-storing bacteria and converted to carbon storage products that provide energy and growth in the subsequent anoxic and aerobic zones. The rbCOD is the primary source of volatile fatty acids (VFAs) for the phosphorus-storing bacteria. The conversion of rbCOD to VFAs occurs quickly through fermentation in the anaerobic zone and 7 to 10 mg of acetate results in about 1.0 mg P removal by enhanced phosphorus removal (Wentzel et al., 1989; Wentzel et al., 1990). The more acetate, the more cell growth, and, thus, more phosphorus removal. Because of the need for organic material for nitrate removal, the amount of rbCOD relative to the amount of TKN in the influent is also an important wastewater parameter.

The diurnal variation in wastewater strength is also an important process consideration. Because the performance of phosphorus-storing bacteria depends on the availability of fermentation substrates, it is important to know if periods of low influent wastewater strength may affect BPR performance. For domestic wastewaters, the influent total BOD and rbCOD concentrations will vary with time over a 24-h period, with lower concentrations in the late evening and early morning hours. For smaller-sized communities, the variations are usually more pronounced and very little rbCOD may be present at certain times. During wet-weather conditions, especially in the winter, BPR may be difficult to achieve due to cold, low strength wastewater that does not readily become anaerobic. Extended periods of reduced rbCOD concentration have been reported to decrease BPR performance for a number of hours after the occurrence of

low substrate concentration (Stephens and Stensel, 1998). The impact of continuous acetate feeding at plants where sludge fermentation has been done to produce additional VFAs has shown the benefit of a steady supply of rbCOD for biological phosphorus removal. In parallel modified Bardenpho trains at Kelowna, Canada, one train was fed fermentation liquor and the other train was used as the control. With continuous VFA addition, the effluent soluble phosphorus concentration decreased from 2.5 to 0.3 mg/L (Oldham and Stevens, 1985), and the VFA/P ratio was 6.7 g/g, an amount lower than the estimated 7 to 10 g/g. Based on these results, it appears that continuous acetate addition may provide more efficient biological phosphorus removal.

Anaerobic Contact Time. The role of the anaerobic contact zone has been described in Sec. 7–11. Detention times of 0.25 to 1.0 h are adequate for fermentation of rbCOD. To account for the effect of the MLVSS concentration in the anaerobic contact zone, a 1-d SRT is recommended for the anaerobic contact zone design (Grady et al., 1999). Barnard (1984) cautioned against using too long an anaerobic contact time due to the potential for a *secondary release* of phosphorus, which is phosphorus release not associated with acetate uptake. When secondary release occurs, bacteria have not accumulated polyhydroxybutyrate (PHB) for subsequent oxidation in the aerobic zone. Polyhydroxybutyrate provides energy for phosphorus uptake and storage. From SBR bench-scale studies, Stephens and Stensel (1998) found that secondary phosphorus release occurred for anaerobic contact times in excess of 3.0 h.

Solids Retention Time. Biological nutrient-removal systems with longer SRTs are less efficient for BPR than shorter SRT designs. Observations of the influent BOD to phosphorus removal ratio for a number of plants as a function of their design SRT are summarized in Table 8-24 (Grady et al., 1999). Processes with longer SRT values had less biological phosphorus removal for a given amount of influent BOD. These data were obtained without measurements of the rbCOD concentration in the wastewater, but provide a general trend on the effect of SRT on BPR removal efficiency. Two adverse effects on phosphorus removal efficiency are associated with lightly loaded, long SRT processes. First, because the final amount of phosphorus removed is proportional to the amount of biological phosphorus-storing bacteria wasted, the phosphorus-storing biomass production is lower so that less phosphorus can be removed. Second, at long SRTs the biological phosphorus bacteria are in a more extended endogenous phase, which will deplete more of their intracellular storage products. If the intracellu-

Table 8-24 Summary of observed influent BOD and COD to phosphorus-removal ratios for different BPR processes[a]

Type of BPR process[b]	BOD/P ratio, g BOD/g P	COD/P ratio, g COD/g P	SRT, d
Phoredox, VIP	15–20	26–34	<8.0
A^2O, UCT	20–25	34–43	7–15
Bardenpho	>25	>43	15–25

[a] Adapted from Grady et al. (1999)

[b] For process descriptions, see Table 8–25.

lar glycogen is depleted, less efficient acetate uptake and PHB storage will occur in the anaerobic contact zone, thus making the overall BPR process less efficient (Stephens and Stensel, 1998).

Waste Sludge Processing. Because phosphorus is removed in the sludge wasted from BPR processes, consideration must be given to the waste sludge processing methods and the potential to recycle excessive amounts of phosphorus back to the BPR process. In Chap. 7, review of the biological phosphorus-removal mechanism showed that phosphorus is released when the bacteria that contain stored phosphorus are subject to anaerobic conditions. Anaerobic conditions in thickening and/or digestion can thus result in the release of significant amounts of phosphorus. The recycle stream from these processes would, in essence, increase the influent phosphorus concentration that would then require a greater amount of influent rbCOD to produce low effluent phosphorus concentrations.

Thickening of waste sludge by dissolved air flotation, gravity belt thickeners, or rotary-drum thickeners is preferred over gravity thickening of waste sludge to minimize phosphorus release. Phosphorus release would be expected from anaerobic and aerobic digestion processes as well. However, less phosphorus release and recycle have been observed than expected for anaerobic and aerobic digestion evaluations (Randall et al., 1992). Based on bench-scale aerobic digestion studies on sludge from a BPR process at the Little Patuxent wastewater treatment plant (WWTP) in Howard County, MD, only 20 percent P release was observed. At the York River, VA, WWTP, only 27 percent of the phosphorus removed was released in an anaerobic digester. The formation of phosphorus precipitates, such as struvite and brushnite, was credited with keeping phosphorus out of solution. Direct land application of liquid, digested sludge or dewatered raw sludge followed by stabilization such as composting minimizes recycled phosphorus loads.

Chemical Addition Capability. Many BPR facility designs include provisions for phosphorus removal by chemical precipitation in addition to biological removal. Where there are insufficient amounts of rbCOD in the influent wastewater, chemical addition is necessary to provide enough phosphorus removal to meet the effluent discharge concentration needed. Alum or iron salts may be used (see Chap. 6) and may be applied at a number of locations in the liquid stream treatment process. Where effluent filtration is used and the additional amount of phosphorus to be removed is small (less than 2.0 mg/L), chemicals may be added and mixed with the flow before filtration. Chemical addition prior to the secondary clarifier is also possible. Where primary treatment is used, alum or iron salts may be added to remove phosphorus prior to the biological process. The biological process is then depended upon to remove the phosphorus to the low concentration required. Present experience indicates that the phosphorus can be removed biologically to dissolved concentrations as low as 0.20 to 0.30 mg/L, provided sufficient rbCOD is available. Iron salts may be preferred in some cases over alum salts for primary treatment applications, because they have the additional advantage of removing sulfide to help reduce odors.

The choice of the chemical addition point can affect the chemical dosage. When added for polishing to achieve low effluent phosphorus concentrations, the metal salt is added at dosages well above the stoichiometric ratio, which is the theoretical amount needed to form a metal/phosphorus precipitate compound. By adding the metal salt

before the biological process, stoichiometric ratios can be used to minimize the chemical dose needed.

Process Control

BPR performance is not just dependent on placing an anaerobic zone in front of the aerobic zone of an activated-sludge process and the amount of rbCOD in the influent wastewater. Process performance is affected by a number of operating conditions including (1) nitrate-removal efficiency in processes in which nitrification occurs, (2) process SRT, (3) control of dissolved oxygen entering the anaerobic zone, (4) phosphorus in recycle streams, and (5) the system effluent suspended solids concentration.

Effect of Dissolved Oxygen and Nitrate in Recycle Flows. Recycle flows to the anaerobic contact zone must be evaluated in terms of their possible effects on BPR, and some recycle streams should be avoided where possible. Filter backwash recycle flows should be sent to the aerobic zone instead of the anaerobic or anoxic zones. Recycle streams with significant concentrations of DO and nitrate can have an adverse impact on process performance. The nitrate concentration in the RAS flow can have a significant effect on the amount of influent rbCOD that is available for BPR. Assuming a synthesis yield of 0.4 g VSS/g rbCOD removed, the amount of rbCOD used by nitrate and oxygen fed to the anaerobic zone can be estimated as follows:

The oxygen used for rbCOD oxidation equals the rbCOD removed minus the COD in the biomass formed:

$$\left(\frac{1.0\ \text{g O}_2}{\text{g rbCOD}}\right) - \left(\frac{1.42\ \text{g O}_2}{\text{g VSS}}\right)\left(\frac{0.4\ \text{g VSS}}{\text{g rbCOD}}\right) = \left(\frac{0.43\ \text{g O}_2}{\text{g rbCOD}}\right) \tag{8-59}$$

or 2.3 g rbCOD used/g DO added

Based on COD used for dissolved oxygen, the COD used for nitrate consumption can be estimated, as the oxygen equivalent of NO_3-N is 2.86 g/g as follows:

$$\frac{\text{g rbCOD}}{\text{g NO}_3\text{-N}} = \left(\frac{2.3\ \text{g rbCOD}}{\text{g O}_2}\right)\left(\frac{2.86\ \text{g O}_2}{\text{g NO}_3\text{-N}}\right) = 6.6\ \text{g rbCOD/g NO}_3\text{-N} \tag{8-60}$$

Based on the above rbCOD/NO_3-N ratio and rbCOD/DO ratio, the impact of DO and nitrate fed into the anaerobic contact zone on the BPR performance can be evaluated. The rbCOD in the influent wastewater added to the anaerobic zone will most likely be removed by bacteria using oxygen and nitrate before it is available for biological phosphorus removal.

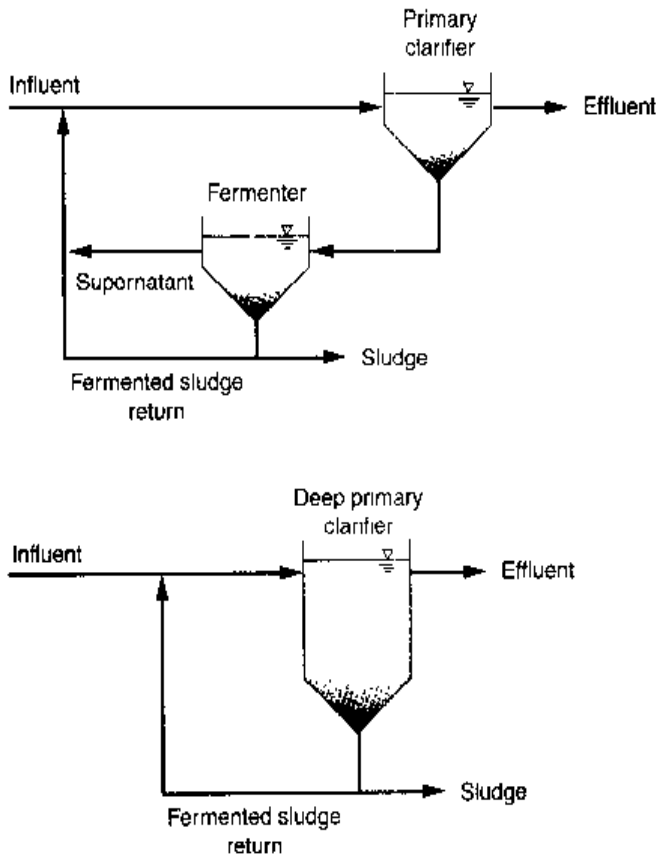
Effect of Recycle Streams with Released Phosphorus. As discussed under Process Design Considerations, recycle streams from sludge thickening or digestion processes may contain high phosphorus concentrations. Equalization and control of the recycle flow and phosphorus load with time may help to minimize the impact of the recycled phosphorus on effluent quality. By adding the recycle streams during times of the day when the influent wastewater strength is higher, a better possibility exists of removing recycled phosphorus in the waste sludge. Recycle streams may also be treated separately with chemical addition to minimize the phosphorus load to the liquid treatment process.

Effluent Suspended Solids. The phosphorus content in the mixed-liquor solids is greater than that from the conventional activated-sludge process due to the biological phosphorus storage. The phosphorus content, on a dry solids basis, may be in the range of 3 to 6 percent (Randall et al., 1992). Thus, the total phosphorus concentration in the effluent can be affected significantly by the system effluent TSS concentration. At 3 to 6 percent phosphorus in the solids, the phosphorus contribution in an effluent having a TSS concentration of 10 mg/L would be 0.3 to 0.6 mg/L, values that are significant if the effluent standard is less than 1.0 mg P/L. Fortunately, most BPR processes exhibit good settling characteristics and have secondary clarifier effluent TSS concentrations of 10 mg/L or less. To provide very low effluent phosphorus concentrations, effluent filtration may be required.

Solids Separation Facilities

Operation of the solids separation facilities affects the process design and performance. If chemical addition is necessary for effluent polishing to achieve low phosphorus levels in the effluent, sufficient clarifier capacity is required to handle the additional chemical precipitate. Typical clarifier overflow rates for biological phosphorus removal are also given in Table 8–7.

Methods to Improve Phosphorus-Removal Efficiency in BPR Systems



The performance of BPR systems is very site-specific and depends on the wastewater characteristics and the plant process design and operation. For wastewaters with relatively low influent rbCOD concentrations, effluent soluble phosphorus concentrations may exceed 1.0 to 2.0 mg/L, whereas effluent concentrations below 0.5 or 1.0 mg/L have been shown for higher-strength wastewaters. Methods to improve performance for overall phosphorus removal include the following:

1. Provide supplemental acetate by direct purchase or by primary sludge fermentation.
2. Reduce the process SRT.
3. Add alum or iron salts in primary treatment or for effluent polishing.
4. Reduce the amount of nitrate and/or oxygen entering the anaerobic zone.

Two methods used to provide additional rbCOD for biological phosphorus removal are to import (purchase) an exogenous carbon source (i.e., acetate) or to produce VFAs from fermentation of primary clarifier sludge. Two examples of primary sludge fermentation design are shown on Fig. 8–31; other designs are also possible. As shown on Fig. 8–31*a*, a fermentation reactor provides residence time and mixing of the primary sludge, and VFAs are released through the primary clarifier for feed to the secondary treatment process anaerobic zone. A deeper depth primary clarifier design (Fig. 8–31*b*) has also been proposed to provide sufficient holding time for the settled primary sludge for hydrolysis and acid fermentation (Barnard, 1984). The underflow sludge is recycled to release VFAs to the liquid stream. Operating issues of odors, mixing, and accumulation of rags in the fermenters must also be considered. The primary tank sludge fermenters are not heated and SRT values ranging from 3 to 5 d, depending on temperature, are generally used to stay below the point where methanogenic activity can start (Rabinowitz and Oldham, 1985). At SRT values greater than 4 to 5 d, methanogenesis activity can be high enough to consume the VFAs. The VFA production ranges from

Figure 8-31

Examples of fermentation reactors for producing volatile fatty acids (VFAs) used for phosphorus removal.

