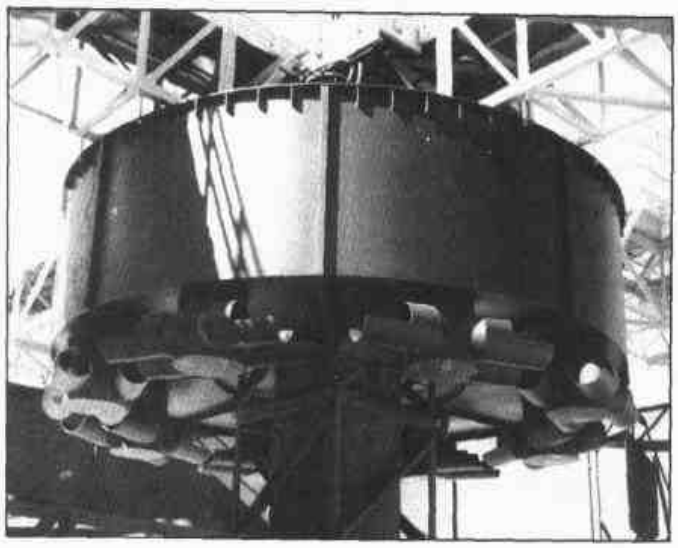
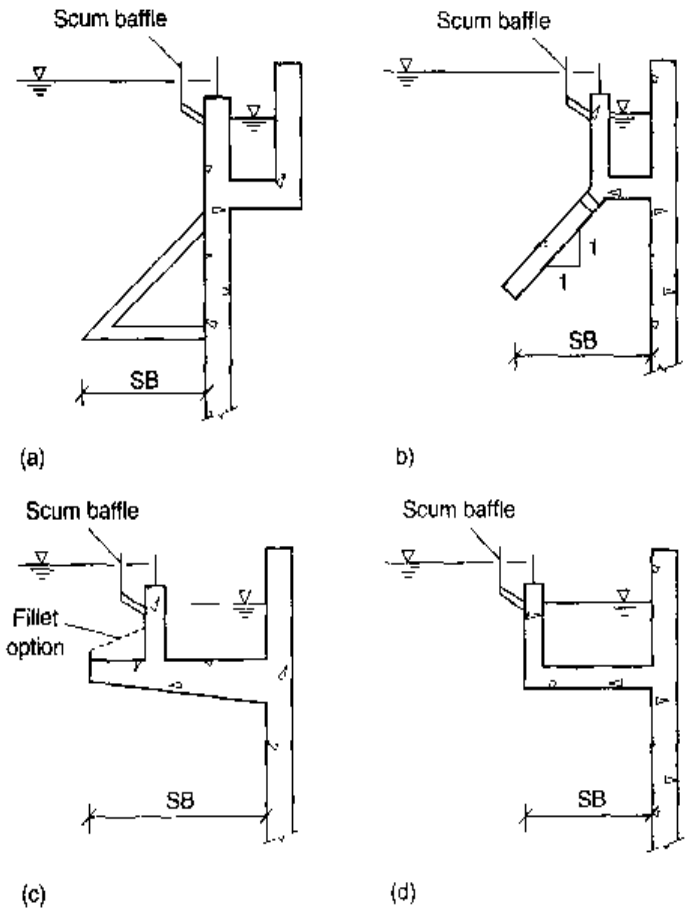
Weir Placement and Loading. When density currents occur in a secondary clarifier, mixed liquor entering the tank flows along the tank bottom until it encounters a countercurrent pattern or an end wall. Unless density currents are considered in the design, solids may be discharged over the effluent weir. Experimental work performed by Anderson (1945) at Chicago on tanks approximately 38 m (126 ft) in diameter indicated that a circular weir trough placed at two-thirds to three-fourths of the radial distance from the center was in the optimum position to intercept well-clarified effluent. With low surface loadings and weir rates, the placement of the weirs in small tanks does



(b)

Figure 8–45

Energy-dissipating inlet devices used in circular clarifiers: (a) schematic of a center column energy-dissipating inlet and flocculating feed well (WEF, 1998) and (b) view of an energy-dissipating feed well. *(Courtesy City of Los Angeles.)*



not significantly affect the performance of the clarifier. Circular clarifiers are manufactured with overflow weirs located near both the center and the perimeter of the tank. If weirs are located at the tank perimeter or at end walls in rectangular tanks, a baffle should be provided to deflect the density currents toward the center of the tank and away from the effluent weir. Alternative baffle arrangements are shown on Fig. 8–46.

Weir loading rates are used commonly in the design of clarifiers, although they are less critical in clarifier design than hydraulic overflow rates. Weir loading rates used in large tanks should preferably not exceed 375 m^3/lin m·d (30,000 gal/lin ft·d) of weir at maximum flow when located away from the upturn zone of the density current, or 250 m^3/lin m·d (20,000 gal/lin ft·d) when located within the upturn zone. In small tanks, the weir loading rate should not exceed 125 m^3/lin m·d (10,000 gal/lin ft·d) at average flow or 250 m^3/lin m·d at maximum flow. The upflow velocity in the immediate vicinity of the weir should be limited to about 3.5 to 7 m/h (~12 to 24 ft/h).

Scum Removal. In many well-operating secondary plants, very little scum is formed in the secondary clarifiers. However, occasions arise when some floating material is present (see "Operating Problems" in Sec. 8–3), necessitating its removal. Where primary settling tanks are not used, skimming of the final tanks is essential. Most designs in recent years provide scum removal for both circular and rectangular secondary clarifiers. Typical scum-removal equipment includes beach and scraper type, rotating pipe-through skimmer, and slotted pipes.

Figure 8–46

Alternative peripheral baffle arrangements: (*a*) Stamford, (*b*) unnamed, (*c*) McKinney (also known as the Lincoln baffle), and (*d*) interior trough. *(WEF, 1998.)*

Scum should not be returned to the plant headworks because microorganisms responsible for foaming (typically *Nocardia*) will be recycled, causing foaming problems to persist because of continuous seeding of the unwanted microorganisms. In some plants, scum is discharged to sludge-thickening facilities or is added directly to digester feed streams, as appropriate.

8–8 SUSPENDED GROWTH AERATED LAGOONS

Suspended growth lagoons are relatively shallow earthen basins varying in depth from 2 to 5 m, provided with mechanical aerators on floats or fixed platforms. The mechanical aerators are used to provide oxygen for the biological treatment of wastewater and to keep the biological solids in suspension. In a few cases, diffused aeration has also been used. Suspended growth aerated lagoons are operated on a flow-through basis or with solids recycle. The purpose of this section is to (1) describe the principal types of suspended growth lagoons and (2) present and illustrate the design considerations for the suspended growth flow-through type of lagoon. Lagoons with solids recycle are essentially the same as the activated-sludge process described in detail in Secs. 8–1 and 8–3. The dual-powered flow-through lagoon system, a modification of the conventional flow-through lagoon, is also considered in this section.

Types of Suspended Growth Aerated Lagoons

The principal types of suspended growth lagoon processes, classified based on the manner in which the solids are handled (Arceivala, 1998), are:

1. Facultative partially mixed
2. Aerobic flow through with partial mixing
3. Aerobic with solids recycle and nominal complete mixing

Differences in the manner in which the solids are handled will affect the treatment efficiency, power requirements, hydraulic and solids retention time, sludge disposal, and environmental considerations. The general characteristics of these lagoon systems are summarized in Table 8–29. Each of the lagoon processes is described below.

Table 8–29
Typical characteristics of different types of aerated suspended growth lagoons[a]

		Type of aerated lagoon		
Item	Unit	Facultative	Aerobic flow-through	Aerobic with solids recycling
TSS	mg/L	50–200	100–400	1500–3000
VSS/TSS	Unitless	50–80	70–80	50–80
Solids retention time, SRT	d	[b]	3–6[c]	Warm: 10–20
			Typically 5	Moderate: 20–30
				Cold: over 30
Hydraulic retention time, τ	d	4–10	3–6	0.25–2.0
			Typically 5	
Overall BOD removal rate, k	d^{-1}	0.5–0.8[d]	0.5–1.5[d]	[e]
Temperature coefficient	Unitless	1.04	1.04	1.04
Depth	m	2–5	2–5	2–5
Mixing regime		Partially mixed	Partially mixed	Nominal complete-mix
Minimum power	$kW/10^3\ m^3$	1–1.25	5.0–8.0	16–20
Sludge		Sludge accumulates internally in the lagoon	Sludge accumulates in external sedimentation facility	Sludge recycled to process from sedimentation tank. Waste sludge is discharged to sludge drying beds
Nitrification		No	Not typically	Likely, especially in warm climates

[a] Adapted from Arceivala (1998).

[b] Because the solids are retained in the lagoon, it is difficult to predict the SRT. It has been estimated that values over 100 d are possible.

[c] Because of incomplete mixing, the actual SRT value can be greater than the τ value.

[d] The removal rate constant for soluble BOD will be considerably higher.

[e] Use kinetic coefficients given in Table 7–9 and the analysis given in Example 8–2 for a complete mix activated sludge process for BOD removal.

Facultative Partially Mixed Lagoon. In the facultative partially mixed lagoon system, the energy input is only sufficient to transfer the amount of oxygen required for biological treatment, but is not sufficient to maintain the solids in suspension. Because the energy input will not maintain the solids in suspension, a portion of the incoming solids will settle along with a portion of the biological solids produced from the conversion of the soluble organic substrate. In time, the settled solids will undergo anaerobic decomposition. The term *facultative* is derived from the observation that the biological conversion, which occurs in the lagoon, is partially aerobic and partially anaerobic. Eventually facultative lagoons must be dewatered and the accumulated solids removed. Because there is essentially no way to manage the events in an aerated facultative lagoon (e.g., wind-driven circulation patterns), the use of facultative lagoons has diminished, especially where discharge limits must be met reliably. Because of the lack of a rational approach to the analysis of facultative lagoons, they are not considered further in this section.

Aerobic Flow-Through Partially Mixed Lagoon. In aerobic flow-through lagoons, the energy input is sufficient to meet the oxygen requirements, but is insufficient to maintain all of the solids in suspension. Operationally, the hydraulic and solids retention times are the same (i.e., τ = SRT). The solids in the effluent are removed prior to discharge in an external sedimentation facility. The analysis and design of aerobic flow-through lagoons is considered in detail in the balance of this section. A typical aerobic flow-through lagoon is shown on Fig. 8–47.

Aerobic Lagoon with Solids Recycle. The aerobic lagoon with solids recycle is essentially the same as the extended aeration activated-sludge process, with the exception that an earthen (typically lined) basin is used in place of a reinforced-concrete reactor basin. As shown in Table 8–29, the hydraulic detention time, at the high end (i.e., 2 d), is longer than that used in a conventional extended aeration process (~1 d). It should be noted that the aeration requirement for an aerobic lagoon with recycle must be higher than the values for an aerobic flow-through lagoon to maintain the solids in suspension. The power levels given in Table 8–29 are designed to maintain most of the solids in suspension, hence the term *nominal complete mix* is used. As noted in the intro-

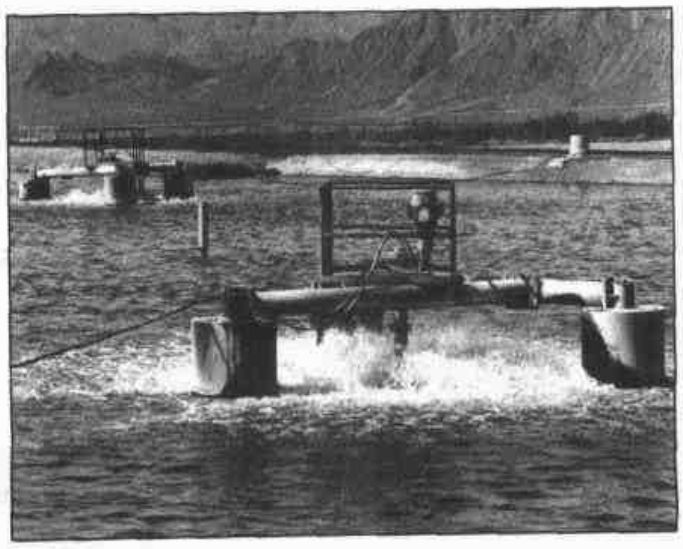


Figure 8–47
View of an aerobic flow-through aerated lagoon with slow-speed surface aerators mounted on floats.

ductory paragraph, because the analysis for the aerobic lagoon with recycle is the same as the activated-sludge process, this process will not be considered further in the following discussion.

Process Design Considerations for Flow-Through Lagoons

Factors that must be considered in the process design of suspended growth flow-through lagoons include (1) BOD removal, (2) effluent characteristics, (3) temperature effects, (4) oxygen requirement, (5) energy requirement for mixing, and (6) solids separation. The first four factors are considered in the following discussion, and their application is illustrated in Example 8–14. The energy required for mixing is discussed in Chap. 5. Solids separation is discussed at the end of this section.

BOD Removal. Because a suspended growth aerobic flow-through lagoon can be considered to be a complete-mix reactor without recycle, the basis of design is SRT, which in this case is equal to the hydraulic retention time τ under ideal flow conditions. The SRT should be selected to assure that (1) the suspended microorganisms will bioflocculate for easy removal by sedimentation and (2) an adequate safety factor is provided. Typical design values of SRT for aerated lagoons used for treating domestic wastes vary from about 3 to 6 d. Once the value of SRT has been selected, the soluble substrate concentration of the effluent can be estimated, and the removal efficiency can then be computed using the equations given earlier in this chapter.

An alternative approach is to assume that the observed BOD removal (either overall, including soluble and suspended solids contribution, or soluble only) can be described in terms of a first-order removal function. The BOD removal is measured between the influent and the lagoon outlet (not the outlet of the sedimentation facilities following the lagoon). The pertinent equation, derived from Eq. (4–102) in Chap. 4, for an ideal single aerated lagoon is

$$\frac{S}{S_o} = \frac{1}{1 + k\tau} \tag{8–72}$$

where S = effluent BOD concentration, g/m^3
S_o = influent BOD concentration, g/m^3
k = overall first-order BOD removal-rate constant, d^{-1}
τ = hydraulic retention time (V/Q), d

Reported overall k values vary from 0.5 to 1.5 d^{-1}. Removal rates for soluble BOD would be higher. Application of this equation is illustrated later in this section. In some cases, to limit short-circuiting in very large lagoons, the total volume required for a flow-through lagoon is distributed between two or three lagoons in series. The appropriate equation for equally sized lagoons in series is Eq. (4–107):

$$C_n = \frac{C_o}{[1 + (kV/nQ)]^n} = \frac{C_o}{[1 + (k/n\tau)]^n} \tag{4–107}$$

where n = number of lagoons in series
V = volume, m^3
Q = flowrate, m^3/s

Effluent Characteristics. The important characteristics of the effluent from an aerated lagoon include the BOD and the TSS concentration. The effluent BOD will be made up of those components previously discussed in connection with the activated-sludge process and occasionally may contain the contribution of small amounts of algae. The solids in the effluent are composed of a portion of the incoming suspended solids, the biological solids produced from waste conversion, and occasionally small amounts of algae. The solids produced from the conversion of soluble organic wastes can be estimated using Eq. (8–15). It should be noted that if the effluent from a suspended growth flow-through aerated lagoon is to meet the minimum standards for secondary treatment (see Chap. 1), settling facilities are needed. Where greater removal of effluent solids is required, slow sand or rock filters are used commonly (Rich, 1999).

Temperature. Because suspended growth aerobic flow-through lagoons are often installed and operated in locations with widely varying climatic conditions, the effects of temperature change must be considered in their design. The two most important effects of temperature are (1) reduced biological activity and treatment efficiency and (2) the formation of ice.

The effect of temperature on biological activity is described in Chap. 7. From a consideration of the influent wastewater temperature, air temperature, surface area of the lagoon, and wastewater flowrate, the resulting temperature in the aerated lagoon can be estimated using the following equation developed by Mancini and Barnhart (1968):

$$T_i - T_w = \frac{(T_w - T_a)fA}{Q} \tag{8–73}$$

where T_i = influent waste temperature, °C
T_w = lagoon water temperature, °C
T_a = ambient air temperature, °C
f = proportionality factor
A = surface area, m^2
Q = wastewater flowrate, m^3/d

The proportionality factor incorporates the appropriate heat-transfer coefficients and includes the effect of surface area increase due to aeration, wind, and humidity. A typical value for f in the eastern United States is 0.5 in SI units. To compute the lagoon temperature, Eq. (8–73) is rewritten as

$$T_w = \frac{AfT_a + QT_i}{Af + Q} \tag{8–74}$$

Alternatively, if climatological data are available, the average temperature of the lagoon may be determined from a heat budget analysis by assuming the lagoon is completely mixed. It should be noted that surface aerators tend to further cool lagoons in cold weather, but submerged diffused air systems add heat to some extent.

Where icing may be a problem, the effect on the operation of lagoons may be minimized by increasing the depth of the lagoon or by altering the method of operation. The effect of reducing the surface area is illustrated in Example 8–13. As computed, reducing the area by one-half increases the temperature about 2.2°C, which corresponds roughly to about a 20 percent increase in the rate of biological activity. As the depth of

the lagoon is increased, maintenance of a completely mixed flow regime becomes difficult. If the depth is increased much beyond 3.7 m, draft tube aerators or diffused aeration must be used.

EXAMPLE 8–13 Effect of Lagoon Surface Area on Liquid Temperature Determine the effect of reducing the surface area of an aerated lagoon from 1 ha to 0.5 ha by doubling the depth for the following conditions:

1. Wastewater flowrate $Q = 3800\ m^3/d$
2. Wastewater temperature $T_i = 15°C$
3. Air temperature during coldest month $T_a = 2°C$
4. Proportionality constant, 0.5

Solution

1. Determine the lagoon water temperature for a surface area of 10,000 m^2 using Eq. (8–74):

$$T_w = \frac{AfT_a + QT_i}{Af + Q} = \frac{(10{,}000\ m^2)(0.5)(2) + (3800\ m^3/d)(15)}{(10{,}000\ m^2)(0.5) + (3800\ m^3/d)}$$

$$= 7.6°C$$

2. Determine the lagoon water temperature for a surface of 5000 m^2.

$$T_w = \frac{AfT_a + QT_i}{Af + Q} = \frac{(5000\ m^2)(0.5)(2) + (3800\ m^3/d)(15)}{(5000\ m^2)(0.5) + (3800\ m^3/d)}$$

$$= 9.8°C$$

Comment Based on the above computation, the increase in temperature achieved by reducing the surface area and doubling the lagoon depth is probably not justified economically.

In multiple lagoon systems, cold-weather effects can be mitigated by seasonal changes in the method of operation. During the warmer months, the lagoons would be operated in parallel; in the winter, they would be operated in series. In the winter operating mode, the downstream aerators could be turned off and removed, and the lagoon surface is allowed to freeze. In spring when the ice melts, the parallel method of operation is again adopted. With this method of operation it is possible to achieve a 60 to 70 percent removal of BOD even during the coldest winter months. Still another method that can be used to improve performance during the winter months is to recycle a portion of the solids removed by settling.

Oxygen Requirement. The oxygen requirement is computed as previously outlined in Sec. 8–3. Based on operating results obtained from a number of industrial and domestic installations, the amount of oxygen required has been found to vary from 0.7 to 1.4 times the amount of BOD removed. The oxygen requirement is considered in Example 8–14 following the discussion of the mixing requirements.

Mixing Requirements. The power requirements for maintaining the solids in suspension are functions of several variables including (1) the type and design of the aeration system, (2) the concentration and nature of the suspended solids, (3) the temperature of the lagoon contents, and (4) the size and geometry (i.e., aspect ratio) of the lagoon. The following relationship has been found for low-speed mechanical aerators (Rich, 1999):

$$P = 0.004X + 5 \text{ for } X \leq 2000 \text{ mg/L} \tag{8-75}$$

where P = energy input, kW/10^3 m^3
X = total suspended solids, mg/L

Other relationships have been proposed by McKinney and Benjes (1965), Fleckseder and Malina (1970), and Murphy and Wilson (1974). The threshold energy input value for the suspension of biosolids is about 1.5 to 1.75 kW/10^3 m^3 (7.5 to 8.75 hp/Mgal). The energy requirement to maintain all of the solids in suspension is considerably greater than the threshold value.

As important as the amount of energy required is the placement of the aerators, to achieve effective dispersion of the oxygen and mixing with sufficient overlap of the dispersion and mixing zones. Because so many different types of aerators are used in aerated lagoons (e.g., high and low speed and aspirating aerators, draft tube aerators, static tubes, and perforated tubing) manufacturers' literature should be consulted to determine appropriate aerator spacing. In a report prepared for the U.S. EPA, the recommended maximum spacing between surface aerators should not exceed 75 m (Crown Zellerbach, 1970). In general, a number of smaller aeration devices, spaced more closely, will be more effective than a few larger devices (Rich, 1999). For depths greater than 3.7 m (12 ft), aerators with draft tubes may be considered to prevent solids deposition.

EXAMPLE 8–14 Design of a Flow-through Aerated Lagoon Design a flow-through aerated lagoon to treat a wastewater flow of 3800 m^3/d, including the number of surface aerators and their kilowatt rating. The treated liquid is to be held in a settling basin (lagoon) with a 2-d detention time before being discharged. Assume that the following conditions and requirements apply:

1. Influent TSS = 200 g/m^3
2. Influent TSS are not degraded biologically
3. Influent sBOD = 200 g/m^3
4. Effluent sBOD = 30 g/m^3
5. Effluent suspended solids after settling = 20 g/m^3
6. Kinetic coefficients: Y = 0.65 g/g, K_S = 100 g/m^3, k = 6.0 g/g·d, k_d = 0.07 g/g·d for T = 20 to 25°C
7. Total solids produced are equal to computed volatile suspended solids divided by 0.85
8. First-order observed soluble BOD removal-rate constant k_{20} = 2.5 d^{-1} at 20°C. *Note:* The overall BOD removal rate constant, which includes particulate BOD, will be lower (see Table 8–29).

9. Summer air temperature = 30°C
10. Winter air temperature during coldest month = 6°C
11. Wastewater temperature during winter = 16°C
12. Wastewater temperature during summer = 22°C
13. Temperature coefficient, $\theta = 1.06$
14. Aeration constants: $\alpha = 0.85$, $\beta = 1.0$
15. Aerator oxygen transfer rate = 1.8 kg O_2/kWh
16. Elevation = 500 m
17. Oxygen concentration to be maintained in liquid = 1.5 g/m^3
18. Lagoon depth = 3.3 m
19. Design SRT = 5 d
20. Power required for mixing = 8 kW/10^3/m^3

Solution

1. On the basis of an SRT of 5 d, determine the surface area of the lagoon.

   Volume = $Q \times \text{SRT} = (3800\ \text{m}^3/\text{d})(5\ \text{d}) = 19{,}000\ \text{m}^3$

   Surface area of lagoon = $V/D = 19{,}000\ \text{m}^3/3.3\ \text{m} = 5758\ \text{m}^2$

2. Estimate the summer and winter liquid temperature using Eq. (8–74).

   Summer:

$$T_w = \frac{AfT_a + QT_i}{Af + Q} = \frac{(5758\ \text{m}^2)(0.5)(30) + (3800\ \text{m}^3/\text{d})(22)}{(5758\ \text{m}^2)(0.5) + (3800\ \text{m}^3/\text{d})} = 25.4°\text{C}$$

   Winter:

$$T_w = \frac{AfT_a + QT_i}{Af + Q} = \frac{(5758\ \text{m}^2)(0.5)(6) + (3800\ \text{m}^3/\text{d})(16)}{(5758\ \text{m}^2)(0.5) + (3800\ \text{m}^3/\text{d})} = 11.7°\text{C}$$

3. Estimate the soluble effluent BOD measured at the lagoon outlet during the summer using Eq. (7–40) from Table 8–5.

$$S = \frac{K_s[1 + (k_d)\,\text{SRT}]}{\text{SRT}(Yk - k_d) - 1}$$

$$= \frac{(100\ \text{g/m}^3)[1 + (0.07\ \text{g/g·d})(5\ \text{d})]}{(0.5\ \text{d})[(0.65\ \text{g/g})(6.0\ \text{g/g·d}) - (0.07\ \text{g/g·d})] - 1} = 7.4\ \text{g/m}^3$$

   (*Note:* The BOD value in the effluent from the settling lagoon will be essentially the same).

   The effluent sBOD value was computed using kinetic-growth constants derived for the temperature in the range from 20 to 25°C. Thus, during the summer months, the effluent requirement of 20 g/m^3 or less will be met easily. Because there is no reliable information on how to correct these constants for the winter temperature of 10°C, an estimate of the effect of temperature can be obtained using the first-order soluble BOD removal-rate constant.

4. Estimate the effluent BOD.
   a. Correct the removal-rate constant for temperature effects using Eq. (2–25) from Table 8–5.

      Summer (25.4°C):

      $$k_{25.4°C} = 2.5(1.06)^{25.4-20} = 3.42/\text{d}$$

      Winter (11.7°C):

      $$k_{11.7°C} = 2.5(1.06)^{11.7-20} = 1.54/\text{d}$$

   b. Determine the effluent BOD values using Eq. (8–72).

      Summer (25.4°C):

      $$S = \frac{S_o}{[1 + (k)\tau]} = \frac{(200\ \text{g/m}^3)}{[1 + (3.42/\text{d})(5\ \text{d})]} = 11.0\ \text{g/m}^3$$

      Winter (11.7°C):

      $$S = \frac{(200\ \text{g/m}^3)}{[1 + (1.54/\text{d})(5\ \text{d})]} = 22.9\ \text{g/m}^3$$

      Based on the above analysis using removal-rate constants, it appears that the effluent requirement of 30 g/m^3 or less will be met during both the summer and winter.

      (*Note:* The foregoing calculations were presented only to illustrate the method. The value of the removal-rate constant must be evaluated for the wastewater in question, in a bench- or pilot-scale test program.)

5. Estimate the concentration of biological solids produced using Eq. (7–43) in Table 8–5. (*Note:* SRT = τ.)

$$X = \frac{Y(S_o - S)}{[1 + (k_d)\,\text{SRT}]} = \frac{(0.65\ \text{g/g})[(200 - 7.4)\ \text{g/m}^3]}{[1 + (0.07\ \text{g/g·d})(5\ \text{d})]} = 92.7\ \text{g/m}^3$$

   An approximate estimate of the biological solids produced can be obtained by multiplying the assumed growth yield constant (BOD basis) by the BOD removed.

6. Estimate the suspended solids in the lagoon effluent before settling.

$$\text{TSS} = 200\ \text{g/m}^3 + \frac{(92.7\ \text{g/m}^3)}{0.85} = 309.1\ \text{g/m}^3$$

   With the extremely low overflow rate provided in a holding basin with a detention time of 2 d, an effluent containing less than 20 g/m^3 of suspended solids should be attainable.

7. Estimate the oxygen requirement using Eq. (7–59) in Table 8–5.

$$R_o = Q(S_o - S) - 1.42\,P_{X,\text{bio}}$$

a. Determine $P_{X,bio}$, the amount of biological solids wasted per day.

$$P_X = (92.7\ g/m^3)(3800\ m^3/d)(1\ kg/10^3\ g) = 352.3\ kg/d$$

b. Assuming the conversion factor for BOD to COD is 1/1.6 (= 0.625), determine the oxygen requirements.

$$R_o = \frac{(3800\ m^3/d)[(200 - 7.4)\ g/m^3]}{(0.625)(10^3\ g/kg)} - (1.42)(352.3\ kg/d)$$

$$= 670.7\ kg/d$$

8. Compute the ratio of oxygen required to sBOD removed.

$$\frac{O_2\ \text{required}}{\text{BOD removed}} = \frac{(670.7\ kg/d)}{(3800\ m^3/d)[(200 - 7.4)\ g/m^3](1\ kg/10^3\ g)} = \frac{0.92\ kg\ O_2}{kg\ BOD}$$

9. Determine the surface aerator power requirements, assuming that the aerators to be used are rated at 1.8 kg O_2/kWh.
   a. Determine the correction factor for surface aerators for summer conditions.
      i. Oxygen saturation concentration at 25.4°C = 8.18 g/m^3 (see Appendix E)
      ii. Oxygen saturation concentration at 25.4°C corrected for altitude (see Fig. 5–68)

$$DO = (0.94)\ (8.18\ g/m^3) = 7.69\ g/m^3$$

   b. Determine the required AOTR.

$$SOTR = AOTR\left[\frac{C_{s,20}}{\alpha(\beta C_{s,T,H} - C)}\right](1.024^{20-T})$$

$$= \frac{(670.7\ kg/d)(9.08\ g/m^3)(1.024)^{20-25.4}}{(0.85)[(1.0)(7.69\ g/m^3) - (1.5\ g/m^3)]} = 1018.3\ kg/d$$

   c. Determine the energy required to supply the needed oxygen.
   The amount of O_2 transferred per day per aerator unit is equal to 1.8 kg O_2/kWh. The total power needed to meet the oxygen requirements is

$$\text{Energy} = \frac{(1018.3\ kg/d)}{(1.8\ kg/kWh)(24\ h/d)} = 23.6\ kW$$

10. Check energy requirement for mixing.
   a. Power requirement

   Lagoon volume = 19,000 m^3

   Power required = (19,000 m^3)(8 kW/10^3 m^3) = 152 kW

   b. Develop aerator options.

Depending upon the lagoon configuration, the following aerator options are possible:

4 — 40 kW aerators
6 — 25 kW aerators
8 — 20 kW aerators

The selection of an aerator option will depend on the geometry of the lagoon site, the type and design of the aerator, and a life cycle cost estimate of the lagoon construction and aerator installation. Special attention should be paid to the zones of mixing and oxygen dispersion (obtained from manufacturers' technical information) to minimize solids deposition and to ensure that aerobic conditions are maintained throughout the lagoon.

Comment In the above example, the energy requirement for mixing is over 6 times the energy requirement to satisfy the oxygen demand. For installations designed to treat domestic wastewater, the energy requirement for mixing is almost always the controlling factor in sizing the aerators. The energy needed to meet the oxygen required is often the controlling factor in sizing the aerators for treating high strength industrial wastes.

Solids Separation. The separation of solids from suspended growth flow through aerated lagoons is accomplished most commonly in a large shallow earthen sedimentation basin (lagoon) designed expressly for the purpose, or in more conventional settling facilities. Where large earthen basins are used, the following requirements must be considered carefully: (1) the detention time must be adequate to achieve the desired degree of suspended solids removal, (2) sufficient volume must be provided for sludge storage, (3) algal growth must be minimized, (4) odors that may develop as a result of the anaerobic decomposition of the accumulated sludge must be controlled, and (5) the need for a lining must be assessed. In some cases, because of local conditions, these requirements may be in conflict with each other.

In most cases, a minimum detention time of 1 d is required to achieve solids separation (Adams and Eckenfelder, 1974). If a 1-d detention time is used, adequate provision must be made for sludge storage so that the accumulated solids will not reduce the actual liquid detention time. Further, if all the solids become deposited in localized patterns, it may be necessary to increase the detention time to counteract the effects of poor hydraulic distribution. Under anaerobic conditions, about 40 to 60 percent of the deposited volatile suspended solids will be degraded each year. Assuming that first-order removal kinetics apply, the following expression can be used to estimate the decay of volatile suspended solids (Adams and Eckenfelder, 1974).

$$W_t = W_o e^{-k_d t} \tag{8-76}$$

where W_t = mass of volatile suspended solids remaining that have not degraded after time t, kg
W_o = mass of solids deposited initially, kg
k_d = decay coefficient, d^{-1} or $year^{-1}$
t = time, d or year

Two problems that are often encountered with the use of settling basins are the growth of algae and the production of odors. Algal growths can usually be controlled by limiting the hydraulic detention time to 2 d or less. If longer detention times must be used, the algal content may be reduced by using either a rock filter or a microstrainer (see Chap. 5). Odors arising from anaerobic decomposition can generally be controlled by maintaining a minimum water depth of 1 m (3 ft). In extremely warm areas, depths up to 2 m (~6 ft) have been needed to eliminate odors, especially those of hydrogen sulfide.

If space for large settling basins is unavailable, conventional settling facilities can be used. To reduce the construction costs associated with conventional concrete and steel settling tanks, lined earthen basins can be used. The design of a large earthen sedimentation basin for an aerated lagoon is illustrated in Example 8–15.

As noted previously, where greater removal of effluent solids is required, it has become common practice to use slow sand or rock filters (Rich, 1999). Rock filters, which may be effective in algae removal, consist of a submerged bed of rocks through which lagoon effluent passes vertically or horizontally. Although rock filters are simple to operate and maintain, effluent quality and dependability of long-term operation are not well documented (U.S. EPA, 1992).

EXAMPLE 8–15 Design of a Large Earthen Sedimentation Basin (Lagoon) for a Suspended Growth Flow-through Lagoon Design an earthen sedimentation basin (lagoon) for the suspended growth flow-through lagoon designed in Example 8–14. Assume that the hydraulic detention time is to be 2 d and that the liquid level above the sludge layer at its maximum level of accumulation is 1.25 m. For the purposes of this example, assume that 70 percent of the total solids discharged to the sedimentation basin are volatile and that the effluent from the sedimentation basin will contain 30 g/m^3 TSS. Also assume that the sedimentation lagoon is cleaned after 4 years.

Solution

1. Determine the mass of sludge that must be accumulated in the basin each year without anaerobic decomposition.

   $$\text{Mass} = Q(\text{TSS}_i - \text{TSS}_e)(365\ \text{d/yr})$$

   where TSS_i = total suspended solids in the influent to the sedimentation basin, g/m^3
   TSS_e = suspended solids in the effluent from the sedimentation basin, g/m^3
   Q = flowrate, m^3/d

   a. Compute the total mass of solids added per year.

   $$\text{Total solids} = \frac{(3800\ \text{m}^3/\text{d})[(309.1 - 30)\ \text{g/m}^3](365\ \text{d/yr})}{(10^3\ \text{g/kg})}$$

   $$= 387{,}112\ \text{kg/yr}$$

   b. Compute the mass of volatile and fixed solids added per year, assuming that VSS = 0.70 × TSS.

i. Volatile solids:

$$VSS = 0.70(387{,}112\ kg/yr) = 270{,}978\ kg/yr$$

ii. Fixed solids:

$$FSS = 387{,}112\ kg/yr\ (1 - 0.7) = 116{,}134\ kg/yr$$

2. Determine the amount of sludge that will accumulate at the end of 4 years. Assume that the maximum volatile solids reduction that will occur is equal to 60 percent and that it will occur within 1 year. To simplify the problem, assume that the deposited volatile suspended solids undergo a linear decomposition. Because the volatile solids will decompose to the maximum extent within 1 year, the following relationship can be used to determine the maximum amount of volatile solids available at the end of each year of operation:

$$VSS_t = [0.7 + 0.4(t - 1)](VSS\ kg/yr)$$

where $(VSS)_t$ = mass of volatile suspended solids at the end of t yr, kg
t = time, years

a. Mass of VSS accumulated at the end of 4 yr:

$$VSS_t = [0.7 + 0.4(4 - 1)]\ (270{,}978\ kg/yr)$$
$$= 514{,}852\ kg$$

b. Total mass of solids (TSS) accumulated at the end of 4 yr:

$$TSS_t = 514{,}852\ kg + (4\ yr)(116{,}134\ kg/yr)$$
$$= 979{,}388\ kg$$

3. Determine the required liquid volume and the dimensions for the sedimentation basin.

a. Volume of sedimentation basin:

$$V = (2\ d)(3800\ m^3/d) = 7{,}600\ m^3$$

b. Surface area of sedimentation basin:

$$A_s = \frac{(7600\ m^3)}{1.25\ m} = 6080\ m^2$$

The aspect ratio for the surface area of the sedimentation basin (ratio of width to length) depends on the geometry of the available site.

4. Determine the depth required for the storage of sludge.

a. Determine the mass of accumulated sludge per square meter.

$$\text{Mass per unit area} = \left(\frac{\text{accumulated sludge}}{\text{surface area of lagoon}}\right)$$
$$= \frac{979{,}388\ kg}{6080\ m^2} = 161.1\ kg/m^2$$

b. Determine the required depth d of the sludge blanket, assuming that the deposited solids are distributed evenly in the lagoon and will compact to an average final value of 15 percent of the initial solids volume and that the density of the accumulated solids is equal to 1.06.

$$d = \frac{(161.1\ \text{kg/m}^2)}{(1.06)(0.15)(1000\ \text{kg/m}^3)}$$

$$d = 1.0\ \text{m}$$

c. Total depth of basin excluding freeboard is

$$\text{Total depth} = 1.25\ \text{m} + 1.0\ \text{m} = 2.25\ \text{m}$$

Comment Where it is difficult to provide the total required depth, it may be necessary to increase the detention time or clean the sedimentation basins more frequently.