0.1 to 0.2 g VFA/g VSS applied to the fermenters. Fermenters can add an additional 10 to 20 mg/L VFA concentration to the influent wastewater, and lower, more consistent effluent soluble phosphorus concentrations have been observed when fermenters are used.

A good example of process changes that can improve BPR performance has been shown for the Kelowna, British Columbia, plant (Oldham and Stevens, 1985), which was one of the first noted successes with primary sludge fermentation. A two-train modified Bardenpho™ facility is used to provide BPR. The first change was to ferment primary sludge in existing tanks that were operated as sludge thickeners with long holding times. The thickener overflow was fed to the Bardenpho anaerobic zone. The fermenter effluent VFA concentration ranged from 110 to 140 mg/L and, when mixed with the primary effluent, resulted in a VFA concentration of 9 to 10 mg/L. The additional VFA supply to the BPR process decreased the average effluent phosphorus concentration from about 1.5 to 0.5 mg/L. Alum was later added before the secondary clarifiers at a dosage of about 8 mg/L (as alum) to further reduce the effluent phosphorus concentration. With both prefermentation and alum addition, the effluent phosphorus concentration averaged less than 0.20 mg/L for the period from September 1989 to August 1990. During 1993, alum addition was stopped and the last two anoxic-aerobic stages of the Bardenpho™ system were taken out of service, when a higher effluent nitrate concentration was allowed. Removing the latter two stages resulted in a lower SRT for the process, and the average effluent phosphorus concentration decreased to 0.10 mg/L. The other benefit claimed for removing the second anoxic zone was that it had longer than necessary detention times for nitrate removal. The second anoxic zone was suspected of causing undesired secondary phosphorus release.

Biological Phosphorus-Removal Process Performance

The following example is designed to illustrate the methodology used in evaluating the performance of a BPR process. Because biological phosphorus- and nitrogen-removal processes are very complex with many dependent interactions, comprehensive simulation models (Barker and Dold, 1997) are very useful for evaluating biological phosphorus- and nitrogen-removal designs.

EXAMPLE 8–10 Biological Phosphorus Removal An A^{2}O™ biological nutrient-removal process receives wastewater with the characteristics shown. The RAS contains 6.0 mg/L NO_3-N and the system is operated at a 7 d SRT. The RAS recycle ratio is 0.5. The anaerobic contact detention time is 0.75 h. Estimate the effluent soluble phosphorus concentration and the phosphorus content of the waste sludge.

Design conditions and assumptions:

1. Wastewater characteristics:

Item	Unit	Value
Flowrate	m^3/d	4000
Total BOD	g/m^3	140
rbCOD	g/m^3	70
nbVSS	g/m^3	20
Inorganic inert matter	g/m^3	10
TKN	g/m^3	35
NO_3-N	g/m^3	0
Phosphorus	g/m^3	7
Temperature	°C	20

Note: g/m^3 = mg/L.

2. 10 g rbCOD/g P is removed by biological phosphorus removal
3. rbCOD/nitrate ratio = 6.6 g rbCOD/g NO_3-N
4. Phosphorus content of heterotrophic biomass = 0.015 g P/g biomass
5. bCOD/BOD ratio = 1.6
6. $NO_x \approx 0.80$ TKN
7. Use coefficients from Tables 8–10 and 8–11

Solution

1. Determine the rbCOD available for biological phosphorus removal using a mass balance at the influent to the reactor.
   a. Develop a mass balance for nitrate

$$Q_{RAS}(NO_3\text{-}N)_{inf} + Q_{RAS}(NO_3\text{-}N)_{RAS} = (Q + Q_{RAS})(NO_3\text{-}N)_{React}$$

   where $Q_{RAS} = 0.5Q$
   $(NO_3\text{-}N)_{React}$ = nitrate feed to reactor

$$Q(0) + 0.5Q(6\ \text{g/m}^3) = 1.5Q(\text{NO}_3\text{-N})_{\text{React}}$$

$$(\text{NO}_3\text{-N})_{\text{React}} = 2\ \text{g}(\text{NO}_3\text{-N})/\text{m}^3$$

b. Determine rbCOD available for P removal

$$\text{rbCOD equivalent} = [2\ \text{g}(\text{NO}_3\text{-N})/\text{m}^3](6.6\ \text{g rbCOD/g})(\text{NO}_3\text{-N})$$

$$= 13.2\ \text{g/m}^3$$

$$\text{rbCOD available for P removal} = (70 - 13.2)\ \text{g/m}^3 = 56.8\ \text{g/m}^3$$

2. Phosphorus removed by BPR mechanism

$$\text{Biological P removal} = \frac{(56.8\ \text{g rbCOD/m}^3)}{(10\ \text{g rbCOD/g P})} = 5.7\ \text{g P/m}^3$$

3. Determine phosphorus used for heterotrophic biomass synthesis in addition to phosphorus storage due to BPR.

$$\text{Biomass production [Eq. (8–15)]: } P_{\text{X,bio}} = \frac{Q(Y)(S_o - S)}{[1 + (k_d)\text{SRT}]} + \frac{Q(Y_n)(\text{NO}_x)}{[1 + (k_{dn})\text{SRT}]}$$

Assume $S_o \simeq S_o - S$

$$\text{bCOD} = 1.6\ \text{BOD} = 1.6(140\ \text{g/m}^3) = 224\ \text{g/m}^3$$

$$\text{NO}_x = 0.80\ \text{TKN} = 0.80(35\ \text{g/m}^3) = 28\ \text{g/m}^3$$

$$P_{x,\text{bio}} = \frac{(4000\ \text{m}^3/\text{d})(0.4\ \text{g/g})(224\ \text{g/m}^3)}{[1 + (0.12\ \text{g/g·d})(7\ \text{d})]}$$

$$+ \frac{(4000\ \text{m}^3/\text{d})(0.12\ \text{g/g})(28\ \text{g/m}^3)}{[1 + (0.08\ \text{g/g·d})(7\ \text{d})]}$$

$$= (194{,}783 + 8615)\ \text{g/d} = 203{,}398\ \text{g/d}$$

P utilized for biomass growth:

$$\text{P used} = (0.015\ \text{g P/g biomass})(203{,}398\ \text{g/d}) = 3015\ \text{g/d}$$

$$\text{In g/m}^3 = \frac{(3015\ \text{g/d})}{(4000\ \text{m}^3/\text{d})} = 0.8\ \text{g/m}^3$$

4. Determine effluent soluble P.

$$\text{P removed} = (5.7 + 0.8)\ \text{g/m}^3 = 6.5\ \text{g/m}^3$$

$$\text{Effluent soluble P} = (7.0 - 6.5)\ \text{g/m}^3 = 0.5\ \text{g/m}^3$$

5. Determine P content of waste sludge.

$$\text{Total P in sludge} = (6.5\ \text{g/m}^3)(4000\ \text{m}^3/\text{d})(1\ \text{kg}/10^3\ \text{g}) = 26.0\ \text{kg/d}$$

Determine total sludge production using Eqs. (8–15) and (8–16).

$$P_{X,TSS} = \frac{(4000\ m^3/d)(0.40\ g/g)(224\ g/m^3)(1\ kg/10^3\ g)}{[1 + (0.12\ g/g{\cdot}d)(7\ d)](0.85)}$$

$$+ \frac{(4000\ m^3)(0.12\ g/g)(28\ g/m^3)(1\ kg/10^3\ g)}{[1 + (0.08\ g/g{\cdot}d)(7\ d)](0.85)}$$

$$+ (20\ g/m^3)(4000\ m^3/d)(1\ kg/10^3\ g)$$

$$+ \frac{(0.15)(0.12\ g/g{\cdot}d)(0.40\ g/g)(4000\ m^3/d)(224\ g/m^3)(7\ d)(1\ kg/10^3\ g)}{[1 + (0.12\ g/g{\cdot}d)(7\ d)]\ (0.85)}$$

$$+ (10\ g/m^3)(4000\ m^3/d)(1\ kg/10^3\ g) + \text{phosphorus stored}$$

$$P_{X,TSS} = (229.2 + 10.1 + 80.0 + 28.9 + 40)\ kg/d$$

$$= 388.2\ kg/d$$

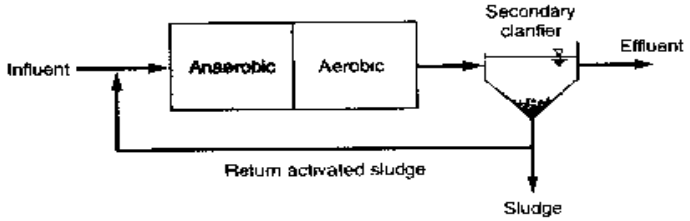
$$\text{Phosphorus, \%} = \frac{(26.0\ kg/d)}{(388.2\ kg/d)} \times 100 = 6.7$$

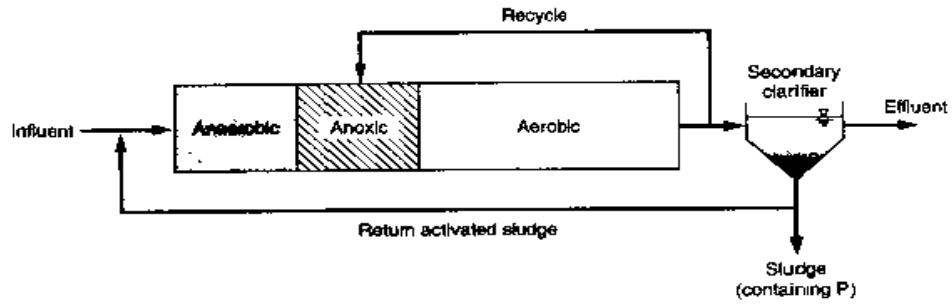
Alternative Processes for Biological Phosphorous Removal

Various modifications to the basic Phoredox process are used for both biological phosphorus and nitrogen removal. Most deal with different designs that are intended to minimize the amount of nitrate fed to the anaerobic zone, some involve short SRTs, and some involve using multiple stages for the anaerobic, anoxic, and aerobic zones.

The principal mainstream processes and the Phostrip sidestream process are described in Table 8–25.

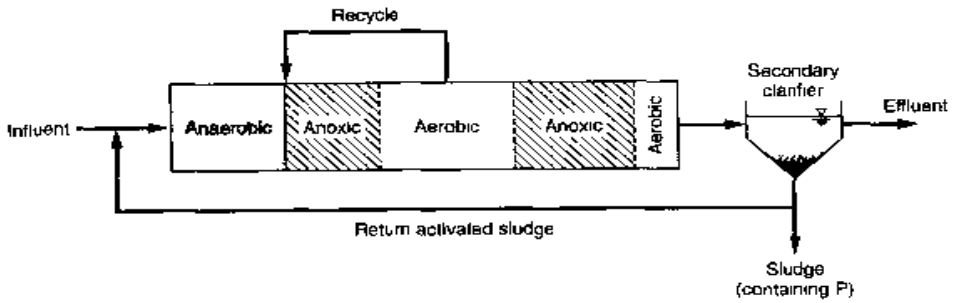
Process Design Parameters





Typical parameters used in the design of biological phosphorus-removal systems are presented in Table 8–26.

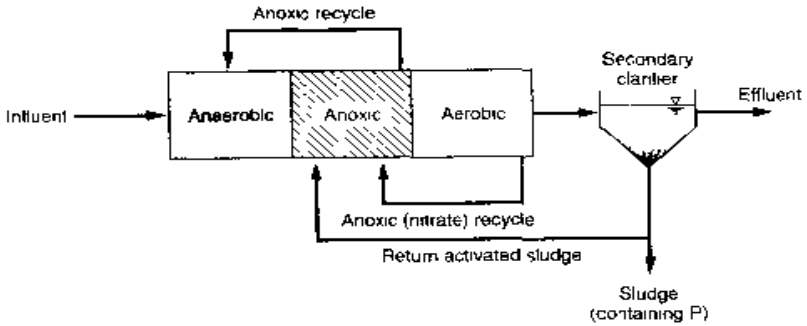
Process Selection Considerations



The processes described for biological phosphorus removal all incorporate the necessary anaerobic contacting between influent wastewater and activated sludge, followed by an aerobic zone for bio-oxidation of stored PHB and phosphorus uptake by the polyphosphate-storing bacteria. The specific designs selected are governed more by other treatment needs such as BOD or nitrogen removal. The advantages and limitations of the biological phosphorus-removal processes are presented in Table 8–27.