Dual-Powered Flow-Through Lagoon System

The dual-powered flow-through lagoon system is a modification of the conventional flow-through lagoon pioneered by Professor Rich (1982, 1996, and 1999). The dual-powered flow-through lagoon system is comprised of a complete-mix lagoon followed by two or three facultative lagoons that serve as settling basins (see Fig. 8–48). The operating principle of the dual-powered flow-through lagoon system may be outlined as follows: From basic considerations, it can be reasoned that secondary treatment involves the following functions: (1) bioconversion of the influent substrate to biomass and end products, (2) flocculation of the biomass, (3) separation of the solids, (4) stabilization of the solids, and (5) storage of the solids until they are reused or disposed of. These functions are optimized in the dual-powered flow-through lagoon system. Bioconversion and flocculation occur in the first complete-mix lagoon. The solids separation, stabilization, and storage are accomplished in the facultative lagoons following the complete-mix lagoon. To minimize the growth of algae, the detention time should be limited and the facultative lagoons should be divided into a series of cells (Rich, 1999).

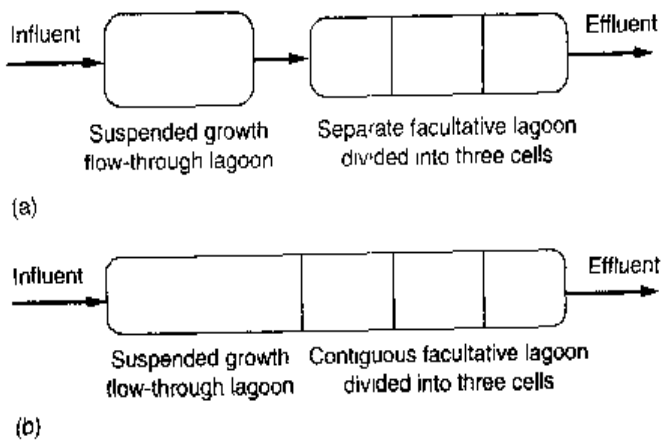

Figure 8–48
Dual-power flow-through lagoon system: (a) with separate facultative lagoon and (b) with contiguous facultative lagoon.

The hydraulic detention time for the complete-mix lagoon will typically vary from 1.5 to 3 d. The energy input in the complete-mix lagoon is on the order of 6 kW/10^3 m^3 (30 hp/Mgal). The total retention time for the facultative lagoons is on the order of 3 d. The energy input into the facultative lagoons is below the threshold value for the suspension of solids, but is sufficient to oxidize soluble organic constituents released from the anaerobic degradation of the solids accumulated on the bottom of the facultative lagoons. The corresponding energy input of the facultative lagoons is on the order of 1.0 to 1.25 kW/10^3 m^3 (5 to 6.25 hp/Mgal). The overall detention time for the two lagoons is typically 4.5 to 6 d. The same procedure used for the design of the flow-through suspended growth lagoon, as detailed in Example 8–14, is used for the design of the complete-mix lagoon of the dual-powered lagoon system. The design procedure for the facultative lagoons is similar to the procedure used in Example 8–15 for the design of a large earthen sedimentation basin. Additional details on dual-powered flow-through lagoon systems may be found in Rich (1999).

8–9 BIOLOGICAL TREATMENT WITH MEMBRANE SEPARATION

Membrane biological reactors (MBRs), consisting of a biological reactor (bioreactor) with suspended biomass and solids separation by microfiltration membranes with nominal pore sizes ranging from 0.1 to 0.4 μm, are finding many applications in wastewater treatment. Membrane biological reactor systems may be used with aerobic or anaerobic suspended growth bioreactors to separate treated wastewater from the active biomass (see Fig. 8–49). The membrane systems described in this section produce an effluent quality equal to the combination of secondary clarification and effluent microfiltration. Membrane biological reactors have been used for treatment of both municipal and industrial wastewater (Brindle and Stephenson, 1996; Van Dijk and Roncken, 1997; Trussell et al., 2000) and for water-reuse applications (Cicek et al., 1998). Membrane systems used in advanced wastewater applications are discussed in Chap. 11. In Sec. 11–6 of Chap. 11, various types of membrane materials, membrane designs, and operating conditions are also described. An overview of membrane biological reactors, process description, operational issues, and process capabilities is described in this section.

Overview of Membrane Biological Reactors

The concept of MBR systems consists of utilizing a bioreactor and microfiltration as one unit process for wastewater treatment thereby replacing, and in some cases supplementing, the solids separation function of secondary clarification and effluent filtration. The ability to eliminate secondary clarification and operate at higher MLSS concentrations provides the following advantages: (1) higher volumetric loading rates and thus shorter reactor hydraulic retention times; (2) longer SRTs resulting in less sludge production; (3) operation at low DO concentrations with potential for simultaneous nitrification-denitrification in long SRT designs; (4) high-quality effluent in terms of low turbidity, bacteria, TSS, and BOD; and (5) less space required for wastewater treatment. Disadvantages of MBRs include high capital costs, limited data on membrane life, potential high cost of periodic membrane replacement, higher energy costs, and the need to control membrane fouling.

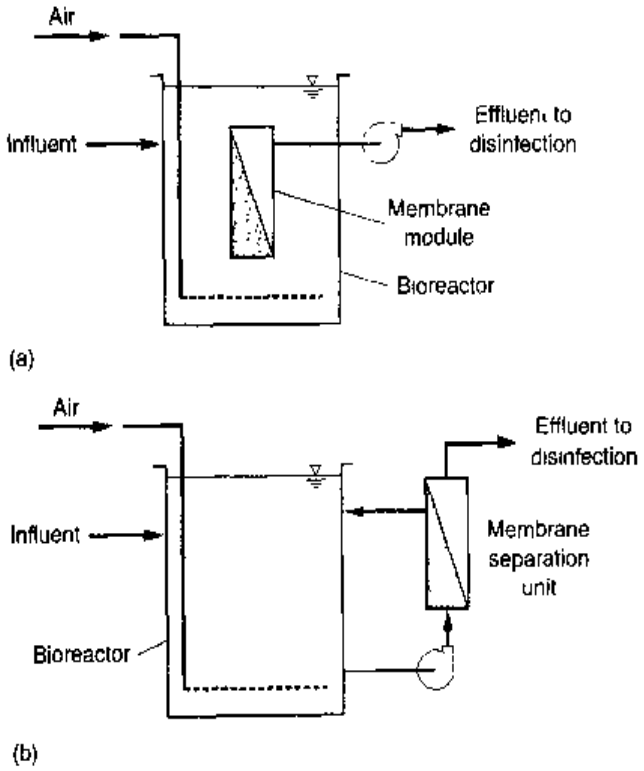

Figure 8–49

Schematic diagram of membrane bioreactors: (*a*) integrated MBR with an immersed membrane module, and (*b*) bioreactor with an external membrane separation unit.

Process Description

Membrane bioreactor systems have two basic configurations: (1) the integrated bioreactor that uses membranes immersed in the bioreactor and (2) the recirculated MBR in which the mixed liquor circulates through a membrane module situated outside the bioreactor.

In the integrated MBR system shown on Fig. 8–49*a*, the key component is the microfiltration membrane that is immersed directly into the activated-sludge reactor. The membranes are mounted in modules (sometimes called cassettes) that can be lowered into the bioreactor. The modules are comprised of the membranes, support structure for the membranes, feed inlet and outlet connections, and an overall support structure. The membranes are subjected to a vacuum (less than 50 kPa) that draws water (permeate) through the membrane while retaining solids in the reactor. To maintain TSS within the bioreactor and to clean the exterior of the membranes, compressed air is introduced through a distribution manifold at the base of the membrane module. As the air bubbles rise to the surface, scouring of the membrane surface occurs; the air also provides oxygen to maintain aerobic conditions.

A proprietary integrated MBR system is shown on Fig. 8–50, the Zenogem® process manufactured by Zenon Environmental, Inc. The Kubota submerged membrane bioreactor marketed by Enviroquip is similar. The Zenogem® microfiltration cassette shown on Fig. 8–50 is composed of hollow fiber membranes and has overall dimensions of 0.91 m wide by 2.13 m long, and approximately 2.44 m high (3 ft by 7 ft by 8 ft). Support facilities required include permeate pumps, chemical storage tanks, chemical feed pumps and all process controls for the membranes, including the motor control center for the membrane process. The membrane support equipment also includes an air-scour system and a back-pulse water-flushing system. The air-scour system consists of coarse bubble diffusers located in the aeration basin and provides continuous agitation on the

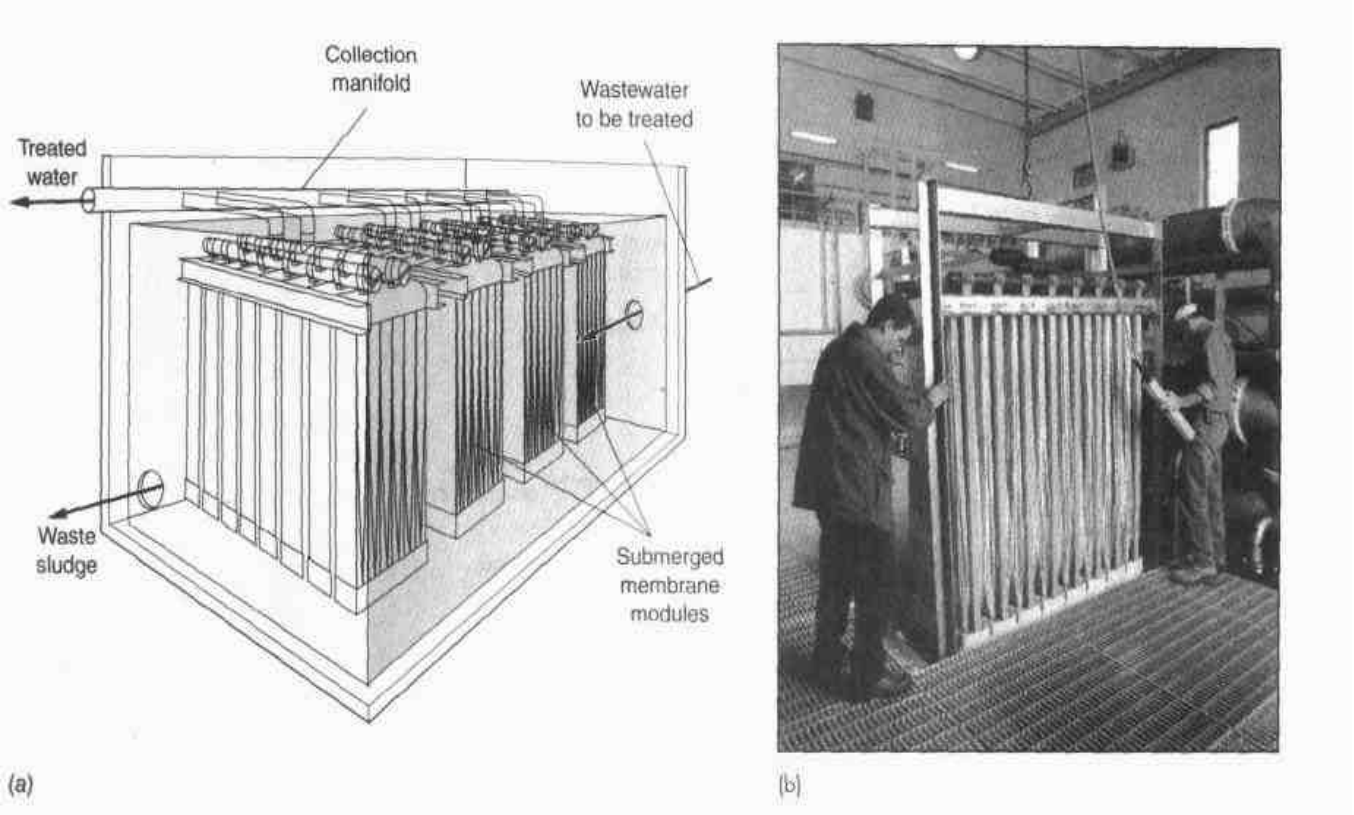

Figure 8–50

outside of the membranes to minimize solids deposition. The air supply for the air-scour system is typically provided in addition to the activated-sludge process air.

The membrane unit manufactured by Kubota consists of a series of membrane cartridges composed of fine porous membranes mounted on both sides of a supporting plate. The cartridges, which have a thickness of 6 m, can be removed individually for cleaning and replacement. Each of the cassettes or modules has a series of tubes that extract effluent from the membranes and connect to a collection manifold. The permeate support facilities are similar to those for the Zenon system.

As of 2001, in addition to Zenon and Kubota, submerged MBR systems in the United States are also marketed by Mitsubishi Rayon Corporation (Mitsubishi) from Japan (Merlo et al., 2000).

Besides submerged membranes, an in-line, recirculated MBR design is being marketed by Lyonnaise-des-Eaux Degremont of France. For this device, activated sludge from the bioreactor is pumped to a pressure-driven tubular membrane where solids are retained inside the membrane and water passes through to the outside. The driving force is the pressure created by high cross velocity through the membrane. The solids are recycled to the activated-sludge basin. The membranes are backwashed systematically to remove solids and cleaned chemically to control pressure buildup.

By replacing solids separation by gravity settling in secondary clarifiers, membranes avoid issues of filamentous sludge bulking and other floc settling and clarification problems, and the aeration tank MLSS concentration is no longer controlled by secondary clarifier solids loading limitations. The MBR systems can operate at much

higher MLSS concentrations (15,000 to 25,000 mg/L) than conventional activated-sludge processes (Cote et al., 1998). Although high concentrations of MLSS as noted above have been reported, MLSS concentrations in the range of 8000 to 10,000 mg/L appear to be most cost-effective when all factors are considered.

The membrane flux rate, defined as the mass or volume rate of transfer through the membrane surface [in terms of $L/m^2 \cdot h$ ($gal/ft^2 \cdot d$)] is an important design and operating parameter that affects the process economics. Lower flux rates are expected at higher MLSS concentrations. As more applications occur for MBR with activated-sludge treatment, more information will be available for long-term membrane flux rates and membrane life.

Membrane Fouling Control

In the activated-sludge reactor, biomass coats the outer layer of the membranes used in an integrated MBR during effluent withdrawal. Finer particles may penetrate the inner pores of the membrane, causing an increase in pressure loss. Continuous membrane fouling control methods are used during the operation of the MBR, with periodic more aggressive cleaning to maintain the filtration capacity of the membrane.

A method developed by Zenon Environmental to control fouling on the outside surfaces of the membrane fibers involves a three-step process. First, coarse bubble aeration is provided at the bottom of the membrane tank directly below the membrane fibers. The air bubbles flow upward between the vertically oriented fibers, causing the fibers to agitate against one another to provide mechanical scouring. Second, filtration is interrupted about every 15 to 30 min and the membrane fibers are backwashed with permeate for 30 to 45 s (Giese and Larsen, 2000). The system remains on-line during backwashing, and the total time for backflushing is about 45 min per day. Typically, a low concentration of chlorine (<5 mg/L) is maintained in the backflush water to inactivate and remove microbes that colonize the outer membrane surface. Third, about three times per week a strong sodium hypochlorite solution (about 100 mg/L) or citric acid is used in the backflush mode for 45 min in a procedure called a "maintenance clean." After the 45-min *in situ* cleaning, the system is flushed with permeate for 15 min. An additional permeate flush-to-drain operation is performed for 10 to 15 min to purge the system of free chlorine once the vacuum is initiated. The total system downtime during a maintenance clean is about 75 min.

The back-pulse system is similar to a typical flushing or cleaning system. A chlorine solution is pumped periodically through the membranes in the reverse direction, similar to backwashing a filter. The cassettes can be removed easily from the aeration basin by an overhead hoist system for a periodic chemical-bath cleaning. When removed for cleaning, the cassettes are submerged in a high-concentration chlorine solution bath in a separate small tank or basin located adjacent to the aeration basin. External cleaning occurs about every 3 to 6 months.

The combination of air scour, backflushing, and maintenance cleaning is not completely effective in controlling membrane fouling, and the pressure drop across the membrane increases with time. The pressure drop across the membranes is monitored to indicate fouling problems and cleaning needs. At a maximum operating pressure drop of ~60 kPa, the membranes are removed from the aeration basin for a recovery cleaning (Fernandez et al., 2000). During recovery cleaning, a membrane cassette is soaked in a tank containing a 1500 to 2000 mg/L sodium hypochlorite solution for

Table 8–30
Typical operational and performance data for a membrane bioreactor[a]

Parameter	Unit	Range
Operational data		
COD loading	$kg/m^3 \cdot d$	1.2–3.2
MLSS	mg/L	5000–20,000
MLVSS	mg/L	4000–16,000
F/M	g COD/g MLVSS·d	0.1–0.4
SRT	d	5–20
τ	h	4–6
Flux	$L/m^2 \cdot d$	600–1100
Applied vacuum	kPa	4–35
DO	mg/L	0.5–1.0
Performance data		
Effluent BOD	mg/L	<5
Effluent COD	mg/L	<30

Effluent TN	mg/L	<10
Effluent turbidity	NTU	<1

[a]From Stephenson et al. (2000).

about 24 h. Spare membranes are typically installed in the aeration tank during recovery cleaning so that there is no reduction in treatment capacity. A similar fouling control procedure has been reported for the Mitsubishi MBR membrane (Merlo et al., 2000). In the Kubota MBR process, the flat-plate membranes are not removed for cleaning, and an infrequent backflush with a 0.5 percent solution of hypochlorite has been shown to be effective (Stephenson et al., 2000).

Process Capabilities

The treatment capability of MBR is evaluated in terms of BOD, TSS, coliform, and nitrogen removal based on laboratory, pilot-plant, and full-scale plant studies. Because the activated-sludge effluent from MBRs is treated by filtration through a nominal 0.40-μm membrane, very low concentrations of effluent suspended solids, turbidity, and BOD are produced that provide an effluent suitable for water reuse following disinfection. Reported operating performance characteristics for MBR systems are summarized in Table 8–30. Low effluent BOD and turbidity concentrations are possible for MBR systems with MLSS concentrations in the range of 6000 to 16,000 mg/L.

Full-scale and pilot-plant systems have been operated with the anoxic/aerobic MLE biological nitrogen-removal process with the result that effluent total nitrogen concentrations of <10 mg/L have been achieved (Mourato et al., 1999; ReVoir et al., 2000; and Giese et al., 2000). Influent recycle flowrate ratios of 4.0 to 6.0 have been used in those studies to feed nitrate to a separate preanoxic tank.

Nitrogen removal in MBR systems has also been done in bench- and pilot-scale tests by using intermittent aeration or operation at low DO concentration to achieve SNdN. An

intermittent aeration study was conducted with an MLSS concentration of 6000 mg/L and on/off aeration intervals of 15 min (Fernandez et al., 2000). An effluent total nitrogen concentration ranging from 7 to 10 mg/L was achieved. Full nitrification was not possible at high MLSS concentrations (up to 13,000 mg/L). probably due to DO limitations in the activated sludge. In a laboratory study, an MBR was operated successfully at low DO concentrations (<1.0 mg/L) to accomplish SNdN (Choo and Stensel, 2000).

8–10 SIMULATION DESIGN MODELS

Activated-sludge processes used today are much more complex with their applications in single-sludge systems expanding from BOD removal to nitrification, denitrification, and phosphorus removal. The reactions involved in these processes are carried out by different types of bacteria that include a mixture of heterotrophic bacteria that are phosphorus-storing and non-phosphorus-storing, and among these, bacteria that can and cannot use nitrate as an electron acceptor, as well as autotrophic nitrifying bacteria. Competition exists between various types of heterotrophic bacteria for carbonaceous substrates. Furthermore, the importance of the wastewater components with regard to nonsoluble, soluble, biodegradable, and nonbiodegradable substrates on reaction rates, oxygen consumption, and sludge production is better understood. Computer modeling provides the tool to incorporate the large number of components and reactions to evaluate activated-sludge performance under both dynamic and steady-state conditions, and to easily design multiple-staged reactors as well as a single-stage complete-mix reactor.

A long list of complex equations would be needed to describe the various reactions in an activated-sludge process involving numerous components such as organic substrates (soluble and particulate), inorganic substrates (ammonia, nitrate, and phosphorus), dissolved oxygen, and various heterotrophic and autotrophic bacteria. Instead of showing the model in terms of numerous equations, a universal approach is to use a matrix model format that simply shows the process reactions and stoichiometric factors that link the components to the various reactions. The advantage is a simple, relatively short format is developed that describes the process. The purpose of this section is to provide a basic introduction to the matrix model approach showing the components and reactions for the model in its simplest form for the activated-sludge process and how the matrix format describes the process. Further, the approach also shows how the matrix model can be interpreted to describe a complete set of equations for a given process component. For example, the Activated Sludge Model No. 1 (ASM1) (Henze et al., 1987*a*) is described, though a more comprehensive version that incorporates biological phosphorus-removal mechanisms is available (Henze et al., 1995; Barker and Dold, 1997). Various software programs are available that apply models for different reactor configurations.

The ASM1 model only describes reactions by heterotrophic bacteria under aerobic and anoxic conditions consuming carbonaceous substrates and autotrophic nitrifying bacteria oxidizing ammonia to nitrate. A more complex model that includes phosphorus-storing bacteria with appropriate anaerobic, anoxic, and aerobic reactions has been developed and is termed the ASM2 model (Henze et al., 1995). The ASM2 model is incorporated into the model results presented by Barker and Dold (1997).

The models are based on *growth* as opposed to *substrate utilization*. Monod specific growth rate kinetics are used in the model to describe the growth of autotrophic or

heterotrophic bacteria; and the substrate, oxygen, and nutrient utilization rates are related to the growth rates by stoichiometric factors. Another important feature of the model is that it uses COD as the common measure of organic substrate and biomass, so that a COD balance exists for substrate utilization, biomass growth, and oxygen consumption. The models also use the lysis-regrowth model for endogenous respiration instead of a net endogenous decay coefficient as presented in this chapter for activated-sludge design. In the lysis-regrowth model, endogenous decay results in the release of biomass particulate material, some of which is biodegradable and is hydrolyzed to provide a source of rbCOD. Another portion remains as cell debris, similar to what has been incorporated for endogenous respiration in the activated-sludge design model presented in this chapter. In order to compute the same amount of sludge production as the endogenous respiration model, the decay coefficient value in the lysis-regrowth model is higher.

Model Matrix Format, Components, and Reactions

A convenient matrix format is used to describe the model without having to present the large number of equations involved. The ASM1 model with components and reaction terms is shown in Table 8–31. The model follows 13 wastewater characterization components, which are defined in Table 8–32. These components have been presented previously in Sec. 8–2. Complete wastewater characterization is an essential feature for using ASM1 and ASM2 models. Components 1 to 5 and 12 are particulate organic material, represented as COD, and are components of the activated-sludge MLVSS concentration. Components 6 to 11 are all soluble substrates and include electron acceptors (oxygen, S_o and nitrate, S_{NO}). The soluble nonbiodegradable COD is represented by S_i, and as shown, no stoichiometric factors are given as it is not involved in any reactions.

Various reaction terms that are described as processes are shown in the last column of Table 8–31. For example, r_j (where $j = 2$) is the growth reaction for heterotrophic bacteria under anoxic conditions. The heterotrophic bacteria growth rate is affected by the readily degradable substrate concentration (S_s), the DO concentration (S_o), and the nitrate concentration (S_{NO}). The term η represents the fraction of heterotrophic bacteria that can use nitrate in place of DO. For cell decay, the death-lysis model is used, which is shown by processes 4 and 5 for heterotrophic and autotrophic bacteria, respectively. The cell debris material produced during biomass decay is indicated by X_p and the production of degradable particulate substrate is indicated by a stoichiometric factor for X_s. The conversion of soluble organic nitrogen (S_{NS}) to ammonia (S_{NH}) is described by process 6. The hydrolysis of particulate organics and particulate organic nitrogen into soluble substrates (S_s and S_{NS}, respectively) under either aerobic or anoxic conditions is described by processes 7 and 8, respectively.

Within the matrix are stoichiometric factors that relate the rate of change in a particular component to a process reaction rate. For example, the process rate j_1 is the growth rate of aerobic heterotrophic bacteria in mg/L·d. Stoichiometric factors relate changes in model components to the growth rate. For component 3, the stoichiometric factor is 1 as

$$R_{B,H} = \hat{\mu}_H \left(\frac{S_s}{K_s + S_s} \right) \left(\frac{S_o}{K_{O,H} + S_o} \right) X_{B,H} \qquad (8\text{–}77)$$

where $R_{B,H}$ = growth rate of heterotrophic biomass, g/m^3·d
S_s = readily biodegradable substrate concentration, g COD/ m^3
$\hat{\mu}_H$ = maximum specific growth rate, g VSS/g VSS·d
K_s = half-velocity coefficient for readily biodegradable substrate, g COD/ m^3
S_o = dissolved oxygen concentration, g/m^3
$K_{O,H}$ = half velocity coefficient for dissolved oxygen concentration, g/m^3
$X_{B,H}$ = heterotrophic biomass concentration g/m^3

Component 7, the readily degradable substrate S_s (see Table 8–32), is used for growth and $-(1/Y_H)$ relates the rate of change in S_s to the rate of heterotrophic growth:

$$R_{S_s} = -\frac{1}{Y_H}(RX_{B,H}) \tag{8–78}$$

The total rate of change for S_s is equal to the sum of the stoichiometric factors in the column below S_s times the respective process rate.

The stoichiometric terms for oxygen consumption are described as follows: For heterotrophic growth ($\Psi_{j,1}$), the term $(1 - Y_H)$ is the g O_2 used/g COD removed. The term $(1-Y_H)$ is divided by Y_H (g cell COD/g COD used) to obtain the stoichiometric factor as g O_2/g cell COD produced, to fit to the matrix format. The stoichiometric term for autotrophic growth contains the factor 4.57. The term is required because ammonia, the substrate for the nitrifying bacteria, is expressed as nitrogen in the matrix S_{NH}, and oxygen is expressed as COD. The oxygen equivalent for ammonia is 4.57 g O_2/g NH_4-N. The amount in the numerator is lower by Y_A, which accounts for the ammonia used in cell synthesis.

Model Applications

The models may be used for a number of purposes: (1) as a research tool to evaluate biological processes and to better understand important parameters that affect a certain type of performance, (2) for wastewater treatment-plant design, and (3) for evaluating the treatment capacity of a given facility. For items 2 and 3, accurate and representative wastewater characterization is critical and dynamic simulations are often used to include the effect of variable flow and concentrations with time.

To evaluate the capacity of an existing plant, the model is calibrated using wastewater characterization and plant performance data. Calibrations based only on comparing the model predictions to the plant effluent concentration are not necessarily valid. Low effluent concentrations normally exist for all soluble degradable components, and thus the ability of the model to predict the plant performance is clouded by analytical accuracy and practical considerations. Intermediate soluble substrate concentrations from aerobic stages and/or anoxic and anaerobic stages provide a more reliable indication of the ability to describe the kinetics for the site. Oxygen uptake rate data are more meaningful for model calibration, since the data reflect different factors in the model including kinetic rates for different reactions and stoichiometric ratios for cell yield and decay. Where oxygen uptake rate data can be obtained for staged systems, it provides a valuable set of data for model calibration.

Typical values for model parameters have been selected and are summarized in Table 8–33. These are referred to as default values, but do not ensure that the model

can then predict the performance of an activated sludge accurately, as some of the coefficient values can be different at different sites. One of the parameters found to vary the most at different sites and often adjusted during model calibration is the maximum specific growth rate of nitrifying bacteria μ_A. Variations in nitrification kinetics may be due to differences in wastewater characteristics and inhibitors on nitrification

Note: All organic compounds (cols. 1–7) and oxygen (8) are expressed as COD; all nitrogenous components (9–12) are expressed as nitrogen. Coefficients must be multiplied by −1 to be expressed as oxygen.

or may also reflect other kinetic changes for which μ_A adjustments improve the overall fit.

The example on page 865 is intended to illustrate how the model matrix is interpreted to describe the rate of concentration change of a model component. Additional information on application of the model may be found in U.S. EPA (1993).

Table 8–32
Definition of ASM1 model components in Table 8–31

Component Number	Component Symbol	Definition
1	X_I	Inert particulate organic matter, mg/L
2	X_S	Slowly biodegradable substrate, mg/L as COD
3	$X_{O,H}$	Heterotrophic biomass, mg/L as COD
4	$X_{O,A}$	Autotrophic biomass, mg/L as COD
5	X_P	Debris from biomass death and lysis, mg/L as COD
6	S_I	Inert soluble organic matter, mg/L as COD
7	S_S	Readily biodegradable substrate, mg/L as COD
8	S_O	Dissolved oxygen, mg/L as O_2 (COD)
9	S_{NO}	Nitrate–nitrogen, mg/L as N
10	S_{NH}	Ammonia–nitrogen, mg/L as N
11	S_{NS}	Soluble biodegradable organic nitrogen, mg/L as N
12	X_{NS}	Particulate degradable organic nitrogen, mg/L as N
13	S_{ALK}	Alkalinity, molar units

Table 8–33
Typical stoichiometric parameter values for the ASM1 model[a]

Symbol	Description	Units	Value
Y_H		g biomass COD/g COD used	0.60
f_D		g cell debris/g biomass COD	0.08
i_n/xb		g N/g active biomass COD	0.086
i_n/xd		g N/g biomass debris COD	0.06
Y_A		g biomass COD/g N oxidized	0.24
μ_H	Maximum specific growth rate of heterotrophic bacteria	d^{-1}	6.0
K_s	Half-velocity constant for heterotrophic bacteria	mg/L	20.0
$K_{O,H}$	DO half-velocity constant	mg/L	0.10
K_{NO}	Nitrate half-velocity constant	mg/L	0.20
$b_{L,H}$	Decay/lysis coefficient, heterotrophic	g/g·d	0.40
η_g	Fraction of heterotrophs using nitrate under anoxic growth	g/g	0.80
η_h	Anoxic/aerobic hydrolysis rate fraction	g/g	0.40
K_a	Ammonification rate constant	L/mg COD·d	0.16
K_h	Particulate hydrolysis maximum specific rate constant	g/g·d	2.21
K_X	Hydrolysis half-velocity constant	g/g·d	0.15
μ_A	Autotrophic maximum specific growth rate	g/g·d	0.76
K_{NH}	Autotrophic half-velocity constant	mg/L	1.0
$K_{O,A}$	Half-velocity DO constant for autotrophs	mg/L	0.75
$b_{L,A}$	Decay constant for autotrophs	g/g·d	0.07

EXAMPLE 8-16 Apply ASM1 Model Matrix Use the ASM1 model matrix to describe the reaction rates for (1) readily degradable COD (S_s) and (2) particulate organic substrates (X_s).

Solution For S_s, $i = 7$, from matrix there are reaction terms where $j = 1, 2, 7$. These stoichiometric factors are $j = 1$, factor $= -1/Y_H$, $j = 2$, factor $= -1/Y_H$, $j = 7$, factor $= 1$. Multiplying the stoichiometric factors by the process rate terms (r_j) yields the following for the rate of change of S_s:

$$R_{S_s} = -\frac{1}{Y_H}\mu_H\left(\frac{S_s}{K_s + S_s}\right)\left(\frac{S_o}{K_{O,H} + S_o}\right)X_{B,H} \quad (1)$$

$$-\frac{1}{Y_H}\mu_H\left(\frac{S_s}{K_s + S_s}\right)\left(\frac{K_{O,H}}{K_{O,H} + S_o}\right)\left(\frac{S_{NO}}{K_{NO} + S_{NO}}\right)\eta X_{B,H} \quad (2)$$

$$+ k_h\left[\frac{(X_s/X_{B,H})}{K_X + (X_s/X_{B,H})}\right]\left(\frac{S_o}{K_{O,H} + S_o}\right) + \eta_h\left(\frac{K_{O,H}}{K_{O,H} + S_o}\right)\left(\frac{S_{NO}}{K_{NO} + S_{NO}}\right)X_{B,H} \quad (7)$$

For X_s, $i = 2$, from matrix there are reaction terms where $j = 4$, 5, and 7.

$$Rx_s = (1 - f_d')\, b_{L,H} X_{B,H} + (1 - f_d')\, b_{L,A} X_{B,A} - k_h\left[\frac{(X_s/X_{B,H})}{K_X + (X_s/X_{B,H})}\right]\left(\frac{S_o}{K_{O,H} + S_o}\right) + \eta_h\left(\frac{K_{O,H}}{K_{O,H} + S_o}\right)\left(\frac{S_{NO}}{K_{NO} + S_{NO}}\right)X_{B,H}$$

PROBLEMS AND DISCUSSION TOPICS

8-1 Given the following laboratory test BOD and UBOD test results for one of the following wastewaters (to be selected by the instructor), determine the biodegradable COD (bCOD) concentration. Assume that values for f_d' and Y_H are 0.15 and 0.40, respectively.

		Wastewater		
Test Parameter	**Unit**	**A**	**B**	**C**
BOD	mg/L	120	200	200
UBOD	mg/L	180	300	340

8-2 An influent wastewater sample is evaluated in a laboratory respirometer test to determine its readily biodegradable COD (rbCOD) concentration. The respirometer bottle is prepared by adding 500 mL of the influent sample with 500 mL of an activated-sludge mixed liquor. The respirometer records the accumulative oxygen consumption with time. The oxygen consumption occurs at a relatively constant rate initially (Phase A), and then the rate declines within 3 minutes to another relatively constant rate (Phase B), which continues for a number of hours. Finally, the oxygen consumption rate declines dramatically again and continues at a relatively

constant rate (Phase C). The respirometer data is summarized in the following table for three different samples (to be selected by instructor). For the selected sample determine the rbCOD concentration of the wastewater in mg/L, assuming the biomass yield for the heterotropic bacteria is 0.4 g VSS/g COD and the oxygen equivalent of the biomass is 1.42 g COD/g VSS.

		Respirometer accumulative oxygen consumption for each phase, mg		
		Sample		
Phase	Duration of phase, h	A	B	C
A	0.8	64	80	58
B	3.2	192	288	192
C	2.0	40	50	46

8–3 For one of the following wastewater samples (as selected by instructor) shown in the following table, with values for conventional wastewater characterization parameters, determine (a) the nonbiodegradable volatile suspended solids (nbVSS) concentration, (b) the inert total suspended solids (iTSS) concentration, and (c) the average COD/VSS ratio. Assume that the bCOD/BOD ratio equals 1.6.

		Wastewater		
Parameter	Unit	A	B	C
TSS	mg/L	220	220	225
VSS	mg/L	200	200	210
BOD	mg/L	200	155	270
sBOD	mg/L	80	80	170
COD	mg/L	544	400	700
sCOD	mg/L	160	160	300

8–4 Using one of the following wastewater characteristics below (as selected by instructor), determine: (a) biodegradable COD (bCOD), (b) slowly biodegradable COD (sbCOD), (c) nonbiodegradable COD (nbCOD), and (d) nonbiodegradable soluble and particulate COD (nbsCOD and nbpCOD) concentrations. Assume that the bCOD/BOD and biodegradable soluble COD/sBOD ratios are both 1.6.

		Wastewater		
Parameter	Unit	A	B	C
COD	mg/L	450	550	420
sCOD	mg/L	130	170	110
rbCOD	mg/L	40	60	30
BOD	mg/L	200	220	160
sBOD	mg/L	60	80	50

8–5 Given the following wastewater characteristics (as selected by instructor), determine (a) the organic nitrogen, (b) the nonbiodegradable particulate organic nitrogen (nbpON), and (c) the biodegradable organic nitrogen (bON) concentrations.

Parameter	Unit	Wastewater A	Wastewater B	Wastewater C
TKN	mg/L	40	45	50
NH_4-N	mg/L	25	30	35
Soluble nonbiodegradable organic nitrogen	mg/L	1.5	1.5	1.5
VSS	mg/L	180	180	190
Nonbiodegradable VSS fraction	Percent	40	40	40

8–6 Using an observed yield value from Fig. 8–7, and Eqs. (8–14) and (7–54) (see Table 8–5), determine (a) the aeration tank volume (m^3) and (b) the amount of sludge wasted daily in kg TSS/d for an activated-sludge system designed to treat a 6000 m^3/d wastewater flow with an influent BOD concentration of 120, 140, or 160 mg/L (as selected by instructor). The SRT is 6 d, the mixed-liquor temperature is 10°C, and primary treatment is used. What is the aeration tank volume and amount of daily sludge production if the SRT is increased to 12 d? Assume that the MLVSS and MLSS concentrations are 2500 mg/L and 3000 mg/L, respectively.

8–7 The following information is given for an activated-sludge system design:

Parameter	Unit	Value
Flow	m^3/d	10,000
Influent BOD	mg/L	150
Effluent BOD	mg/L	2
τ	h	4
SRT	d	6
Synthesis yield, Y	g VSS/g bCOD	
Wastewater A		0.40
Wastewater B		0.50
Wastewater C		0.30
Cell debris yield, f_d	g VSS/g VSS	0.15
Endogenous decay, k_d	g VSS/g VSS·d	0.08
nbVSS	mg/L	40
Temperature	°C	10

Note: Value A, B, or C to be selected by instructor.

Assume no nitrification occurs due to the SRT selected and low temperature. Determine (a) the aeration tank oxygen requirements in kg/d, (b) the aeration tank oxygen uptake rate in mg/L·hr, and (c) the aeration tank biomass concentration (mg/L).

8–8 The following information is given for an activated-sludge system designed with a long enough SRT to provide complete nitrification:

Parameter	Unit	Value
Flow	m^3/d	10,000
Influent BOD	mg/L	150
Effluent BOD	mg/L	2
Influent TKN	mg/L	35
Effluent NH_4-N	mg/L	0.5
τ	h	8.0
SRT	d	15
Temperature	°C	10
Cell debris yield, f_d	g VSS/g VSS	0.10
Synthesis yield, Y	g VSS/g bCOD	
Wastewater A		0.40
Wastewater B		0.50
Wastewater C		0.30
Endogenous decay, k_d	g VSS/g VSS·d	0.08
Nitrifier yield, Y_n	g VSS/g NH_4-N	0.12
Nitrifier decay, k_{dn}	g VSS/g VSS·d	0.06

Note: Value A, B, or C to be selected by instructor.

Determine (a) the aeration tank oxygen requirements in kg/d, (b) the aeration tank oxygen uptake rate in mg/L·hr, (c) the aeration tank biomass concentration (mg/L), and (d) the portion of the total oxygen required that is needed for nitrification.

8–9 Using Eqs. (8–15) and (8-16), compare the amount of sludge wasted daily as (a) VSS, (b) TSS, and (c) biomass for operation at an SRT of 10 and 20 days for the following wastewater and design conditions. Assume complete nitrification. Repeat the calculation without accounting for cell debris. How much error is introduced?

Parameter	Unit	Value
Flow	m^3/d	15,000
Influent BOD	mg/L	200
Effluent BOD	mg/L	2
Influent TKN	mg/L	35
Effluent NH_4-N	mg/L	0.5
Heterotrophic yield, Y	g VSS/g bCOD	0.4
Heterotrophic decay, k_d	g VSS /g VSS-d	0.10
Cell debris yield, f_d	g VSS /g VSS	0.15
Nitrifier yield, Y_n	g VSS /g NH_4-N	0.12

(continued)

(*Continued*)

Parameter	Unit	Value
Nitrifier decay, k_{dn}	gVSS/gVSS·d	0.08
nbVSS	mg/L	
Wastewater A		100
Wastewater B		120
Wastewater C		80
Temperature	°C	15

Note: Value A, B, or C to be selected by instructor.

8–10 An industrial wastewater from food processing is to be treated in an activated-sludge process. The wastewater consists of mainly soluble carbonaceous BOD with low nitrogen and phosphorus concentrations. For the summary of wastewater characteristics and design assumptions given in the following table, determine the amount of nitrogen and phosphorus that must be added to the influent flow as mg/L and in kg/d. Assume that residual NH_4-N and the soluble phosphorus concentrations of 0.10 mg/L are needed to prevent nutrient limitations.

Parameter	Unit	Value
Flow	m^3/d	3000
Influent soluble bCOD	mg/L	
Wastewater A		2000
Wastewater B		3000
Wastewater C		2500
Effluent soluble bCOD	mg/L	5
Influent NH_4-N	mg/L	20
Influent phosphorus as P	mg/L	5
SRT	d	10
Synthesis yield, Y	g VSS/g COD	0.4
Heterotrophic decay, k_d	g VSS/g VSS-d	0.10
Cell debris yield, f_d	g VSS/g VSS	0.10

Note. Value A, B, or C to be selected by instructor.

8–11 A 2-L settleometer is used to perform an SVI test. The MLSS concentration for the test is 3500 mg/L and the settled sludge volume after 30 min is 840 mL. What is the sludge volume index?

8–12 According to Eq. (8–20) the secondary clarifier surface overflow rate may be approximated from an estimate of the mixed-liquor initial interfacial settling velocity (V_i), and Eq. (8–22) may be used to estimate V_i from the expected SVI value and design MLSS concentration. Using these equations, determine the surface overflow rate for a clarifier designed for an expected SVI of up to 180, 200, or 220 mL/g (as selected by instructor). Assume a safety factor value of 2.0. How does the calculated overflow rate compare to the range of design values in Table 8–7 for an air activated-sludge system without a selector?

8–13 Two 20-m-diameter circular clarifiers are used for liquid-solids separation for an air activated-sludge system. The MLSS concentration is 3000 mg/L and the return activated-sludge recycle ratio is 50 percent. Assuming average solids loading rate values, within the range shown in Table 8–7, of 4, 5, or 6 kg/m^2·h (as selected by instructor), determine the allowable average influent flowrate in m^3/d and the return MLSS concentration.

8–14 A completely mixed activated-sludge system treating domestic wastewater is operated at an SRT of 15 days at 12°C, such that complete nitrification occurs. The clarifier surface overflow rate is 1 m/h at average flow conditions, but the clarifier has a high sludge blanket with significant solids loss in the effluent. Describe (a) the specific steps you recommend to investigate the cause of the bulking sludge condition, (b) possible short-term immediate action to reduce the effluent TSS concentration, and (c) the selector alternatives that can be considered for bulking sludge control. Which one would you use and why?

8–15 Using the kinetic coefficients in Table 8–10 and 8–11, plot the following as a function of SRT (ranging from 3.0 to 20.0 days) for the municipal wastewater described in the table below. Assume that the MLSS concentration is 2500 mg/L. The parameters to plot are (a) solids wasted as kg TSS/d, (b) aeration tank volume (m^3) and τ (h), (c) observed yield, as g TSS/g BOD_r, and g TSS/g $bCOD_r$, (d) effluent soluble bCOD concentration, (e) effluent NH_4-N concentration, and (f) oxygen requirements, kg/d.

Parameter	Unit	Value
Flow	m^3/d	20,000
BOD	mg/L	
Wastewater A		220
Wastewater B		250
Wastewater C		180
bCOD/BOD	g/g	1.6
TSS	mg/L	220
VSS	mg/L	200
nbVSS	mg/L	
Wastewater A		100
Wastewater B		120
Wastewater C		80
TKN	mg/L	40
Temperature	°C	15
Aeration tank DO	mg/L	2.0

Note: Value A, B, or C to be selected by instructor.

8–16 Solve Problem 8–15 using primary clarification, assuming 35 percent BOD removal, 65 percent TSS and VSS removal, 10 percent TKN removal, and 80 percent nbVSS removal.

8–17 An activated-sludge system is to be designed for nitrification to achieve an effluent NH_4-N concentration of 0.50, 0.80, or 1.0 mg/l. (as selected by the instructor) at a reactor DO concentration

of 2.0 mg/L and 10°C temperature. The peak/average TKN load is 1.8. Determine the design SRT. Use coefficients from Table 8–11.

8–18 A completely mixed activated-sludge system has a hydraulic retention time (τ) of 8.3, 10.8, or 13.1 hours (as selected by the instructor), an aeration tank DO concentration of 2.0 mg/L, and an MLSS concentration of 3000 mg/L. For the municipal wastewater characteristics given below determine (a) the aeration tank average SRT and (b) the nitrification safety factor for a desired average effluent NH_4-N concentration of 0.5 mg/L.

Parameter	Unit	Value
Temperature	°C	10
Flow	m^3/d	15,000
BOD removal	mg/L	130
nbVSS	mg/L	30
TSS	mg/L	70
VSS	mg/L	60
TKN	mg/L	40

8–19 A 3000 m^3/d industrial wastewater with a soluble COD concentration of 1800 mg/L is to be treated in a completely mixed activated-sludge process at 15°C and 2500 mg/L MLSS concentration. Using the kinetic coefficients and assumptions provided below determine (a) the aeration tank volume (m^3) and τ (h), (b) the oxygen required (kg/d), (c) the sludge production (kg TSS/d), (d) the effluent BOD concentration from the secondary clarifiers, (e) the clarifier diameter (m), assuming two clarifiers, and (f) the air flowrate for fine bubble diffused air aeration. Assume very little excess NH_4-N exists after cell synthesis needs are met so that nitrification is not significant.

Parameter	Unit	Value
bCOD/BOD	g/g	1.6
μ_m	g VSS/g VSS·d	3.0
K_s	mg bCOD/L	60.0

Parameter	Unit	Value
Elevation	m	300
Effective DO saturation depth	m	2.5
Aeration tank liquid depth	m	5.0
Clean H_2O oxygen transfer efficiency	%	30

Note: Value A, B, or C to be selected by instructor.

8–20 An oxidation ditch process is designed for the following wastewater using the conventional design approach of no primary treatment, a 24-hour aeration tank detention time, and 3500 mg/L MLSS concentration. The lowest expected mixed-liquor temperature is 10°C and an average effluent NH_4-N concentration of 1.0 mg/L is required with a 1.5 safety factor for peak loads. Mechanical surface aerators are used to provide a DO concentration in the aeration zone of 2.0 mg/L. Determine (a) the SRT (d), (b) the sludge production (kg TSS/d), (c) the MLVSS concentration, (d) the oxygen required (kg/d), (e) the total required aeration horsepower, and (f) the ratio of the total volume provided to the necessary nitrification volume.

		Values		
Parameter	Unit	Wastewater A	Wastewater B	Wastewater C

Note: Value A, B, or C to be selected by instructor.

8–21 For the same wastewater characteristics and mixed-liquor temperature as in Problem 8–20 and assuming uniform continuous flow, two sequencing batch reactor tanks are operated under the following conditions:

Fraction of tank liquid depth used for decent depth = 0.20

Aeration time = 2 h

Settle time = 1 h

Decant time = 0.5 h

Determine (a) the fill time (hr), (b) the total time/cycle (hr), (c) the total full volume of each tank (m^3), (d) the SBR SRT assuming an MLSS concentration of 3500 mg/L, and (e) the decant pumping rate (m^3/min).

8–22 A sequencing batch reactor treating the following wastewater is operated under the following conditions:

Temperature = 10°C

Aeration time/cycle = 2.5 h

Fill volume/total liquid volume per cycle = 0.30

SRT = 20 d

DO = 2.0 mg/L

Two SBR reactor tanks are used and the full volume for each SBR tank = 3000 m^3.

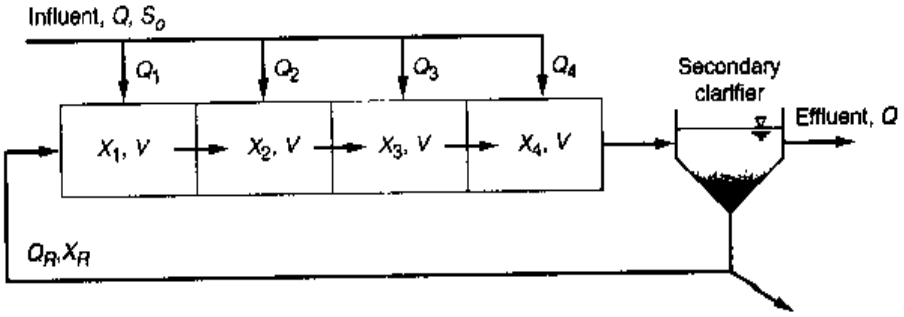
		Value		
Parameter	**Unit**	**Wastewater A**	**Wastewater B**	**Wastewater C**
Flow	m^3/d	6000	6000	6000
BOD	mg/L	250	250	250
TKN	mg/L	45	40	30

Note: Value A, B or C to be selected by instructor.

Determine the nitrification safety factor, defined as the actual aeration time/required aeration time per cycle to achieve an effluent NH_4-N concentration of 0.50 mg/L. Use kinetic coefficients values from Table 8–11.

8–23 An SBR tank has a total liquid depth of 5.5 m when full. The desired operating MLSS concentration is 3500 mg/L. If the SVI is 150, 180, or 200 mL/g (as selected by instructor), determine the possible fill volume to total liquid volume ratio, assuming a 0.6 m clear liquid depth above the settled sludge blanket.

8–24 Repeat computations for Example 8–5 using the same design conditions and assumptions, but for an effluent NH_4-N concentration of 1.0, 2.0, and 4.0 mg/L (as selected by instructor). How do the advantages of the staged system compare to the single-stage nitrification system as the desired effluent NH_4-N concentration is increased?



8–25 A four-stage activated-sludge system with equal tank volumes of 240 m^3/stage is used to treat an industrial wastewater with a soluble BOD concentration of 300 mg/L. The influent flow is 4000 m^3/day and the RAS recycle ratio of 0.5. The active biomass concentration is 1600 mg/L. For the following biokinetic information determine: (a) the substrate concentration in each stage (mg/L as soluble bCOD), (b) the oxygen required per stage (kg/d), and (c) the percent of the total oxygen required per stage. Hint: to start the solution assume a 4th stage soluble bCOD concentration of 1.0 mg/L.

Parameter	Unit	Value
k, maximum specific substrate utilization rate	g COD/g VSS·d	1.2
K_s, half velocity coefficient	mg COD/L	
Wastewater A		50
Wastewater B		75
Wastewater C		100
Y, yield	g VSS/g COD removed	0.35
k_d, endogenous decay	g VSS/g VSS·d	0.10

Note: Value A, B, or C to be selected by instructor.

8–26 Compare the following activated-sludge processes in terms of effluent quality, space requirements, complexity, energy requirements, operational requirements, and ability to handle variable flows and loads: completely mixed, pure oxygen, contact stabilization, and oxidation ditch.

8–27 A four-pass step-feed activated-sludge system, shown in the figure below, has equal aeration tank volumes in each pass of 240 m^3. Using the design parameters given below, determine the MLVSS concentration in each tank.

		Values		
Parameter	Unit	Wastewater A	Wastewater B	Wastewater C
X_R	mg VSS/L	10,000	10,000	10,000
Q_R	m^3/d	2,000	4,000	6,000
Q	m^3/d	4,000	4,000	4,000
Q_1	m^3/d	800	800	800
Q_2	m^3/d	1,200	1,200	1,200
Q_3	m^3/d	1,000	1,000	1,000
Q_4	m^3/d	1,000	1,000	1,000

Note: Value A, B, or C to be selected by instructor.

8–28 The following describes the operating conditions of an anoxic/aerobic process as shown in Example 8–5 for 85 percent nitrogen removal.

Parameter	Unit	Value
Flow	m^3/d	1,000
BOD	mg/L	200
rbCOD	mg/L	
Wastewater A		60
Wastewater B		95
Wastewater C		120

TKN	mg/L	35
Temperature	°C	15
MLSS	mg/L	3,500
Biomass (VSS)	mg/L	1,620
RAS (TSS)	mg/L	10,000
Aerobic volume	m^3	460
Aerobic SRT	days	10.0
Biomass nitrogen content	g N/g VSS	0.12
Effluent NH_4-N	mg/L	1.0

Note: Value A, B, or C to be selected by instructor.

Determine (a) the internal recycle ratio and flowrate (m^3/d), (b) the anoxic tank volume and τ for a single-stage anoxic reactor, and (c) the anoxic tank volume and τ for each stage of a three-stage anoxic tank with equal volumes per stage, (d) the final alkalinity concentration, and (e) the oxygen required (kg/d) for the anoxic/aerobic process versus the aerobic system without the pre-anoxic tank.

8–29 An existing activated-sludge system is operated at a minimal temperature of 10°C. The system is to be modified to an anoxic/aerobic process with the anoxic tank accounting for 10 percent of its total volume. For the following design wastewater conditions and total tank volume, determine (a) the effluent NH_4-N and NO_3-N concentrations, assuming a 1.5 safety factor for nitrification, and (b) the minimal internal recycle ratio needed to match the nitrate removal capacity of the anoxic tank. Use necessary coefficients from Tables 8–10 and 8–11.

Parameter	Unit	Value
Flow	m^3/d	8000
bCOD	mg/L	240
rbCOD	mg/L	
Wastewater A		25
Wastewater B		50
Wastewater C		75
nbVSS	mg/L	60

(continued)

(*Continued*)

Parameter	Unit	Value
TSS	mg/L	80
VSS	mg/L	70
TKN	mg/L	40
MLSS	mg/L	3500
Tank volume	m^3	3600
RAS ratio	Unitless	0.50
Biomass nitrogen content	g N/g VSS	0.12
Aeration tank DO	mg/L	2.0

Note: Value A, B, or C to be selected by instructor.

8–30 An oxidation ditch system is operated with a single mechanical surface aerator such that one-half of the tank volume is aerobic with the DO concentration varying from 0 to 2.0 mg/L. For the information given below, determine the effluent NH_4-N (assuming 1.5 safety factor) and NO_3-N concentrations.

Parameter	Unit	Value
Ditch volume	m^3	4600
MLSS	mg/L	3500
Temperature	°C	10
BOD	mg/L	
Wastewater A		250
Wastewater B		220
Wastewater C		200
nbVSS	mg/L	80
TKN	mg/L	40
TSS	mg/L	220
VSS	mg/L	210

Note: Value A, B, or C to be selected by instructor.

8–31 For the following wastewater characteristics design an SBR system, using two tanks, to produce an effluent NO_3-N and NH_4-N concentration of 6 mg/L and 1.0 mg/L, respectively. Assume that the aeration, settle, and decant times per cycle are 2.0, 1.0, and 0.5 hours, respectively, and the MLSS concentration is 4000 mg/L. Determine (a) the fill volume fraction, (b) the volume of each SBR tank, (c) the decant pumping rate, and (d) the nitrification safety factor. Assume the aeration DO concentration is 2.0 mg/L and only anoxic mixing occurs during the fill period.

Parameter	Unit	Value
Flow	m^3/d	5000
BOD	mg/L	250
rbCOD	mg/L	50
nbVSS	mg/L	120
TKN	mg/L	
Wastewater A		45
Wastewater B		40
Wastewater C		35
TSS	mg/L	220
VSS	mg/L	210
Temperature	°C	12

Note: Value A, B, or C to be selected by instructor.

8–32 For the suspended-growth postanoxic denitrification process design example shown in Example 8–9 a design SRT of 5 d was used. Determine (a) the change in the methanol dose requirement (kg/d), (b) the amount of sludge produced (kg/d), and (c) the anoxic tank volume if a design SRT of 15 d is used instead. If methanol costs $0.05/kg, would the longer SRT design be more economical?

8–33 An A^2O system for biological nitrogen and phosphorus removal is designed with a 15-d SRT. An observed yield of 0.60 g TSS/g BOD removed is estimated and the following wastewater characteristics following primary treatment have been obtained:

Parameter	Unit	Value
BOD	mg/L	
Wastewater A		150
Wastewater B		140
Wastewater C		120
TKN	mg/L	35
TSS	mg/L	82
VSS	mg/L	72
pH	units	7.2

Note: Value A, B, or C to be selected by instructor.

Determine (a) the estimated effluent soluble phosphorus concentration for the biological phosphorus-removal process and (b) the phosphorus content (in percent on a dry weight basis) of

the waste sludge. What additional wastewater characterization parameter would you recommend obtaining to better estimate the effluent phosphorus concentration?

8–34 An A^2O process is operated with a 12 d SRT and achieves the following effluent nutrient concentrations with internal and return activated sludge (RAS) recycle ratios of 3.0 and 0.5, respectively.

Effluent soluble P concentration = 0.50 mg/L

Effluent NO_3-N concentration = 5.0 mg/L

Assuming that the influent wastewater characteristics and SRT remain the same, determine (a) the change in effluent soluble phosphorus and NO_3-N concentrations if the internal recycle ratio is changed to 2.0, 2.5, or 2.8 (as selected by instructor) and the RAS ratio is increased to 1.0 and (b) how much additional influent rbCOD is consumed by nitrate fed to the anaerobic zone.

8–35 State whether the effluent phosphorus concentration for an A^2O system will increase, decrease, or remain the same for the following changes in the wastewater characteristics or process operating conditions. Refer to basic process fundamentals to explain the basis for your answer.

1. The SRT is increased.
2. The influent rbCOD concentration increases.
3. The clarifier effluent suspended solids concentration increases.
4. A higher NO_3-N concentration exists in the return activated-sludge recycle.
5. The influent particulate BOD concentration increases.

8–36 Given the settling data in the following table from tests with mixed liquor from an activated-sludge plant, determine the percent RAS recycle rate if the clarifier overflow rate is 0.82, 1.0, or 1.2 m/h (as selected by instructor) and the RAS MLSS concentration is 10,500 mg/L. What will the recycle rate be if the RAS MLSS concentration is 15,000 mg/L?

	Sludge liquid/solids interface depth in column test as a function of time and initial mixed-liquor concentration					
	MLSS concentration, mg/L					
Time, min	**1000**	**2000**	**3000**	**5000**	**10,000**	**15,000**
0	0	0	0	0	0	0
10	117.1	90.5	41.2	17.1	4.9	3.0
20	189.0	167.1	84.1	34.1	10.1	6.1
30	192.1	182.9	127.7	50.9	14.9	9.1
40	193.0	188.1	156.1	68.0	20.1	11.9
50	193.0	189.0	166.2	85.1	25.9	14.0
60	193.9	189.9	172.0	102.1	31.1	15.9

Note: Data in table corresponds to the distance from the top of the settling column to the sludge interface at indicated time, cm.

8–37 Two secondary clarifiers are operating with an overflow rate of 1 m/h and the activated-sludge tank MLSS concentration is 4000 mg/L. Based on sludge thickening tests, the interfacial settling velocity can be described by the following relationship:

$$V_i = V_o(e^{-kX})$$

where V_i = interfacial settling velocity, m/d
X = MLSS concentration, g/L
V_o = 172 m/d
k = 0.4004 L/g

(a) Plot the solids flux due to thickening as a function of the MLSS concentration in g/L.
(b) On the same curve draw the overflow rate operating flux line and show the operating state point.
(c) Determine the solids flux rate and recycle ratio for operating the clarifiers at an underflow concentration of 10, 11, or 12 g/L (as selected by instructor).
(d) Determine the MLSS concentration possible with only one clarifier in operation using the above underflow concentration. Indicate the new overflow rate operating flux line and operating state point.

8–38 Design an aerated lagoon to treat 10,000 m^3/d of wastewater under the following conditions:

1. Influent soluble BOD and suspended solids = 150 mg/L
2. Overall first-order BOD removal-rate constant = 2.0 d^{-1} at 20°C
3. Summer temperature = 27°C
4. Winter temperature = 7°C
5. Wastewater temperature = 15°C
6. Temperature coefficient = 1.07
7. $\alpha = 0.85$; $\beta = 1.0$
8. Elevation = 1250 m
9. Oxygen concentration to be maintained = 2.0 mg/L
10. Lagoon depth = 2 m
11. Hydraulic residence time = 10 d
12. Temperature proportionally constant $f = 12 \times 10^6$

Determine the surface area, summer and winter temperatures in the lagoon, and the effluent BOD in summer and winter. If the growth yield is approximately 0.5 (BOD basis), determine the biological solids concentration in the lagoon, the oxygen requirements, and the power requirements for summer and winter conditions. Use surface aerators rated at 1.5 kg O_2/kW·h.

8–39 A conventional activated-sludge process with an aeration tank volume of 4600 m^3 is operated with a 6-d SRT and 2500 mg/L MLSS concentration, when treating the following wastewater after primary treatment:

Parameter	Unit	Value
Flow	m^3/d	15,000
BOD	mg/L	150
nbVSS	mg/L	35
TSS	mg/L	80
VSS	mg/L	68
TKN	mg/L	35

The system must be upgraded to treat additional flow and to provide nitrification to produce an effluent NH_4-N concentration of 1.0 mg/L. A 12-d SRT is selected and membrane separation will replace the secondary clarifier operation, due to limited space for additional aeration tanks. Assuming the same wastewater characteristics, and using the same aeration tank volume with an MLSS concentration of 10,000, 12,000, or 15,000 mg/L (as selected by instructor), determine (a) the new wastewater treatment flowrate possible, (b) the previous and new volumetric BOD loadings (kg/m^3·d) and F/M ratios, and (c) the membrane surface area needed assuming a flux rate of 900 L/m^2·d.

8–40 Using the ASM1 Model matrix described in Table 8–31, write the sum of all the rate equations that describe the rate of change of the following model components:

Heterotrophic biomass concentration
Autotrophic biomass concentration
Readily biodegradable COD concentration
Slowly biodegradable COD concentration

PROBLEMS AND DISCUSSION TOPICS 971

REFERENCES 976

The concept of attached growth processes was introduced in Chap. 7, along with the fundamental mechanisms of mass transfer of substrate and electron acceptors into the biofilms that develop in attached growth systems. In this chapter, various attached growth and combined biological processes used for wastewater treatment are discussed. The attached growth processes considered in detail in this chapter include (1) trickling filters, (2) rotating biological contactors, and (3) combined attached and suspended growth processes. In addition, the activated-sludge processes with fixed-film packing, submerged attached growth processes, and attached growth denitrification processes are introduced and discussed. The use of attached growth biofilters for odor control is discussed in Sec. 15–3 in Chap. 15.

9–1 BACKGROUND

To introduce the discussion and analysis of attached growth processes, it will be helpful to briefly review the evolution of these processes and to consider the impact of mass transfer on the performance of these processes.

Evolution of Attached Growth Processes

Attached growth processes can be grouped into three general classes: (1) nonsubmerged attached growth processes, (2) suspended growth processes with fixed-film packing, and (3) submerged attached growth aerobic processes. The evolution of each of the processes in these groupings is discussed below.

Nonsubmerged Attached Growth Processes. Trickling filters with rock packing have been a common, simple, and low-energy process used for secondary treatment since the early 1900s. A trickling filter is a nonsubmerged fixed-film biological reactor using rock or plastic packing over which wastewater is distributed continuously. Treatment occurs as the liquid flows over the attached biofilm. The concept of a trickling filter grew from the use of contact filters in England in the late 1890s. Originally they were watertight basins filled with broken stones and were operated in a cyclic mode. The bed was filled with wastewater from the top, and the wastewater was allowed to contact the packing for a short time. The bed was then drained and allowed to rest before the cycle was repeated. A typical cycle required 12 h (6 h for operation and 6 h of resting). The limitations of the contact filter included a relatively high incidence of clogging, the long rest period required, headloss, and the relatively low loading that could be used. Because of the clogging problems, larger packing was used until a rock size of 50 to 100 mm (2 to 4 in) was reached (Crites and Tchobanoglous 1998).

In the 1950s, plastic packing began to replace rock in the United States. The use of plastic packing allowed the use of higher loading rates and taller filters (also known as biotowers) with less land area, improved process efficiency, and reduced clogging. In the 1960s, practical designs were developed for rotating biological contactors (RBCs), which provided an alternative attached growth process where the packing is rotated in the wastewater treatment tank, versus pumping and applying the wastewater over a static packing. Both trickling filters and RBCs have been used as aerobic attached growth processes for BOD removal only, combined BOD removal and nitrification, and for tertiary nitrification after secondary treatment by suspended growth or attached growth

processes. The principal advantages claimed for these aerobic attached growth processes over the activated-sludge process are as follows:

- Less energy required
- Simpler operation with no issues of mixed liquor inventory control and sludge wasting
- No problems of bulking sludge in secondary clarifiers
- Better sludge thickening properties
- Less equipment maintenance needs
- Better recovery from shock toxic loads

In comparison to the activated-sludge process, many disadvantages often cited for trickling filters, such as a poorer effluent quality in terms of BOD and TSS concentrations, greater sensitivity to lower temperatures, odor production, and uncontrolled solids sloughing events, are related more to the specific process and final clarifier designs than to the actual process capabilities (WEF, 2000). In general, the actual limitations of the processes (1) make it difficult to accomplish biological nitrogen and phosphorus removal compared to single-sludge biological nutrient removal suspended growth designs, and (2) result in an effluent with a higher turbidity than activated-sludge treatment. Trickling filters and RBCs have also been used in combined processes with activated sludge to utilize the benefits of both processes, in terms of energy savings and effluent quality.

Suspended Growth Processes with Fixed-Film Packing. The placement of packing material in the aeration tank of the activated-sludge process dates back to the 1940s with the Hays and Griffith processes (WEF, 2000). Present-day designs use more engineered packings and include the use of packing materials that are suspended in the aeration tank with the mixed liquor, fixed packing material placed in portions of the aeration tank, as well as submerged RBCs. The advantages claimed for these activated-sludge process enhancements are as follows:

- Increased treatment capacity
- Greater process stability
- Reduced sludge production
- Enhanced sludge settleability
- Reduced solids loadings on the secondary clarifier
- No increase in operation and maintenance costs

Submerged Attached Growth Processes. Beginning in the 1970s and extending into the 1980s, a new class of aerobic attached growth processes became established alternatives for biological wastewater treatment. These are upflow and downflow packed-bed reactors and fluidized-bed reactors that do not use secondary clarification. Their unique advantage is the small footprint with an area requirement that is a fraction (one-fifth to one-third) of that needed for activated-sludge treatment. Though they are more compact, their capital costs are generally higher than that for activated-sludge treatment. In addition to BOD removal, submerged attached growth

processes have also been used for tertiary nitrification and denitrification following suspended or attached growth nitrification.

Downflow and upflow packed-bed reactors, fluidized-bed reactors, and submerged RBCs can be used for postanoxic denitrification. Trickling filters and upflow packed-bed reactors are also used for preanoxic denitrification.

Mass Transfer Limitations

A significant process feature of attached growth processes in contrast to activated-sludge treatment is the fact that the performance of biofilm processes is often diffusion-limited. Substrate removal and electron donor utilization occur within the depth of the attached growth biofilm and subsequently the overall removal rates are a function of diffusion rates and the electron donor and electron acceptor concentrations at various locations in the biofilm. By comparison, the process kinetics for the activated-sludge process are generally characterized by the bulk liquid concentrations.

The diffusion-limited concept is especially important when considering the measurable bulk liquid DO concentrations on attached growth process biological reaction rates. Where a DO concentration of 2 to 3 mg/L is generally considered satisfactory for most suspended growth aerobic processes, such low DO concentrations can be limiting for attached growth processes. For uninhibited nitrification in the biofilm a much higher DO concentration may be required, as shown in Chap. 7, depending on the ammonia concentration.

The concept of diffusion limitations on nitrification rates and the ability to develop anaerobic layers within the biofilm may be exploited to accomplish both nitrification and denitrification in attached growth processes with positive bulk liquid DO concentrations. Investigators have shown how aerobic and anaerobic layers can be developed in the biofilm to accomplish nitrogen removal by nitrification and denitrification (Chui et al., 1996; Richter and Kruner, 1994; and Meaney and Strickland, 1994).

9–2 TRICKLING FILTERS

Trickling filters have been used to provide biological wastewater treatment of municipal and industrial wastewaters for nearly 100 years. As noted above, the trickling filter is a nonsubmerged fixed-film biological reactor using rock or plastic packing over which wastewater is distributed continuously. Treatment occurs as the liquid flows over the attached biofilm. The depth of the rock packing ranges from 0.9 to 2.5 m (3 to 8 ft) and averages 1.8 m (6 ft). Rock filter beds are usually circular, and the liquid wastewater is distributed over the top of the bed by a rotary distributor (see Fig. 9–1). Many conventional trickling filters using rock as the packing material have been converted to plastic packing to increase treatment capacity. Virtually all new trickling filters are now constructed with plastic packing.

Trickling filters that use plastic packing have been built in round, square, and other shapes with depths varying from 4 to 12 m (14 to 40 ft). In addition to the packing, other components of the trickling filter include a wastewater dosing or application system, an underdrain, and a structure to contain the packing. The underdrain system is important both for collecting the trickling filter effluent liquid and as a porous structure through which air can circulate. The collected liquid is passed to a sedimentation tank where the solids are separated from the treated wastewater. In practice, a portion of the liquid col-

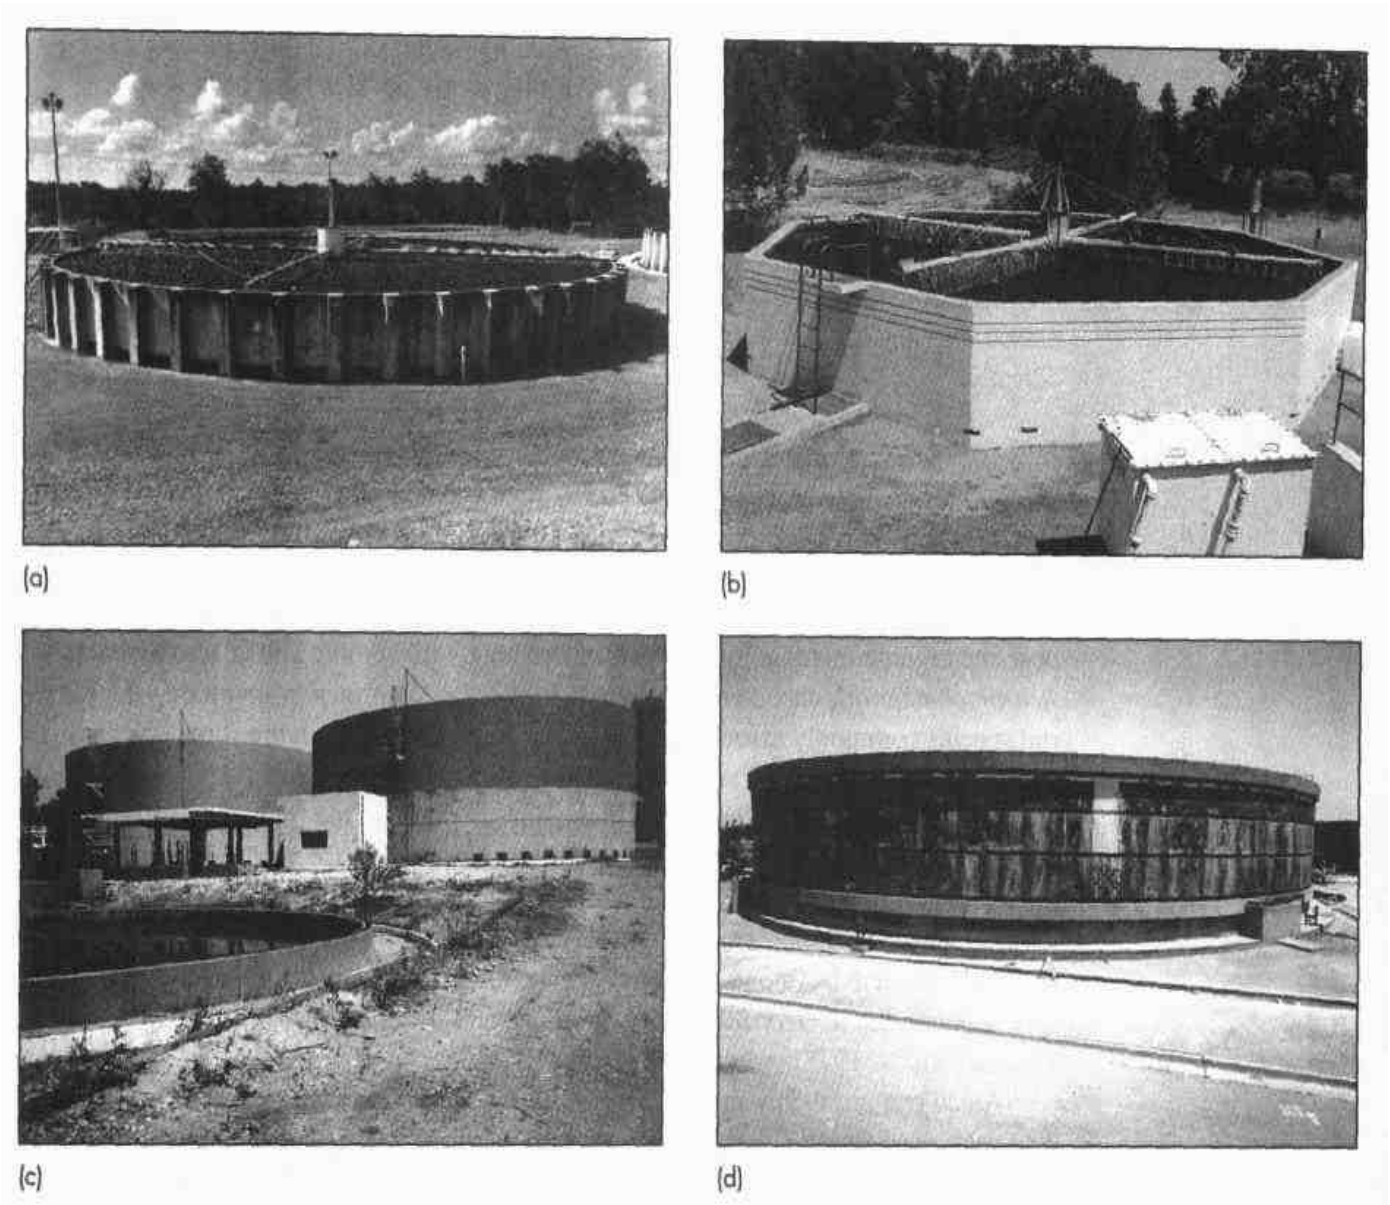

Figure 9–1

Typical examples of trickling filters: (a) conventional shallow-depth rock trickling filter, (b) seven-sided trickling filter (older design) with rock replaced by random plastic packing, (c) intermediate-depth trickling filter converted to tower trickling filter, and (d) one of four tower trickling filters 10 m high and 50 m in diameter with plastic packing. Blowers, used to provide air for biological treatment, are located in the enclosures shown at the bottom left- and right-hand side of the tower filter. See Fig. 9–4 for examples of the rotary distributors used to apply wastewater to the top of the filter packing.

lected in the underdrain system or the settled effluent is recycled to the trickling filter feed flow, usually to dilute the strength of the incoming wastewater and to maintain enough wetting to keep the biological slime layer moist.