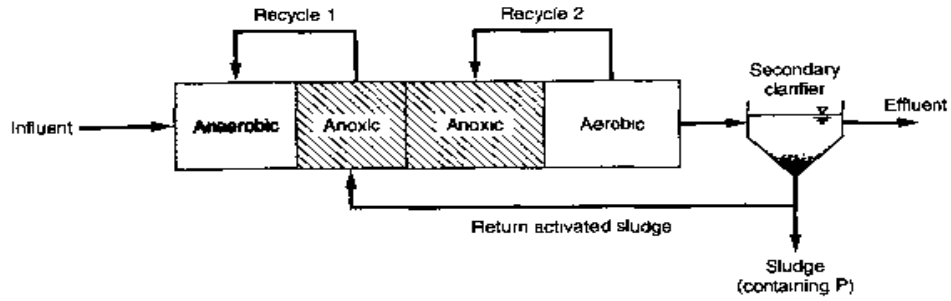
Biological phosphorus-removal efficiency is affected by the overall activated-sludge process as well as the influent wastewater characteristics (Randall et al., 1992). Lower phosphorus-removal efficiency occurs for systems with longer SRTs, more nitrate and/or oxygen input to the anaerobic zone, and less readily biodegradable COD

Table 8–25
Description of suspended growth processes for phosphorus removal



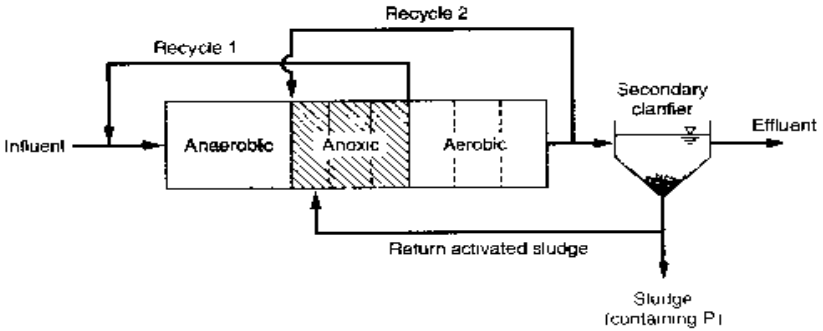
Process	Description
(a) Phoredox (A/O)  	The basic process configuration for biological phosphorus removal consists of an anaerobic zone followed by an aerobic zone. Barnard (1974) was the first to clarify the need for anaerobic contacting between activated sludge and influent wastewater before aerobic degradation to accomplish biological phosphorus removal. Barnard identified it as the Phoredox process. The A/O process is a patented version of Barnard's findings by Air Products and Chemicals, Inc., and the main difference is the use of multiple-staged anaerobic and aerobic reactors. In these processes there is no nitrification, and the anaerobic detention time is 30 min to 1 h to provide the selective condition described in Sec. 7–11 for biological phosphorus removal. The SRT of the aerobic zone mixed liquor is 2 to 4 d, depending on the temperature
(b) A^2/O  	The proprietary A^2/O process is a modification of the A/O process and provides an anoxic zone for denitrification. The detention period in the anoxic zone is approximately 1 h. The anoxic zone is deficient in dissolved oxygen, but chemically bound oxygen in the form of nitrate or nitrite is introduced by recycling nitrified mixed liquor from the aerobic section. Use of the anoxic zone minimizes the amount of nitrate fed to the anaerobic zone in the return activated sludge

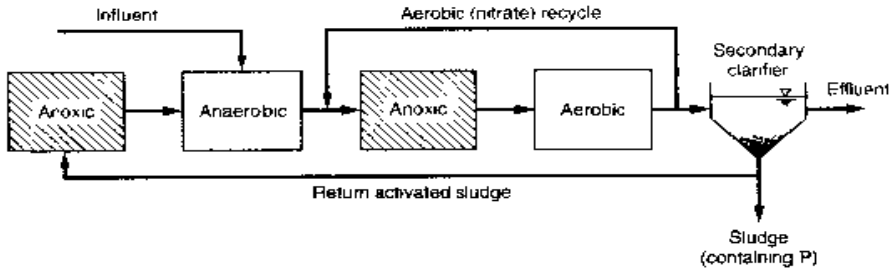
(c) Modified Bardenpho (5-stage)



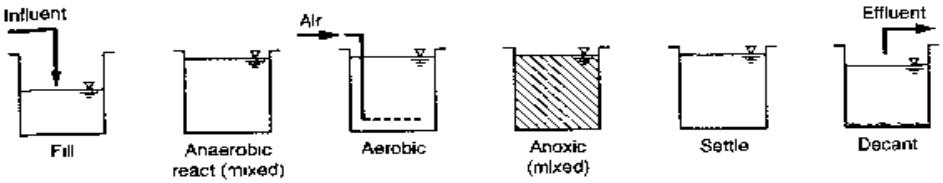
The Bardenpho process, described in Table 8–21, can be modified for combined nitrogen and phosphorus removal. The staging sequence and recycle method are different from the A^2/O process. The 5-stage system provides anaerobic, anoxic, and aerobic stages for phosphorus, nitrogen, and carbon removal. A second anoxic stage is provided for additional denitrification using nitrate produced in the aerobic stage as the electron acceptor, and the endogenous organic carbon as the electron donor. The final aerobic stage is used to strip residual nitrogen gas from solution and to minimize the release of phosphorus in the final clarifier. Mixed liquor from the first aerobic zone is recycled to the anoxic zone. The 5-stage process uses a longer SRT (10 to 20 days) than the A^2/O process, and thus increases the carbon oxidation capability

(d) UCT (standard and modified)





The UCT process stands for the University of Cape Town (South Africa) treatment process where it was developed. The UCT process was developed to minimize the effect of nitrate in weaker wastewaters in entering the anaerobic contact zone. The amount of nitrate in the anaerobic zone is critical to the biological phosphorus-removal efficiency. The UCT process is similar to the A^2/O process with two exceptions. The return activated sludge is recycled to the anoxic stage instead of the aeration stage, and the internal recycle is from the anoxic stage to the anaerobic stage. By returning the activated sludge to the anoxic stage, the introduction of nitrate to the anaerobic stage is eliminated, thereby improving the uptake of phosphorus in the anaerobic stage. The internal recycle feature provides for increased organic utilization in the anaerobic stage. The mixed liquor from the anoxic stage contains substantial soluble BOD but little nitrate. The recycle of the anoxic mixed liquor provides for optimal conditions for fermentation uptake in the anaerobic stage. Because the mixed liquor is at a lower concentration, the anaerobic detention time must be longer than that used in the Phoredox process, and is in the range of 1 to 2 h. The anaerobic recycle rate is typically 2 times the influent flowrate



In the modified UCT process shown on the second diagram, the return activated sludge is directed to an anoxic reactor that does not receive internal nitrate recycle flow. The nitrate is reduced in this tank, and the mixed liquor from the reactor is recycled to the anaerobic tank. The second anoxic tank follows the first anoxic tank and receives internal nitrate recycle flow from the aeration tank to provide the major portion of nitrate removal for the process

(continued)

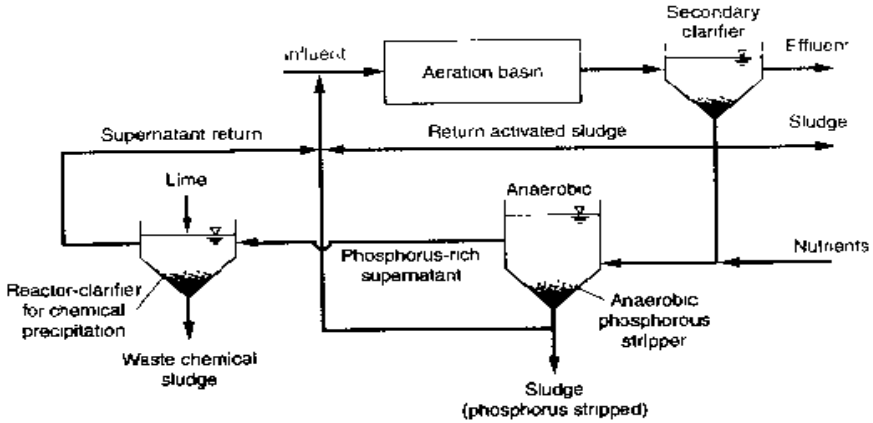


Table 8–25 *(Continued)*

Process	Description
(e) VIP  	The VIP process stands for the Virginia Initiative Plant (Daigger et al., 1988). The VIP process is similar to the A^2/O and UCT processes except for the methods used for recycle systems. In the VIP process, all the zones are staged consisting of at least two completely mixed cells in series. The return activated sludge is discharged to the inlet of the anoxic zone along with nitrified recycle from the aerobic zone. The mixed liquor from the anoxic zone is returned to the head end of the anaerobic zone. The VIP process is also designed as a high-rate system, operating with much shorter SRTs, which maximize biological phosphorus-removal efficiency. The combined SRT of the anaerobic and anoxic zones is generally 1.5 to 3 d, while the anaerobic and anoxic τ values are typically 60 to 90 min each. The aeration zone is designed for nitrification
(f) Johannesburg process  	The process, which originated in Johannesburg, South Africa, is an alternative to the UCT or modified UCT processes to minimize nitrate feeding to the anaerobic zone to maximize biological phosphorus removal for weak wastewaters. The return activated sludge is directed to an anoxic zone that has sufficient detention time to reduce the nitrate in the mixed liquor before it is fed to the anaerobic zone. The nitrate reduction is driven by the endogenous respiration rate of the mixed liquor, and the anoxic zone detention time depends on the mixed liquor concentration, temperature, and the nitrate concentration in the return sludge stream. Compared to the UCT process, a higher MLSS concentration can be maintained in the anaerobic zone, which has a detention time of about 1 h

(g) SBR with biological phosphorus removal

(h) PhoStrip

If sufficient nitrate is removed during the SBR operation, an anaerobic reaction period can be developed during and after the SBR fill period. An anoxic operating period is used after a sufficient aerobic time elapses for nitrification and nitrate production. Alternatively cyclic aerobic and anoxic periods can be used during the react period. The nitrate concentration is thus minimized before settling, and little nitrate is available to compete for rbCOD in the fill and initial react period. Thus, anaerobic conditions occur in the fill and initial react period, so that rbCOD uptake and storage by phosphorus-accumulating bacteria can occur instead of rbCOD consumption by nitrate-reducing bacteria

The PhoStrip process is in essence an anaerobic/aerobic process. The anaerobic condition is created by holding RAS long enough in a gravity thickener with residence times generally in the range of 8 to 12 h (Levin et al., 1975). The released phosphorus is elutriated, usually by adding primary effluent or raw wastewater, which also enhances the anaerobic condition. The overflow from the stripper tank is then treated chemically for phosphorus removal and the RAS is directed to the aerobic tank. Lime is usually used as a chemical to precipitate phosphorus from the stripper tank overflow. The lime dose needed to raise the pH for phosphorus removal is a function of the wastewater alkalinity and not the amount of phosphorus present. If alum and ferric salts are used instead, the dose is proportional to the amount of phosphorus released. Even though chemical treatment is used for phosphorus removal, there is some enhanced phosphorus removal in the waste sludge due to the development of phosphorus-storing bacteria. As shown, the phosphorus-removal performance would be hindered by nitrification

Table 8–26
Typical design parameters for commonly used biological phosphorus-removal processes[a]

Design parameter/process	SRT, d	MLSS, mg/L	τ, h			RAS, % of influent	Internal recycle, % of influent
			Anaerobic zone	Anoxic zone	Aerobic zone		
A/O	2–5	3000–4000	0.5–1.5	—	1–3	25–100	
A^2/O	5–25	3000–4000	0.5–1.5	0.5–1	4–8	25–100	100–400
UCT	10–25	3000–4000	1–2	2–4	4–12	80–100	200–400 (anoxic) 100–300 (aerobic)
VIP	5–10	2000–4000	1–2	1–2	4–6	80–100	100–200 (anoxic) 100–300 (aerobic)
Bardenpho (5-stage)	10–20	3000–4000	0.5–1.5	1–3 (1st stage) 2–4 (2nd stage)	4–12 (1st stage) 0.5–1 (2nd stage)	50–100	200–400
PhoStrip	5–20	1000–3000	8–12		4–10	50–100	10–20
SBR	20–40	3000–4000	1.5–3	1–3	2–4		

[a] Adapted from WEF (1998).

Table 8–27
Advantages and limitations of phosphorus-removal processes

Process	Advantages	Limitations
Phoredox (A/O)	Operation is relatively simple when compared to other processes	Phosphorus removal declines if nitrification occurs
	Low BOD/P ratio possible	Limited process control flexibility is available
	Relatively short hydraulic retention time	
	Produces good settling sludge	
	Good phosphorus removal	
A^2O	Removes both nitrogen and phosphorus	RAS containing nitrate is recycled to anaerobic zone, thus affecting phosphorus-removal capability
	Provides alkalinity for nitrification	
	Produces good settling sludge	Nitrogen removal is limited by internal recycle ratio
	Operation is relatively simple	
	Saves energy	Needs higher BOD/P ratio than the A/O process
UCT	Nitrate loading on anaerobic zone is reduced, thus increasing phosphorus-removal capobility	More complex operation
	For weaker wastewater, process can achieve improved phosphorus removal	Requires additional recycle system
	Produces good settling sludge	
	Good nitrogen removal	
VIP	Nitrate loading on anaerobic zone is reduced, thus increasing phosphorus-removal capability	More complex operation
	Produces good settling sludge	Requires additional recycle system
	Requires lower BOD/P ratio than UCT	More equipment required for staged operation
Bardenpho (5-stage)	Can achieve 3 to 5 mg/L TN in unfiltered effluent	Less efficient phosphorus removal
	Produces good settling sludge	Requires larger tank volumes
SBR	Both nitrogen and phosphorus removal are possible	More complex operation for N and P removal
	Process is easy to operate	Needs larger volume than SBR for N removal only
	Mixed-liquor solids cannot be washed out by hydraulic surges	Effluent quality depends upon reliable decanting facility
	Quiescent settling may produce lower effluent TSS concentration	Design is more complex
	Flexible operation	Skilled maintenance is required
		More suitable for smaller flowrates
PhoStrip	Can be incorporated easily into existing activated-sludge plants	Requires lime addition for phosphorus precipitation
	Process is flexible; phosphorus-removal performance is not controlled by BOD/phosphorus ratio	Requires higher mixed-liquor dissolved oxygen to prevent phosphorus release in final clarifier
	Significantly less chemical usage than mainstream chemical precipitation process	Additional tank capacity required for stripping
	Can achieve reliable effluent orthophosphate concentrations less than 1 mg/L	Lime scaling may be a maintenance problem

in the influent wastewater. Shorter SRT systems like the VIP or Phoredox processes provide more biological phosphorus removal for the same amount of influent BOD than the modified Bardenpho process, for example. In some applications, other sources of rbCOD are obtained to enhance biological phosphorus removal.

8–7 SELECTION AND DESIGN OF PHYSICAL FACILITIES FOR ACTIVATED-SLUDGE PROCESSES

The physical facilities used in the design of activated-sludge treatment systems are presented and discussed in this section. The subjects discussed include (1) the aeration system, (2) aeration tanks and appurtenances, (3) solids separation, and (4) solids separation facilities. A recently developed technology, membrane separation, is also finding application for biological treatment and solids separation and is discussed in Sec. 8–8 and in Chap. 11.

Aeration System

The aeration system design for the activated-sludge process must be adequate to (1) satisfy the bCOD of the waste, (2) satisfy the endogenous respiration by the biomass, (3) satisfy the oxygen demand for nitrification, (4) provide adequate mixing, and (5) maintain a minimum dissolved oxygen concentration throughout the aeration tank. If the oxygen transfer efficiency of the aeration system is known or can be estimated, the actual air requirements for diffused air aeration or installed power of mechanical surface aerators may be determined. The characteristics of air diffusers and the energy requirements for mixing for diffused air and mechanical aeration systems are discussed in Sec. 5–12 in Chap. 5.