Influent wastewater is normally applied at the top of the packing through distributor arms that extend across the trickling filter inner diameter and have variable openings to provide a uniform application rate per unit area. The distributor arms are rotated by the force of the water exiting through their opening or by the use of electric drives. The electric drive designs provide more control flexibility and a wider range of distributor

rotational speeds than possible by the simple hydraulic designs. In some cases, especially for square or rectangular filters, fixed flat-spray nozzles have been used.

Primary clarification is necessary before rock trickling filters, and generally used also before trickling filters with plastic packing, though fine screens (smaller than 3-mm openings) have been used successfully with plastic packing (WEF, 1998). With increases in plastic and rubber floatable materials in wastewater, screening of these materials is important to reduce fouling of the packing. In some installations a wire-mesh screen is placed over the top of plastic packing to collect debris that can be vacuumed off periodically.

A slime layer develops on the rock or plastic packing in the trickling filters and contains the microorganisms for biodegradation of the substrates to be removed from the liquid flowing over the packing. The biological community in the filter includes aerobic and facultative bacteria, fungi, algae, and protozoans. Higher animals, such as worms, insect larvae, and snails, are also present.

Facultative bacteria are the predominating organisms in trickling filters, and decompose the organic material in the wastewater along with aerobic and anaerobic bacteria. *Achromobacter, Flavobacterium, Pseudomonas,* and *Alcaligenes* are among the bacterial species commonly associated with the trickling filter. Within the slime layer, where adverse conditions prevail with respect to growth, the filamentous forms *Sphaerotilus natans* and *Beggiatoa* will be found. In the lower reaches of the filter, the nitrifying bacteria will be present. The fungi present are also responsible for waste stabilization, but their role is usually important only under low-pH conditions or with certain industrial wastes. At times, fungi growth can be so rapid that the filter clogs and ventilation becomes restricted. Among the fungi species that have been identified are *Fusazium, Mucor, Penicillium, Geotrichum, Sporatichum,* and various yeasts (Hawkes, 1963; Higgins and Burns, 1975).

Algae can grow only in the upper reaches of the filter where sunlight is available. *Phormidiun, Chlorella.* and *Ulothrix* are among the algae species commonly found in trickling filters (Hawkes, 1963; Higgins and Burns, 1975). Generally, algae do not take a direct part in waste degradation, but during the daylight hours they add oxygen to the percolating wastewater. From an operational standpoint, the algae may be troublesome because they can cause clogging of the filter surface, which may cause odors.

The protozoa in the filter are predominantly of the ciliate group, including *Vorticella, Opercularia,* and *Epistylis* (Hawkes, 1963; Higgins and Burns, 1975). Their function is to feed on the biological films and, as a result, effluent turbidity decreases and the biofilm is maintained in a higher growth state. The higher animals, such as worms, snails, and insects, feed on the biological film. Snails are especially troublesome in trickling filters used mainly for nitrification, where they have been known to consume enough of the nitrifying bacteria to significantly reduce treatment efficiency (Timpany and Harrison, 1989).

The slime layer thickness can reach depths as much as 10 mm. Organic material from the liquid is adsorbed onto the biological film or slime layer. In the outer portions of the biological slime layer (0.1 to 0.2 mm), the organic material is degraded by aerobic microorganisms. As the microorganisms grow and the slime layer thickness increases, oxygen is consumed before it can penetrate the full depth, and an anaerobic environment is established near the surface of the packing. As the slime layer increases in thickness, the substrate in the wastewater is used before it can penetrate the inner

depths of the biofilm. Bacteria in the slime layer enter an endogenous respiration state and lose their ability to cling to the packing surface. The liquid then washes the slime off the packing, and a new slime layer starts to grow. The phenomenon of losing the slime layer is called *sloughing* and is primarily a function of the organic and hydraulic loading on the filter. The hydraulic loading accounts for shear velocities, and the organic loading accounts for the rate of metabolism in the slime layer. Hydraulic loading and trickling filter sloughing can be controlled by using a wastewater distributor with an electric motor drive to vary rotational speed (Albertson, 1989).

The mechanisms of biological film loss in plastic and rock packing are different. Continuous, small-scale sloughing of the film occurs in high-rate plastic filters due to hydraulic shear, while large-scale, spring-time sloughing occurs in rock filters located in temperate zones. Sloughing is due to the activity of insect larvae, which become active in the warmer spring temperatures and consume and mechanically dislodge thick biofilms that accumulate over the winter. When a rock filter sloughs, the effluent before settling will contain higher amounts of BOD and TSS than the applied wastewater (Hawkes, 1963).

Trickling Filter Classification and Applications

Trickling filter applications and loadings, based on historical terminology developed originally for rock filter designs, are summarized in Table 9–1. Trickling filter designs

Table 9–1
Historical classification of trickling filters applications[a]

Design characteristics	Low or standard rate	Intermediate rate	High rate	High rate	Roughing
Type of packing	Rock	Rock	Rock	Plastic	Rock/plastic
Hydraulic loading, $m^3/m^2 \cdot d$	1–4	4–10	10–40	10–75	40–200
Organic loading, kg $BOD/m^3 \cdot d$	0.07–0.22	0.24–0.48	0.4–2.4	0.6–3.2	>1.5
Recirculation ratio	0	0–1	1–2	1–2	0–2
Filter flies	Many	Varies	Few	Few	Few
Sloughing	Intermittent	Intermittent	Continuous	Continuous	Continuous
Depth, m	1.8–2.4	1.8–2.4	1.8–2.4	3.0–12.2	0.9–6
BOD removal efficiency, %	80–90	50–80	50–90	60–90	40–70
Effluent quality	Well nitrified	Some nitrification	No nitrification	No nitrification	No nitrification
Power, $kW/10^3\ m^3$	2–4	2–8	6–10	6–10	10–20

[a] Adapted from Metcalf & Eddy, Inc. (1979) and WEF (2000)

Note: $m^3/m^2 \cdot d \times 24.5424 = gal/ft^2 \cdot d$.

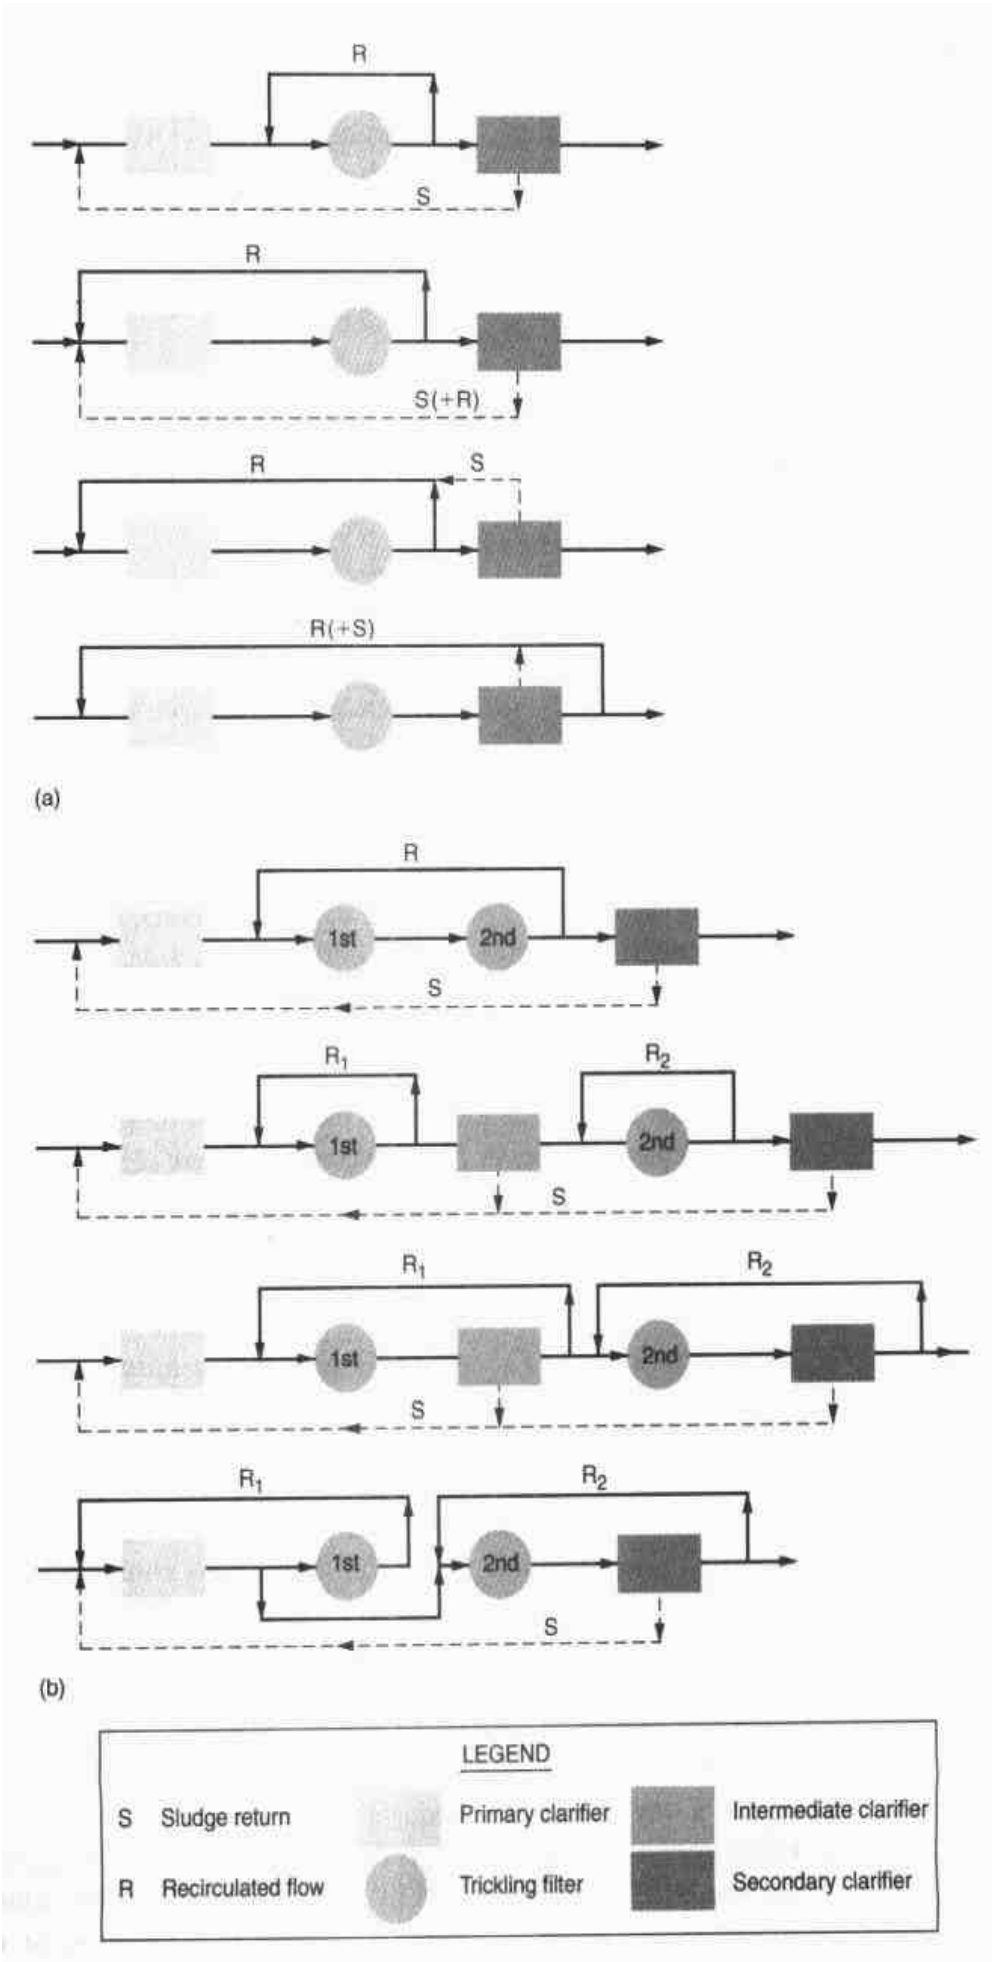
$kg/m^3 \cdot d \times 62.4280 = lb/10^3\ ft^3 \cdot d$.

$kW/10^3\ m^3 \times 5.0763 = hp/10^3\ gal$.

are classified by hydraulic or organic loading rates. Rock filter designs have been classified as low- or standard-rate, intermediate-rate, and high-rate. Plastic packing is used typically for high-rate designs; however, plastic packing has also been used at lower organic loadings, near the high end of those used for intermediate-rate rock filters. Much higher organic loadings have been used for rock or plastic packing designs in "roughing" applications where only partial BOD removal occurs.

Low-Rate Filters. A low-rate filter is a relatively simple, highly dependable device that produces an effluent of consistent quality with an influent of varying strength. The filters may be circular or rectangular in shape. Generally, feed flow from a dosing tank is maintained by suction level controlled pumps or a dosing siphon. Dosing tanks are small, usually with only a 2-min detention time based on twice the average design flow, so that intermittent dosing is minimized. Even so, at small plants, low nighttime flows may result in intermittent dosing and recirculation may be necessary to keep the packing moist (U.S. EPA, 1974). If the interval between dosing is longer than 1 or 2 h, the efficiency of the process deteriorates because the character of the biological slime is altered by a lack of moisture.

In most low-rate filters, only the top 0.6 to 1.2 m (2 to 4 ft) of the filter packing will have appreciable biological slime. As a result, the lower portions of the filter may be populated by autotrophic nitrifying bacteria, which oxidize ammonia nitrogen to nitrite and nitrate forms. If the nitrifying population is sufficiently well established, and if climatic conditions and wastewater characteristics are favorable, a well-operated low-rate filter can provide good BOD removal and a highly nitrified effluent.



With a favorable hydraulic gradient, the ability to use gravity flow is a distinct advantage. If the site is too flat to permit gravity flow, pumping will be required. Odors are a common problem, especially if the wastewater is stale or septic, or if the weather is warm. Filters should not be located where the odors would create a nuisance. Filter flies (*Psychoda*) may breed in the filters unless effective control measures are used.

Intermediate- and High-Rate Filters. High-rate filters use either a rock or plastic packing. The filters are usually circular and flow is usually continuous. Recirculation of the filter effluent or final effluent permits higher organic loadings, provides higher dosing rates on the filter to improve the liquid distribution and better control of the slime layer thickness, provides more oxygen in the influent wastewater flow, and returns viable organisms. Recirculation also helps to prevent ponding in the filter and to reduce the nuisance from odors and flies (U.S. EPA, 1974). Intermediate- and high-rate trickling filters may be designed as single- or two-stage processes. Flow diagrams for various trickling filter configurations are shown on Fig. 9–2. Two filters in series operating at the same hydraulic application rate ($m^3/m^2 \cdot h$) will typically perform as if they were one unit with the same total depth (WEF, 2000).

Roughing Filters. Roughing filters are high-rate-type filters that treat an organic load of more than 1.6 $kg/m^3 \cdot d$ (100 lb $BOD/10^3$ $ft^3 \cdot d$) and hydraulic loadings up to 190 $m^3/m^2 \cdot d$ (3.2 $gal/ft^2 \cdot min$). In most cases, roughing filters are used to treat wastewater prior to secondary treatment. Most roughing filters are designed using plastic packing (WPCF, 1988). One of the advantages of roughing filters is the low energy

Figure 9–2

Typical trickling filter process flow diagrams: (*a*) single stage and (*b*) two-stage. Where used, the most common flow diagrams are the first two of each series.

requirement for BOD removal of higher strength wastewaters as compared to activated-sludge aeration. Because the energy required is only for pumping the influent wastewater and recirculation flows, the amount of BOD removal per unit of energy input can increase as the wastewater strength increases until more recirculation is needed to dilute the influent wastewater concentration or to increase wetting efficiency. The energy requirement for a roughing application may range from 2 to 4 kg BOD applied/kWh versus 1.2 to 2.4 kg BOD/kWh for activated-sludge treatment.

Two-Stage Filters. A two-stage filter system, with an intermediate clarifier to remove solids generated by the first filter, is most often used with high-strength wastewater (Fig. 9–2*b*). Two-stage systems are also used where nitrification is required. The first-stage filter and intermediate clarifier reduce carbonaceous BOD, and nitrification takes place in the second stage.

Nitrification. Both BOD removal and nitrification can be accomplished in rock or plastic packing trickling filters operated at low organic loadings (Stenquist et al., 1974; Parker and Richards, 1986). Heterotrophic bacteria, with higher yield coefficients and faster growth rates, are more competitive than nitrifying bacteria for space on the fixed-film packing. Thus, significant nitrification occurs only after the BOD concentration is appreciably reduced. Bruce et al. (1975) demonstrated that the effluent BOD had to be less than 30 mg/L to initiate nitrification and less than 15 mg/L for complete nitrification. Harremoës (1982) considered the soluble BOD, and concluded that a concentration less than 20 mg/L is needed to initiate nitrification. Nitrification can also be accomplished in separate trickling filters following secondary treatment.

Design of Physical Facilities

Factors that must be considered in the design of trickling filters include (1) type and physical characteristics of filter packing to be used; (2) dosing rate; (3) type and dosing characteristics of the distribution system; (4) configuration of the underdrain system; (5) provision for adequate airflow (i.e., ventilation), either natural or forced air; and (6) settling tank design.

Filter Packing. The ideal filter packing is a material that has a high surface area per unit of volume, is low in cost, has a high durability, and has a high enough porosity so that clogging is minimized and good air circulation can occur. Typical trickling filter packing materials are shown on Fig. 9–3. The physical characteristics of commonly used filter packings, including those shown on Fig. 9–3, are reported in Table 9–2. Until the mid-1960s, the material used was either high-quality granite or blast-furnace slag. Since the 1960s, plastic packing material, either cross-flow or vertical-flow, has become the packing of choice in the United States.

Where locally available, rock has the advantage of low cost. The most suitable material is rounded river rock or crushed stone, graded to a uniform size so that 95 percent is within the range of 75 to 100 mm (3 to 4 in). The specification of size uniformity is a way of ensuring adequate pore space for wastewater flow and air circulation. Other important characteristics of filter packing materials are strength and durability. Durability may be determined by the sodium sulfate test, which is used to test the soundness of concrete aggregates (U.S. EPA, 1974). Because of the weight of the pack-

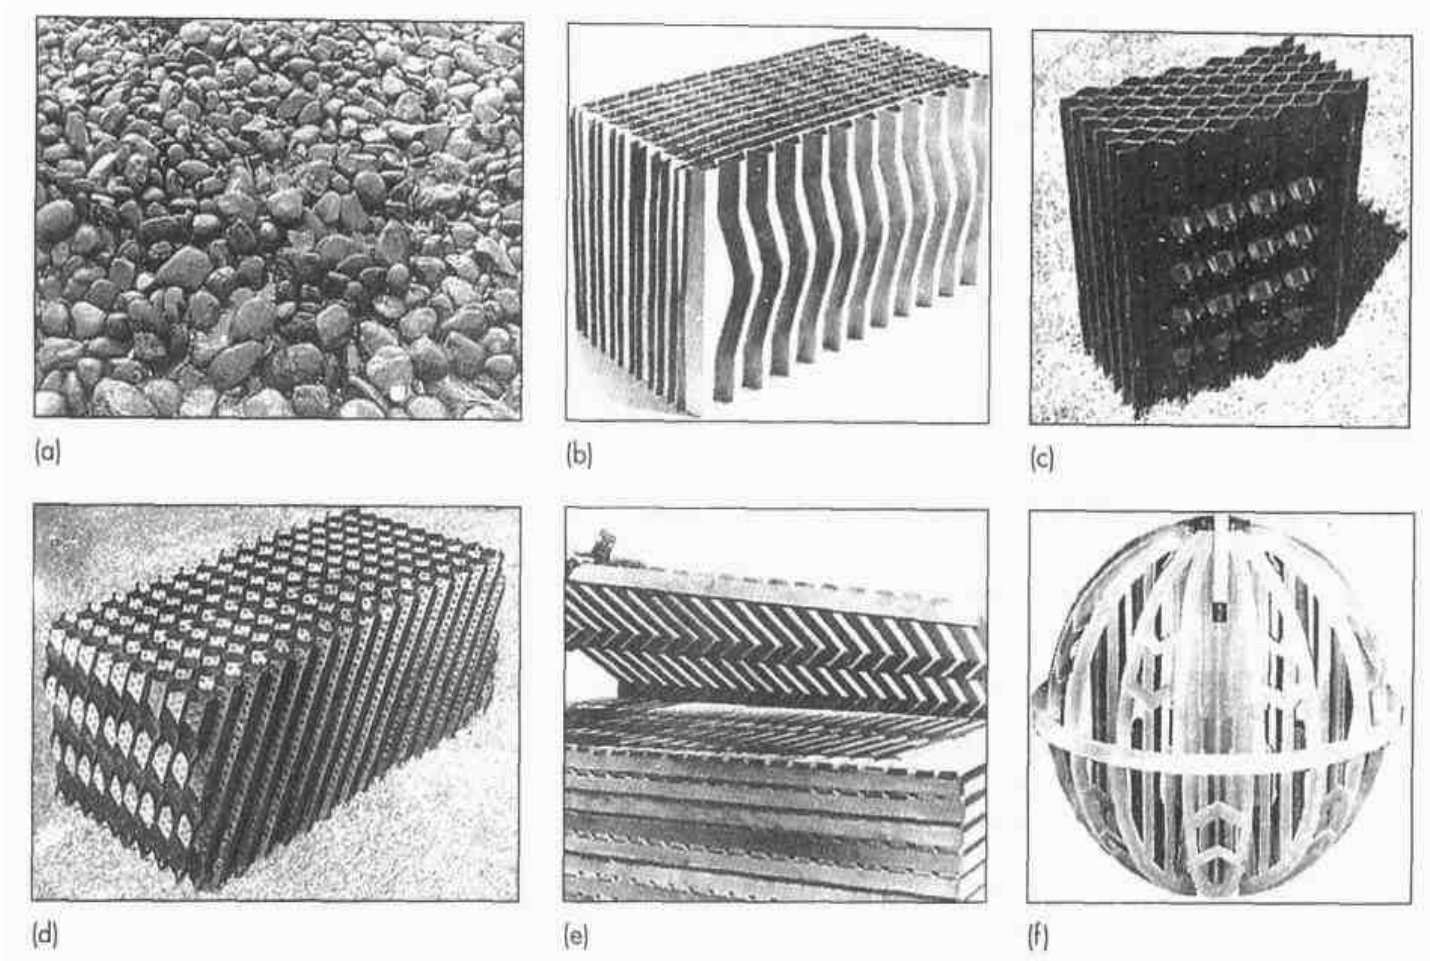


Figure 9–3

Typical packing material for trickling filters: (*a*) rock, (*b*) and (*c*) plastic vertical-flow, (*d*) plastic cross-flow, (e) redwood horizontal, and (*f*) random pack. *[Figs. (c) and (d) from American Surfpac Corp., (e) from Neptune Microfloc, and (f) from Jaeger Products, Inc.]* Note: the random pack material is often used in air stripping towers.

ing, the depth of rock filters is usually on the order of 2 m (6 ft). The low void volume of rock limits the space available for airflow and increases the potential for plugging and flow short circuiting. Because of plugging, the organic loadings to rock filters are more commonly in the range of 0.3 to 1.0 kg BOD/m^3·d.

Various forms of plastic packings are shown on Fig. 9–3. Molded plastic packing materials have the appearance of a honeycomb. Flat and corrugated sheets of polyvinyl chloride are bonded together in rectangular modules. The sheets usually have a corrugated surface for enhancing slime growth and retention time. Each layer of modules is turned at right angles to the previous layer to further improve wastewater distribution. The two basic types of corrugated plastic sheet packing are vertical and cross flow (see Fig. 9–3*b*, *c*, and *d*). Both types of packing are reported to be effective in BOD and TSS removal over a wide range of loadings (Harrison and Daigger, 1987; Aryan and Johnson, 1987). Biotowers as deep as 12 m (40 ft) have been constructed using plastic packing, with depths in the range of 6 m (20 ft) being more common. In biotowers with vertical plastic packing, cross-flow packing can be used for the uppermost layers to enhance

Table 9-2
Physical properties of trickling filter packing materials

Packing material	Nominal size, cm	Approx. unit weight, kg/m³	Approx. specific surface area, m²/m³	Void space, %	Application[a]
River rock (small)	2.5–7.5	1250–1450	60	50	N
River rock (large)	10–13	800–1000	45	60	C, CN, N
Plastic—conventional	61 × 61 × 122	30–80	90	>95	C, CN, N
Plastic—high specific surface area	61 × 61 × 122	65–95	140	>94	N
Plastic random packing—conventional	Varies	30–60	98	80	C, CN, N
Plastic random packing—high specific surface area	Varies	50–80	150	70	N

[a]C = BOD removal; N = tertiary nitrification; CN = combined BOD and nitrification.
Note: kg/m³ × 0.0624 = lb/ft³.
m²/m³ × 0.0305 = ft²/ft³.

the distribution across the top of the filter. The high hydraulic capacity, high void ratio, and resistance to plugging offered by these types of packing can best be used in a high-rate-type filter. Redwood or other wood packings have been used in the past, but with the limited availability of redwood, wood packing is seldom used currently.

Plastic packing has the advantage of requiring less land area for the filter structure than rock due to the ability to use higher loading rates and taller trickling filters. Grady et al. (1999) noted that when loaded at the similar low organic loadings rates (less than 1.0 kg BOD/m³·d), the performance of rock filters compared to filters with plastic packing is similar. At higher organic loading rates, however, the performance of filters with plastic packing is superior. The higher porosity, which provides for better air circulation and biofilm sloughing, is a likely explanation for the improved performance.

Dosing Rate. The dosing rate on a trickling filter is the depth of liquid discharged on top of the packing for each pass of the distributor. For higher distributor rotational speeds, the dosing rate is lower. In the past, typical rotational speeds for distributors were about 0.5 to 2 min per revolution (WEF, 2000). With two to four arms, the trickling filter is dosed every 10 to 60 s. Results from various investigators have indicated that reducing the distributor speed results in better filter performance. Hawkes (1963) showed that rock trickling filters dosed every 30 to 55 min/rev outperformed a more conventional operation of 1 to 5 min/rev. Besides improved BOD removal, there were dramatic reductions in the *Psychoda* and *Anisopus* fly population, biofilm thickness, and odors. Albertson and Davies (1984) showed similar advantages from an investigation of reduced distributor speed. At a higher dosing rate, the larger water volume

applied per revolution (1) provides greater wetting efficiency, (2) results in greater agitation, which causes more solids to flush out of the packing, (3) results in a thinner biofilm, and (4) helps to wash away fly eggs. The thinner biofilm creates more surface area and results in a more aerobic biofilm.

If the high dosing rate is sustained to control the biofilm thickness, the treatment efficiency may be decreased because the liquid contact time in the filter is less. A daily intermittent high dose, referred to as a *flushing dose,* is used to control the biofilm thickness and solids inventory. A combination of a once-per-day high flushing rate and a lower daily sustained dosing rate is recommended as a function of the BOD loading as shown in Table 9–3 (WEF, 2000). The data in Table 9–3 are guidelines to establish a dosing range. Optimization of the dosing rate and flushing rate and frequency is best determined from field operation. Flexibility in the distributor design is needed to provide a range of dosing rates to optimize the trickling filter performance.

The rotational speed for a rotary distributor can be determined using the following relationship (Albertson, 1989):

$$n = \frac{(1 + R)(q)(10^3 \text{ mm/m})}{(A)(DR)(60 \text{ min/h})} \tag{9-1}$$

where n = rotational speed, rev/min
q = influent applied hydraulic loading rate, $m^3/m^2 \cdot h$
R = recycle ratio
A = number of arms in rotary distributor assembly
DR = dosing rate, mm/pass of distributor arm

The dosing rate, DR, has also been referred to as the SK value, which stands for *Sp lkraft,* a term used in the German regulations to define dosing in the early 1980s. To achieve the suggested dosing rates, the speed of the rotary distributor can be controlled by (1) reversing the location of some of the existing orifices to the front of the distributor arm, (2) adding reversed deflectors to the existing orifice discharges, or (3) converting the rotary distributor to a variable-speed electric drive (Albertson, 1995).

Table 9–3
A guideline for trickling filter dosing rate as a function of BOD loading[a]

BOD loading kg/m³·d	Operating dose, mm/pass[b]	Flushing dose, mm/pass[b]
0.25	10–30	≥200
0.50	15–45	≥200
1.00	30–90	≥300
2.00	40–120	≥400
3.00	60–180	≥600
4.00	80–240	≥800

[a]From WEF (2000).
[b]mm/pass represents the amount of liquid applied for each pass of each distributor arm.
Note: kg/m³·d × 62.4280 = lb/10³ ft³·d.

Distribution Systems. A distributor consists of two or more arms that are mounted on a pivot in the center of the filter and revolve in a horizontal plane (see Fig. 9–4). The arms are hollow and contain nozzles through which the wastewater is discharged over the filter bed. The distributor assembly may be driven either by the dynamic reaction of the wastewater discharging from the nozzles or by an electric motor. The flow-driven rotary distributor for trickling filtration has been used traditionally for the process because it is reliable and easy to maintain. Motor drives are used in more recent designs. The speed of rotation, which varies with the flowrate and the organic loading rate, can be determined using Eq. (9–1). Clearance of 150 to 225 mm (6 to 9 in) should be allowed between the bottom of the distributor arm and the top of the bed. The clearance permits the wastewater streams from the nozzles to spread out and cover the bed uniformly, and it prevents ice accumulations from interfering with the distributor motion during freezing weather.

Distributors are manufactured for trickling filters with diameters up to 60 m (200 ft). Distributor arms may be of constant cross section for small units, or they may be tapered to maintain minimum transport velocity. Nozzles are spaced unevenly so that greater flow per unit of length is achieved near the periphery of the filter than at the center. For uniform distribution over the area of the filter, the flowrate per unit of length should be proportional to the radius from the center. Headloss through the distributor is in the range of 0.6 to 1.5 m (2 to 5 ft). Important features that should be considered in selecting a distributor are the ruggedness of construction, ease of cleaning, ability to handle large variations in flowrate while maintaining adequate rotational speed, and corrosion resistance of the material and its coating system.

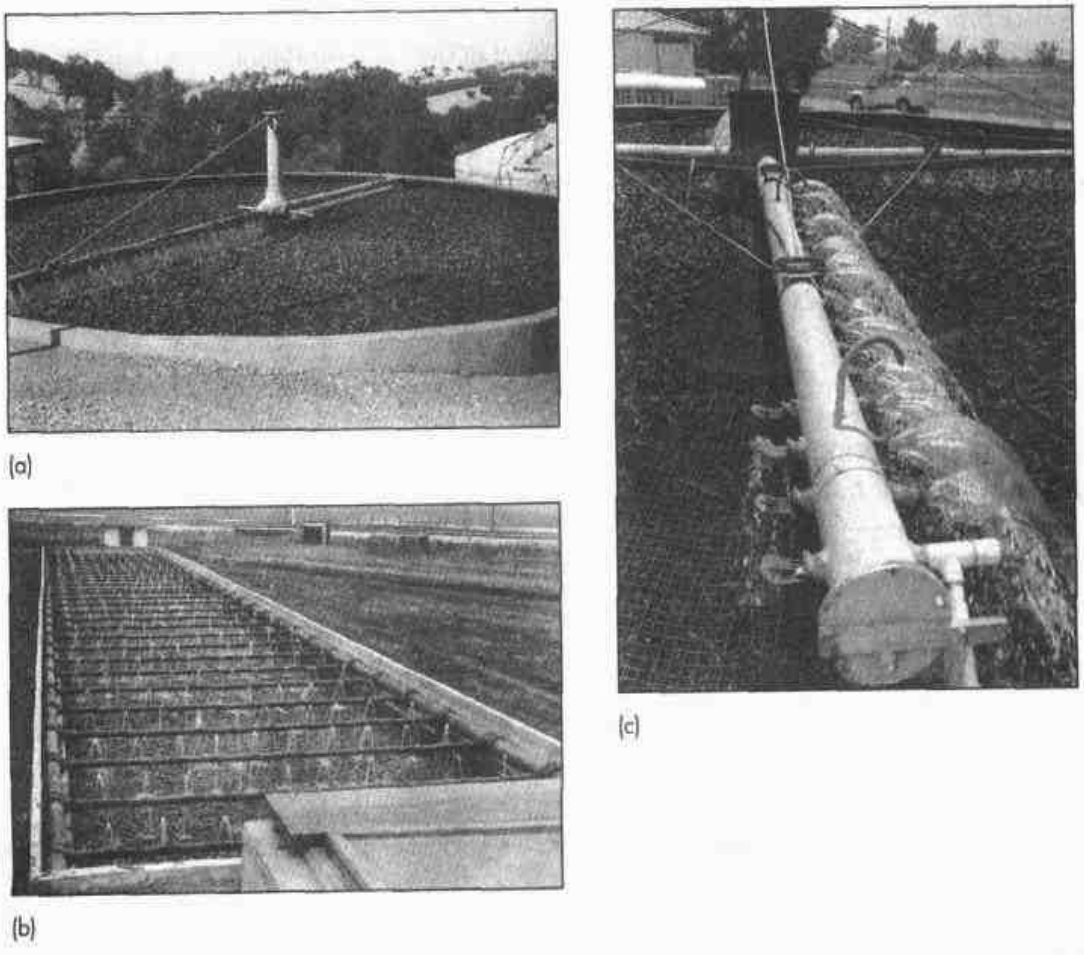

Figure 9–4

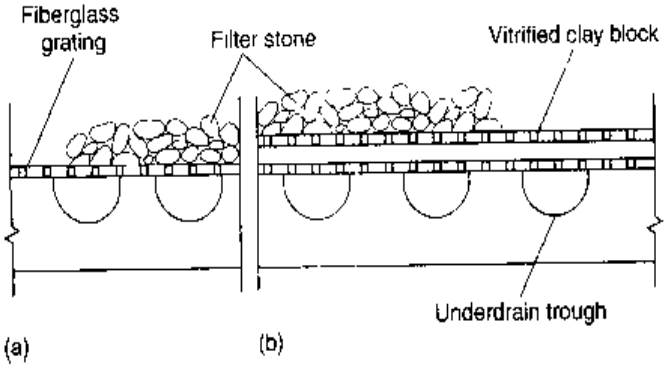
Typical distributors used to apply wastewater to trickling filter packing: (a) view of conventional rock filter with two-arm rotary distributor, (b) view of early (circa 1920) rock filter with a fixed distribution system (*Library of Congress*), and (c) view of top of tower trickling filter with four-arm rotary distributor.

In the past, fixed nozzle distribution systems were used for shallow rock filters (see Fig. 9–4*b*). Fixed nozzle distribution systems consist of a series of spray nozzles located at the points of equilateral triangles covering the filter bed. A system of pipes placed in the filter is used to distribute the wastewater uniformly to the nozzles. Special nozzles having a flat spray pattern are used, and the pressure is varied systematically so that the spray falls first at a maximum distance from the nozzle and then at a decreasing distance as the head slowly drops. In this way, a uniform dose is applied over the whole area of the bed. Half-spray nozzles are used along the sides of the filter. In current practice, fixed nozzle systems are seldom used.

Underdrains. The wastewater collection system in a trickling filter consists of underdrains that catch the filtered wastewater and solids discharged from the filter packing for conveyance to the final sedimentation tank. The underdrain system for a rock filter usually has precast blocks of vitrified clay or fiberglass grating laid on a reinforced-concrete subfloor (see Fig. 9–5). The floor and underdrains must have sufficient strength to support the packing, slime growth, and the wastewater. The floor and underdrain block slope to a central or peripheral drainage channel at a 1 to 5 percent grade. The effluent channels are sized to produce a minimum velocity of 0.6 m/s (2 ft/s) at the average daily flowrate (WPCF, 1988). Underdrains may be open at both ends, so that they may be inspected easily and flushed out if they become plugged. The underdrains also allow ventilation of the filter, providing the air for the microorganisms that live in the filter slime. The underdrains should be open to a circumferential channel for ventilation at the wall as well as to the central collection channel.

The underdrain and support system for plastic packing consists of either a beam and column or a grating. A typical underdrain system for a tower filter is shown on Fig. 9–6. The beam and column system typically has precast-concrete beams supported by columns or posts. The plastic packing is placed over the beams, which have channels in their tops to ensure free flow of wastewater and air. All underdrain systems should be designed so that forced-air ventilation can be added at a later date if filter operating conditions should change.

Airflow. An adequate flow of air is of fundamental importance to the successful operation of a trickling filter to provide efficient treatment and to prevent odors. Natural draft has historically been the primary means of providing airflow, but it is not always adequate and forced ventilation using low-pressure fans provides more reliable and controlled airflow.



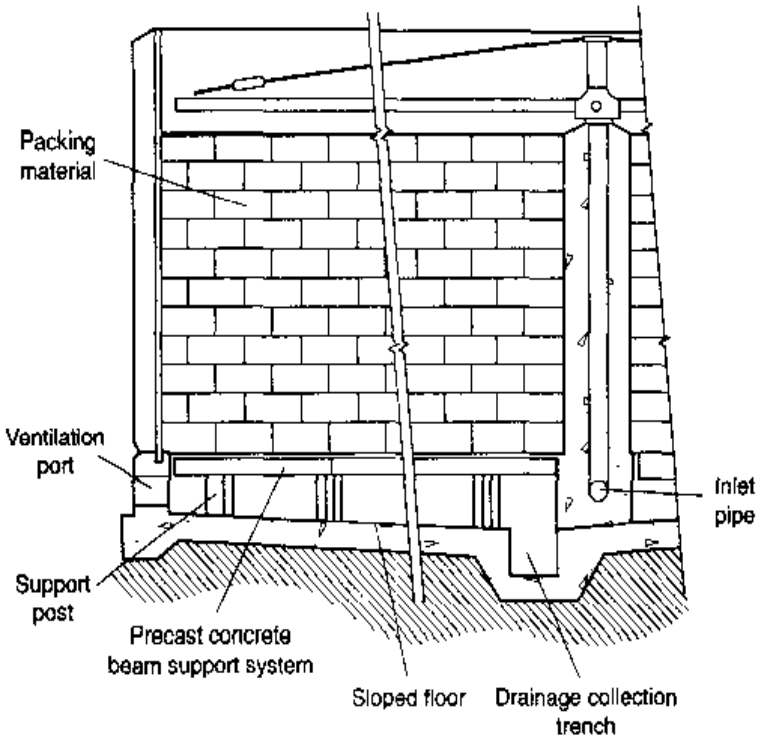


Figure 9–5
Typical underdrain for rock filter: (*a*) fiberglass grating and (*b*) vitrified clay block.

Figure 9–6
Typical underdrain system for tower filter.

In the case of natural draft, the driving force for airflow is the temperature difference between the ambient air and the air inside the pores. If the wastewater is colder than the ambient air, the pore air will be cold and the direction of flow will be downward. If the ambient air is colder than the wastewater, the flow will be upward. The latter is less desirable from a mass transfer point of view because the partial pressure of oxygen (and thus the oxygen transfer rate) is lowest in the region of highest oxygen demand. In many areas of the country, there are periods, especially during the summer, when essentially no airflow occurs through the trickling filter because temperature differentials are negligible.

Draft, which is the pressure head resulting from the temperature and moisture differences, may be determined from Eq. (9–2) (Schroeder and Tchobanoglous, 1976):

$$D_{air} = 353\left(\frac{1}{T_c} - \frac{1}{T_h}\right)Z \tag{9-2}$$

where D_{air} = natural air draft, mm of water
T_c = cold temperature, K
T_h = hot temperature, K
Z = height of the filter, m

A more conservative estimate of the average pore air temperature is obtained by using the log mean temperature T_m for T_h in Eq. (9–2).

$$T_m = \frac{T_2 - T_1}{\ln\ (T_2/T_1)} \tag{9-3}$$

where T_2 = colder temperature, K
T_1 = warmer temperature, K

The volumetric air flowrate may be estimated by setting the draft equal to the sum of the head losses that result from the passage of air through the filter and underdrain system (Albertson and Okey, 1988).

Where natural draft is used, the following needs to be included in the design:

1. Underdrains and collecting channels should be designed to flow no more than half full to provide a passageway for the air.
2. Ventilating access ports with open grating types of covers should be installed at both ends of the central collection channel.
3. Large-diameter filters should have branch collecting channels with ventilating manholes or vent stacks installed at the filter periphery.
4. The open area of the slots in the top of the underdrain blocks should not be less than 15 percent of the area of the filter.
5. One square meter gross area of open grating in ventilating manholes and vent stacks should be provided for each 23 m^2 of filter area (10 ft^2/250 ft^2).

The use of forced- or induced-draft fans is recommended for trickling filter designs to provide a reliable supply of oxygen. The costs for a forced-draft air supply are minimal compared to the benefits. For a 3800 m^3/d (1.0 Mgal/d) wastewater treatment flow the estimated power requirement is only about 0.15 kW (0.2 hp) (WEF, 2000). As an approximation, an airflow of 0.3 $m^3/m^2 \cdot min$ (1 $ft^3/ft^2 \cdot min$) of filter area in either direction is recommended. A downflow direction has some advantage by providing contact time for treating odorous compounds released at the top of the filter and by providing a richer air supply where the oxygen demand is highest. Forced-air designs should provide multiple air distribution points by the use of fans around the periphery of the tower or the use of air headers below the packing material, as there is very little headloss through the filter packing to promote air distribution. For applications with extremely low air temperature, it may be necessary to restrict the flow of air through the filter to keep it from freezing.

Little has been done to quantify the amount of oxygen used in trickling filters and the actual oxygen transfer efficiency. The following formulations are based on earlier work by Dow Chemical during the development of plastic packing material for trickling filter applications. In developing these formulations, it was assumed that the oxygen transfer efficiency was about 5 percent. The required oxygen supply is given as follows:

BOD removal only:

$$R_o = (20\ \text{kg/kg})[0.80e^{-.9L_B} + 1.2e^{-0.17L_B}](\text{PF}) \tag{9-4}$$

BOD removal and nitrification:

$$R_o = (40\ \text{kg/kg})[0.80e^{-.9L_B} + 1.2e^{-0.17L_B} + 4.6N_{ox}/\text{BOD}](\text{PF}) \tag{9-5}$$

where R_o = oxygen supply, kg O_2/kg BOD applied
L_B = BOD loading to filter, kg BOD/$m^3 \cdot d$
N_{ox}/BOD = ratio of influent nitrogen oxidized to influent BOD, mg/mg
PF = peaking factor, maximum to average load

The air application rate at 20°C and 1.0 atm is computed as follows: From Appendix B, the density of air at 20°C and 1.0 atm is 1.204 kg/m^3, and the percent of oxygen by

weight in air is 23.18 percent. Thus, the volume of oxygen per kg of air is 3.58 m^3/kg [1/(1.204 kg/m^3)(0.2318)] and the required airflow is given by

$$AR_{20} = \frac{(R_o)(Q)(S_o)(3.58\ m^3/kg\ O_2)}{(10^3\ g/kg)(1440\ min/d)} \tag{9-6}$$

where AR_{20} = airflow rate at 20°C and 1.0 atm, m^3/min
Q = wastewater flowrate, m^3/d
S_o = primary effluent BOD, g/m^3

The airflow rate is corrected for temperature and pressure according to the ideal gas law:

$$AR_{T_A} = AR_{20}\left(\frac{273.15 + T_A}{273.15}\right)\left(\frac{760}{P_o}\right) \tag{9-7}$$

where AR_{T_A} = airflow rate at ambient air temperature, °C
T_A = ambient air temperature, °C
P_o = pressure at treatment plant site, mm Hg

A further correction to the calculated airflow is recommended for temperatures above 20°C to account for the lower oxygen saturation concentration at higher temperatures and the higher biological uptake rates in the filter. For each degree Celsius above 20°C the airflow rate is increased by 1 percent.

$$AR_{T>20°C} = AR_T\left(1 + \frac{T_A - 20}{100}\right) \tag{9-8}$$

The pressure drop through the packing is related to the superficial air velocity as follows:

$$\Delta P = N_p\left(\frac{v^2}{2g}\right) \tag{9-9}$$

where ΔP = total headlosses, kPa
g = acceleration of gravity, 9.81 m/s^2
v = superficial velocity, m/s
N_p = tower resistance as number of velocity heads lost

The tower resistance term N_p is the sum of all the individual headlosses related to the airflow. Headloss occurs as air moves through the inlet, underdrain, and packing material. The packing loss in terms of number of velocity headlosses was developed by Dow Chemical for the original vertical packing:

$$N_p = 10.33(D)e^{(1.36\times10^{-2})(L/A)} \tag{9-10}$$

where N_p = packing headloss in terms of velocity heads
D = packing depth, m
L = liquid loading rate, kg/h
A = tower cross-section area, m^2

Although similar correlations have not been developed for other packing materials, recommended correction factors that can be used to obtain N_p values for other packing materials based on the value determined using Eq. (9–10) are given in Table 9–4. To estimate the total headloss, the value of N_p, computed using Eq. (9–10), is often multiplied by a factor of 1.3 to 1.5 to include inlet, underdrain, and other minor losses.

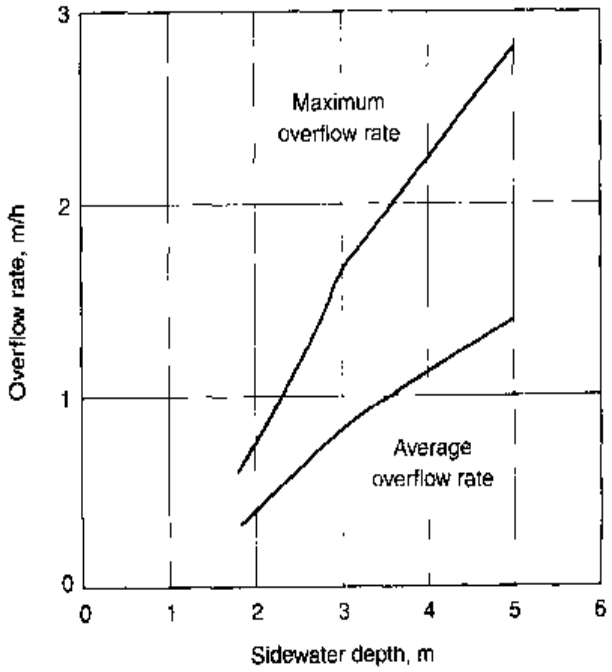

Table 9–4
Correction factors for computing headloss in nonvertical trickling filter packings based on Eq. (9–10)[a]

Packing	Specific surface area, m^2/m^3	Correction factor
Rock	45	2.0
Plastic cross flow	100	1.3
Plastic cross flow	140	1.6
Plastic random	100	1.6

[a] Adapted from WEF (2000).
Note: $m^2/m^3 \times 0.3048 = ft^2/ft^3$.

Settling Tanks. The function of settling tanks that follow trickling filters is to produce a clarified effluent. They differ from activated-sludge settling tanks in that the clarifier has a much lower suspended solids content and sludge recirculation is not necessary. All the sludge from trickling filter settling tanks is sent to sludge-processing facilities or returned to the primary clarifiers to be settled with primary solids. Trickling filter performance has historically suffered from poor clarifier designs. The use of shallow clarifiers for trickling filter applications, with relatively high overflow rates, was recommended in previous versions of the "Ten States Standards" (GLUMRB1997). Unfortunately, the use of shallow clarifiers typically resulted in poor clarification efficiency. Clarifier overflow rates recommended currently in the Ten States Standards are more in line with those used for the activated-sludge process. Clarifier designs for trickling filters should be similar to designs used for activated-sludge process clarifiers (see Sec. 8–7 in Chap. 8), with appropriate feedwell size and depth, increased sidewater depth, and similar hydraulic overflow rates. Recommended overflow rates as a function of the clarifier sidewater depth are given on Fig. 9–7. With proper clarification designs, single-stage trickling filters can achieve a less than 20 mg/L concentration of BOD and TSS.

Figure 9–7
Recommended trickling filter clarifier overflow rates as a function of the clarifier sidewall depth. *(Adapted from WEF, 2000.)*

EXAMPLE 9–1 Determine Trickling Filter Airflow Rate Requirements and Pressure Drop for Forced Ventilation Determine the forced-ventilation air requirement and pressure drop in a trickling filter with cross-flow plastic packing, given the following design and operating information.

Wastewater characteristics:

1. Wastewater flowrate = 19,000 m^3/d (220 L/s)
2. Primary effluent BOD = 140 mg/L (g/m^3)
3. Temperature = 20°C

Design assumptions:

1. BOD loading = 0.56 kg BOD/m^3·d
2. Organic loading peaking factor = 1.4
3. Tower diameter = 22 m
4. Number of towers = 2
5. Depth of packing = 6.1 m
6. Headloss correction factor for inlet and other minor losses = 1.5
7. Headloss correction factor for cross-flow packing = 1.3 (see Table 9–4)
8. Air temperature = −7 to 28°C
9. Humidity = 20 to 100 %

Solution

1. Determine the required oxygen supply rate using Eq. (9–4).

$$R_o = (20\ \text{kg/kg})[0.80e^{-9L_B} + 1.2e^{-0.17L_B}](\text{PF})$$

$$L_B = 0.56\ \text{kg BOD/m}^3\cdot\text{d}$$

$$\text{PF} = 1.4$$

$$R_o = 20[0.80e^{-9(0.56)} + 1.2e^{-0.17(0.56)}](1.4) = 30.69\ \text{kg O}_2\text{/kg BOD applied}$$

2. Determine airflow rate for the given conditions.
   a. Using Eq. (9- 6), determine the airflow rate at standard conditions.

$$AR_{\text{STD}} = \frac{R_o(Q)(S_o)(3.58\ \text{m}^3\text{/kg O}_2)}{(10^3\ \text{g/kg})(1440\ \text{min/d})}$$

$$= \frac{(30.69\ \text{kg/kg})(19{,}000\ \text{m}^3\text{/d})(140\ \text{g/m}^3)(3.58\ \text{m}^3\text{/kg O}_2)}{(10^3\ \text{g/kg})(1440\ \text{min/d})}$$

$$= 203\ \text{m}^3\text{/min}$$

   b. Correct the air flowrate for temperature and pressure using Eq. (9–7).

$$AR_{TA} > AR_{\text{STD}}\left(\frac{273.15 + T_A}{273.15}\right)$$

$$T_A = 28°\text{C}$$

$$AR_{28} = (203\ \text{m}^3/\text{min})\left(\frac{273.15 + 28}{273.15}\right) = 223.8\ \text{m}^3/\text{min}$$

c. Correct the air flowrate for lower oxygen saturation using Eq. (9–80).

$$AR = AR_{TA}\left(1 + \frac{T_A - 20}{100}\right)$$

$$T_A = 28°\text{C}$$

$$AR = (223.8)\left(1 + \frac{28 - 20}{100}\right) = 241.7\ \text{m}^3/\text{min}$$

3. Determine pressure drop in the cross-flow packing.

a. Determine the value of N_p using Eq. (9–10). The value of N_p will then be used to determine the pressure drop using Eq. (9–9).

$$N_P = 10.33\ (D)e^{(1.36 \times 10-5)(L/A)}$$

Solve for L/A, kg/m^2·h

Hydraulic application rate = $q = Q/A$

$Q = (19{,}000\ \text{m}^3/\text{d})(1\ \text{d}/24\ \text{h}) = 792\ \text{m}^3/\text{h}$

Area of single tower $A = \dfrac{\pi D^2}{4} = \dfrac{\pi(22\text{m})^2}{4} = 380\ \text{m}^2$

$$q = \frac{792}{380} = 2.08\ \text{m}^3/\text{m}^2 \cdot \text{h}$$

$$\frac{L}{A} = (2.08\ \text{m}^3/\text{m}^2\cdot\text{h})(10^3\ \text{L}/\text{m}^3)(1\ \text{kg/L})$$

$$= 2080\ \text{kg}/\text{m}^2\cdot\text{h}$$

Packing depth = 6.1 m

$$N_P = 10.33\ (6.1)e^{(1.36\times10^{-5})(2080)}$$

$$= 64.8$$

Headloss correction factor for cross-flow packing = 1.3

Headloss correction factor for inlet and other losses = 1.5

$N_P = (1.5)(1.3)(64.8) = 126.3$

b. Solve for the pressure drop using Eq. (9–9)

$$\Delta P = N_P\left(\frac{v^2}{2g}\right)$$

$$\text{Superficial velocity } v = \frac{\text{air flowrate/tower}}{\text{area of tower}}$$

$$v = \frac{(241.7/2)}{380.0} = 0.32 \text{ m/min} = 0.005 \text{ m/s}$$

$$\Delta P = 126.3\left(\frac{v^2}{2g}\right)$$

$$= \frac{(126.3)(0.005 \text{ m/s})^2}{2(9.8 \text{ m/s}^2)} = 0.00016 \text{ m}$$

Air density at 28°C = 1.175 kg/m^3 (see Appendix B)

$$\Delta P = (0.00016 \text{ m})(1.175 \text{ kg/m}^3)\ (9.8 \text{ m/s}^2)$$

$$= 0.0018 \text{ N/m}^2 = 0.0018 \text{ Pa} = 1.8 \times 10^{-6} \text{ kPa}$$

4. Compare to natural draft pressure per Eqs. (9–2) and (9–3).
   a. Determine log mean temperature using Eq. (9–3).

      Wastewater temperature = 20°C

      Air temperature = 28°C

      $$T_m = \frac{T_2 - T_1}{\ln (T_2/T_1)} = \frac{28 - 20}{\ln (28/20)} = 23.8°\text{C}$$

   b. Determine draft using Eq. (9–2).

      $$D_{\text{air}} = 353\left(\frac{1}{T_c} - \frac{1}{T_m}\right)Z$$

      $$T_c = 273.15 + 20 = 293.15 \text{ K}$$

      $$T_m = 273.15 + 23.8 = 296.95 \text{ K}$$

      $$D_{\text{air}} = 353\left(\frac{1}{293.15} - \frac{1}{296.95}\right)6.1 = 0.094 \text{ mm}$$

   c. Compare draft to estimated headloss.

      Convert mm of water to pressure expressed in Pa.

      $$\text{Draft} = (0.094 \text{ mm } H_2O)\left(\frac{9.797 \text{ Pa}}{\text{mm } H_2O}\right) = 0.921 \text{ Pa}$$

      Thus, draft (0.921 Pa) > headloss (0.0018 Pa)

Comment More draft is available for these temperature differences than is needed; but for periods where the wastewater and air temperatures are very close, sufficient oxygen will not be available, which may result in the formation of malodorous gases such as hydrogen sulfide. Note that the pressure drop for the necessary air flowrate is very low and multiple air feed points are needed to assure uniform air distribution.

Process Design Considerations

The trickling filter process appears simple, consisting of a bed of packing material through which wastewater flows and an external clarifier. In reality, a trickling filter is a very complex system in terms of the characteristics of the attached growth and internal hydrodynamics. In view of these complexities, trickling filter designs are based mainly on empirical relationships derived from pilot-plant and full-scale plant experience. In this section trickling filter performance for BOD removal and nitrification, features that affect performance, and commonly used process design approaches are reviewed.

Effluent Characteristics. Historically, trickling filters have been considered to have major advantages of using less energy than activated-sludge treatment and being easier to operate, but have disadvantages of more potential for odors and lower-quality effluent. Some of these shortcomings, however, have been due more to inadequate ventilation, poor clarifier design, inadequate protection from cold temperatures, and the dosing operation. With proper design, trickling filters have been used successfully in a number of applications. Typical applications, process loadings, and effluent quality are summarized in Table 9–5.

Loading Criteria. In the activated-sludge process, biodegradation efficiency was shown to be related to the average SRT for the biomass or the F/M ratio. For both of these parameters, the solids or biomass can be sampled and reasonably well quantified. However, for trickling filters quantifying the biomass in the system is not possible, and only recently has progress been made to control the solids inventory to some degree by the dosing operation (Albertson, 1989). The attached growth is not uniformly distributed in the trickling filter (Hinton and Stensel, 1994), the biofilm thickness can vary, the biofilm solids concentration may range from 40 to 100 g/L, and the liquid does not uniformly flow over the entire packing surface area, which is referred to as the wetting efficiency. With the inability to quantify the biological and hydrodynamic properties of field trickling filter systems, broader parameters such as volumetric organic loading, unit area loadings, and hydraulic application rates have been used as design and operating parameters to relate to treatment efficiency.

Table 9–5
Trickling filter applications, loadings, and effluent quality

Application	Loading		Effluent quality	
	Unit	Range	Unit	Range
Secondary treatment	kg BOD/m^3·d[a]	0.3–1.0	BOD, mg/L TSS, mg/L	15–30 15–30
Combined BOD removal and nitrification	kg BOD/m^3·d g TKN/m^2·d[b]	0.1–0.3 0.2–1.0	BOD, mg/L NH_4-N, mg/L	<10 <3
Tertiary nitrification	g NH_4-N/m^2·d	0.5–2.5	NH_4-N, mg/L	0.5–3
Partial BOD removal	kg BOD/m^3·d	1.5–4.0	% BOD removal	40–70

[a] Volumetric loading.

[b] Loading based on packing surface area

Note: kg/m^3·d × 62.4280 = lb/10^3 ft^3·d.

g/m^2·d × 0.204 = lb/10^3 ft^2·d.

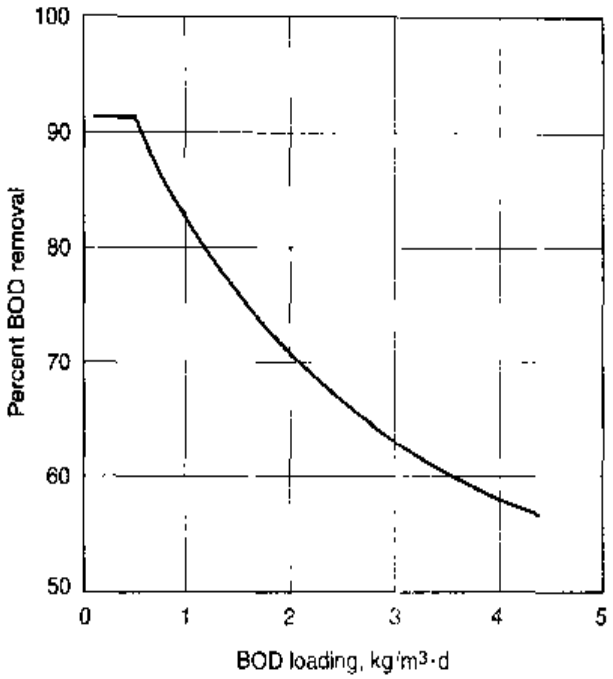

Figure 9–8
Example of trickling filter performance at 20°C. Effect of BOD loading removal efficiency for plastic media filter.

For BOD removal, the volumetric BOD loading has been correlated well with treatment performance for both BOD removal and nitrification in combined BOD and nitrification trickling filter designs. The original design model for rock trickling filters was developed by the National Research Council (NRC) in the early 1940s at military installations (Mohlman et al., 1946). The NRC formulations were based on field data for BOD removal efficiency and the organic loading rate. The NRC design model was used even though there was a significant amount of data scatter. Bruce and Merkens (1970 and 1973) found that the organic loading rate controlled trickling filter performance and not the hydraulic application rate. For combined BOD removal and nitrification systems, nitrification efficiency has been related to the volumetric BOD loading (Stenquist and Kelly, 1980; U.S. EPA, 1975; and Daigger et al., 1993). Examples of the effect of BOD loading on BOD removal are illustrated on Fig. 9–8. At low BOD loadings, BOD removal efficiency reaches a maximum plateau level of about 90 percent. In actual plant operations considerable scatter will exist around the curve due to variations in solids sloughing, wastewater characteristics (sBOD fraction), and clarification efficiency.

For tertiary nitrification applications, very little BOD is applied to the trickling filter and a thin biofilm develops on the packing that consists of a high proportion of nitrifying bacteria. The nitrification removal efficiency is related to the packing surface area and correlated with the specific nitrogen loading rate in terms of g NH_4-N removed/m^2 packing surface area·d (Duddles et al., 1974; Okey and Albertson, 1989; Parker et al., 1990; U.S. EPA, 1993; and Anderson et al., 1994). Surface nitrification rates for tertiary nitrification towers with plastic packing are shown by Fig. 9–9, along with the effect of temperature on nitrification rates. The specific nitrification rates for the Central Valley facility are much higher than reported previously for trickling filters. The higher rate was credited to the use of cross flow instead of vertical plastic packing material and better biofilm control procedures. Higher NH_4-N concentrations were also present. The lower rates for the Zurich facility were attributed to a poorer wetting efficiency and a less uniform biofilm coverage. The analysis of trickling filter loading is illustrated in Example 9–2.

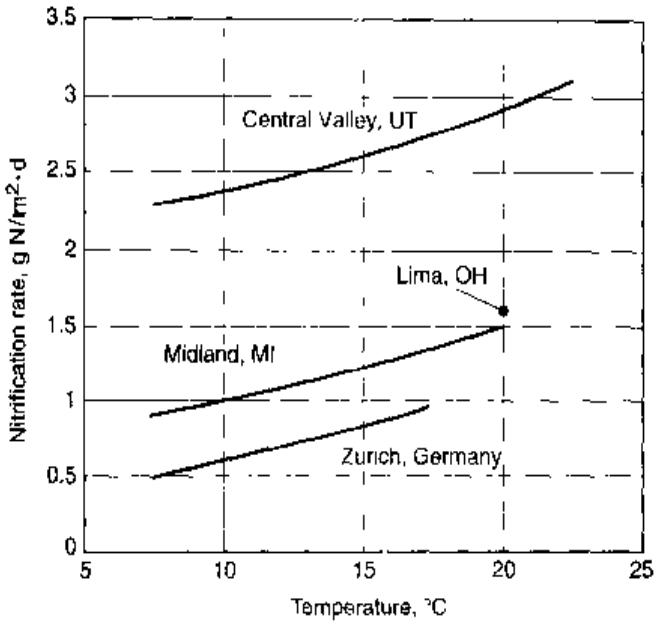

Figure 9–9
Effect of temperature on nitrification rates for tower trickling filters. (Adapted from Parker et al., 1990.)

EXAMPLE 9–2 Trickling Filter Loading A 10-m-diameter single-stage trickling filter contains conventional cross-flow plastic packing at a depth of 6.1 m. Primary effluent with the characteristics given below is applied to the filter. What is the volumetric BOD and TKN loading? What is the specific TKN loading? What is the approximate BOD removal efficiency at 20°C? Can nitrification be expected?

Primary effluent wastewater characteristics

Item	Unit	Value
Flowrate	m^3/d	4000
BOD	g/m^3	120
TSS	g/m^3	80
TKN	g/m^3	25

Note: g/m^3 = mg/L

Solution

1. Determine the volume of the trickling filter packing material.

Volume $V = (A)(D)$

$$A = \frac{\pi(10\ m^2)}{4} = 78.5\ m^2$$

$$V = (78.5\ m^2)(6.1\ m) = 479\ m^3$$

2. Determine the BOD loading.

   BOD loading rate = QS_o/V

   $$= \frac{(4000\ \text{m}^3/\text{d})(120\ \text{g/m}^3)(1\ \text{kg}/10^3\ \text{g})}{479\ \text{m}^3} = 1.0\ \text{kg/m}^3\cdot\text{d}$$

3. Determine the TKN loading rate.

   $$\text{TKN} = \frac{(4000\ \text{m}^3/\text{d})(25\ \text{g/m}^3)(1\ \text{kg}/10^3\text{g})}{479\ \text{m}^3} = 0.21\ \text{kg TKN/m}^3\cdot\text{d}$$

4. Estimate the approximate BOD removal efficiency.

   From Fig. 9–8, at a loading of 1.0 kg BOD/m^3·d, the BOD removal efficiency is about 82 percent.

5. Can nitrification be expected?
   No. Based on the data given in Table 9–5, the BOD loading for combined BOD removal and nitrification is too high (1.0 kg/m^3·d), even though the TKN loading is appropriate. At the higher BOD loading, the heterotrophic bacteria outcompete the nitrifying bacteria for sites on the packing surface and thus control the slime biomass population.

6. What is the specific TKN loading?

   From Table 9–2, the specific surface area of the packing is ≈ 90 m^2/m^3

   Total surface area = (90 m^2/m^3)(479 m^3) = 43,110 m^2

   $$\text{Specific TKN loading} = \frac{QN_o}{A} = \frac{(4000\ \text{m}^3/\text{d})(25\ \text{g/m}^3)}{43{,}110\ \text{m}^2}$$

   $$= 2.3\ \text{g N/m}^2\cdot\text{d}$$

Comment In summary, it is important to note that wide variations will be observed in the nitrification rates depending on site-specific conditions.

BOD Removal Design. The first empirical design equations for BOD removal were developed for rock trickling filters from an analysis of trickling filter performance at 34 plants at military installations treating domestic wastewater (Mohlman et al., 1946). The effect of volumetric BOD loading and recirculation ratio on treatment performance was accounted for in the equations. The equations given below should only be used as an estimate of performance as they are based on a limited data base and the influent BOD values at the installations sampled were relatively high compared to most municipal primary effluents. The BOD removal includes the effect of the secondary clarifier, so that if the equation overpredicts treatment performance, improved and deeper secondary clarifier designs used today may help in meeting expected treatment performance.

For a single-stage or first-stage rock filter, the NRC equation is

$$E_1 = \frac{100}{1 + 0.4432\sqrt{\frac{W_1}{VF}}} \tag{9–11}$$

where E_1 = BOD removal efficiency for first-stage filter at 20°C, including recirculation, percent
W_1 = BOD loading to filter, kg/d
V = volume of filter packing, m^3
F = recirculation factor

The recirculation factor is calculated using Eq. (9–12):

$$F = \frac{1 + R}{(1 + R/10)^2} \tag{9–12}$$

where F = recirculation factor
R = recycle ratio, unitless

The recirculation factor represents the average number of passes of the influent organic matter through the filter. The factor $R/10$ accounts for the fact that the benefits of recirculation decrease as the number of passes increase. Recycle ratios used generally vary from 0 to 2.0. For a two-stage trickling filter system (see Fig. 9–2*b*) the BOD removal efficiency of the second stage is given as follows:

$$E_2 = \frac{100}{1 + \frac{0.4432}{1 - E_1}\sqrt{\frac{W_2}{VF}}} \tag{9–13}$$

where E_2 = BOD removal efficiency for the second-stage filter at 20°C, percent
E_1 = fraction of BOD removal in the first-stage filter
W_2 = BOD loading applied to the second-stage filter, kg/d

The effect of wastewater temperature on the BOD removal efficiency is calculated as follows:

$$E_T = E_{20}(1.035)^{T-20} \tag{9–14}$$

where E_T = BOD removal efficiency at temperature T in °C, percent
E_{20} = BOD removal efficiency at 20°C, percent

EXAMPLE 9–3 Trickling Filter Sizing Using NRC Equations A municipal wastewater having a BOD of 250 g/m^3 is to be treated by a two-stage trickling filter. The desired effluent quality is 25 g/m^3 of BOD. If both of the filter depths are to be 1.83 m and the recirculation ratio is 2:1, find the required filter diameters. Assume the following design assumptions apply. (Note: g/m^3 = mg/L.)

Design assumptions:

1. Flowrate = 7570 m^3/d
2. Wastewater temperature = 20°C
3. BOD removal in primary sedimentation = 35 percent
4. $E_1 = E_2$

Solution

1. Compute E_1 and E_2.

$$\text{Overall efficiency} = \left\{\frac{[(200 - 25)\ g/m^3]}{(200\ g/m^3)}\right\}(100) = 87.5\%$$

$$E_1 + E_2(1 - E_1) = 0.875$$

$$E_1 = E_2 - 0.646$$

2. Compute the recirculation factor using Eq. (9–12).

$$F = \frac{1 + R}{(1 + R/10)^2} = \frac{1 + 2}{(1.2)^2} = 2.08$$

3. Compute the BOD loading for the first filter.

$$\text{Primary effluent BOD} = (1.0 - 0.35)(250\ g/m^3) = 163\ g/m^3$$

$$W_1 = (163\ g/m^3)(7570\ m^3/d)(1\ kg/10^3\ g) = 1234\ kg\ BOD/d$$

4. Compute the volume for the first stage using Eq. (9–11).

$$E_1 = \frac{100}{1 + 0.4432\sqrt{\frac{W_1}{VF}}}$$

$$64.6 = \frac{100}{1 + 0.4432\sqrt{\frac{1234}{V(2.08)}}}$$

$$V = 388\ m^3$$

5. Compute the diameter of the first filter.

$$A = \frac{V}{D} = \frac{388\ m^3}{1.83\ m} = 212\ m^2$$

$$D = 16.4\ m$$

6. Compute the BOD loading for the second-stage filter.

$$W_2 = (1 - E_1)\,W_1 = (1 - 0.646)(1234\ kg\ BOD/d) = 437\ kg\ BOD/d$$

7. Compute the volume of the second-stage filter using Eq. (9–13).

$$E_2 = \frac{100}{1 + \dfrac{0.4432}{1 - E_1}\sqrt{\dfrac{W_2}{VF}}}$$

$$64.6 = \frac{100}{1 + \dfrac{0.4432}{1 - 0.646}\sqrt{\dfrac{437}{V(2.08)}}}$$

$$V = 1096 \text{ m}^3$$

8. Compute the diameter of the second filter.

$$A = \frac{V}{D} = \frac{1096 \text{ m}^3}{1.83 \text{ m}} = 599 \text{ m}^2$$

$$D = 27.6 \text{ m}$$

9. Compute the BOD loading to each filter.
   a. First-stage filter:

$$\text{BOD loading} = \frac{(1234 \text{ kg/d})}{388 \text{ m}^3} = 3.18 \text{ kg/m}^3\cdot\text{d}$$

   b. Second-stage filter:

$$\text{BOD loading} = \frac{(437 \text{ kg/d})}{1096 \text{ m}^3} = 0.40 \text{ kg/m}^3\cdot\text{d}$$

10. Compute the hydraulic loading to each filter.
   a. First-stage filter:

$$\text{Hydraulic loading} = \frac{(1 + 2)(7570 \text{ m}^3/\text{d})}{(1440 \text{ min/d})(212 \text{ m}^2)}$$
$$= 0.0744 \text{ m}^3/\text{m}^2\cdot\text{min}$$

   b. Second-stage filter:

$$\text{Hydraulic loading} = \frac{(1 + 2)(7570 \text{ m}^3/\text{d})}{(1440 \text{ m/d})(599 \text{ m}^2)}$$
$$= 0.0263 \text{ m}^3/\text{m}^2\cdot\text{min}$$

Comment To accommodate standard rotary distributor mechanisms, the diameters of the two filters should be rounded to the nearest 1.5 m (5 ft). To reduce construction costs, the two trickling filters are often made the same size. Where two filters of equal diameter are used, the removal efficiencies will be unequal. In many cases, the hydraulic loading rate will be limited by state standards.

Formulations for Plastic Packing. In the general equations developed for trickling filters with plastic packing, BOD removal was related to the hydraulic application rate. The formulations are based on the early work of Velz (1948), who observed that the BOD remaining with depth in a trickling filter could be modeled as a first-order relationship, and Howland (1958) and Schulze (1960), who described the hydraulic detention time. Howland (1958) proposed that the liquid contact time with the biofilm is proportional to the filter depth and inversely proportional to the hydraulic application rate as follows:

$$t = \frac{CD}{q^n} \tag{9-15}$$

$$q = \frac{Q}{A} \tag{9-16}$$

where t = liquid contact time, min
C = constant for packing used
D = depth of packing, m
q = hydraulic loading rate, L/m^2·min
n = hydraulic constant for the packing material used, unitless
Q = influent flowrate, L/min
A = filter cross section area, m^2

According to Eq. (9–15), as the influent flowrate to the trickling filter increases, the detention time does not decrease in direct proportion to the flow, because the liquid film thickness increases.