To meet sustained organic loadings at peak conditions discussed in Chap. 3, aeration equipment should be designed with a peaking factor of at least 1.5 to 2.0 times the average BOD load. Aeration equipment should also be sized based on a residual dissolved oxygen (DO) of 2 mg/L in the aeration tank at the average load and 1.0 mg/L at peak load. The Ten States Standards [GLUMRBSS (1978)] require the aeration system to be capable of providing oxygen to meet the diurnal peak oxygen demand or 200 percent of the design average, whichever is larger with a residual DO of 2.0 mg/L. The aeration equipment must be designed with enough flexibility to (1) meet minimum oxygen demands, (2) prevent excessive aeration and save energy, and (3) meet maximum oxygen demands.

Aeration Tanks and Appurtenances

After the activated-sludge process and the aeration system have been selected and a preliminary design has been prepared, the next step is to design the aeration tanks and support facilities. The following discussion covers (1) aeration tanks, (2) flow distribution, and (3) froth control systems. Energy requirements for aeration tank mixing are discussed in Sec. 5–12 in Chap. 5

Aeration Tanks. Aeration tanks usually are constructed of reinforced concrete and left open to the atmosphere. A sectional view of a typical aeration tank using porous tube diffusers is shown on Fig. 8–32. The rectangular shape permits common-wall con-

Figure 8-32
View of a typical plug-flow activated-sludge reactor with porous diffusers located near the bottom of reactor on left side and shallow coarse bubble diffusers located on right side.

struction for multiple tanks. The total tank capacity required should be determined from the biological process design. For plants in a capacity range of 0.22 to 0.44 m^3/s (5 to 10 Mgal/d), at least two tanks should be provided (a minimum of two tanks is preferred for smaller plants as well, for redundancy). In the range of 0.44 to 2.2 m^3/s (10 to 50 Mgal/d), four tanks are often provided to allow operational flexibility and ease of maintenance. Large plants, over 2.2 m^3/s (50 Mgal/d) in capacity, should contain six or more tanks. Some of the largest plants have from 30 to 40 tanks arranged in several groups or batteries. Although the air bubbles dispersed in the wastewater occupy perhaps 1 percent of the total volume, no allowance is made for this in tank sizing.

If the wastewater is to be aerated with diffused air, the geometry of the tank may significantly affect the aeration efficiency and the amount of mixing obtained. The depth of wastewater in the tank should be between 4.5 and 7.5 m (~15 and 25 ft) to maximize the energy efficiency of the diffuser systems. Freeboard from 0.3 to 0.6 m (1 to 2 ft) above the waterline should be provided. The width of the tank in relation to its depth is important if spiral-flow mixing is used in the plug-flow configuration. The width-to-depth ratio for such tanks may vary from 1.0:1 to 2.2:1, with 1.5:1 being the most common. In large plants, the channels become quite long and sometimes exceed 150 m (~500 ft) per tank. Tanks may consist of one to four channels with round-the-end flow in multiple-channel tanks. The length-to-width ratio of each channel should be at least 5:1. Where complete-mix diffused air systems are used, the length-to-width ratio may be reduced to save construction cost.

For tanks with diffusers on both sides or in a grid or panel pattern, greater widths are permissible. The important point is to restrict the width of the tank so that "dead spots" or zones of inadequate mixing are avoided. The dimensions and proportions of each independent unit should be such as to maintain adequate velocities so that deposition of solids will not occur. In spiral-flow tanks, triangular baffles or fillets may be placed longitudinally in the corners of the channels to eliminate dead spots and to deflect the spiral flow.

Table 8–28
Typical aeration tank dimensions for mechanical surface aerators

Aerator size		Tank depth		Tank width	
hp	kW	ft	m	ft	m
10	7.5	10–12	3–3.6	30–40	9–12
20	15	12–14	3.6–4.2	35–50	10.5–15
30	22.5	13–15	3.9–4.5	40–60	12–18
40	30	12–17	3.6–5.1	45–65	13.5–20
50	37.5	15–18	4.5–5.5	45–75	13.5–23
75	56	15–20	4.5–6	50–85	15–26
100	75	15–20	4.5–6	60–90	18–27

For mechanical aeration systems, the most efficient arrangement is one aerator per tank. Where multiple aerators are installed in the same tank for best efficiency, the length-to-width ratio of the tank should be in even multiples with the aerator centered in a square configuration to avoid interference at the hydraulic boundaries. The width and depth should be sized in accordance with the power rating of the aerator as illustrated in Table 8–28. Two-speed aerators are desirable to provide operating flexibility to cover a wide range of oxygen demand conditions. Freeboard of about 1 to 1.5 m (3.5 to 5 ft) should be provided for mechanical aeration systems.

Individual tanks should have inlet and outlet gates or valves so that they may be removed from service for inspection and repair. The common walls of multiple tanks must therefore be able to withstand the full hydrostatic pressure from either side. Aeration tanks must have adequate foundations to prevent settlement, and, in saturated soil, they must be designed to prevent flotation when the tanks are dewatered. Methods of preventing flotation include thickening the floor slab, installing hold-down piles, or installing hydrostatic pressure relief valves. Drains or sumps for aeration tanks are desirable for dewatering. In large plants where tank dewatering might be more common, it may be desirable to install mud valves in the bottoms of all tanks. The mud valves should be connected to a central dewatering pump or to a plant drain discharging to the wet well of the plant pumping station. Dewatering systems are commonly designed to empty a tank in 12 to 24 h.

Flow Distribution. For wastewater treatment plants containing multiple units of primary sedimentation basins and aeration tanks, consideration has to be given to equalizing the distribution of flow to the aeration tanks. In many designs, the wastewater from the primary sedimentation basins is collected in a common conduit or channel for transport to the aeration tanks. For efficient use of the aeration tanks, a method of splitting or controlling the flowrate to each of the individual tanks should be used. Methods commonly used are splitter boxes equipped with weirs or control valves or aeration tank influent control gates. Hydraulic balancing of the flow by equalizing the headloss from the primary sedimentation basins to the individual aeration tanks is also practiced. Flow regimes using a form of step feed particularly need a positive means of flow control. Where channels are used for aeration tank influent or effluent transport, they can be equipped with aeration devices to prevent deposition of solids. The air required ranges from 0.2 to 0.5 m^3/lin m·min (2 to 5 ft^3/lin ft·min) of channel.

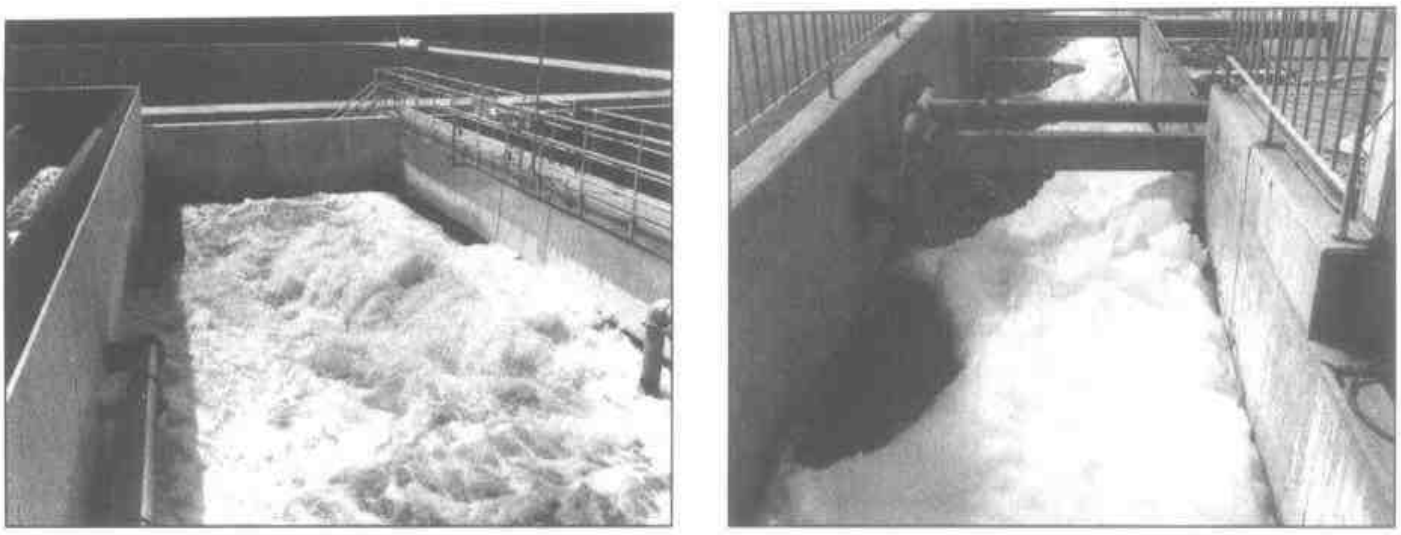

Figure 8–33

Typical non-*Nocardia* froth on activated-sludge aeration tank sludge return channels.

Froth Control Systems. Wastewater normally contains soap, detergents, and other surfactants that produce foam when the wastewater is aerated. If the concentration of mixed-liquor suspended solids is high, the foaming tendency is minimized. Large quantities of foam may be produced during startup of the process, when surfactants are present in the wastewater. The foaming action produces a froth that contains sludge solids, grease, and large numbers of wastewater bacteria (see Fig. 8–33). The wind may lift the froth off the tank surface and blow it about, contaminating whatever it touches. The froth, besides being unsightly, is a hazard to those working with it because it is very slippery, even after it collapses. In addition, once the froth has dried, it is difficult to remove.

It is important, therefore, to consider some method for controlling froth formation, particularly in spiral-flow tanks where the froth collects along the side of the tank, aerated channels, and free-fall from weirs. A commonly used system for spiral-roll tanks consists of a series of spray nozzles mounted above the surface in areas where the froth collects. Screened effluent or clear water is sprayed through these nozzles and physically breaks down the froth as it forms. Another approach is to meter a small quantity of antifoaming chemical additive into the spray water.

***Nocardia* Foam Control.** *Nocardia* foam, discussed in Sec. 8–3, is a thick layer of brown, biological foam that forms on the top of aeration tanks and clarifiers. When the *Nocardia* organisms grow in sufficient numbers, they tend to trap air bubbles that subsequently float to the surface and accumulate as scum. When *Nocardia* foam occurs, it should be removed from the system, as it will also cause foaming problems in anaerobic and aerobic digesters. *Nocardia* foam has been controlled by spraying a chlorine solution directly into the foam layer. In some cases, spray nozzles have been installed within a hood located across the width of plug-flow aeration tanks. The addition of a cationic polymer to the activated-sludge process has also been used to control the production of *Nocardia* foam (Shao et al., 1997). Chlorinating the return activated sludge (RAS) for bulking control may not be effective, as it may cause floc breakup and inhibit BOD removal and nitrification.

Solids Separation

The separation of solids in the activated-sludge process is a very important function in order to provide well-clarified effluent and concentrated solids that are returned to the biological treatment system or wasted to the solids processing facilities. The design of secondary clarifiers following suspended growth biological treatment considers two functions: (1) a sufficient time is needed to provide gravity settling of particles and a relatively clear liquid and (2) thickening of the settled solids to provide higher solids concentration in the return activated sludge. The clarification design considerations and parameters that relate to mixed-liquor settling and thickening characteristics were discussed previously in Sec. 8–3.

For solids-thickening considerations, the solids loading rate ($kg/m^2 \cdot d$), which is the rate of solids feed relative to the clarifier cross-sectional area, is the primary process parameter. In this section, methods are presented to determine solids loading rates as a function of the sludge-settling properties and clarifier return sludge flowrate. The analysis to determine acceptable loadings requires knowledge of the sludge-thickening characteristics. Thus, the procedures presented in this section are more applicable for the evaluation and optimization of existing systems than the design for new systems. For new systems where data are not available, the design parameters given in Table 8–7 may be used.

Two methods of clarifier analysis are described: solids flux and state point analyses. Both methods are based on the same principles.

Solids Flux Analysis. The area required for thickening of the applied mixed liquor depends on the limiting solids flux that can be transported to the bottom of the sedimentation basin. Because the solids flux varies with the characteristics of the sludge, column settling tests should be conducted to determine the relationship between the sludge concentration and the settling rate. The required area can then be determined using the solids flux analysis procedure described below. The depth of the thickening portion of the sedimentation tank must be sufficient to (1) ensure maintenance of an adequate sludge blanket depth so that unthickened solids are not recycled, and (2) temporarily store excess solids that may be applied.

A method used to determine the area required for hindered settling is based on an analysis of the solids (mass) flux. Data derived from settling tests must be available when applying this method, which is based on an analysis of the mass flux (movement across a boundary) of the solids in the settling basin.

In a settling basin that is operating at steady state, a constant flux of solids is moving downward, as shown on Fig. 8–34. Within the tank, the downward flux of solids is brought about by gravity (hindered) settling and by bulk transport due to the underflow that is being pumped out and recycled. At any point in the tank, the mass flux of solids due to gravity (hindered) settling is

$$SF_g = C_i V_i (1\ kg/10^3\ g) \tag{8–61}$$

where SF_g = solids flux due to gravity, $kg/m^2 \cdot h$
C_i = concentration of solids at the point in question, g/m^3
V_i = settling velocity of the solids at concentration C_i, m/h

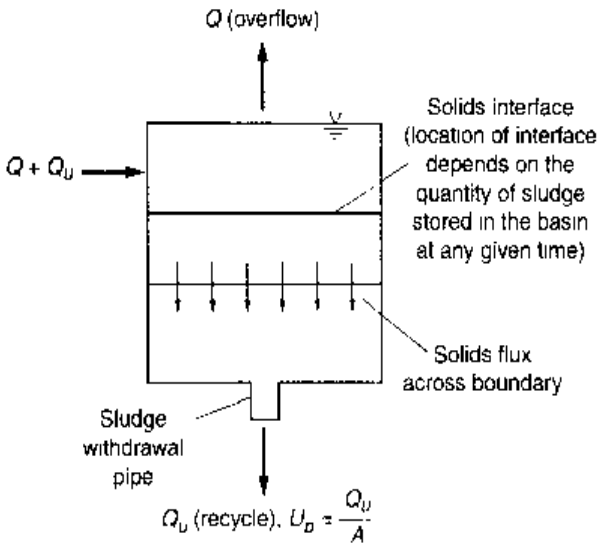

Figure 8–34
Definition sketch for a settling basin operating at steady state.

The mass flux of solids due to the bulk movement of the suspension is

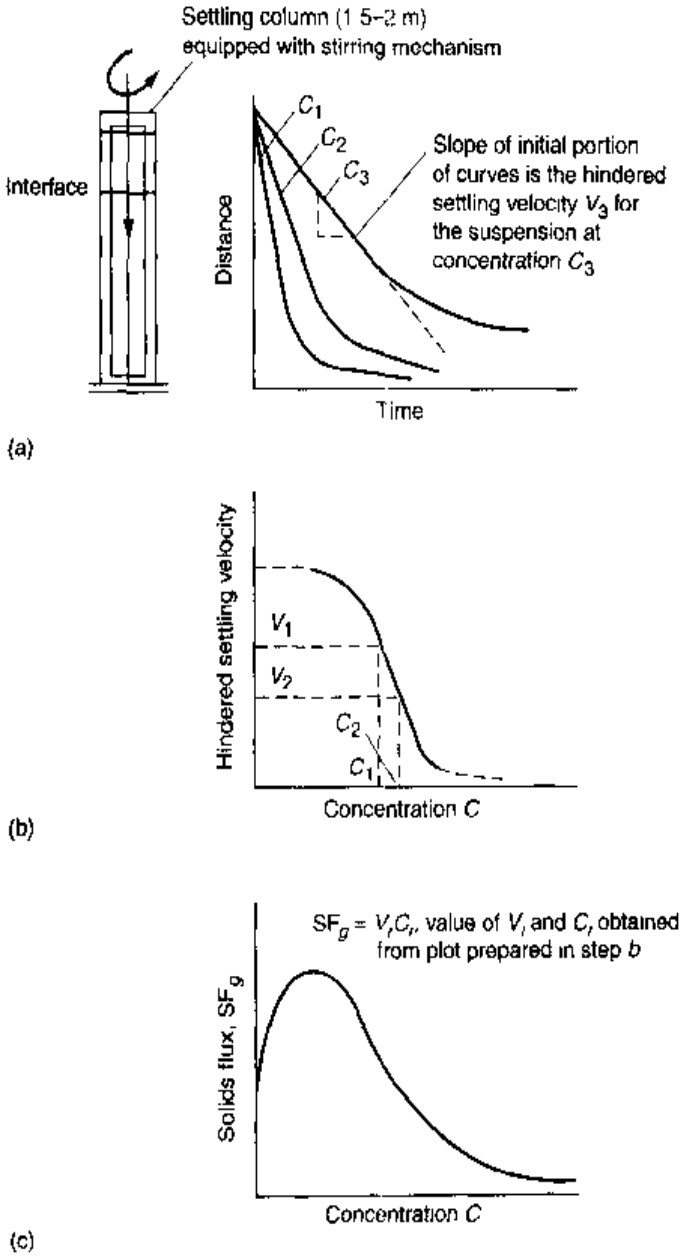
$$SF_u = C_i U_b (1\ kg/10^3\ g) = C_i \frac{Q_u}{A} (1\ kg/10^3\ g) \quad (8\text{–}62)$$

where SF_u = solids flux due to underflow, $kg/m^2 \cdot h$
U_b = bulk downward velocity, m/h
Q_u = underflow flowrate, m^3/h
A = cross-sectional area, m^2

The total mass flux SF_t of solids is the sum of previous components and is given by

$$SF_t = SF_g + SF_u \quad (8\text{–}63)$$

$$SF_t = (C_i V_i + C_i U_b)(1\ kg/10^3\ g) \quad (8\text{–}64)$$



In the above equations, the flux of solids due to gravity (hindered) settling depends on the concentration of solids and the settling characteristics of the solids at that concentration. The procedure used to develop a solids flux curve from column settling test data is illustrated on Fig. 8–35. At low concentrations (below about 1000 mg/L), the movement of solids due to gravity is small, because the settling velocity of the solids is more or less independent of concentration. If the velocity remains essentially the same as the solids concentration increases, the total flux due to gravity starts to increase as the solids concentration starts to increase. At very high solids concentrations, the hindered-settling velocity approaches zero, and the total solids flux due to gravity again becomes extremely low. Thus, it can be concluded that the solids flux due to gravity must pass through a maximum value as the concentration is increased (see Figs. 8–35*c* and 8–36).

The solids flux due to bulk transport is a linear function of the concentration with slope equal to U_b, the underflow velocity (see Fig. 8–36). The total flux, which is the sum of the gravity and the underflow flux, is also shown on Fig. 8–36. Increasing or decreasing the flowrate of the underflow causes the total-flux curve to shift upward or downward. Because the underflow velocity can be controlled, it is used for process control.

The required cross-sectional area for thickening is determined as follows: As shown on Fig. 8–36, if a horizontal line is drawn tangent to the low point on the total-flux curve, its intersection with the vertical axis represents the limiting solids flux SF_L

Figure 8-35

Procedure for preparing a plot of solids flux due to gravity as a function of solids concentration: (a) hindered settling velocities derived from column settling tests for suspension at different concentrations, (b) plot of hindered settling velocities obtained in step (a) versus corresponding concentration, and (c) plot of completed value of solids flux versus corresponding concentration.

that can be processed in the settling basin. The corresponding underflow concentration is obtained by dropping a vertical line to the X axis from the intersection of the horizontal line and the underflow flux line assuming the gravity flux is negligible at the bottom of the settling basin and the solids are removed by bulk flow. The fact that the gravity flux is negligible at the bottom of the tank can be verified by performing a materials balance around the portion of the settling tank that lies below the depth where the limiting solids flux occurs and comparing the gravity settling velocity of the sludge to the velocity in the sludge withdrawal pipe. If the quantity of solids discharged to the settling basin is greater than the limiting solids-flux value defined on Fig. 8–36, the solids will build up in the settling basin and, if adequate storage capacity is not provided, ultimately overflow at the top. Using the limiting solids-flux value, the required area derived from a materials balance is given by

$$A = \frac{(Q + Q_u)C_o}{SF_L}\,(1\ \text{kg}/10^3\ \text{g}) \qquad (8\text{–}65)$$

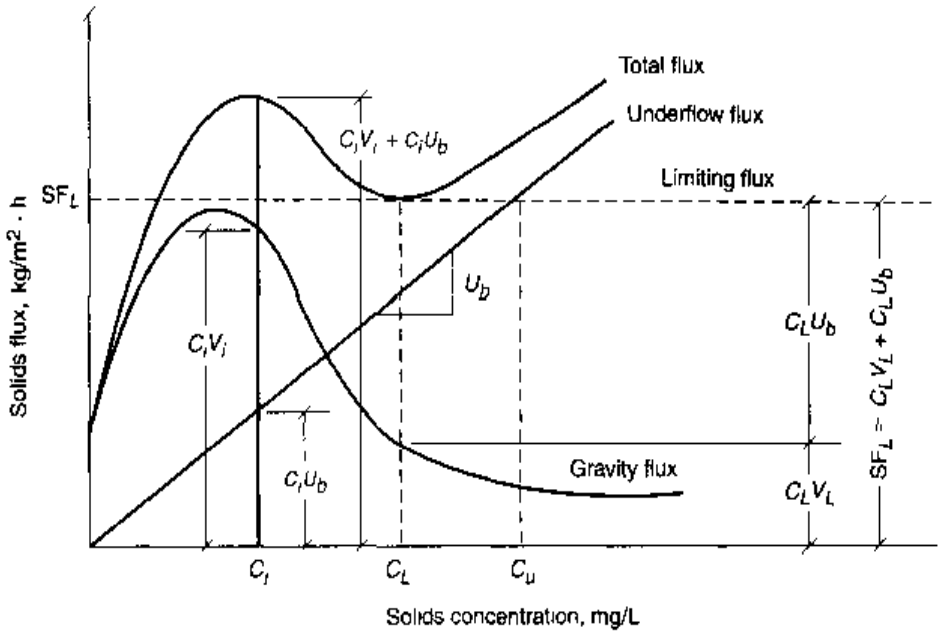


Figure 8–36
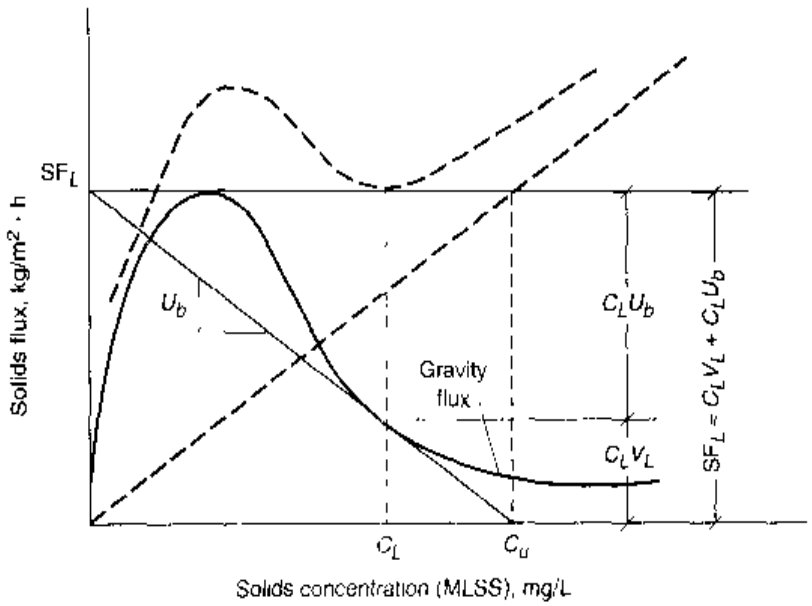
Definition sketch for the analysis of settling data using the solids flux method of analysis.

$$A = \frac{(1 + \alpha)QC_o}{SF_L}\,(1\ \text{kg}/10^3\ \text{g}) \tag{8–66}$$

where A = cross-sectional area, m^2
$(Q + Q_u)$ = total volumetric flowrate to settling basin (overflow + underflow), m^3/d
C_o = influent solids concentration, g/m^3
SF_L = limiting solids flux, $kg/m^2 \cdot d$
$\alpha = Q_u/Q$

Referring to Fig. 8–36, if a thicker underflow concentration is required, the slope of the underflow flux line must be reduced. The reduced slope, in turn, will lower the value of the limiting flux and increase the required settling area. In an actual design, the use of several different flowrates for the underflow should be evaluated.



An alternative graphical method of analysis to that presented on Fig. 8–36 for determining the limiting solids flux is shown on Fig. 8–37. The graphical analysis is derived from Eq. (8–64) in which the minimal SF_t is defined where its derivative with respect to C_i equals zero:

$$\frac{\partial SF_t}{\partial C_i} = 0 = V_i - U_b \tag{8–67}$$

Thus, as shown on Fig. 8–37, the solids concentration at the limiting solids flux is C_L and $V_iC_L = U_bC_L$. The value of the limiting flux on the ordinate is obtained by drawing a line tangent to the flux curve passing through the desired underflow and intersecting the ordinate. The geometric relationship of this method to that given on Fig. 8–36 is shown by the line for U_b on Fig. 8–37. The method detailed on Fig. 8–37 is especially useful where the effect of the use of various underflow concentrations on the size of the treatment facilities (aerator and sedimentation basin) is to be evaluated. Application of the solids flux method of analysis is illustrated in Example 8–11.

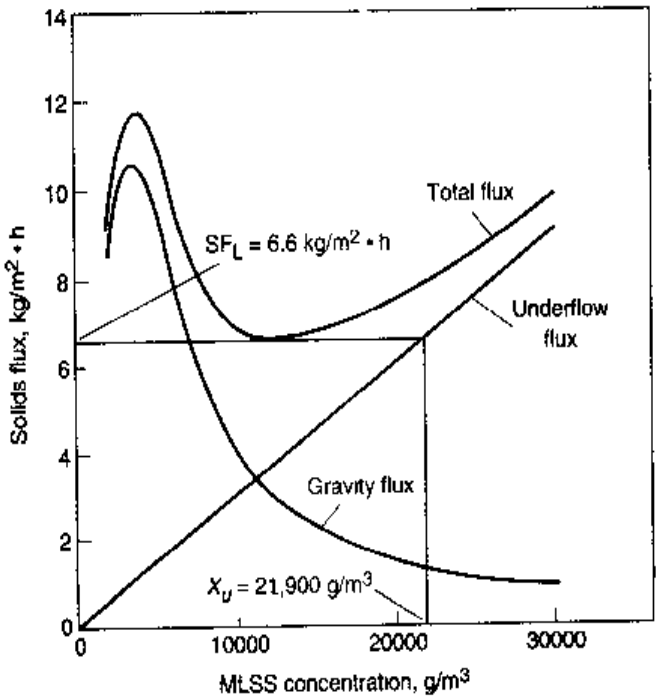
Figure 8–37

Alternative definition sketch for the analysis of settling data using the solids flux method of analysis

EXAMPLE 8–11 Application of Solids Flux Analysis Given the following settling data for a biological sludge, derived from a pure-oxygen activated-sludge pilot plant, estimate the maximum concentration of the aerator mixed-liquor biological suspended solids that can be maintained if the sedimentation tank application rate $Q + Q_r$ has been fixed at 25 $m^3/m^2 \cdot d$ and the sludge recycle rate Q_r is equal to 40 percent. The definition sketch for this problem is shown on Fig. 8–9*b* on page 691. As shown, settled and thickened biological solids from the sedimentation tank are returned to the aeration tank to maintain the desired level of biological solids in the aerator. Assume that the solids wasting rate Q_w is negligible in this example.

MLSS, g/m^3	Initial settling velocity, m/h
2,000	14.0
3,000	11.5
4,000	9.1
5,000	7.0
6,000	4.2
7,000	3.0
8,000	2.2
9,000	1.6
10,000	1.2
15,000	0.5
20,000	0.2
30,000	0.1

Note: g/m^3 = mg/L.



Solution

1. Develop the gravity solids-flux curve from the given data and plot the curve.
   a. Set up a computation table to determine the solids-flux values corresponding to the given solids concentrations.

MLSS, g/m³	Solids flux,[a] kg/m²·h
2,000	8.54
3,000	10.53
4,000	11.03
5,000	10.65
6,000	7.68
7,000	6.37
8,000	5.36
9,000	4.41
10,000	3.70
15,000	2.25
20,000	1.40
30,000	0.81

[a] Solids flux = $X(g/m^3)V(m/h)$ $(1\ kg/10^3\ g)$.

   b. Plot the gravity solids-flux curve (see following figure).