By considering the change in BOD concentration in the filter with time for depth as a first-order reaction, the following equation is derived:

$$\frac{ds}{dt} = -kS \tag{9-17}$$

where k = an experimentally determined rate constant
S = BOD concentration at time t

and using Eq. (9–15) to determine the time in the filter, Schulze derived the following equation:

$$\frac{S_e}{S_o} = e^{-kD \cdot Q^n} \tag{9-18}$$

where S_e = BOD concentration of settled filter effluent, mg/L (g/m^3)
S_o = influent BOD concentration, mg/L (g/m^3)
k = an experimentally determined rate constant
D = packing depth, m
Q = hydraulic application rate, m^3/m^2·d
n = constant, characteristic of packing used

The values of k and n determined by Schulze at 20°C were 0.69/d and 0.67.

Germain applied the Schulze equation in 1966 to trickling filters with plastic packing (WEF, 2000) as follows:

$$\frac{S_e}{S_0} = e^{-kD_1q^n} \tag{9-19}$$

where S_e = BOD concentration of settled filter effluent, mg/L (g/m^3)
S_0 = influent BOD concentration to the filter, mg/L (g/m^3)
k = wastewater treatability and packing coefficient, $(L/s)^{0.5}/m^2$ (based on $n = 0.5$)
D = packing depth, m
q = hydraulic application rate of primary effluent, excluding recirculation, L/m^2·s
n = constant characteristic of packing used

The value for n is normally assumed to be 0.50 and pilot-plant or full-scale plant influent and effluent BOD concentration data are used to solve for k. Values for k were developed from more than 140 pilot-plant studies by Dow Chemical Company with vertical plastic packing with a specific surface area of about 90 m^2/m^3. Similar tests have been done by other suppliers for a variety of packings. Most of these tests have been done with packing depths of 6.1 to 6.7 m (20 to 22 ft).

It should be noted that the clarification design and dosing cycle and method can affect pilot-plant results used to calculate a value for k (Daigger and Harrison, 1987). In summary, the value for k is affected by many factors, including the wastewater characteristics, filter and clarifier design, and operating conditions.

The commonly accepted temperature correction for k is as follows:

$$k_T = k_{20}(1.035)^{T-20} \tag{9-20}$$

Other formulations have been proposed (WEF, 2000) to describe the performance of plastic packing filters, including models by Eckenfelder (1963) and Eckenfelder and Barnhart (1963). One of the modified equations termed the modified Velz equation, as given below, includes a factor for the specific surface area of the packing and recirculation flow.

$$S_e = \frac{S_0}{(R+1)\exp\left\{\dfrac{k_{20}A_s D\theta^{T-20}}{[q(R+1)]^n}\right\} - R} \tag{9-21}$$

where S_0 = influent BOD, mg/L
S_e = effluent BOD, mg/L
R = recirculation ratio, recycle flowrate divided by influent flowrate
k_{20} = filter treatability constant at 20°C, $(L/s)^{0.5}/m^2$
A_s = clean packing specific surface area, m^2/m^3
D = depth of packing, m
θ = temperature correction coefficient, 1.035
q = hydraulic application rate, L/m^2·s
n = constant characteristic of packing used

Because the BOD removal is determined as a function of hydraulic application rate, application of Eqs. (9–19) and (9–21) without regard to the fundamental effect of organic loading can lead to erroneous designs. For example, to achieve the same BOD removal efficiency, Eq. (9–19) would predict a smaller packing volume requirement by increasing the packing depth greater than 6.1 m. However, as the volume is reduced, the organic loading increases and thus the treatment efficiency should decline. By assuming that the BOD removal efficiency is equal at the same organic loading, the value for k had to be adjusted for depth and influent BOD concentration. The k value is normalized to a specified depth and influent BOD concentration, as follows (WEF, 2000):

$$k_2 = k_1\left(\frac{D_1}{D_2}\right)^{0.5}\left(\frac{S_1}{S_2}\right)^{0.5} \tag{9–22}$$

where k_2 = normalized value of k for the site-specific packing depth and influent BOD concentration
k_1 = k value at depth of 6.1 m (20 ft) and influent BOD of 150 mg/L (g/m^3)
S_1 = 150 g BOD/m^3
S_2 = site-specific influent BOD concentration, g BOD/m^3
D_1 = 6.1 m (20 ft) packing depth, m
D_2 = site-specific packing depth, m

Normalized values of k_1 at 20°C, determined from Dow Chemical Company pilot-plant studies, are summarized in Table 9–6. The k_1 values reported in Table 9–6 can be used as a rough approximation of treatability differences for different wastewaters. Wastewaters that would have the lowest treatment efficiencies are from refineries, Kraft mills, and textile mills.

Recirculation. The minimum hydraulic application rate recommended by Dow Chemical (WEF, 2000) is 0.5 L/m^2·s (0.75 gal/ft^2·min) to provide maximum efficiency. Shallow tower designs require recirculation to provide minimum wetting rates. When above the minimum hydraulic application rate, recirculation was reported to have little

Table 9–6 Normalized Germain equation k_1 values from pilot-plant studies for different wastewaters

Type of wastewater	k_1 value, $(L/s)^{0.5}/m^2$
Domestic	0.210
Fruit canning	0.181
Kraft mill	0.108
Meat packing	0.216
Pharmaceutical	0.221
Potato processing	0.351
Refinery	0.059
Sugar processing	0.165
Synthetic dairy	0.170
Textile mill	0.107

Note: $(L/s)^{0.5}/m^2 \times 0.3704 = (gal/min)^{0.5}/ft^2$.

benefit (Germain, 1966). For filters with low hydraulic application rates and higher organic loadings, recirculation may improve efficiency. For design systems such as rock filters with low hydraulic application rates, recirculation provides a higher flow to improve wetting and flushing of the filter packing.

Solids Production. Solids production from trickling filter processes will depend on the wastewater characteristics and the trickling filter loading. At lower organic loading rates, a greater amount of the particulate BOD is degraded, the biomass has a longer SRT, and, as a result, less biomass is produced. A procedure that can be used to evaluate the solids production for trickling filters is presented later in this chapter in Sec. 9–4, which deals with combined trickling filter activated-sludge processes.

Mass Transfer Limitations. One of the concerns in the process design for trickling filters is at what organic loading the filter performance becomes limited by oxygen transfer. When this condition occurs, treatment efficiency at the higher organic load is limited and odors may be produced due to anaerobic activity in the biofilm. Based on an evaluation of the data in the literature, for influent BOD concentrations in the range of 400 to 500 mg/L, oxygen transfer may become limiting (Schroeder and Tchobanoglous, 1976). Hinton and Stensel (1994) reported that oxygen availability controlled organic substrate removal rates at soluble biodegradable COD loadings above 3.3 kg/m^3·d.

EXAMPLE 9–4 Design of Trickling Filter with Plastic Packing Given the following design flowrates and primary effluent wastewater characteristics, determine the following design parameters for a trickling filter design assuming 2 towers at 6.1 m depth, cross-flow plastic packing with a specific surface area of 90 m^2/m^3, a packing coefficient n value of 0.5, and a 2-arm distributor system. The required minimum wetting rate = 0.5 L/m^2·s. Assume a secondary clarifier depth of 4.2 m.

Design Conditions

Item	Unit	Primary effluent	Target effluent
Flow	m^3/d	15,140	
BOD	g/m^3	125	20
TSS	g/m^3	65	20
Minimum temp.	°C	14	

Note: g/m^3 = mg/L

Using the above information, determine:

1. Diameter of tower trickling filter, m
2. Volume of packing required, m^3
3. Recirculation rate required, if any

4. Total pumping rate, m^3/h
5. Flushing and normal dose rate, mm/pass
6. Flushing and normal distributor speeds, min/rev
7. Clarifier diameter, m (assume the ratio of the peak to average flowrate is 1.5)

Solution

1. Determine k_{20} for the design conditions using Eq. (9–22).

$$k_2 = k_1\left(\frac{D_1}{D_2}\right)^{0.5}\left(\frac{S_1}{S_2}\right)^{0.5}$$

a. Solve for k_2.

From Table 9–6, $k_1 = 0.210\ (L/s)^{0.5}/m^2$

Trickling filter depth = 6.1 m

$$= 0.210\left(\frac{6.1\text{ m}}{6.1\text{ m}}\right)^{0.5}\left[\frac{(150\text{ g/m}^3)}{(125\text{ g/m}^2)}\right]^{0.5} = 0.230(\text{L/s})^{0.5}/\text{m}^2$$

b. Correct k_2 for temperature effect using Eq. (9–20).

i. $k_T = k_{20}\,(1.035)^{T-20}$

ii. $k_{14} = 0.230(1.035)^{14-20} = 0.187$

2. Determine the hydraulic application rate and the filter area, volume, and diameter.

a. Using Eq. (9–19), determine the hydraulic application rate.

$$\frac{S_e}{S_o} = e^{-kD/q^n}$$

$$q = [kD/\ln (S_o/S_e)]^{1/n}$$

$$q = [0.187(6.1)/\ln (125/20)]^{1/0.5}$$

$$q = 0.3875\ \text{L/m}^2\cdot\text{s}$$

b. Determine the tower area.

$Q = 15{,}140\ m^3/d = 175.2\ L/s$

Filter area $= Q/q = (175.2\ L/s)/(0.3875\ L/m^2\cdot s) = 452.2\ m^2$

c. Determine the packing volume.

Packing volume $= (452.2\ m^2)\ (6.1\ m) = 2758\ m^3$

d. Determine the tower diameter.

Area/tower $= 452.2\ m^2/2 = 226.1\ m^2$

Diameter = 17 m each for two filters

3. Determine the recirculation rate and the recirculation ratio.
   a. Determine the recirculation rate.

      The minimum wetting rate = 0.5 L/m²·s

      $q + q_r = 0.5$ L/m²·s

      $q_r = 0.5 - 0.39 = 0.11$ L/m²·s

   b. Determine the recirculation ratio.

      $R = q_r/q = 0.11/0.39 = 0.28$

4. Determine the pumping rate.

   $q + q_r = 0.5$ L/m²·s

   Total pumping rate = (0.5 L/m²·s)(452.2 m²)

   = 226 L/s = 814 m³/h

5. Determine flushing and normal dose rate using the data given in Table 9–3.
   a. Determine BOD loading.

      BOD loading = $Q S_0/V$

      $$= \frac{(15{,}140 \text{ m}^3/\text{d})(125 \text{ mg/L})(1 \text{ kg}/10^3 \text{ g})}{2758 \text{ m}^3}$$

      = 0.69 kg/m³·d

   b. Determine the dosing rates.

      From Table 9–3, the estimated flushing and operation dose rates are:

      i. Flushing dose = 300 mm/pass

      ii. Operating dose = 50 mm/pass

6. Determine the distributor speed using Eq. (9–1).
   a. For flushing:

      $$n = \frac{(1 + R)\, q(10^3 \text{ mm/min})}{(A)(DR)(60 \text{ min/h})}$$

      $A = 2$

      $$q = \frac{(15{,}140 \text{ m}^3/\text{d})}{(452.2 \text{ m}^2)(24 \text{ hr/d})} = 1.4 \text{ m}^3/\text{m}^2\cdot\text{h}$$

      $R = 0.28$

      $$n = \frac{(1 + 0.28)(1.4)(1000)}{(2)(300)(60)} = 0.0498 \text{ rev/min (i.e., 20 min/rev)}$$

b. For normal operation:

$$n = \frac{(1 + 0.28)(1.4)(1000)}{(2)(50)(60)} = 0.30 \text{ rev/min (i.e., 3.33 min/rev)}$$

Note: Because of the different speed requirements for normal and flushing operation, a distributor drive with variable speed capability should be used.

7. Determine clarifier diameter.

Clarifier depth = 4.2 m

From Fig. 9–7, the recommended overflow rate for peak and average flowrates is 1.1 and 2.4 m/h, respectively. Because the ratio of the peak to average flowrate is 1.5, the average overflow rate controls the design.

Flowrate = (15,140 m^3/d)/(24 h/d) = 630.8 m^3/h

Clarifier area = (630.8 m^3/h)/(1.1 m/h) = 573.5 m^2

Use 2 clarifiers.

Area for each = 573.5 m^2/2 = 286.7 m^2

Diameter of each = 14.1 m

8. Design summary:

Parameter	Unit	Value
Number of filters	number	2
Diameter	m	17
Depth	m	6.1
Total packing volume	m^3	2758
BOD loading	kg/m^3·d	0.69
Hydraulic application rate	L/m^2·s	0.39
Total pumping rate	m^3/h	814
Recirculation ratio	unitless	0.28
Distributor arms	number	2
Normal distributor speed	min/rev	3.33
Flushing distributor speed	min/rev	20
Clarifiers	number	2
Clarifier depth	m	4.2
Clarifier diameter	m	14.1

Nitrification Design

Two types of process design approaches have been used to accomplish biological nitrification in trickling filters, either in a combined system along with BOD removal or in a tertiary application following secondary treatment and clarification for BOD removal.

The secondary treatment process may be a suspended growth or fixed-film process. Empirical design approaches based on pilot-plant and full-scale plant results are again used to guide nitrification designs in view of the difficulty in predicting the actual biofilm coverage area, wetting efficiency, and biofilm thickness and density.

Major impacts on nitrification performance are the influent BOD concentration and dissolved oxygen concentration within the trickling filter bulk liquid. As the BOD to TKN ratio of the influent wastewater increases, a greater proportion of the trickling filter packing area is covered by heterotrophic bacteria and the apparent nitrification rate ($kg/m^3 \cdot d$) based on the total trickling filter volume is decreased. A number of investigations have shown that BOD, if at high enough concentration, inhibits nitrification. Studies by Harremoes (1982) showed that nitrification (1) could occur at a maximum rate at soluble BOD (sBOD) concentrations below 5 mg/L, (2) was inhibited in proportion to the sBOD concentration above 5 mg/L, and (3) was insignificant, in proportion to the sBOD concentration of 30 mg/L or more. In a study with a flat plat experimental design, Huang and Hopson (1974) demonstrated a steady inhibition of nitrification rates occurred as the sBOD concentration was increased from 1.0 to 8.0 mg/L. Figueroa and Silverstein (1991) found that nitrification rates in fixed-film processes are inhibited at BOD concentrations above 10 mg/L, which finding is in agreement with observations by others (Parker and Richards, 1986).

Design Basis for Combined BOD Removal and Nitrification. Nitrification efficiency has been correlated with the volumetric BOD loading for rock trickling filters (U.S. EPA, 1975). For 90 percent nitrification efficiency, a BOD loading of less than 0.08 kg $BOD/m^3 \cdot d$ (5 lb $BOD/10^3$ $ft^3 \cdot d$) is recommended. At a loading of about 0.22 kg $BOD/m^3 \cdot d$ (14 lb $BOD/10^3$ $ft^3 \cdot d$), about 50 percent nitrification efficiency could be expected. It was noted that increased recirculation rates improved nitrification performance.

Instead of volumetric BOD loading values, the nitrification efficiency has been related to the BOD loading based on the packing surface area. In comparing nitrification performance for both rock and plastic packing, Parker and Richards (1986) found that the nitrification efficiency was similar at similar BOD surface loading rates (g $BOD/m^2 \cdot d$) for both packings. A surface loading rate as low as 2.4 g $BOD/m^2 \cdot d$ is necessary for $\geq$90 percent NH_4-N removal.

Daigger et al. (1994) found that the oxidation of BOD and NH_4-N in trickling filters with plastic packing could be characterized by a volumetric oxidation rate defined as follows:

$$VOR = \frac{[S_o + 4.6(NO_x)]Q}{(V)(10^3\ g/kg)} \tag{9–23}$$

where VOR = volumetric oxidation rate, $kg/m^3 \cdot d$
S_o = influent BOD concentration, g/m^3
NO_x = amount of ammonia-nitrogen oxidized, g/m^3
Q = influent flowrate, m^3/d
V = packing volume, m^3

Using Eq. (9–23), the volumetric oxidation rate for three trickling filter plants with nitrification was determined and the 90th percentile value varied from 0.75 to 1.0 $kg/m^3 \cdot d$.

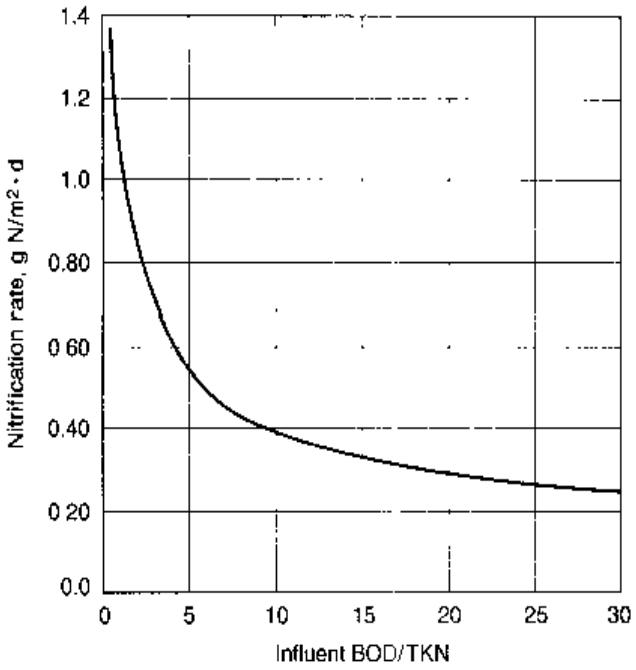

Figure 9–10
Effect of influent wastewater BOD/TKN ratio on nitrification rate in trickling filters with plastic packing used for both BOD removal and nitrification. *[Adapted from Okey and Albertson, WEF (2000).]*

The amount of nitrification can then be estimated by using the VOR value and the influent BOD concentration.

Using data from four different studies, Okey and Albertson (WEF, 2000) found a linear relationship between the specific nitrification rate ($g/m^2 \cdot d$) and the influent BOD/TKN ratio for combined systems. The range of results and the relationship is illustrated by Fig. 9–10. The data included in this correlation were for operation at temperatures ranging from 9 to 20°C. The following equation, represented on Fig. 9–10, is 25 percent below the mean of the observations reported on Fig. 9–10 to allow a design that provides nitrification rates consistent with most of the data.

$$R_n = 0.82\left(\frac{\text{BOD}}{\text{TKN}}\right)^{-0.44} \tag{9–24}$$

where R_n = nitrification rate, g $N/m^2 \cdot d$

$\frac{\text{BOD}}{\text{TKN}}$ = influent BOD to TKN ratio, g/g

The authors concluded that the DO concentration had a greater effect on the nitrification rates than temperature. The effect of DO concentration is supported by fundamental mass transfer considerations in which it can be shown that a bulk liquid DO concentration of 2.8 mg/L is required for nitrification without oxygen diffusion limitations, at a liquid NH_4-N concentration of 1.0 mg/L.

EXAMPLE 9–5 Combined BOD Removal and Nitrification in a Trickling Filter with Plastic Packing Determine the volume of plastic packing required for 90 percent TKN removal in trickling filter with a depth of 6.1 m for the wastewater characteristics given. How does the computed volume compare to the volumetric oxidation rate prediction?

Assume the specific surface area of plastic packing material is 100 m^2/m^3. Also, determine the hydraulic application rate.

Wastewater characteristics

Parameter	Unit	Value
Flow	L/s	100
BOD	g/m^3	160
TKN	g/m^3	25
TSS	g/m^3	70

Note: g/m^3 = mg/L

Solution

1. Determine the specific TKN removal rate using Eq. (9–24).

$$R_n = 0.82\left(\frac{\text{BOD}}{\text{TKN}}\right)^{0.44}$$

$$\text{BOD/TKN} = 160/25 = 6.4$$

$$R_n = 0.82(6.4)^{-0.44}$$

$$= 0.36 \text{ g/m}^2\cdot\text{d}$$

2. Determine the TKN removal.

$$Q = 100 \text{ L/s} = 8640 \text{ m}^3/\text{d}$$

$$\text{TKN removal} = 0.90(8640 \text{ m}^3/\text{d})(25 \text{ g/m}^3)$$

$$= 194{,}400 \text{ g/d}$$

3. Determine the required surface area of packing.

$$A_s = \frac{(194{,}400 \text{ g/d})}{R_n} = \frac{(194{,}400 \text{ g/d})}{(0.36 \text{ g/m}^2\cdot\text{d})} = 540{,}000 \text{ m}^2$$

4. Determine the volume of packing material.

$$\text{Vol} = \frac{540{,}000 \text{ m}^2}{(100 \text{ m}^2/\text{m}^3)} = 5400 \text{ m}^3$$

5. Determine the hydraulic application rate.

$$\text{Filter area} = \frac{\text{volume}}{\text{depth}} = \frac{5400 \text{ m}^3}{6.1 \text{ m}} = 885 \text{ m}^2$$

Hydraulic application rate q

$$q = \frac{Q}{A} = \frac{(100 \text{ L/s})}{885 \text{ m}^2} = 0.11 \text{ L/m}^2\cdot\text{s}$$

To meet the minimum hydraulic application rate given previously as 0.5 $L/m^2 \cdot s$, recirculation will be required.

6. Determine the BOD loading based on volume and surface area.
   a. Loading based on volume

$$\text{BOD loading} = \frac{(8640\ m^3/d)(160\ g/m^3)(1\ kg/10^3\ g)}{5400\ m^3} = 0.26\ kg/m^3 \cdot d$$

   b. Loading based on area

$$\text{BOD loading} = (0.26\ kg/m^3 \cdot d)[1/(100\ m^2/m^3)](10^3\ g/kg)$$
$$= 2.6\ g/m^2 \cdot d$$

7. Determine the volumetric oxidation rate using Eq. (9–23).

$$VOR = \frac{[S_o + 4.6(NO_x)]Q}{V(10^3\ g/kg)}$$

$$S_o = 160\ g/m^3$$

$$NO_x = 0.90(25) = 22.5\ g/m^3$$

$$VOR = \frac{[(160\ g/m^3) + 4.6(22.5\ g/m^3)](8640\ m^3/d)}{(5400\ m^3)(10^3\ g/kg)}$$

$$= 0.42\ kg/m^3 \cdot d$$

Comments The computed value for the BOD loading, based on the packing material surface area, is within the range reported by Parker and Richards (1986). The computed value for the volumetric oxidation rate is a little lower than the volumetric oxidation rates reported by Daigger et al. (1994).

Tertiary Nitrification. A number of facilities exist where trickling filters with plastic packing are used after secondary treatment for nitrification. The influent BOD concentration is relatively low at <10 mg/L and in some cases less than 5 mg/L. Nitrification trickling filter performance will depend on the ammonia loading rate, oxygen availability, temperature, and packing design. Effluent NH_4-N concentrations will vary with summer and winter operation and can range from <1.0 mg/L at warm temperatures and from <1 to 4 mg/L at cold temperatures. Hydraulic application rates may range from 0.40 to 1.0 $L/m^2 \cdot s$. The process performance has been described as relative to a packing surface nitrification rate. Surface nitrification rates, as given on Fig. 9–9, have ranged from 1.0 to 3.0 $g/m^2 \cdot d$ with about a 20 to 50 percent decline in the observed rate as the temperature decreases from 20 to 10°C (Parker et al., 1990). The higher nitrification rates, reported on Fig. 9–9 for Central Valley, represent the results obtained at higher hydraulic loading rates, with effluent NH_4-N concentrations above 5 mg/L. Other investigators have observed minimal temperature effects for tertiary nitrification, and have attributed the minimal observed rate change more to the effect of dissolved oxygen concentration and hydraulics (Okey and Albertson, 1989).

It is generally well accepted that in the upper portion of the trickling filter the nitrification rate is limited by oxygen availability and diffusion into the biofilm. To overcome the oxygen limitation, forced-draft air is generally used to assure maximum oxygen availability. Higher hydraulic rates that provide better wetting efficiency and agitation of the biofilm surface generally produce better performance. Because plugging is less of an issue with the exception of snails (see subsequent section), a medium-density packing material is preferred (i.e., specific surface area of about 100 m^2/m^3) to provide more area as a function of the percent of the reactor volume.

In a large fraction of the nitrification tower, the NH_4-N concentration is high enough so that the nitrification rate is oxygen-limited and thus zero-order with respect to nitrogen. Farther down in the packing as the NH_4-N concentration decreases, the nitrification rate is limited by the NH_4-N concentration and thus decreases. The decline in nitrification rate is further affected by a lower growth of nitrifying bacteria due to the low amount of NH_4-N available. The use of nitrification trickling filters in series with operational modifications has been shown to compensate for this limitation (Boller and Gujer, 1986). The order of operation of the towers is reversed every few days so that a higher nitrifying bacteria population can be developed and be available where the NH_4-N concentration is low. Anderson et al. (1994) showed a 20 percent improvement in nitrification efficiency with this method.

The generally accepted design approach to determine the volume of packing required and hydraulic application rates for nitrification trickling filters is based on an empirical equation that can be used to describe the NH_4-N surface removal flux (WEF, 2000).

$$r_n(Z, T) = r_{n,\max}\left(\frac{N}{K_n + N}\right)e^{-rZ} \tag{9-25}$$

where $r_n(Z, T)$ = NH_4-N surface removal rate or nitrification rate at depth z and temperature T, g/m²·d
$r_{n,\max}$ = maximum NH_4-N surface removal rate at temperature T(°C), g/m²·d
N = bulk liquid NH_4-N concentration, mg/L
K_n = half-velocity constant, mg/L
r = empirical constant describing the decrease in rates as a function of depth
Z = depth in tower, m

The decline in nitrification rate with depth, accounted for by the term rZ, could be due to (1) a decrease in nitrifying biofilm growth where the NH_4-N concentration is lower, (2) predator organism activity, and (3) a change in wetting efficiency. The value for $r_{n,\max}$ is assumed to be controlled by the oxygen transfer characteristics of the tower and biofilm. The value of $r_{n,\max}$ has been determined by observations on zero-order nitrification rates in tertiary trickling filter operations where N is significantly greater than K_n. An accepted value for K_n is 1.5 mg/L (Grady et al., 1999). No temperature correction is recommended between 10 and 25°C. Below 10°C the following temperature correction coefficient is recommended (WEF, 2000):

$$r_{n,\max(T)} = r_{n,\max(10)}(1.045)^{T-10} \tag{9-26}$$

Specific values for $r_{n,\max}$, K_n, and r will be site-specific and can be obtained by pilot-plant studies or possibly an analysis of full-scale plants with similar wastewater characteristics.

Table 9–7
Reported maximum surface specific nitrification rates for tertiary nitrification trickling filters

Location	Packing[a]	Range of $r_{n,max}$ values, g N/m²·d	Reference
Central Valley, UT	XF 138	2.1–2.9	Parker, 1990
Malm , Sweden	XF 138	1.6–2.8	Parker, 1995
Littleton/Englewood, CO	XF 138	1.2–2.3	Parker, 1997
Midland, MI	VF 89	1.1–1.8	WEF, 2000
Lima, OH	VF 89	1.2–1.8	WEF, 2000
Zurich, Switzerland	VF 92	1.6	WEF, 2000
Zurich, Switzerland	XF 223	1.2	WEF, 2000

[a]XF = cross flow, VF = vertical, 89, 92, 138, 223 m^2/m^3.
Note: $g/m^2 \cdot d \times 0.204 = lb/10^3\ ft^2 \cdot d$.

Without specific data, conservative design values must be used. Zero-order specific nitrification rates [$r_{n,max(T)}$] vary widely as reported in Table 9–7. Cross-flow plastic packing appears to produce higher nitrification rates. The higher nitrification rates may be due to better flow distribution and greater wetting of the packing to develop a higher biofilm surface area. However, the higher-density cross-flow packing material did not appear to do as well.

The design procedure to determine volume of packing required for nitrifying towers requires a stepwise design procedure using zero-order and first-order nitrification rates based on Eq. (9–25). In the proposed procedure, the depth effect is ignored because of a lack of data, and, instead, the amount of ammonia oxidized is calculated at incremental depths. First, the zero-order rate [$r_{n,max(T)}$] is used to calculate the volume of packing needed to reduce the NH_4-N concentration to a value that is high enough to approximate the zero-order rate. An NH_4-N concentration of 5 to 7 mg/L is used typically. Below a concentration value of 5 to 7 mg/L, the volume of packing required can be calculated in increments of decreasing NH_4-N concentration, to determine the surface removal rate for each increment and the corresponding packing volume requirements.

EXAMPLE 9–6 Tertiary Nitrification Trickling Filter Design A two-stage nitrification filter is to treat a flow of 6000 m^3/d after secondary treatment. The influent NH_4-N concentration is 25 g/m^3 and an effluent NH_4-N concentration of 1.0 g/m^3 is desired. From pilot-plant studies the $r_{n,max}$ value is 1.5 $g/m^2 \cdot d$ and the K_n value is 1.5 g/m^3, at a temperature of 15°C. A medium-density cross-flow plastic packing material with a specific surface area of 138 m^2/m^3 will be used, as little BOD or TSS exists in the influent wastewater to pose plugging problems. Use a hydraulic application rate of 1.0 $L/m^2 \cdot s$ to provide good packing wetting. Assume $r = 0$ and that the effluent NH_4-N concentration from the zero-order nitrification rate portion of the tower is 6 g/m^3. (Note g/m^3 = mg/L.) For the purpose of this example, synthesis has been neglected, which represents a conservative approach.

Solution

1. Determine the volume of packing material at a zero-order nitrification rate to reduce the NH_4-N concentration from 25 to 6.0 g/m^3. Because no recirculation is used, the NH_4-N concentration at the top of the tower is 25 g/m^3.

   $r_{n,\max} = 1.5$ g/m^2·d

   NH_4-N removed at zero order = [(25 − 6) g/m^3](6000 m^3/d) = 114,000 g/d

   $$\text{Packing surface area} = \frac{(114{,}000 \text{ g/d})}{(1.5 \text{ g/m}^2\text{·d})} = 76{,}000 \text{ m}^2$$

   $$\text{Volume of packing material} = \frac{76{,}000 \text{ m}^2}{(138 \text{ m}^2/\text{m}^3)} = 551 \text{ m}^3$$

2. Solve for first-order rates in concentration increments of 1 g/m^3.

   The required computations for the concentration increment from 6 → 5 g/m^3 are illustrated below.

   Average NH_4-N = 5.5 g/m^3

   Determine the rate of surface removal using Eq. (9–25).

   $$r_n = r_{n,\max}\left(\frac{N}{K_n + N}\right)$$

   $$r_n = (1.5 \text{ g/m}^2\text{·d})\left(\frac{5.5}{1.5 + 5.5}\right) = 1.18 \text{ g/m}^2\text{·d}$$

   NH_4-N removed = (1.0 g/m^3) (6000 m^3/d) = 6000 g/d

   $$\text{Required packing surface area} = \frac{(6000 \text{ g/d})}{(1.18 \text{ g/m}^2\text{·d})} = 5085 \text{ m}^2$$

   Volume = 5085 m^2/(138 m^2/m^3) = 36.8 m^3

3. Calculations for other increments are summarized in the following table.

NH_4-N increment, g/m^3	Avg. NH_4-N, g/m^3	r_n, g/m^2·d	NH_4-N removed, g/d	Volume, m^3
25–6	15.5	1.50	114,000	551
6–5	5.5	1.18	6000	37
5–4	4.5	1.13	6000	38
4–3	3.5	1.05	6000	41
3–2	2.5	0.94	6000	46
2–1	1.5	0.75	6000	58
			Total	771

4. Determine cross-section area of trickling filter.

$$\text{Area} = \frac{\text{flow}}{\text{hydraulic application rate}}$$

$$\text{Area} = \frac{(6000\ \text{m}^3/\text{d})(1\ \text{d}/86{,}400\ \text{s})(10^3\ \text{L}/\text{m}^3)}{(1.0\ \text{L}/\text{m}^2\cdot\text{s})} = 69\ \text{m}^2$$

$$\text{Diameter} = \sqrt{\frac{4(69\ \text{m}^2)}{\pi}} = 9.4\ \text{m}$$

5. Determine the depth of the trickling filter packing.

$$\text{Volume} = (A)(\text{depth})$$

$$\text{Depth} = \frac{771\ \text{m}^3}{69\ \text{m}^2} = 11\ \text{m}$$

Depth per trickling filter in series

$$\text{Depth/tower} = \frac{11\ \text{m}}{2} = 5.5\ \text{m}$$

Predator Problems. A significant problem for nitrifying filters is the development of a snail population, which may graze on the biofilm to reduce the nitrifying bacteria population and nitrification performance. In addition, snails can cause problems with plugging of channels and pumps, accumulating in digesters, and causing wear and tear on equipment. A sump can be provided in an effluent collection chamber upstream of the secondary clarifiers to facilitate removal of snails from the effluent. Methods proposed to control snails are periodic flooding of the trickling filter, reducing the distributor speed to create higher flushing rates, high pH dosing, chlorination, saline water dosing, and dosing with copper sulfate at 0.4 g/L (WEF, 2000). Periodic flooding does not appear to control snails but does eliminate filter flies. Some success has been claimed for reduced distributor speed and high pH treatment. An alkaline backwash to control the snail population and increase nitrification rates was demonstrated successfully at the Littleton/Englewood, CO, wastewater treatment plant (Parker et al., 1997). The nitrification tower trickling filters were flooded on three separate occasions, from October to November 1993, after nitrification efficiency had declined due to predator growth. For the first backwash, the pH was 10, but a pH of 9.0 was used for the last two backwashes to minimize loss of nitrification activity. After the high-pH backwash, nitrification efficiency improved and was maintained long-term.