2. Determine the underflow bulk velocity. Referring to the definition sketch, the applied loading on the sedimentation facilities equals $(Q + Q_r)$, which per unit area is equal to 25 $m^3/m^2 \cdot d$. The underflow velocity U_b is therefore equal to

$$U_b = [0.4Q/(Q + 0.4Q)](25\ m^3/m^2 \cdot d)$$

$$= 7.14\ m/d = 0.30\ m/h$$

3. Develop the total-flux curve for the system, and determine the value of the limiting flux and maximum underflow concentration.
   a. Plot the underflow curve on the solids-flux curve using the following relationship:

$$SF_u = X_i U_b (1\ kg/10^3\ g)$$

   where X_i = MLSS concentration, g/m^3
   U_b = bulk underflow velocity, m/h

   For example, at $X_i = 10{,}000\ g/m^3$,

$$SF_u = (10{,}000\ g/m^3)(0.30\ m/h)(1\ kg/10^3\ g) = 3.0\ kg/m^2 \cdot h$$

   b. Plot the total solids-flux curve by summing the values of the gravity and underflow solids flux (see solids-flux curve).
   c. From the solids-flux curve, the limiting solids flux is found to be equal to

$$SF_L = 6.6\ kg/m^2 \cdot h$$

   d. From the solids-flux curve, the maximum underflow solids concentration is equal to 21,900 g/m^3.
4. Estimate the maximum solids concentration that can be maintained in the reactor.
   a. Write a mass balance for the system within the boundary, neglecting the rate of cell growth within the reactor. Let X_o = influent TSS to the aeration tank.

$$QX_o + Q_R X_R = (Q + Q_R)X$$

   b. Assuming the $X_o = 0$ ($X_o << X_R$) and that $Q_R/Q = 0.4$, solve for the concentration of MLSS in the reactor.

$$0.4Q\ (21{,}900\ g/m^3) = (1 + 0.4)QX$$

$$X = 6257\ g/m^3$$

Comment As shown in the above analysis, the concentration of the return solids will affect the maximum concentration of solids that can be maintained in the aerator. Thus, the sedimentation tank must be considered an integral part of the design of an activated-sludge treatment process.

State Point Analysis. The state point analysis procedure extends the principles of the solids-flux analysis to provide a convenient means to assess different mixed-liquor concentrations and clarifier operating conditions relative to the limiting solids-flux operating condition (Keinath et al., 1977; Keinath, 1985). The state point as shown on Fig. 8–38*a* is the intersection of the clarifier overflow solids-flux rate and underflow solids-flux rate lines. Thus, the analysis accounts for the actual mixed-liquor concentration, clarifier hydraulic application rate, and return activated-sludge recycle rate, and whether the combination of these operating parameters results in a condition that is within the clarifier solids-flux limitations for a sludge with specific thickening characteristics.

On Fig. 8–38*a*, the clarifier overflow solids flux is

$$SF_Q = \frac{Q(X)}{A} \tag{8–68}$$

where SF_Q = overflow solids-flux rate, $kg/m^2 \cdot d$
Q = clarifier effluent flowrate, m^3/d
A = clarifier cross-section area, m^2
X = aeration tank MLSS concentration, g/L

The aeration tank MLSS concentration (X) at any point along the overflow solids-flux line is found by constructing a vertical line to the X axis. The underflow operating line represents the negative slope of the clarifier underflow velocity as was also shown on Fig. 8–36. The y intercept of the horizontal line drawn from the point of intersection

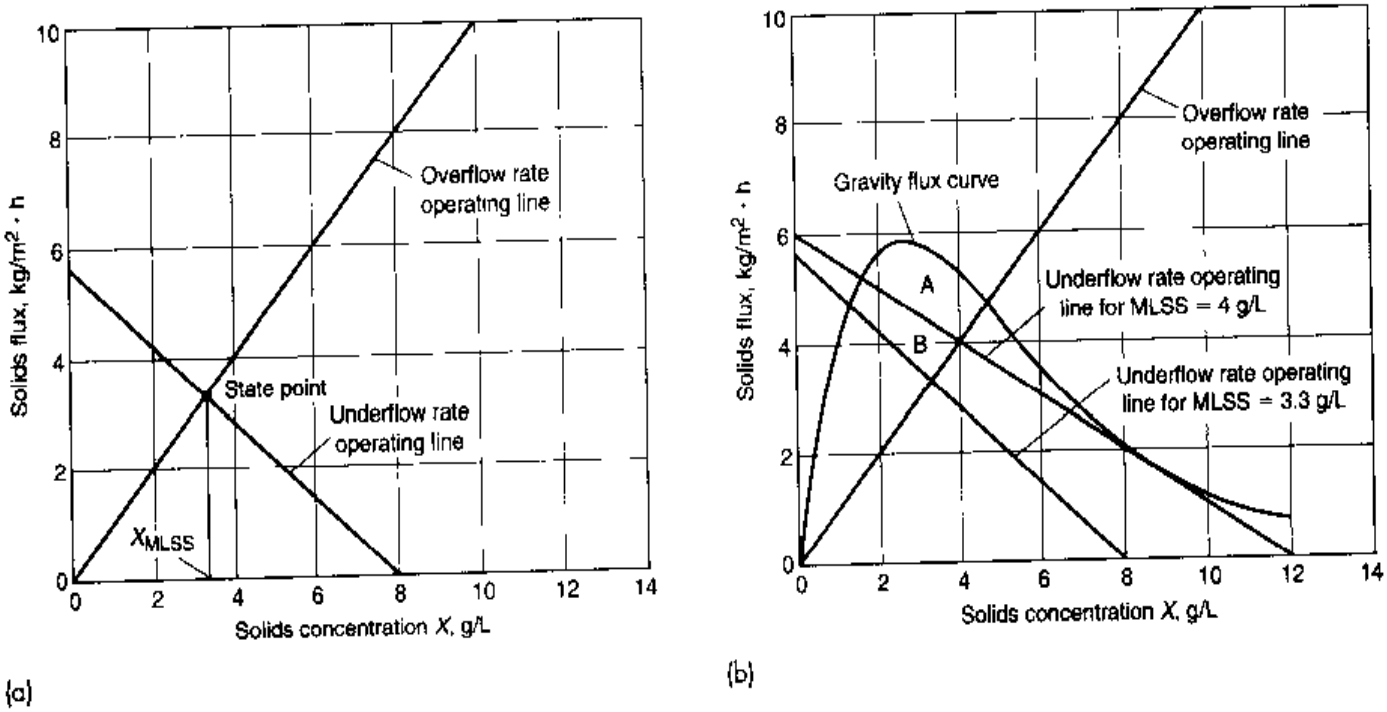


Figure 8–38
State point analysis for assessing clarifier operating conditions: (*a*) state point at intersection of overflow rate and underflow rate operating lines and (*b*) underloaded (*B*) and critically loaded (*A*) state points relative to settling flux curve.

of the vertical line and operating line is the total solids flux (SF_X) to the clarifier. Evaluating the slope of the underflow flux rate line shows that U_b equals

$$U_b = \frac{SF_t - SF_Q}{0 - X_{MLSS}} \tag{8–69}$$

$$U_b = \frac{[(Q + Q_R)X_{MLSS}/A]}{-X_{MLSS}} \tag{8–70}$$

$$U_b = -\frac{Q_R}{A} \tag{8–71}$$

The state point and underflow solids-flux line can be compared to the gravity flux curve to determine if the clarifier operation is within its solids-flux limitation (see Fig. 8–38*b*). The underflow line at state point *B* is tangent to the gravity flux curve, which, as shown on Fig. 8–37, represents the limiting solids-flux condition. Thus, the clarifier is critically loaded for this underflow velocity and state point with MLSS concentration. If the operation is changed to obtain a higher MLSS concentration, and the underflow line crosses the lower limb of the gravity flux curve, the limiting solids flux will be exceeded and the clarifier blanket will rise to the effluent weir. At state point *A* on Fig. 8–38*b*, a lower MLSS concentration is used and the underflow line is thus well below the lower limb of the gravity flux curve. An underloaded operation exists relative to the solids loading.

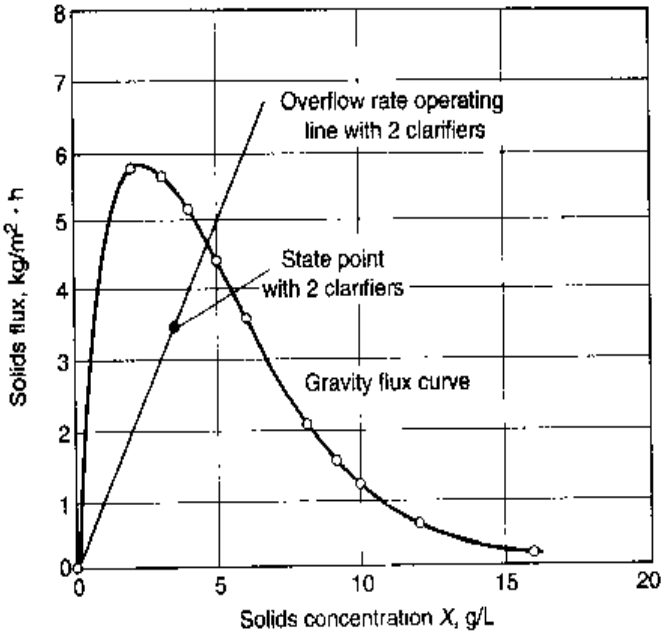
The state point analysis procedure provides a method to evaluate various clarifier overflow rates, and MLSS concentrations give a gravity flux curve that represents the activated-sludge settling properties. The state point analysis technique can be used with settling tests on activated-sludge mixed liquor at an existing facility to determine an optimal MLSS concentration and return sludge recycle ratio for a given influent flow condition. Application of state point analysis is illustrated in Example 8–12.

EXAMPLE 8–12 Evaluate Secondary Clarifier Operating Conditions Using State Point Analysis Determine acceptable operating conditions using the following solids-settling test results for one or two clarifiers in operation in an activated-sludge system. The system is to be evaluated at a maximum month design flowrate of 15,070 m^3/d and the following design conditions.

Design conditions:

1. Two 20-m-diameter clarifiers are installed.
2. With both clarifiers in operation, the desired MLSS concentration is 3500 mg/L.
3. Evaluate the feasibility of operating the clarifier with underflow concentrations of 10, 12, and 14 g/L and determine the recycle ratios.

4. Determine the MLSS concentration with one clarifier in operation using an underflow solids concentration of 12 g/L.
5. Determine the solids loading to the clarifier for the 12 g/L underflow concentration and MLSS = 3500 g/m^3 for (a) two-clarifier operation and (b) one clarifier.
6. The solids settling results are:



Mixed-liquor solids concentration, g/m^3	Interfacial settling velocity, m/h
2,000	2.90
3,000	1.90
4,000	1.30
5,000	0.90
6,000	0.60
8,000	0.26
9,000	0.17
10,000	0.12
12,000	0.05
16,000	0.01

Note: g/m^3 = mg/L.

Solution

1. Develop gravity flux curve (shown below) using Eq. (8–61), $SF_g = C_i V_i$.

C_i, g/L	V_i, m/h	SF_g, kg/m^2·h
2.0	2.90	5.80
3.0	1.90	5.70
4.0	1.30	5.20
5.0	0.90	4.50
6.0	0.60	3.60
8.0	0.26	2.08
9.0	0.17	1.53
10.0	0.12	1.20
12.0	0.05	0.60
16.0	0.01	0.16

2. Add overflow rate operating line and MLSS concentration state point at 3500 mg/L overflow solids flux using Eq. (8–68), $SF_Q = Q(X)/A$.
   a. Determine the clarifier surface area.

$$A \text{ (area/clarifier)} = \pi D^2/4 = \pi\ (20)^2/4 = 314\ \text{m}^2$$

$$\text{Total area (2 clarifiers)} = 2 \times 314 = 628\ \text{m}^2$$

   b. Determine the overflow rate expressed in terms of X.

$$SF_Q = \frac{Q(X)}{A} = \frac{(15{,}070\ \text{m}^3/\text{d})(X)}{628\ \text{m}^2} = 23.997\ \text{m/d}(X)$$

   c. Determine the plotting point of an underflow concentration of 3500 mg/L (3.5 g/L).
   Sample calculation: if $X = 3.5$ g/L $= 3.5$ kg/m^3,

$$SF_Q = (23.997\ \text{m/d})(3.5\ \text{kg/m}^3)(1\ \text{d}/24\ \text{h}) = 3.5\ \text{kg/m}^2\cdot\text{h}$$

3. Evaluate underflow conditions at 10, 12, and 14 g/L (see following figure).
   a. Analysis for an underflow concentration of 14 g/L.
   Draw a line that intercepts 14 g/L on the x axis and passes through the state point. The line intercepts the y axis at 4.67 kg/m^2·h; however, this is not a feasible operating condition as the line crosses above the gravity flux curve. For 10 and 12 g/L underflow concentrations, the lines cross below the gravity flux curve; therefore, both concentrations are feasible.

b. Calculate recycle ratio at 10 g/L (10 kg/m^3) underflow concentration. Determine the slope of the underflow operating rate curve from the figure. The intercept on the x axis is 5.38 kg/m^2·h and the slope is negative and is equal to the recycle velocity, m/h.

$$\text{Operating curve slope} = \frac{[(5.38 - 0)\ \text{kg/m}^2\cdot\text{h}]}{[(0 - 10)\ \text{g/m}^3]} = -0.538\ \text{m/h}$$

$$\text{Underflow velocity} = -(-0.538\ \text{m/h}) = 0.538\ \text{m/h}$$

$$\text{Clarifier overflow rate} = \frac{(15{,}070\ \text{m}^3/\text{d})(1\ \text{d}/24\ \text{h})}{628\ \text{m}^2} = 1.0\ \text{m/h}$$

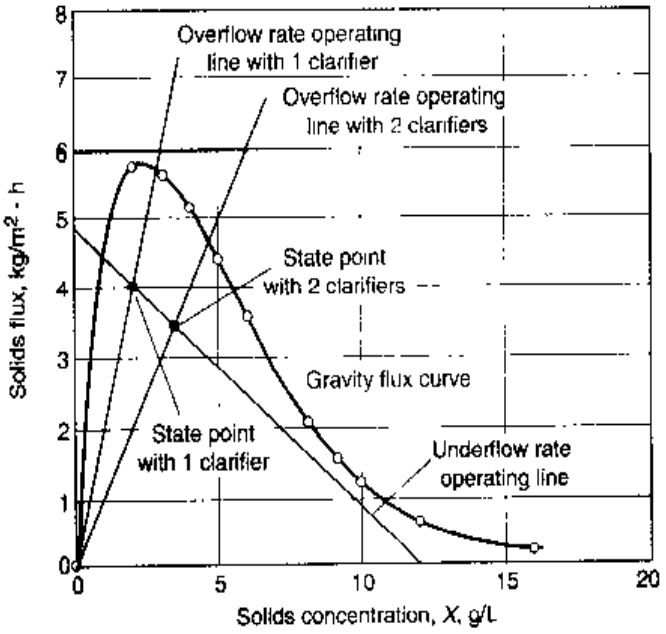
$$\text{Recycle ratio} = \frac{(0.538\ \text{m/h})}{(1\ \text{m/h})} = 0.538$$

c. Check recycle ratio at 10 g/L underflow concentration using solids balance.

$$X_R Q_R = (Q_R + Q)X$$

$X_R R = (1 + R)X$ where R = recycle ratio

$$R = \left(\frac{X_R}{X} - 1\right)^{-1} = \left[\frac{(10\ \text{g/L})}{(3.5\ \text{g/L})} - 1\right]^{-1}$$



$$R = 0.538$$

d. Calculate recycle ratio at 12 g/L (12 kg/m^3) underflow concentration using the same procedure as above.

$$\text{Underflow velocity} = \frac{[(4.94 - 0)\ \text{kg/m}^2\cdot\text{h}]}{[(0 - 12)\ \text{g/m}^3]} = 0.41\ \text{m/h}$$

$R = 0.41$

4. Determine what MLSS concentration is possible with one clarifier operating and underflow solids concentration = 12 g/L.
Using the gravity flux curve, draw an overflow operating rate line for one clarifier (see following figure).

For $A = 314\ \text{m}^3$ and $X = 2$ g/L,

$$SF_Q = \frac{(15{,}070\ \text{m}^3/\text{d})(1\ \text{d}/24\ \text{h})(2\ \text{kg/m}^3)}{314\ \text{m}^2} = 4\ \text{kg/m}^2\cdot\text{h}$$

The MLSS concentration possible is the "state point" where the overflow rate operating line intersects the underflow rate operating line. In the above figure, the state point is approximately 2.1 g/L = 2100 mg/L MLSS.

5. Determine clarifier solids loading
   a. For 2 clarifiers: $A = 628\ \text{m}^2$; MLSS = 3.5 g/L, and $R = 0.41$

$$\text{Solids loading} = Q(1 + R)(X)/A$$

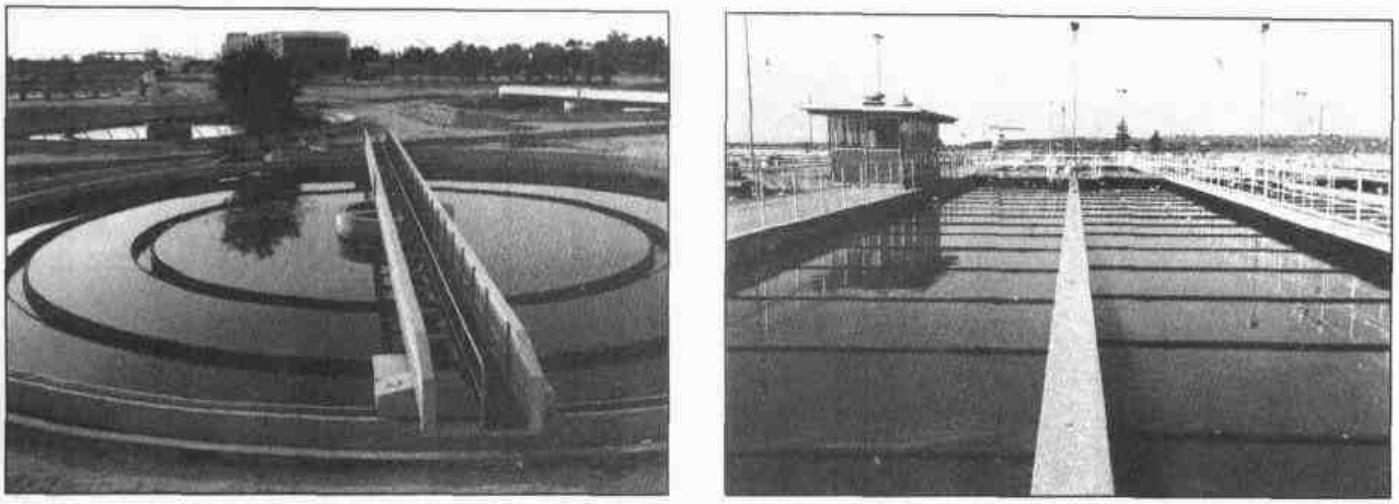
$$= \frac{(15{,}070\ \text{m}^3/\text{d})(1 + 0.41)(3.5\ \text{kg/m}^3)}{(628\ \text{m}^2)(24\ \text{h/d})} = 4.93\ \text{kg/m}^2\cdot\text{h}$$

b. For one clarifier: $A = 314\ m^2$

$$\text{Clarifier overflow rate} = \frac{(15{,}070\ m^3/d)(1\ d/24\ h)}{(314\ m^2)} = 2.0\ m/h$$

Underflow velocity (from step 3d) = 0.41 m/h

$R = 0.41\ m/h / 2.0\ m/h = 0.205$

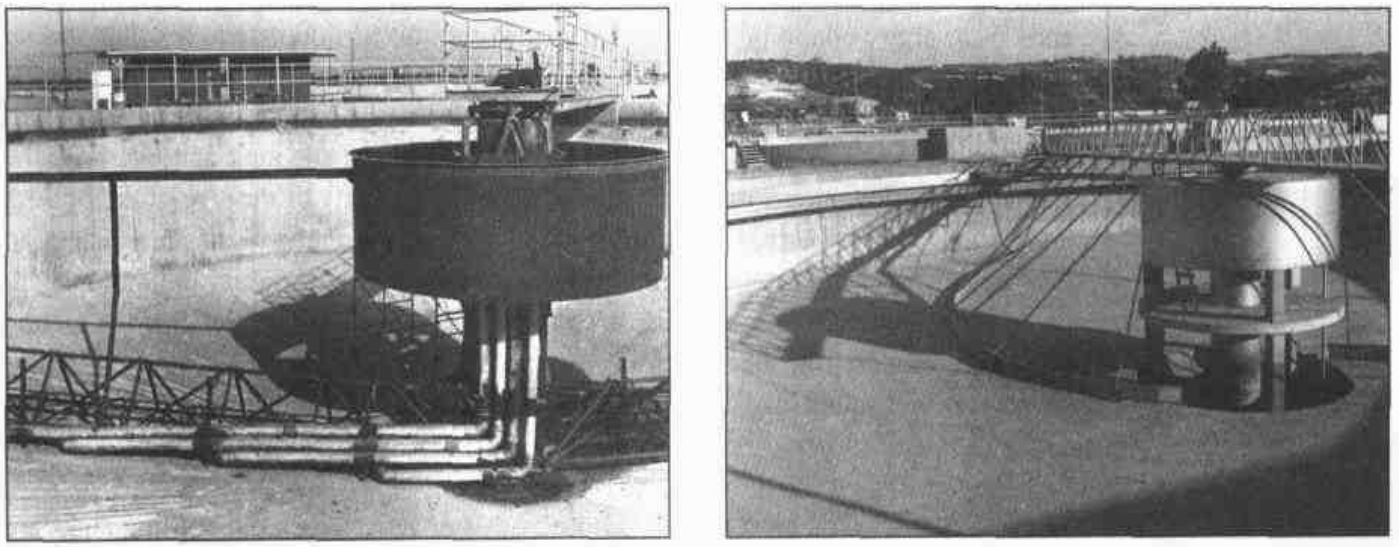


$$\text{Solids loading} = \frac{(15{,}070\ m^3/d)(1 + 0.205)(2.1\ kg/m^3)}{(314\ m^2)(24\ h/d)} = 5.06\ kg/m^2 \cdot h$$

Design of Solids Separation Facilities

Solids separation is the final step in the production of a well-clarified, stable effluent low in BOD and suspended solids and, as such, represents a critical link in the operation of an activated-sludge treatment process. Although much of the information presented in Chap. 5 for the design of primary sedimentation tanks is applicable, the presence of a large volume of flocculent solids in the mixed liquor requires that special consideration be given to the design of activated-sludge settling tanks. As mentioned previously, these solids tend to form a sludge blanket in the bottom of the tank that will vary in thickness. The blanket may fill the entire depth of the tank and overflow the weirs at peak flowrates if the return sludge pumping capacity or the size of the settling tank is inadequate. Further, the mixed liquor, on entering the tank, has a tendency to flow as a density current, interfering with the separation of the solids and the thickening of the sludge. To cope successfully with these characteristics, the following factors must be considered in the design of secondary sedimentation tanks: (1) tank types, (2) surface and solids loading rates, (3) sidewater depth, (4) flow distribution, (5) inlet design, (6) weir placement and loading rates, and (7) scum removal.

Tank Types. The most commonly used types of activated-sludge settling tanks are either circular or rectangular (see Fig. 8–39*a* and *b*). Square tanks are used on occasion but they are not as effective in retaining separated solids as circular or rectangular tanks. Solids accumulate in the corners of the square tanks and are frequently swept over the weirs by the agitation of the sludge collectors. Circular tanks have been constructed with diameters ranging from 3 to 60 m (10 to 200 ft), although the more common range is from 10 to 40 m (~30 to 140 ft). The tank radius should preferably not exceed five times the sidewater depth.



Two basic types of circular tanks are used for secondary sedimentation: center-feed and rim-feed (see Fig. 5–41 in Chap. 5). Both types use a revolving mechanism to transport and remove the sludge from the bottom of the clarifier. Mechanisms are of two types: those that scrape or plow the sludge to a center hopper similar to the types used in primary sedimentation tanks, and those that remove the sludge directly from the tank bottom through suction orifices that serve the entire bottom of the tank in each revolution. Of the latter, in one type the suction is maintained by reduced static head on the

(a) (b)

Figure 8–39

Typical secondary clarifiers: (*a*) circular with peripheral drive mechanism for sludge collection and (*b*) rectangular.

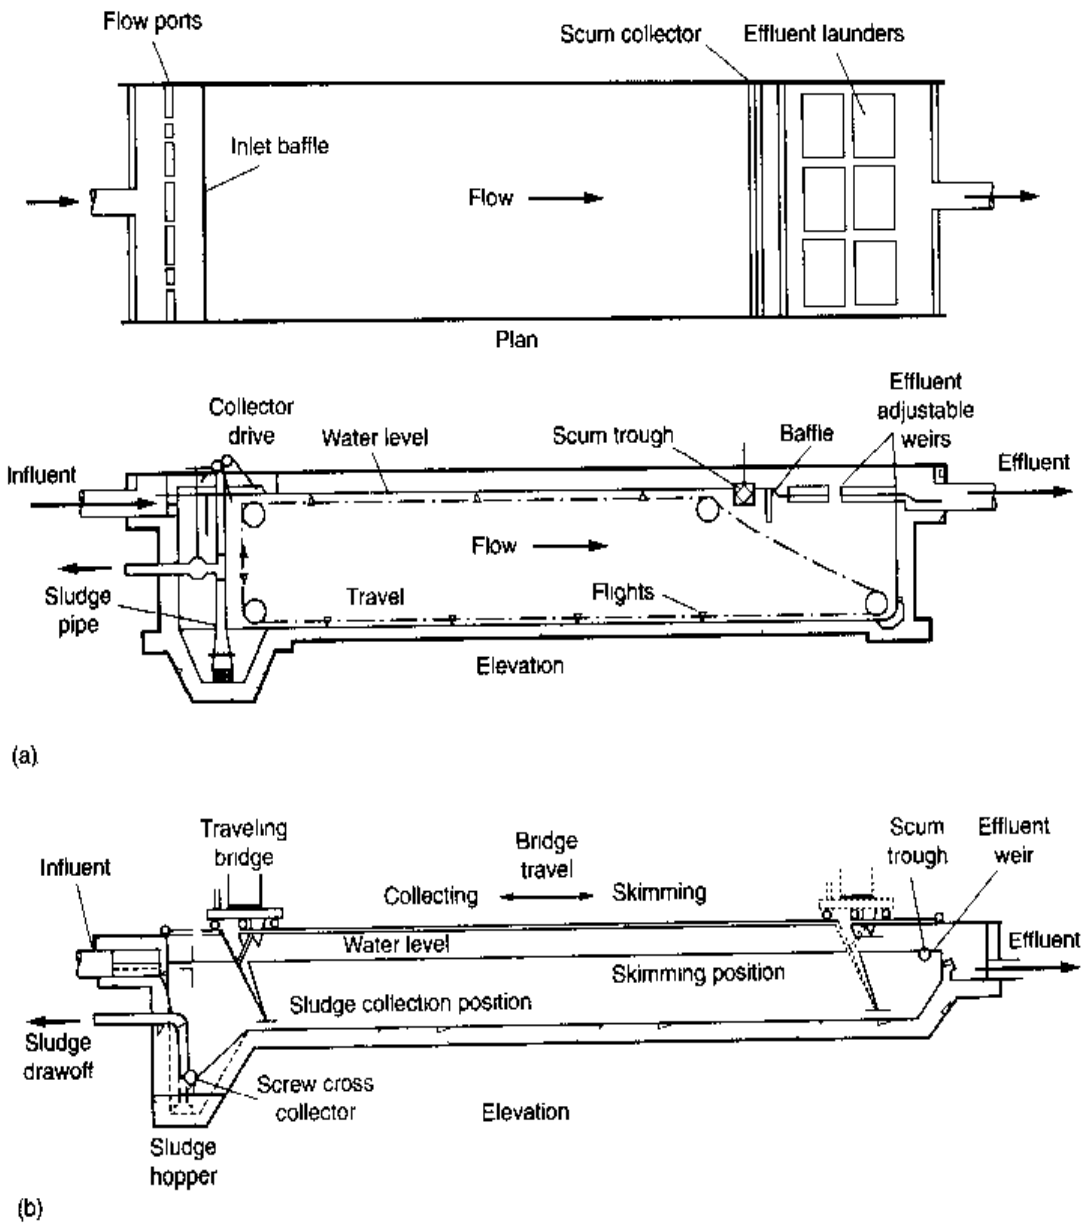
(a) (b)

Figure 8–40

Typical circular sludge-collection mechanisms: (*a*) suction-type and (*b*) spiral-type scraper used commonly in Europe.

individual suction pipes (Fig. 8–40*a*). In another patented suction system, sludge is removed through a manifold either hydrostatically or by pumping. Spiral-type scrapers are also used to accelerate movement of settled solids from the tank periphery to the collection sump (Fig. 8–40*b*).