9–3 ROTATING BIOLOGICAL CONTACTORS

Rotating biological contactors (RBCs) were first installed in West Germany in 1960 and later introduced in the United States. Hundreds of RBC installations were installed in the 1970s and the process has been reviewed in a number of reports (U.S. EPA, 1984,

1985, and 1993; WEF, 1998 and 2000). An RBC consists of a series of closely spaced circular disks of polystyrene or polyvinyl chloride that are submerged in wastewater and rotated through it (see Fig. 9–11). The cylindrical plastic disks are attached to a horizontal shaft and are provided at standard unit sizes of approximately 3.5 m (12 ft) in diameter and 7.5 m (25 ft) in length. The surface area of the disks for a standard unit is about 9300 m^2 (100,000 ft^2), and a unit with a higher density of disks is also available with approximately 13,900 m^2 (150,000 ft^2) of surface area. The RBC unit is partially

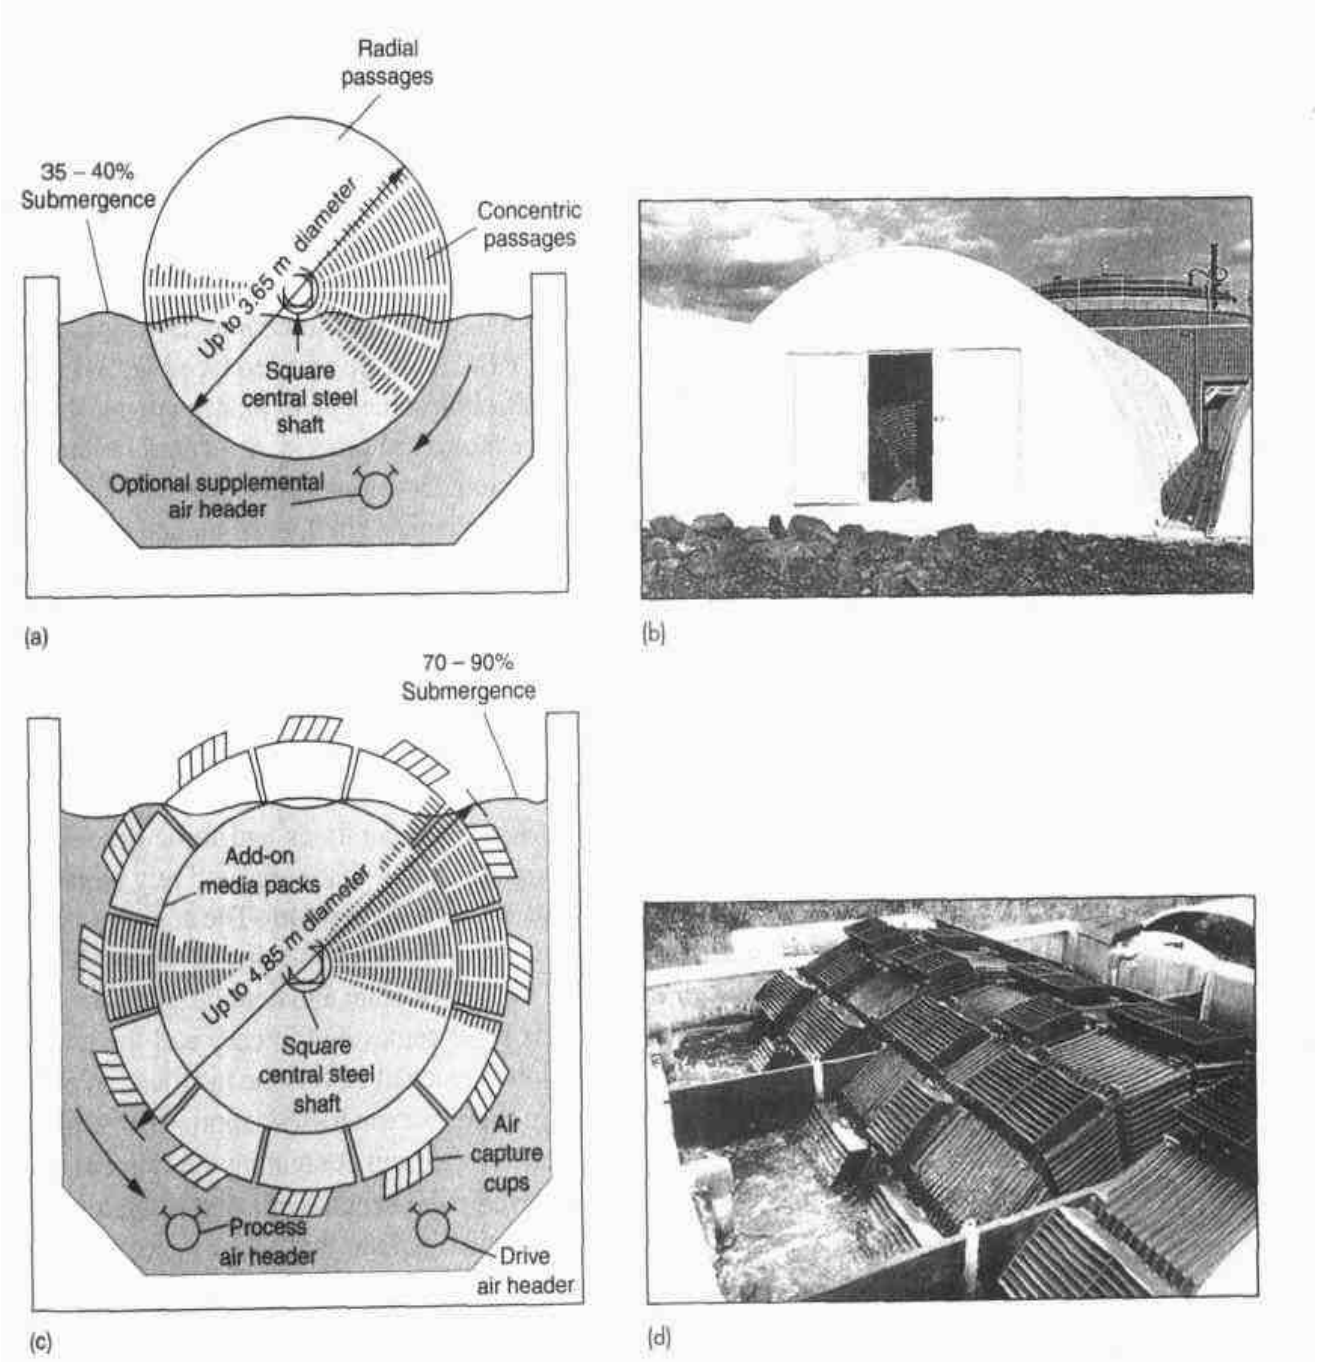

Figure 9–11

Typical RBC units: (a) conventional RBC with mechanical drive and optional air input, (b) conventional RBC in enclosed reactor, (c) submerged-type RBC equipped with air capture cups (air is used both to rotate and to aerate the biodisks), and (d) typical submerged RBC equipped with air capture cups. *(From Envirex Inc.)*

submerged (typically 40 percent) in a tank containing the wastewater, and the disks rotate slowly at about 1.0 to 1.6 revolutions per minute (see Fig. 9–11*a*). Mechanical drives are normally used to rotate the units, but air-driven units have also been installed. In the air-driven units, an array of cups (see Fig. 9–11*c*) is fixed to the periphery of the disks and diffused aeration is used to direct air to the cups to cause rotation. As the RBC disks rotate out of the wastewater, aeration is accomplished by exposure to the atmosphere. Wastewater flows down through the disks, and solids sloughing occurs. Similar to a trickling filter, RBC systems require pretreatment of primary clarification or fine screens and secondary clarification for liquid/solids separation.

A submerged RBC design was also introduced in the early 1980s but has seen limited applications. The submergence is 70 to 90 percent and air-drive units are used to provide oxygen and rotation. The advantages claimed for the submerged unit are reduced loadings on the shaft and bearings, improved biomass control by air agitation, the ability to use larger bundles of disks, and ease of retrofit into existing aeration tanks. However, because of the comparatively low levels of dissolved oxygen in the liquid, biological degradation activity by the submerged units may be oxygen-limited. To prevent algae growth, protect the plastic disks from the effects of ultraviolet exposure, and to prevent excessive heat loss in cold weather, RBC units are covered (see Fig. 9–11*b*).

The history of RBC installations has been troublesome due to inadequate mechanical design and lack of full understanding of the biological process. Structural failure of shafts, disks, and disk support systems has occurred. Development of excessive biofilm growth and sloughing problems has also led to mechanical shaft, bearing, and disk failures. Many of these problems were related to a lack of conservatism in design and scale-up issues from pilot-plant to full-scale units. Many of the problems associated with earlier installations have been solved and numerous RBC installations are operating successfully.

Process Design Considerations

There are many similarities between RBC design considerations and those described for trickling filters. Both systems develop a large biofilm surface area and rely on mass transfer of oxygen and substrates from the bulk liquid to the biofilm. The complexity in the physical and hydrodynamic characteristics requires that the design of the RBC process be based on fundamental information from pilot-plant and field installations. As for trickling filters, the organic loading affects BOD removal efficiency and the nitrogen loading after a minimal BOD concentration is reached affects the nitrification efficiency. In contrast to the trickling filter where the wastewater flow approaches a plug flow hydraulic regime, the RBC units are rotated in a basin containing the wastewater, so that separate baffled basins are needed to develop the benefits of a staged biological reactor design. The design of an RBC system must include the following considerations: (1) staging of the RBC units, (2) loading criteria, (3) effluent characteristics, and (4) secondary clarifier design. Typical design information for RBCs is presented in Table 9–8.

Staging of RBC Units. Staging is the compartmentalization of the RBC disks to form a series of independent cells. Based on mass transfer and biological kinetic fundamentals, higher specific substrate removal rates will occur in RBC biofilms at higher

Table 9–8
Typical design information for rotating biological contactors

Parameter	Unit	Treatment level[a]		
		BOD removal	BOD removal and nitrification	Separate nitrification
Hydraulic loading	$m^3/m^2 \cdot d$	0.08–0.16	0.03–0.08	0.04–0.10
Organic loading	g sBOD/$m^2 \cdot d$	4–10	2.5–8	0.5–1.0
	g BOD/$m^2 \cdot d$	8–20	5–16	1–2
Maximum 1st-stage organic loading	g sBOD/$m^2 \cdot d$	12–15	12–15	
	g BOD/$m^2 \cdot d$	24–30	24–30	
NH_3 loading	g N/$m^2 \cdot d$		0.75–1.5	
Hydraulic retention time	h	0.7–1.5	1.5–4	1.2–3
Effluent BOD	mg/L	15–30	7–15	7–15
Effluent NH_4-N	mg/L		<2	1–2

[a] Wastewater temperature above 13°C (55°F).
Note: g/$m^2 \cdot d \times 0.204$ = lb/10^3 $ft^2 \cdot d$.
$m^3/m^2 \cdot d \times 24.5424$ = gal/$ft^2 \cdot d$.

bulk liquid substrate concentrations. Because a low effluent substrate concentration and high specific substrate removal rates are generally the ultimate treatment goal, reduced disk area requirements can be realized only by using staged-RBC units.

The RBC process application typically consists of a number of units operated in series. The number of stages depends on the treatment goals, with two to four stages for BOD removal and six or more stages for nitrification. Stages can be accomplished by using baffles in a single tank or by use of separate tanks in series. Staging promotes a variety of conditions where different organisms can flourish in varying degrees from stage to stage. The degree of development in any stage depends primarily on the soluble organic concentration in the stage bulk liquid. As the wastewater flows through the system, each subsequent stage receives an influent with a lower organic concentration than the previous stage. Typical RBC staging arrangements are illustrated on Fig. 9–12.

For small plants, RBC drive shafts are oriented parallel to the direction of flow with disk clusters separated by baffles (see Fig. 9–12*a*). In larger installations, shafts are mounted perpendicular to flow with several stages in series to form a process train (see Fig. 9–12*b*). To handle the loading on the initial units, step feed (see Fig. 9–12*d*) or a tapered system (see Fig. 9–12*e*) may be used. Two or more parallel flow trains should be installed so the units can be isolated for turndown or repairs. Tank construction may be reinforced concrete or steel, with steel preferred at smaller plants. Treatment systems employing RBCs have been used for BOD removal, pretreatment of industrial wastewater, combined BOD removal and nitrification, tertiary nitrification, and denitrification. The principal advantages of the RBC process are simplicity of operation and relatively low energy costs.

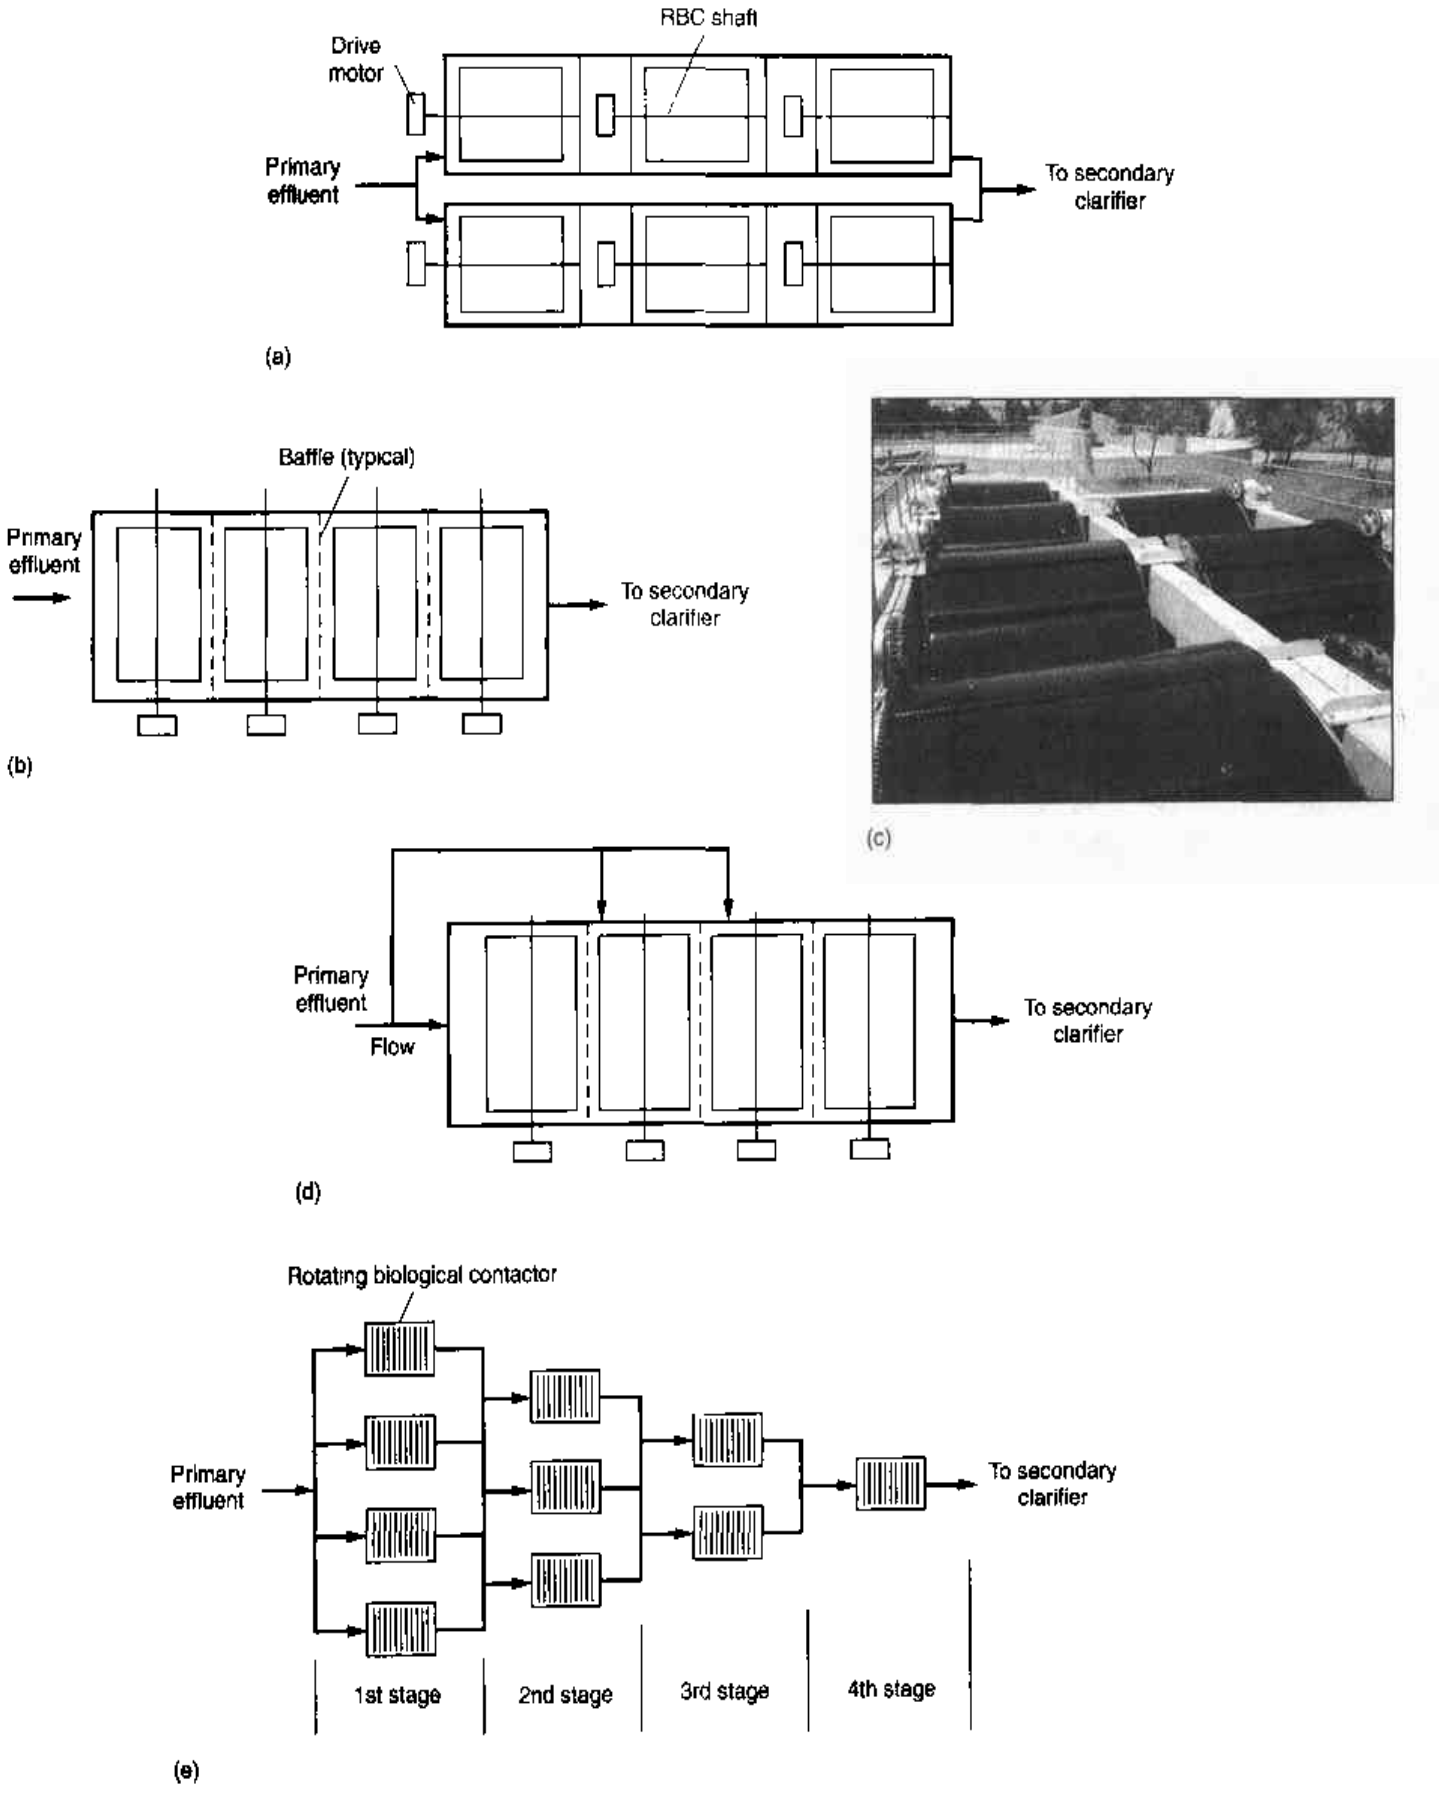

Figure 9-12

Typical RBC staging arrangements: (*a*) flow parallel to shaft, (*b*) flow perpendicular to shaft, (*c*) view of RBCs with flow perpendicular to shaft, (*d*) step feed flow, and (*e*) tapered feed flow parallel to shaft.

The History of RBC Loading Criteria. Based on experience, the performance of an RBC system is related to the specific surface loading rate of total and soluble BOD for BOD removal and NH_4-N for nitrification. For successful treatment, the loading rates must be within the oxygen transfer capability of the system. Poor performance, odors, and biofilm sloughing problems have occurred when the oxygen demand due to the BOD loading has exceeded the oxygen transfer capability. A characteristic of this problem is the development of *Beggiatoa*, a reduced-sulfur oxidizing bacteria, on the outer portion of the biofilm, which prevents sloughing (U.S. EPA, 1984). A thick biofilm can develop to create enough weight to stress the structural strength of the plastic disks and shaft.

Under overloaded conditions, anaerobic conditions develop deep in the attached film. Sulfate is reduced to H_2S, which diffuses to the outer layer of the biofilm, where oxygen is available. *Beggiatoa*, a filamentous bacteria, which is able to oxidize the H_2S and other reduced sulfur compounds, forms a tenacious whitish biofilm that does not slough under the normal RBC rotational sheer conditions. In designing RBC units, it is important to select a low enough BOD loading for the initial units in the staged design to prevent overloading. Odor problems are most frequently caused by excessive organic loadings, particularly in the first stage.

Because the soluble BOD is used more rapidly in the first stage of an RBC system, most manufacturers of RBC equipment specify a specific soluble BOD loading in the range of 12 to 20 g sBOD/m^2·d (2.5 to 4.1 lb sBOD/10^3 ft^2·d) for the first stage. Assuming a 50 percent soluble BOD fraction, the total BOD loading ranges from 24 to 30 g BOD/m^2·d. For some designs that involve higher-strength wastewaters, the loading criteria are met by splitting the flow to multiple RBC units in the first stage or using a step feeding approach as shown on Fig. 9–12*d*.

For nitrification, the design approach for RBC systems can be very similar to that shown for tertiary nitrification trickling filters after the sBOD concentration is depleted in RBC units preceding nitrification. An sBOD concentration of less than 15 mg/L must be met before a significant nitrifying population can be developed on the RBC disks (Pano and Middlebrooks, 1983). The maximum nitrogen surface removal rate has been observed to be about 1.5 g N/m^2·d (U.S. EPA, 1985), which is quite similar to values observed for trickling filters.

Effluent Characteristics. Treatment systems with RBCs can be designed to provide secondary or advanced levels of treatment. Effluent BOD characteristics for secondary treatment are comparable to well-operated activated-sludge processes. Where a nitrified effluent is required, RBCs can be used to provide combined treatment for BOD and ammonia nitrogen, or to provide separate nitrification of secondary effluent. Typical ranges of effluent characteristics are indicated in Table 9–8. An RBC process modification in which the disk support shaft is totally submerged has been used for denitrification of wastewater (see Sec. 9–7).

Physical Facilities for RBC Process

The principal elements of an RBC unit and their importance in the process are described in this section. The suppliers of RBC equipment differ in their disk designs, shafts, and packing support, and configuration designs. The principal elements of an RBC system design are the shaft, disk materials and configuration, drive system, enclosures, and settling tanks.

Shafts. The RBC shafts are used to support and rotate the plastic disks. Maximum shaft length is presently limited to 8.23 m (27 ft) with 7.62 m (25 ft) occupied by disks. Shorter shaft lengths ranging from 1.52 to 7.62 m (5 to 25 ft) are also available. Shaft shapes include square, round, and octagonal, depending on the manufacturer. Steel shafts are coated to protect against corrosion and thickness ranges from 13 to 30 mm (0.5 to 1.25 in) (WEF, 1998). Structural details and the life expectancy of the disk shaft are important design considerations.

Disk Materials. High-density polyethylene is the material used most commonly for the manufacture of RBC disks, which are available in different configurations or corrugation patterns. Corrugations increase the available surface area and enhance structural stability. The types of RBC disks, classified based on the total area of disks on the shaft, are commonly termed low- (or standard) density, medium-density, and high-density. Standard-density disks, defined as disks with a surface area of 9300 m^2 (100,000 ft^2) per 8.23 m (27 ft) shaft, have larger spaces between disks and are normally used in the lead stages of an RBC process flow diagram. Medium- and high-density disk assemblies have surface areas of 11,000 to 16,700 m^2 (120,000 to 180,000 ft^2) per 8.23-m (27-ft) shaft, and are used typically in the middle and final stages of an RBC system where thinner biological growths occur.

Drive Systems. Most RBC units are rotated by direct mechanical drive units attached directly to the central shaft. Motors are typically rated at 3.7 or 5.6 kW (5 or 7.5 hp) per shaft. Air-drive units are also available. The air-drive assembly consists of deep plastic cups attached to the perimeter of the disks, an air header located beneath the disks, and an air compressor. Airflows necessary to achieve design rotational speeds are about 5.3 m^3/min (190 scfm) for a standard-density shaft and 7.6 m^3/min (270 scfm) for a high-density shaft. The release of air into the cups creates a buoyant force that causes the shaft to turn. Both systems have proved to be mechanically reliable. Variable-speed features can be provided to regulate the speed of rotation of the shaft.

Tankage. Tankage for RBC systems has been optimized at 0.0049 m^3/m^2 (0.12 gal/ft^2) of disk area, resulting in a stage volume of 45 m^3 (12,000 gal) for a shaft with a disk area of 9300 m^2. Based on this volume, a detention time of 1.44 h is provided for a hydraulic loading of 0.08 $m^3/m^2 \cdot d$ (2 $gal/ft^2 \cdot d$). A typical sidewater depth is 1.5 m (5 ft) to accommodate a 40 percent submergence of the disks.

Enclosures. Segmented fiberglass reinforced plastic covers are usually provided over each shaft. In some cases, units have been housed in a building for protection against cold weather, to improve access, or for aesthetic reasons. RBCs are enclosed to (1) protect the plastic disks from deterioration due to ultraviolet light, (2) protect the process from low temperatures, (3) protect the disks and equipment from damage, and (4) control the buildup of algae in the process.

Settling Tanks. Settling tanks for RBCs are similar to trickling filter settling tanks in that all of the sludge from the settling tanks is removed to the sludge processing facilities. Typical design overflow rates for settling tanks used with RBCs are similar to that described for trickling filters with plastic packing in Sec. 9–2.

RBC Process Design

Empirical design approaches have been developed for RBC systems based on pilot-plant and full-scale plant data and that consider such fundamental factors as the disk surface area and specific loadings in terms of g/m^2 disk area·d. Approaches for designing staged RBC systems for BOD removal and nitrification are presented in this section.

BOD Removal. Design models for BOD removal in RBC systems are reviewed in WEF (2000). In a design comparison, the models generally resulted in lower recommended BOD loadings than that determined from manufacturer's literature and were, in some cases, similar for BOD removals below 90 percent. Of these, a second-order model by Opatken (U.S. EPA 1985) is selected to estimate RBC surface area requirements, as the model was developed with data from nine full-scale plants and includes staged reactor designs.

The second-order model was converted to SI units by Grady et al. (1999), and terms were converted to account for disk surface area. The model can be used to estimate the soluble BOD concentration in each stage.

$$S_n = \frac{-1 + \sqrt{1 + (4)(0.00974)(A_s/Q)S_{n-1}}}{(2)(0.00974)(A_s/Q)} \qquad (9\text{–}27)$$

where S_n = sBOD concentration in stage n, mg/L
A_s = disk surface area on stage n, m^2
Q = flowrate, m^3/d

Because Eq. (9–27) applies only to sBOD concentrations, a secondary clarifier effluent sBOD/BOD ratio of 0.50 is assumed to design for an effluent BOD concentration. Similarly, without sBOD concentration data for the primary effluent fed to the RBC system, an sBOD/BOD ratio of 0.50 to 0.75 can be assumed. Because the design is based on sBOD, the first-stage RBC soluble unit organic loading rate should be equal to or less than 12 to 15 g sBOD/m^2·d to determine the first-stage disk area and effluent sBOD concentration from Eq. (9–27). The computational procedure used to size an RBC system for BOD removal is summarized in Table 9–9 and illustrated in Example 9–7.

Table 9–9
Computation procedure for the design of a rotating biological contactor (RBC) process

Item	Description
1	Determine influent and effluent sBOD concentrations and wastewater flowrate
2	Determine the RBC disk area for the first stage based on a maximum sBOD of 12 to 15 g sBOD/m^3·d
3	Determine the number of RBC shafts using a standard disk density of 9300 m^2/shaft
4	Select the number of trains for the design, flow per train, number of stages, and disk area/shaft in each stage. For the lower loaded stages a higher disk density may be used
5	Based on the design assumptions made in Step 4, calculate the sBOD concentration in each stage. Determine if the effluent sBOD concentration will be achieved. If not, modify the number of stages, number of shafts per stage, and/or disk area per stage. If the effluent sBOD concentration is met, evaluate alternatives to further optimize the design. Note that the procedure lends itself to spreadsheet calculations
6	Develop the secondary clarifier design

Note: g/m^3·d × 0.0624 = lb/10^3 ft^3·d

EXAMPLE 9–7 Staged RBC Design for BOD Removal Given the following design conditions, develop a process design for a staged RBC system.

Parameter	Unit	Primary effluent	Target effluent
Flowrate	m^3/d	4000	
BOD	g/m^3	140	20
sBOD	g/m^3	90	10
TSS	g/m^3	70	20

Note: g/m^3 = mg/L

Solution

1. Determine number of RBC shafts for the first stage.

   Assume 1st-stage sBOD = 15 $g/m^2 \cdot d$

   sBOD loading = (90 g/m^3) 4000 m^3/d = 360,000 g/d

   $$\text{Disk area required} = \frac{(360{,}000\ g/d)}{(15\ g/m^2 \cdot d)} = 24{,}000\ m^2$$

   Use 9300 m^2/shaft

   $$\text{Number of shafts} = \frac{24{,}000\ m^2}{(9300\ m^2/\text{shaft})} = 2.6$$

   Use 3 shafts for first stage at 9300 m^2/shaft.

2. Select number of trains and number of stages.

   Assume: 3 trains with 3 stages/train

   $$\text{Flowrate/train} = \frac{(4000\ m^3/d)}{3\ \text{trains}} = 1333.3\ m^3/d$$

3. Calculate sBOD concentration in each stage using the shaft area and flow to each train. Use Eq. (9–27).

a. Stage 1

$$S_1 = \frac{-1 + \sqrt{1 + (4)(0.00974)(A_s/Q)S_o}}{(2)(0.00974)(A_s/Q)}$$

$S_o = 90\ \text{g/m}^3$

$A_s/Q = 9300\ \text{m}^2/(1333.3\ \text{m}^3/\text{d}) = 6.97\ \text{d/m}$

$$S_1 = \frac{-1 + \sqrt{1 + 24.6}}{0.136} = 29.8\ \text{g/m}^3$$

b. Repeat calculation similar to (*a*) above. Solving for S_2 and S_3 yields

$S_2 = 14.8\ \text{g/m}^3$

$S_3 = 9.1\ \text{g/m}^3$

Because the goal was 10 g/m^3 for S_3, the proposed design is satisfactory.

4. Determine the organic and hydraulic loadings.

a. First stage organic loading

$$L_{org} = \frac{(4000\ \text{m}^3/\text{d})(90\ \text{g sBOD/m}^3)}{(3)(9300\ \text{m}^2)} = 12.9\ \text{g sBOD/m}^2\cdot\text{d}$$

b. Overall organic loading

$$L_{org} = \frac{(4000\ \text{m}^3/\text{d})(140\ \text{g/m}^3)}{(3\ \text{stage})(3\ \text{shaft/stage})(9300\ \text{m}^2/\text{shaft})} = 6.7\ \text{g BOD/m}^2\cdot\text{d}$$

c. Hydraulic loading

$$\text{HLR} = \frac{(4000\ \text{m}^3/\text{d})}{(3\ \text{stage})(3\ \text{shafts/stage})(9300\ \text{m}^2/\text{shaft})} = 0.05\ \text{m}^3/\text{m}^2\cdot\text{d}$$

5. Summary:

Parameter	Unit	Value
No. of trains	number	3
Flowrate/train	m^3/d	1333.3
No. of stages	number	3
Total disk area/stage	m^2	9300
First-stage sBOD loading	g BOD/m^2·d	12.9
Total number of shafts	number	3
Overall organic loading	g BOD/m^2·d	6.7
Hydraulic loading/shaft	m^3/m^2·d	0.05

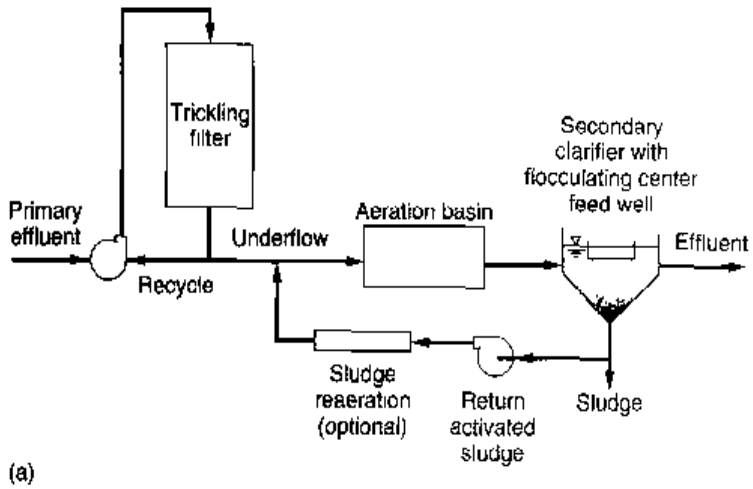
Comment At the lower sBOD concentrations in stages 2 and 3, some nitrification is likely.

Nitrification. Treatment systems employing RBC units can be used to develop nitrifying biofilms for nitrification of secondary effluents or at low sBOD loadings where nitrification can occur in BOD removal systems. For tertiary nitrification the same procedure used for the design of trickling filters (Sec. 9–2) can be followed. A $r_{n,max}$ value of 1.5 g N/m^2·d is recommended based on field test results (U.S. EPA, 1984). For combined BOD removal and nitrification, nitrification will be prevented or inhibited by the addition of sBOD to the RBC unit. The nitrifying bacteria can compete for space on the RBC disk once the sBOD concentration is reduced to 10 to 15 mg/L. The sBOD concentration remaining in an RBC tank will be related to the sBOD loading. Pano and Middlebrooks (1983) provide a relationship to show the effect of the sBOD loading on the nitrification rates:

$$F_{r_n} = 1.00 - 0.1\ \text{sBOD} \tag{9-28}$$

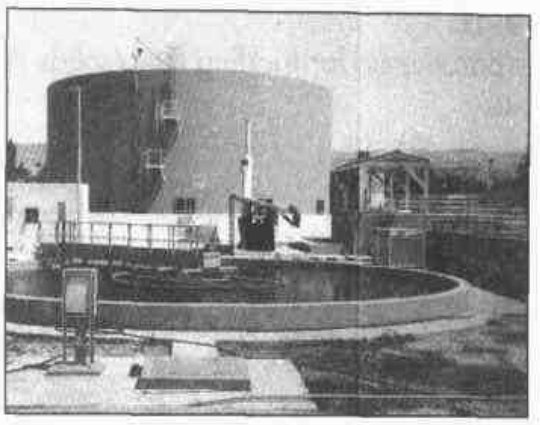
where F_{r_n} = fraction of nitrification rate possible without sBOD effect
sBOD = soluble BOD loading, g/m^2·d

At an sBOD loading rate of 10 g sBOD/m^2·d, the nitrification rate is predicted to be zero.



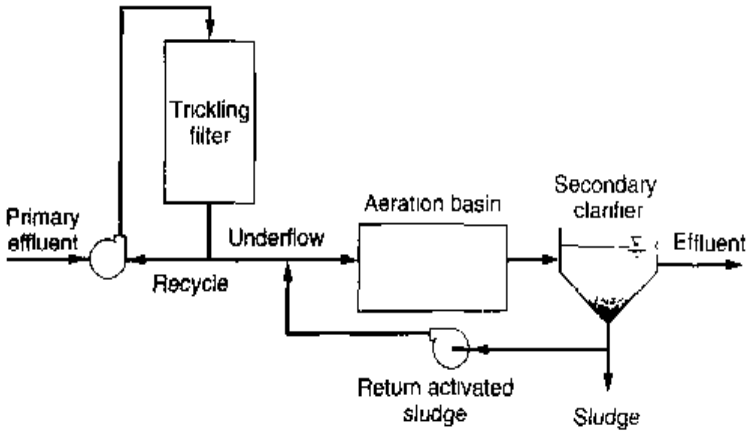
9–4 COMBINED AEROBIC TREATMENT PROCESSES

Several treatment process combinations have been developed that couple trickling filters with the activated-sludge process. The combined biological processes are known as dual processes or coupled trickling filter/activated-sludge systems. Combined processes have resulted as part of plant upgrading where either a trickling filter or activated-sludge process is added; they have also been incorporated into new treatment plant designs (Parker et al., 1994). Combined processes have the advantages of the two individual processes, which can include (1) the stability and resistance to shock loads of the attached growth process, (2) the volumetric efficiency and low energy requirement of attached growth process for partial BOD removal, (3) the role of attached growth pretreatment as a biological selector to improve activated-sludge settling characteristics, and (4) the high-quality effluent possible with activated-sludge treatment. The three principal types of combined processes are described below.



Trickling Filter/Solids Contact and Trickling Filter/ Activated-Sludge Processes

The first group of the combined treatment processes, as illustrated on Fig. 9–13, is commonly referred to as the *trickling filter/solids contact* (TF/SC) or *trickling filter/activated-sludge* (TF/AS) process. The principal difference between these processes is the shorter aeration period in the TF/SC process of minutes versus hours for the TF/AS process. Both processes use a trickling filter (with either rock or plastic packing), an activated-sludge aeration tank, and a final clarifier. In both processes, the trickling filter effluent is fed directly to the activated-sludge process without clarification and the return activated sludge from the secondary clarifier is fed to the activated-sludge aeration basin. A process modification that has been incorporated only into the TF/SC process (see Fig. 9–13*a*, *c*, and *d*) is a return-sludge aeration tank and flocculating center-feed well for the clarifier. The TF/AS process is illustrated on Fig. 9–13*b*.



The most common application for the TF/AS process is where the trickling filter is designed as a roughing filter for 40 to 70 percent BOD removal and may be referred to

(b)

(d)

Figure 9–13

Combined trickling filter/activated-sludge processes: (*a*) schematic flow diagram of trickling filter/solids contact (TF/SC) process, (*b*) schematic flow diagram of trickling filter/activated-sludge (TF/AS) process, (*c*) view of trickling filter/solids contact (TF/SC) process, and (*d*) view of solids contact unit shown on the right-hand side of photo in (*c*).

as a *roughing filter/activated-sludge* (RF/AS) process. The trickling filter loading is about 4 times that used for the TF/SC process (see Table 9–10). The aeration basin hydraulic retention time may be 50 to 70 percent of that used in the conventional activated-sludge process. The RF/AS process is attractive for treating higher-strength industrial wastewater because of the relatively low energy use per quantity of BOD removed on the trickling filter. The use of the trickling filter also results in good SVI values for the activated-sludge mixed liquor, as it acts as a biological selector in removing soluble BOD (Biesinger et al., 1980).