Rectangular tanks must be proportioned to achieve proper distribution of incoming flow so that horizontal velocities are not excessive. The maximum length of rectangular tanks normally should not exceed 10 times the depth, but lengths up to 90 m (300 ft) have been used successfully in large plants. Where widths of rectangular tanks exceed 6 m (20 ft), multiple sludge collection mechanisms may be used to permit tank widths



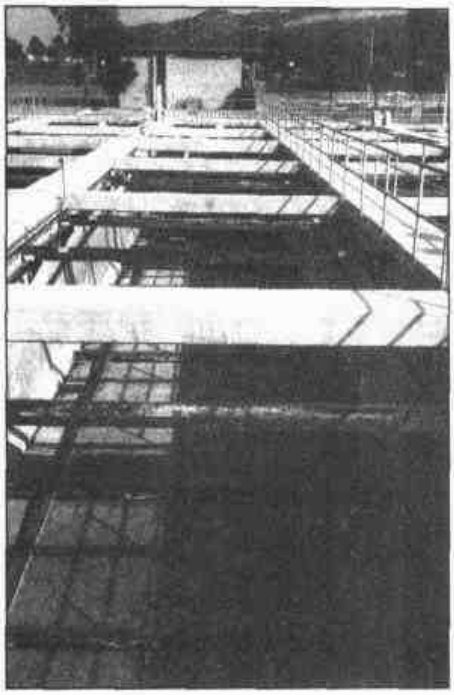


Figure 8–41
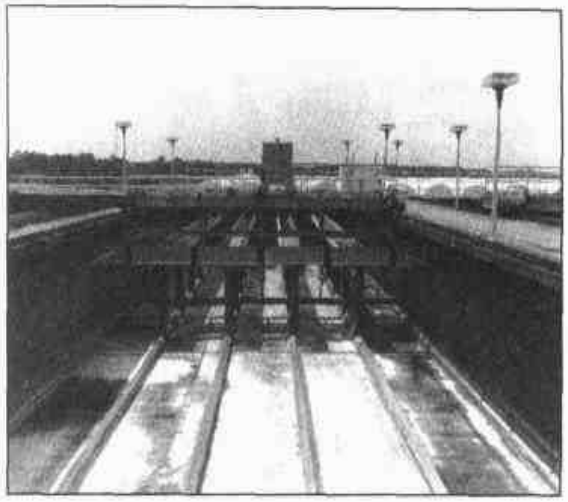
Typical rectangular sludge-collection mechanisms: (*a*) chain and flight and (*b*) traveling bridge.



up to 24 m (80 ft). Regardless of tank shape, the sludge collector selected should be able to meet the following operational conditions: (1) the collector should have enough capacity so that when a high sludge-recirculation rate is desired, channeling of the overlying liquid through the sludge will not result, and (2) the mechanism should be sufficiently rugged to transport and remove very dense sludges that could accumulate in the settling tank during periods of mechanical breakdown or power failure.

Two types of sludge collectors are commonly used in rectangular tanks: (1) traveling flights, and (2) traveling bridges (see Figs. 8–41 and 8–42). Traveling flights are similar to those used for the removal of sludge in primary settling tanks. For very long tanks, it is desirable to use two sets of chains and flights in tandem with a central hopper to receive the sludge to minimize the sludge transport distance. Sludge may be collected at the influent or effluent end of the tank. The traveling bridge, which is similar to a traveling overhead crane, travels along the sides of the sedimentation tank or on a support structure if several bridges are used. The bridge serves as the support for the sludge-removal system, which usually consists of a scraper or a suction manifold from

Figure 8-42
Views of sludge-collection mechanisms in rectangular tanks: (a) chain and flight and (b) traveling bridge.

(a)

(b)

which the sludge is pumped. The sludge is discharged to a collection trough that runs the length of the tank.

Other types of settling tanks that are used include stacked clarifiers, tube and plate settlers (see Chap. 5), and intrachannel clarifiers. Stacked clarifiers (see Fig. 5–45 in Chap. 5) are used in installations where limited land area is available for clarifiers. Stacked clarifiers are used at the Deer Island Wastewater Treatment Plant in Boston, MA, for secondary sedimentation and were selected because of limited land area.

The efficiency of conventional or shallow clarifiers may be improved by the installation of tubes or parallel plates to establish laminar flow (see Fig. 5–25 in Chap. 5). Constructed of bundles of tubes or plates set at selected angles (usually 60°) from the horizontal, tube and plate settlers have a very short settling distance and circulation is dampened because of the small size of the tubes. Solids that collect in the tubes or on the plates tend to slide out due to gravitational forces. The major drawback in wastewater treatment is a tendency of the tubes and plates to clog because of the accumulation of biological growths, grease, and small objects that pass through coarse screens.

Intrachannel clarifiers are proprietary devices that have been developed to improve the performance of the oxidation ditch activated-sludge process and to save the cost of constructing external final clarifiers. The concept incorporates a clarifier, configured somewhat similar to a boat, installed in the oxidation ditch channel. These devices permit liquid and solids separation and sludge return to occur within the aeration channel. Sludge wasting is done from either the aeration channel or the intrachannel clarifier. Disadvantages of intrachannel clarifiers include loss of independency of reactors and clarifiers, wasting dilute sludge, loss of RAS chlorination potential for controlling bulking sludge, and lack of metered RAS control (WEF, 1998).

Surface and Solids Loading Rates. When it is necessary to design secondary settling facilities without the benefit of settling tests, published values for surface and solids loading rates are often used. Because of the large amount of solids that may

be lost in the effluent if design criteria are exceeded, effluent overflow rates based on peak flow conditions are used commonly. An alternative design basis is to use the average dry-weather flowrate (ADWF) and a corresponding surface loading rate and also check for peak flow and loading conditions. Either condition may govern the design parameters. Typical surface and solids loading rates were given previously in Table 8–7 for secondary clarifier design.

Sidewater Depth. Liquid depth in a secondary clarifier is normally measured at the sidewall in circular tanks and at the effluent end wall for rectangular tanks. The liquid depth is a factor in the effectiveness of suspended solids removal and in the concentration of the return sludge. Other factors such as inlet design, type of sludge-removal equipment, sludge blanket depth, and weir type and location also affect clarifier performance. In recent years, the trend has been toward increasing liquid depths to improve overall performance. Typical sidewater depths are presented in Table 8–7 in Sec. 8–3. Current practice favors a minimum sidewater depth of 3.5 m (~12 ft) for large secondary clarifiers, and depths ranging up to 6 m (20 ft) have been used. The cost of tank construction has to be considered in selecting a sidewater depth, especially in areas of high groundwater levels. Tanks with depths less than 3.5 m (~12 ft) often have difficulty containing the typically low-density activated sludge, and low-density sludge blankets are more easily disturbed by hydraulic fluctuations. Deeper tanks therefore provide greater flexibility of operation and a larger margin of safety when changes in the activated-sludge system occur.

Flow Distribution. Flow imbalance between multiple process units can cause under- or overloading of the individual units and affect overall system performance. In plants where parallel tanks of the same size are used, flow between the tanks should be equalized. In cases where the tanks are not of equal capacity, flows should be distributed in proportion to surface area. Methods of flow distribution to the secondary sedimentation tanks include weirs, flow distribution boxes, flow control valves, hydraulic distribution using hydraulic symmetry, and feed gate or inlet port control (see Fig. 8–43). Effluent weir control, although frequently used to effect flow splitting, is usually ineffective and should be used only where there are two tanks of equal size.

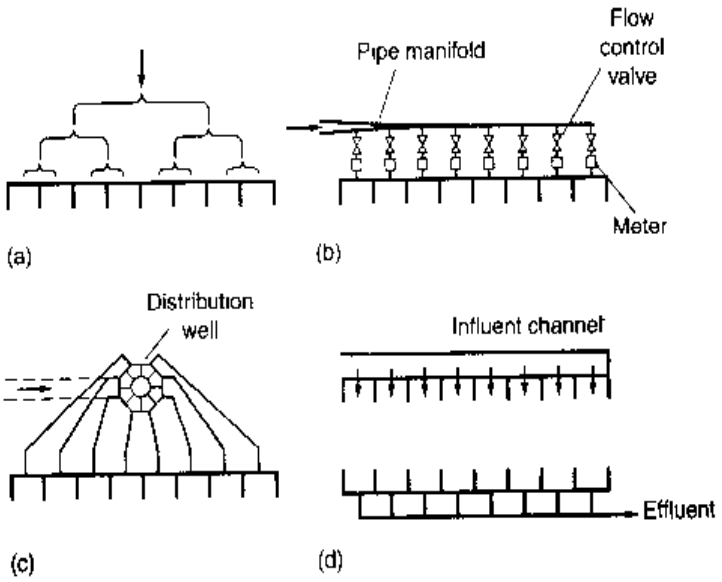


Figure 8–43
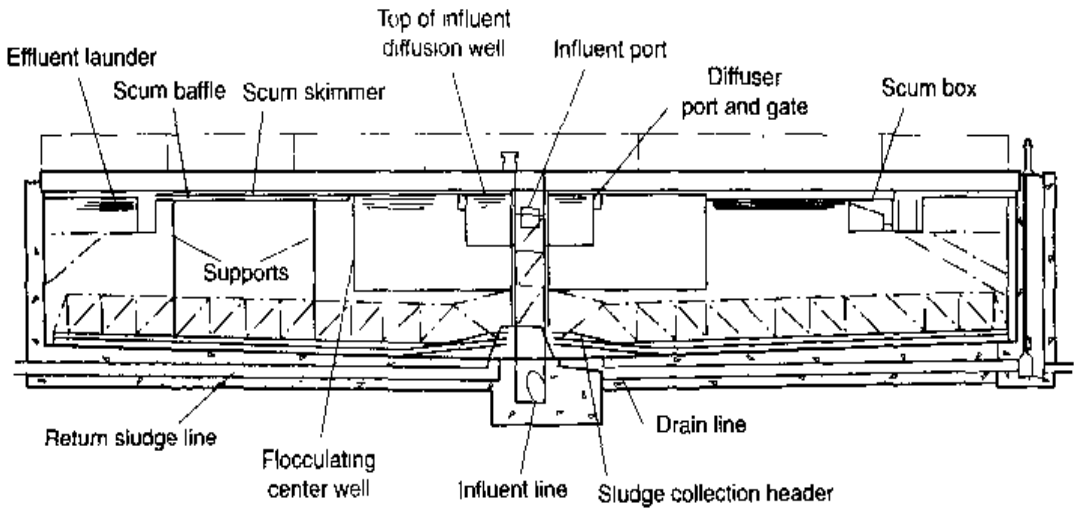
Alternative methods of flow splitting: (a) hydraulic symmetry, (b) flow measurement and feedback control, (c) hydraulic split with weirs, and (d) inlet feed gate control.



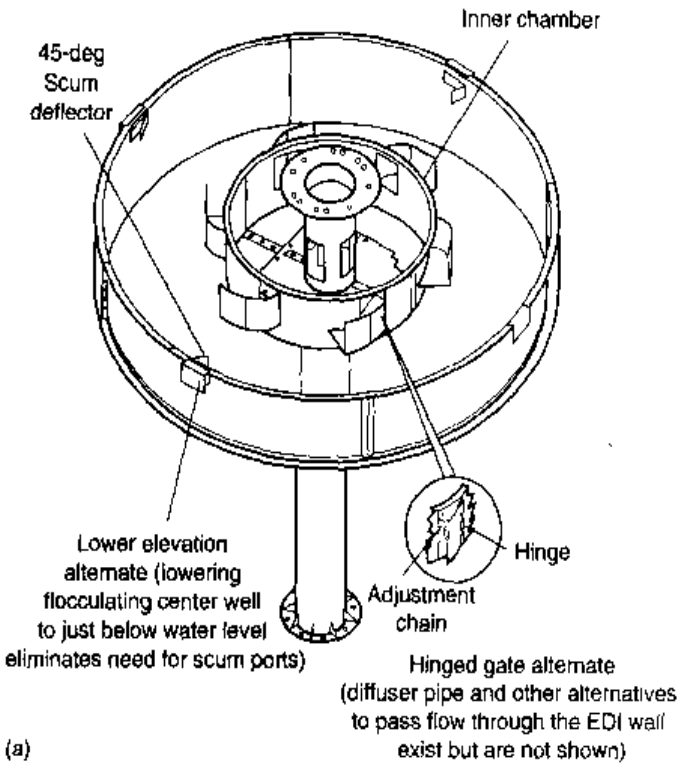


Figure 8–44
Typical secondary clarifier with a flocculating center feed well.

Tank Inlet Design. Poor distribution or jetting of the tank influent can increase the formation of density currents and scouring of settled sludge, resulting in unsatisfactory tank performance. Tank inlets should dissipate influent energy, distribute the flow evenly in horizontal and vertical directions, mitigate density currents, minimize sludge blanket disturbance, and promote flocculation. In circular center-feed tanks, a common design is to use small, solid-skirted, cylindrical baffles to dissipate the influent energy and distribute flow. Studies indicate that a density current waterfall can be created using skirted baffles resulting in poor vertical flow distribution (Crosby and Bender, 1980). Methods to overcome these problems include the use of a large center diffusion well or a flocculating-type clarifier (Fig. 8–44). The large center diffusion well, with a minimum diameter of 25 percent of the tank diameter, provides a greater area for dissipation of the influent energy and distribution of the incoming mixed liquor. The bottom of the feed well should end well above the sludge blanket interface in order to minimize turbulence and resuspension of the solids. Flocculating center-feed clarifiers can incorporate an energy-dissipating inlet (EDI) and means to promote flocculation in the center-feed well (see Fig. 8–45*a*). Typical flocculation feed wells have diameters of 30 to 35 percent of the tank diameter. An alternative device for dissipating energy, developed by the City of Los Angeles, is shown on Fig. 8–45*b*. Operationally, the flow is discharged from a centerwell through a series of downward-facing discharge ports. By arranging the discharge ports so they discharge facing each other, the momentum energy is dissipated as the discharge streams impact each other. In rectangular tanks, inlet ports or baffles should be provided to achieve flow distribution. Inlet port velocities are typically 75 to 150 mm/s (15 to 30 ft/min) (WPCF, 1985).