The main differences between the TF/SC and RF/AS processes are in their trickling filter loadings and activated-sludge SRT values, which are summarized in Table 9–10. A relatively low organic load for the trickling filter is used for the TF/SC process, and the purpose of the aeration tank is to remove remaining soluble BOD and to develop a flocculent activated-sludge mass that incorporates dispersed solids from trickling filter sloughing. The process is able to produce an advanced treatment effluent quality, which is low in TSS and BOD concentrations, near 10 mg/L and typically less

Table 9–10
Process parameters for trickling filter/solids contact (TF/SC) and roughing filter/activated sludge (RF/AS) processes[a]

Process	Trickling filter loading,[b] kg BOD/m³·d	Activated sludge			Clarifier peak overflow rate, m/h
		τ, min	SRT, d	MLSS, mg/L	
TF/SC	0.3[c]–1.2	10–60	0.3–2.0	1000–3000	1.8–3.0
RF/AS	1.2–4.8	10–60	2.0–7.0	2500–4000	2.0–3.5

[a] Adapted in part from Parker and Bratby (2001).
[b] Loading rates are for cross-flow plastic packing.

Note: kg/m³·d × 62.4280 = lb/10³ ft³·d.
m/h × 0.4090 = gal/ft²·min.

than 15 mg/L (Norris et al., 1982; Harrison et al., 1984). The detention time and SRT of the TF/SC aeration contact basin is quite low, ranging from 0.15 to 1.0 h and 0.5 to 2.0 d, respectively. In some designs an aerated channel is used to provide the aerobic contact time. The sBOD concentration has been estimated by the following plug-flow reactor model, based on first-order kinetics (Matasci et al., 1986).

$$\ln \frac{S}{S_0} = -k_{20}\theta^{(T-20)}Xt \tag{9–29}$$

where S_0 = mixed-liquor soluble BOD at the contact tank inlet, mg/L
S = soluble carbonaceous BOD after time t, mg/L
k_{20} = first-order reaction rate coefficient at 20°C, L/mg·min
θ = temperature correction coefficient (assume θ = 1.035)
T = wastewater temperature, °C
X = MLVSS, mg/L
t = contact time based on total flow in the tank, min

The value of S_0 at the beginning of the contact tank can be related to the soluble effluent BOD in the trickling filter effluent by the following mass balance:

$$(1 + R)S_0 = RS_e + S_1 \tag{9–30}$$

where R = return-sludge recycle ratio
S_e = trickling filter soluble BOD
S_1 = aerobic solids-contact tank effluent soluble BOD

Reported values for k_{20} range from 2.0 to 3.3 × 10^{-5} L/mg·min. Newbry et al. (1988) observed values of 1.4 × 10^{-5} and 3.5 × 10^{-5} L/mg·min for different operating periods that had different amounts of inert material in the wastewater. Newbry et al. (1988) further showed that at an SRT of 1.0 d or more for the aeration basin, the effluent sBOD and TSS concentration could be minimized. They also showed that the trickling filter organic

loading affected the TF/SC effluent TSS and BOD concentrations. Based on the results reported by Newbry et al. (1988), the trickling filter BOD loading should be less than 7.0 kg BOD/m^3·d with an aeration tank SRT of 1.0 d to maximize performance.

The TF/SC process has also been demonstrated for nitrification applications. At a low enough organic loading, nitrification can occur in the trickling filter. At BOD loadings ranging from 0.40 to 0.70 kg/m^3·d, nitrification occurred in a high-density trickling filter tower at Windsor, Ontario, at temperatures ranging from 11 to 20°C (Parker et al., 1998). The trickling filter effluent NH_4-N concentration averaged 2.8 mg/L, and the final effluent concentration averaged 1.9 mg/L with an aeration contact zone detention time of 15 min and 2 to 4 d SRT. Chemical treatment was used with primary clarification to result in low enough BOD (30 to 70 g/m^3) and TSS concentrations to allow use of the high-density plastic packing without plugging problems. Daigger et al. (1994) also showed similar performance characteristics for low-loaded trickling filters in the TF/SC process and noted that nitrifying bacteria sloughed from the trickling filter result in nitrification in the contact activated-sludge process at lower than theoretical SRTs due to the seed population.

Activated Biofilter and Biofilter Activated-Sludge Processes

The second group of combined processes is similar to the first, described above, with the exception that the RAS is returned directly to the trickling filter as illustrated on Fig. 9–14 and an aeration basin may or may not be used. The two combined processes are termed

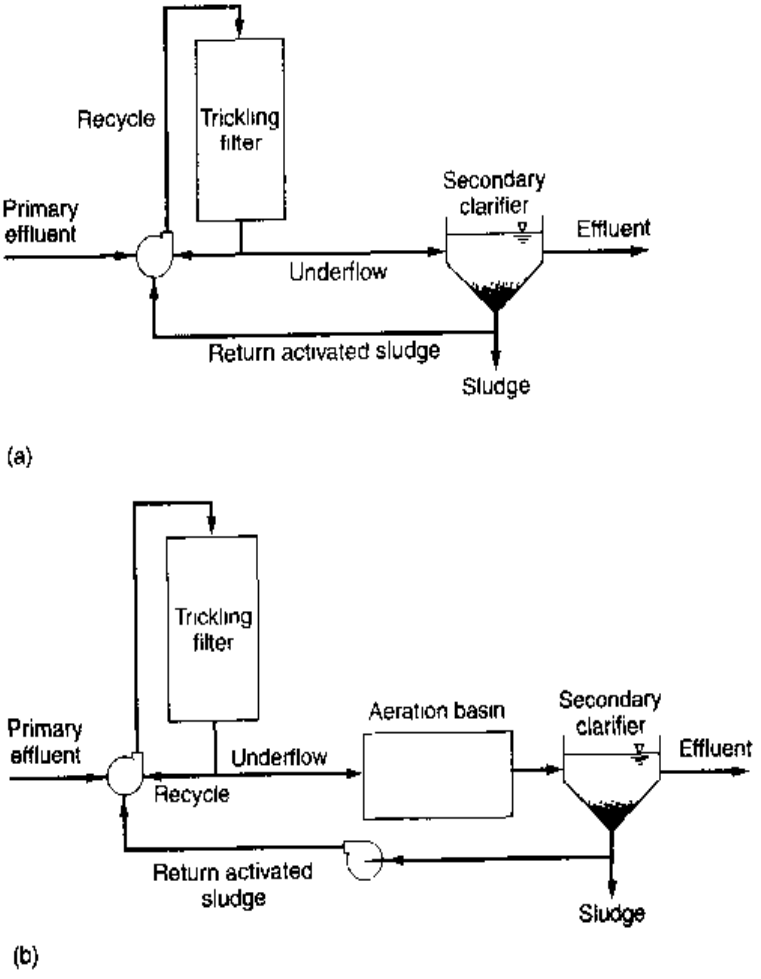

Figure 9–14

Combined trickling filter/activated-sludge process with return sludge recycle to trickling filter: (*a*) schematic flow diagram of activated biofilter (ABF) and (*b*) schematic flow diagram of biofilter/activated sludge (BF/AS).

Table 9–11
Process parameters for activated biofilter (ABF) and biofilter/activated sludge (BF/AS)

Process	Trickling filter loading, kg BOD/m³·d	Activated sludge			Clarifier peak overflow rate, m/h
		τ, h	SRT, d	MLSS, mg/L	
ABF	0.36–1.2	—	0.5–2.0	1500–4000	1.8–3.0
BF/AS	1.2–4.8	2–4	2.0–7.0	1500–4000	2.0–3.5

Note: kg/m³·d × 62.4280 = lb/10³ ft³-d.
m/h × 0.4090 = gal/ft²·min.

the *activated biofilter* (ABF) and the *biofilter/activated-sludge* (BF/AS) process. The ABF and BF/AS processes are not used much today, in part because the original designs relied on redwood filter packing, which is available only at prohibitive cost.

In both cases, rock cannot be used because of the potential plugging and oxygen availability problems created by feeding return activated sludge to the trickling filter. High-rate plastic packing can be used in lieu of redwood packing. The ABF process can produce a secondary effluent quality at low organic loads (see Table 9–11) to the trickling filter. At higher organic loading rates, an acceptable secondary effluent quality with the ABF process has been difficult to produce. To improve effluent quality, the ABF process is followed by a short HRT aeration basin, which fits the description of the BF/AS process (see Fig. 9–14*b*) (Harrison and Timpany, 1988). In essence the BF/AS process is very similar to the RF/AS process with the exception of RAS return to the trickling filter instead of to the aeration basin. Harrison et al. (1984) showed similar performance for BF/AS and RF/AS processes for full-scale plants surveyed. Typical parameters for the ABF and the BF/AS processes are given in Table 9–11.

Series Trickling Filter-Activated-Sludge Process

In the third approach employing combined processes, a trickling filter and an activated-sludge process are operated in series, with an intermediate clarifier between the trickling filter and activated-sludge process (see Fig. 9–15). The combination of a trickling filter process followed by an activated-sludge process is often used (1) to upgrade an existing activated-sludge system, (2) to reduce the strength of wastewater where industrial and domestic wastewater is treated in common treatment facilities, and (3) to protect a nitrification activated-sludge process from toxic and inhibitory substances. In systems treating high-strength wastes, intermediate clarifiers are used between the trickling filters and the activated-sludge units to reduce the solids load to the activated-sludge system and to minimize the aeration volume required. Typical process design parameters for the trickling filter activated-sludge process are given in Table 9–12.

Design Considerations for Combined Trickling Filter Activated-Sludge Systems

For the combined processes without intermediate clarification, the activated-sludge design is affected by the trickling filter design loading and performance. The amount of

Figure 9–15

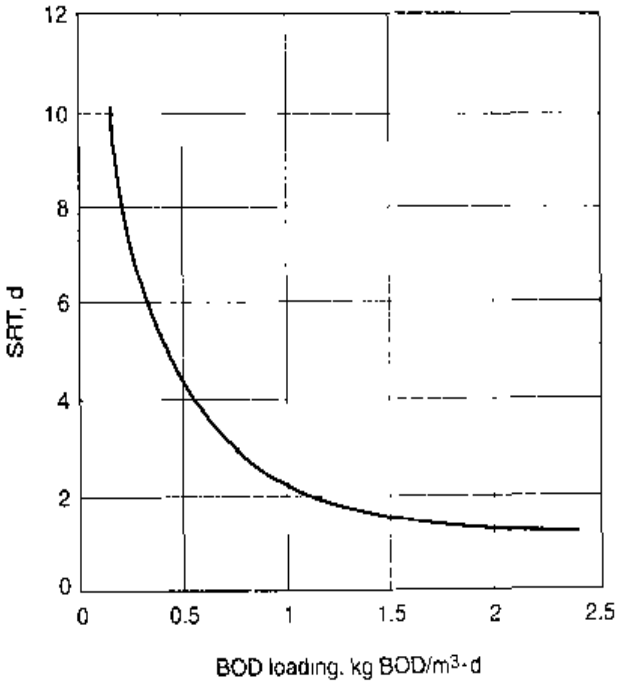
oxygen required in the activated-sludge aeration basin depends on how much BOD is removed in the trickling filter. All of the solids produced, which are the biological solids plus the influent nonbiodegradable solids, will end up in the activated-sludge aeration tank, but the amount of biomass is affected by how much BOD is removed in the trickling filter. An estimate of the SRT in the trickling filter as a function of the BOD loading is presented on Fig. 9-16. At higher BOD loadings the concentration of biomass produced in the trickling filter can be determined based on the estimated SRT and amount of BOD removed in the trickling filter.

The amount of BOD removed in the trickling filter is difficult to predict. Both particulate and soluble BOD are removed by biomass in the trickling filter, and current empirical design models (Sec. 9–2) are generally based on influent and final settled BOD, and thus do not distinguish between particulate (pBOD) and soluble BOD (sBOD) removal rates. These models may be used to estimate the sBOD removal as the final suspended solids concentration after settling and their BOD contribution can be estimated. However, pBOD not degraded in the trickling filter will most likely be degraded in the activated-sludge process, therefore affecting the oxygen demand. Thus,

Figure 9–16

Equivalent SRT for biosolids in a trickling filter as a function of the BOD loading. *(Adapted from WEF, 2000.)*



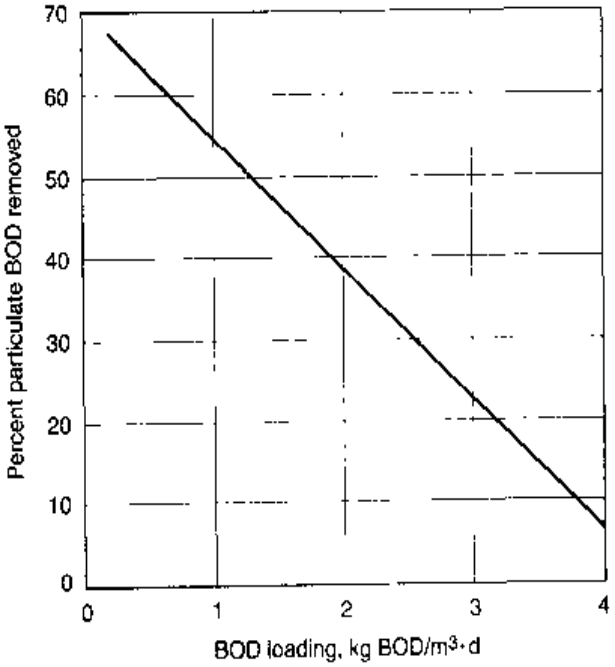


Figure 9–17

Approximate amount of particulate BOD degraded in a trickling filter as a function of organic loading. *(From Bogus, 1989.)*

to determine the oxygen required for the activated-sludge process, the amount of pBOD degraded in the trickling filter is critical.

The removal of pBOD was studied in a combined trickling filter activated-sludge pilot plant over a wide range of trickling filter BOD loadings. Intensive sampling with COD and BOD solids balances on the trickling filter were used to determine the amount of pBOD degradation (Bogus, 1989). The amount of pBOD degraded increased as the BOD loading to the trickling filter was decreased. An estimate of the percent of influent pBOD degraded as a function of the BOD loading is provided on Fig. 9–17. With

an estimate of the amount of pBOD and sBOD removal in the trickling filter and the trickling filter SRT, the amount of biomass produced can be calculated. With that information the amount of oxygen demand satisfied in the trickling filter can be estimated. The trickling filter biomass and nondegraded pBOD and sBOD concentrations can then be used to estimate the activated-sludge aeration basin oxygen demand. The sBOD/BOD ratio in the effluent from the trickling filter will typically vary from 0.25 to 0.50. A solids balance is also done to determine the basin volume as a function of the design SRT and MLSS concentration. The biomass yield and endogenous decay coefficients and basic equations are the same as that presented in Sec. 7–4 and 7–5 in Chap. 7.

The design procedure to determine the oxygen requirements, sludge production, and aeration volume of the activated-sludge basin for a combined trickling filter activated-sludge process including RF/AS and TF/SC processes is summarized in Table 9–13. An example of a TF/SC design is provided in Example 9–8 using the procedure outlined in Table 9–13.

Table 9–13
Computation procedure for the design of a combined trickling filter activated-sludge process

Item	Description
1	Select a BOD loading for the trickling filter that is compatible with the combined process selection
2	Select the SRT of the activated-sludge process. For highly loaded trickling filters longer SRTs will be used in the activated-sludge process
3	Determine the trickling filter tower size and BOD removal. Estimate the soluble BOD removal in the trickling filter
4	Based on the BOD loading to the trickling filter, use Fig. 9–17 to determine fraction of particulate BOD removed in the trickling filter
5	Use Fig. 9–16 to estimate the biomass SRT in the trickling filter. Use this value to estimate the biomass production
6	From the biomass production in the trickling filter and the amount of BOD removed, perform a mass balance on the ultimate BOD, including biomass production, to determine the amount of oxygen demand satisfied in the trickling filter
7	Assume that the portion of influent BOD not degraded in the trickling filter is degraded in the activated-sludge basin, if the SRT is $\geq$10 d. Otherwise, base the soluble BOD removal on Fig. 9–17. From the BOD removal calculate the biomass production in the activated-sludge tank. Adjust the biomass produced from the trickling filter by the loss due to endogenous decay in the activated-sludge tank
8	Based on the total biomass produced, perform an ultimate BOD mass balance to determine the total oxygen demand for the entire system. Subtract the amount of oxygen demand satisfied in the trickling filter to obtain the oxygen requirements for the activated-sludge tank. Add a sufficient peaking factor to account for variable loadings to short detention time basins
9	Sum the sludge production from biomass, nonbiodegradable VSS (nbVSS) in the influent wastewater, and inorganic TSS (TSS—VSS) in the influent wastewater
10	Using the net sludge production SRT and assumed MLSS concentration, calculate the volume of the activated-sludge aeration tank
11	Evaluate solids and hydraulic loadings for the secondary clarifier design

EXAMPLE 9–8 Trickling Filter/Solids Contact (TF/SC) Process Design For the following wastewater characteristics, determine the following design elements for a trickling filter/solids contact (TF/SC) process:

1. Trickling filter diameter and hydraulic application rate
2. The amount of oxygen demand satisfied in the trickling filter, kg/d
3. The amount of oxygen required in the activated-sludge aeration tank, kg/d
4. The amount of solids wasted per day, kg/d
5. The volume and hydraulic retention time of the aeration tank

Wastewater characteristics

Item	Unit	Value
Flow	m^3/d	5000
BOD	g/m^3	130
sBOD	g/m^3	90
TSS	g/m^3	60
VSS	g/m^3	52
nbVSS	g/m^3	20
Temperature	°C	15

Note: $g/m^3 = mg/L$

For TF/SC design assume the following conditions apply:

1. Number of trickling filters = 2
2. Plastic packing coefficient $k_{20} = 0.21(L/s)^{0.5}/m^2$ (see Table 9–6)
3. Depth of packing = 6.1 m
4. Trickling filter BOD loading = 0.70 kg BOD/m^3·d
5. Biomass yield $Y = 0.6$ g VSS/g BOD
6. Endogenous decay $k_d = 0.08$ g/g·d
7. UBOD/BOD = bCOD/bsCOD = 1.6
8. Trickling filter effluent sBOD = 0.5 BOD
9. Activated-sludge SRT = 1.0 d
10. MLSS = 2500 g/m^3
11. Secondary clarifier sBOD/BOD = 0.5
12. Biomass VSS/TSS ratio = 0.85

Solution

1. Determine the hydraulic application rate and the trickling filter diameter.
   a. Determine the hydraulic application rate.
   The organic volumetric loading rate, as given by Eq. (7–67), is

$$L_{org} = \frac{QS_o}{(V)(10^3\ g/kg)} = \frac{QS_o}{(A)(D)(10^3\ g/kg)} = \frac{qS_o}{D(10^3\ g/kg)}$$

where A = cross-sectional area, m^2
D = depth of packing, m
q = hydraulic application rate, $m^3/m^2 \cdot d$

Solving for q yields

$$q = \frac{(L_{org})(D)(10^3\ g/kg)}{S_o}$$

Substitute known quantities and solve for q

$$q = \frac{(0.70\ kg/m^3 \cdot d)(6.1\ m)(10^3\ g/kg)}{(130\ g/m^3)}$$

$$= 32.85\ m^3/m^2 \cdot d$$

b. Determine the trickling filter tower diameter.

$$A = \frac{Q}{q} = \frac{(5000\ m^3/d)}{(32.85\ m^3/m^2 \cdot d)} = 152.2\ m^2$$

For 2 towers, area/tower = 76.1 m^2

Diameter/tower = 9.8 m

2. Determine the amount of soluble and particulate BOD removed in the trickling filter and the BOD in the effluent from the trickling filter using Eq. (9–19).
   a. Determine the soluble BOD removed using Eq. (9–19) and the fact that sBOD = 0.5 BOD.

$$\frac{S_e}{S_o} = e^{-kD/q^n}$$

Correct the removal rate coefficient for temperature using Eq. (9–20).

$$k_{15°C} = k_{20°C}(1.035)^{15\ -\ 20}$$

$$= 0.21(1.035)^{\ -5} = 0.177\ (L/s)^{0.5}/m^2$$

Normalize the removal rate coefficient using Eq. (9–22).

$$k_{15°C} = k_1\left(\frac{D_1}{D_2}\right)^{0.5}\left(\frac{S_1}{S_2}\right)^{0.5} = 0.177\left(\frac{6.1}{6.1}\right)^{0.5}\left(\frac{150}{130}\right)^{0.5}$$

$$= 0.177(1.074) = 0.19(L/s)^{0.5}/m^2$$

$$\frac{S_e}{S_o} = e^{-0.19(6.1)/0.38^{0.5}}$$

$$\frac{S_e}{S_o} = 0.152$$

$$S_e = 0.152(130) = 19.7\ g/m^3$$

The sBOD removed in the trickling filter effluent is:

sBOD removed = 90 g/m^3 − 0.5(19.7 g/m^3) = 80.1 g/m^3

b. Determine the particulate BOD removed.

Particulate BOD in influent = BOD − sBOD

pBOD = (130 − 90) g/m^3 = 40 g/m^3

From Fig. 9–17, amount of pBOD removed at 0.70 kg BOD/m^3·d = 56%

pBOD in trickling filter effluent = (1 − 0.56)(40 g/m^3) = 17.6 g/m^3

The pBOD removed in the trickling filter effluent is:

pBOD removed = 40 g/m^3 − 17.6 g/m^3 = 22.4 g/m^3

c. Determine the BOD in the trickling filter effluent.

Trickling filter effluent BOD = sBOD + pBOD = (9.9 + 17.6) g/m^3

= 27.5 g/m^3

3. Determine oxygen demand satisfied in the trickling filter.

From Fig. 9–16, the trickling filter SRT = 2.5 d at an organic rate of 0.70 kg BOD/m^3·d

Determine biomass produced using Eq. (7–43) (Note, SRT = τ):

$$X = \frac{Y(S_o - S)}{1 + (k_d)\text{SRT}}$$

Substrate removal ($S_o - S$) in trickling filter = (130 − 27.5) = 102.5 g/m^3

$$X_{TF} = \frac{0.6(102.5 \text{ g/m}^3)}{[1 + (0.08 \text{ g/g·d})(2.5 \text{ d})]} = 51.2 \text{ g/m}^3$$

For short SRT values, cell debris [Eq. (7–50)] is negligible and is not included here.

Determine the oxygen satisfied in trickling filter with a COD balance.

O_2 used = $\text{bCOD}_{\text{IN}} - \text{bCOD}_{\text{OUT}} - 1.42X$

= 1.6(130 g/m^3 − 27.5 g/m^3) − 1.42(51.2 g/m^3)

Oxygen used in trickling filter = 91.1 g/m^3

4. Determine biomass produced in solids contact (SC) aeration tank.

Approximate BOD removed = 27.5 g/m^3, SRT = 1 d

Biomass due to oxidation of organic matter

$$X_{SC} = \frac{0.6(27.5 \text{ g/m}^3)}{[1 + (0.08 \text{ g/g·d})(1 \text{ d})]} = 15.3 \text{ g/m}^3$$

Trickling filter biomass remaining after endogenous decay of filter biomass

$$X_{TF,\text{decay}} = \frac{(51.2\ \text{g/m}^3)}{[1 + (0.08\ \text{g/g·d})(1\ \text{d})]} = 47.4\ \text{g/m}^3$$

Total biomass produced or fed to the SC aeration tank = 47.4 g/m^3 + 15.3 g/m^3 = 62.7 g/m^3

5. Determine oxygen demand in SC aeration tank in g/m^3 and kg O_2/d.

   Total oxygen consumed = 1.6(130 g/m^3) − 1.42(62.7 g/m^3) = 119 g/m^3

   Activated-sludge oxygen demand = total demand − TF demand

   = 119 g/m^3 − 91.1 g/m^3 = 27.9 g/m^3

   kg O_2/d = (27.9 g/m^3) (5000 m^3/d) (1 kg/10^3 g) = 140 kg/d

6. Determine the amount of solids wasted per day (TSS).
   a. Determine the inert inorganic solids

      Inert solids = TSS − VSS = 60 g/m^3 − 52 g/m^3 = 8 g/m^3

   b. Determine the total solids wasted per day expressed in g/m^3.

      Total solids = biomass + inert inorganics + nbVSS

      $$= \frac{(62.7\ \text{g VSS/m}^3)}{(0.85\ \text{g VSS/g TSS})} + 8\ \text{g/m}^3 + 20\ \text{g/m}^3 = 101.8\ \text{g/m}^3$$

   c. Determine the total solids wasted per day expressed in kg/d.

      P_X = (101.8 g/m^3) (5000 m^3/d) (1 kg/10^3 g)

      = 509 kg/d solids wasted

7. Determine the solids contact aeration tank volume and the corresponding hydraulic detention time.
   a. Determine the solids contact aeration tank volume using Eq. (7–55).

      $$(X_{\text{TSS}})(V) = P_{X,\text{TSS}}(\text{SRT})$$

      $$V = \frac{P_{X,\text{TSS}}(\text{SRT})}{X_{\text{TSS}}} = \frac{(509\ \text{kg/d})(1.0\ \text{d})(10^3\ \text{g/kg})}{(2500\ \text{g/m}^3)} = 203.6\ \text{m}^3$$

   b. Determine the hydraulic detention time in the solids contact aeration tank.

      $$\tau = \frac{(203.6\ \text{m}^3)(24\ \text{h/d})}{(5000\ \text{m}^3/\text{d})} = 0.98\ \text{h}$$

Comments Most of the BOD removal and oxygen demand is satisfied in the trickling filter. The g O_2 supplied in the activated sludge per g BOD removed for the system is 0.21 [(27.9 mg/L)/(130 mg/L)] which agrees well with published information. The clarifier recycle flowrate is determined in a similar manner to that shown in Chap. 8 for the suspended growth processes.

9–5 ACTIVATED SLUDGE WITH FIXED-FILM PACKING

Several types of synthetic packing materials have been developed for use in activated-sludge processes. These packing materials may be suspended in the activated-sludge mixed liquor or fixed in the aeration tank. A term used to describe these types of processes is an integrated fixed-film activated-sludge process (Sen et al., 1994*a*, 1994*b*). These processes are intended to enhance the activated-sludge process by providing a greater biomass concentration in the aeration tank and thus offer the potential to reduce the basin size requirements. They have also been used to improve volumetric nitrification rates and to accomplish denitrification in aeration tanks by having anoxic zones within the biofilm depth. Because of the complexity of the process and issues related to understanding the biofilm area and activity, the process designs are empirical and based on prior pilot-plant or limited full-scale results. In this section these processes are introduced and described and some design considerations and parameters are presented.

Processes with Internal Suspended Packing for Attached Growth

There are now more than 10, and counting, different variations of processes in which a packing material of various types is suspended in the aeration tank of the activated-sludge process (see Fig. 9–18). Typical examples of activated-sludge treatment processes with suspended packing include the Captor®, Linpor®, and Kaldnes®.

Captor® and Linpor®. In the Captor® and Linpor® processes foam pads with a specific density of about 0.95 g/cm^3 are placed in the bioreactor in a free-floating fashion and retained by an effluent screen (see Fig. 9–19). The pad volume can account for 20 to 30 percent of the reactor volume. Dimensions of the various packing materials are presented in Table 9–14. Mixing from the diffused aeration system circulates the foam pads in the system, but without additional mixing methods, they may tend to accumulate at the effluent end of the aeration basin and float at the surface (Brink et al., 1996; Golla et al., 1994). An air knife has been installed to continuously clean the screen and a pump is used to return the packing material to the influent end of the reac-

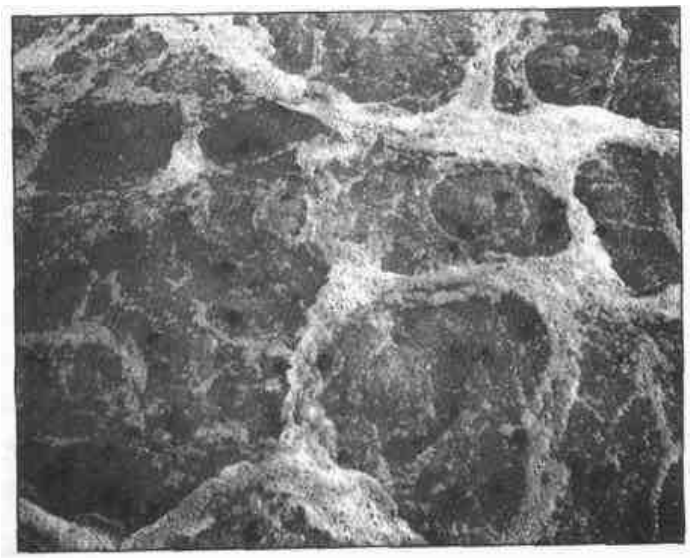

Figure 9–18

View of suspended packing in activated-sludge aeration tank with proper mixing. Without proper mixing the suspended packing tends to accumulate on the surface of the reactor.

Figure 9–19
Typical flow diagram for Captor® and Linpor® processes.

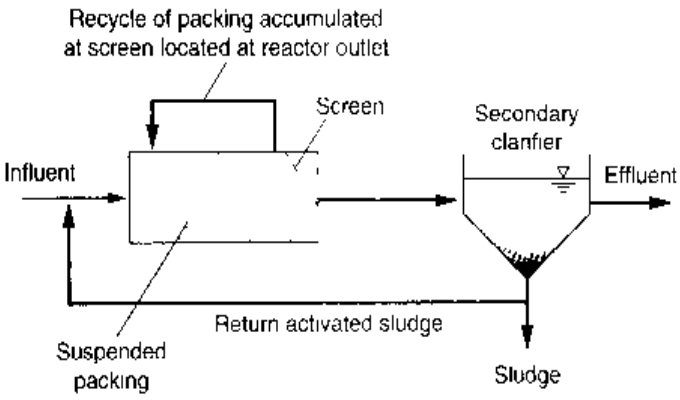

Table 9–14
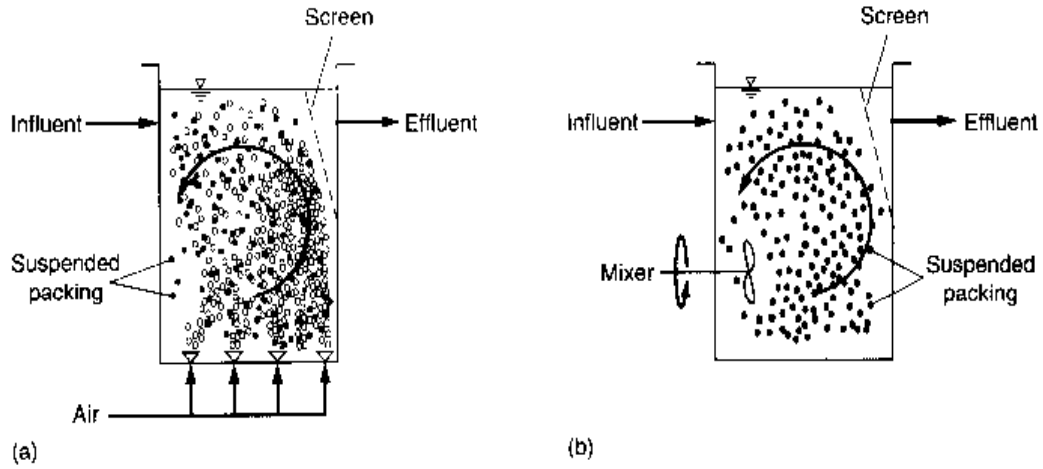
Packing material for suspended fixed-film activated-sludge process

	Packing specifications	
Name	**Material**	**Dimensions, mm**
Captor®	Polyurethane	30 × 25 × 25
Linpor®	Polyurethane	10 to 13 cubes

tor. Solids are removed from a conventional secondary clarifier and wasting is from the return line as in the activated-sludge process.



The principal advantage for the sponge packing systems is the ability to increase the loading on an existing plant without increasing the solids load on existing secondary clarifiers, as most of the biomass is retained in the aeration basin. Loading rates for BOD of 1.5 to 4.0 kg/m^3·d with equivalent MLSS concentrations of 5000 to 9000 mg/L have been achieved with these processes (WEF, 2000). Based on the results with full-scale and pilot-scale tests with the sponge packing installed it appears that nitrification can occur at apparent lower SRT values, based on the suspended growth mixed liquor, than those for activated sludge without internal packing.

Kaldnes®. A *moving-bed biofilm reactor* (MBBR) has been developed by a Norwegian company, Kaldnes Miljøteknologi. The process consists of adding small cylindrical-shaped polyethylene carrier elements (specific density of 0.96 g/cm^3) in aerated or non-aerated basins to support biofilm growth (see Fig. 9–20). The small cylinders are about 10 mm in diameter and 7 mm in height with a cross inside the cylinder and longitudinal fins on the outside. The biofilm carriers are maintained in the reactor by the use of a perforated plate (5 × 25 mm slots) at the tank outlet. Air agitation or mixers are applied in a manner to continuously circulate the packing. The packing may fill 25 to 50 percent of the tank volume. The specific surface area of the packing is about 500 m^2/m^3 of bulk packing volume. The MBBR does not require any return activated-sludge flow or backwashing. A final clarifier is used to settle sloughed solids. The MBBR process provides an advantage for plant upgrading by reducing the solids loading on existing clarifiers (Rusten et al., 1998 and 2000). The presence of packing material discourages the use of more efficient fine bubble aeration equipment, which would require periodic drainage of the aeration and removal of the packing for diffuser cleaning.

Two different applications in which the MBBR has been applied are illustrated on Fig. 9–21. The first is a more common design application for BOD removal, nitrification, and denitrification (Rusten et al., 1995). For the anoxic-aerobic treatment mode (see Fig. 9–21*a*), a 6-stage reactor design is used. Chemical addition for phosphorus removal is done after the MBBR. The Kaldnes packing is added to provide a specific packing surface area of 200 to 400 m^2/m^3 in the reactors. In the second application the MBBR is used in place of the trickling filter in the solids contact process (see

Figure 9–20

Note: $m^2/m^3 \times 0.3048 = ft^2/ft^3$.
$kg/m^3 \cdot d \times 62.4280 = lb/10^3\ ft^3 \cdot d$.

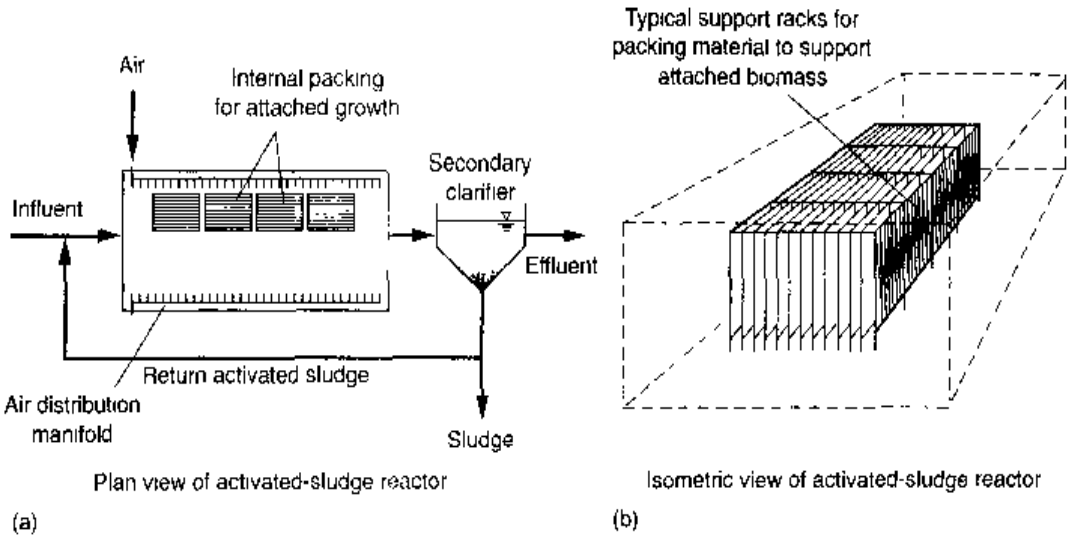

Fig. 9–21*b*). Typical process design parameters for the moving-bed biofilm reactor and the moving-bed biofilm reactor/solids contact (MBBR/SC) processes are reported in Tables 9–15 and 16, respectively.

Processes with Internal Fixed Packing for Attached Growth

There are now more than half a dozen, and counting, different variations of processes in which a fixed packing material is placed in the aeration tank of the activated-sludge process. Three typical examples of fixed packing processes include the Ringlace® and BioMatrix® processes, Bio-2-Sludge® process, and submerged RBCs.

Figure 9–22

Placement of Ringlace® packing in an activated-sludge reactor: (*a*) schematic of placement of packing in activated-sludge reactor and (*b*) isometric view of packing placed in activated-sludge reactor. *(Adapted from Ringlace, Inc.)*

Ringlace®. Ringlace® packing is a looped polyvinyl chloride material that is about 5 mm in diameter. It is placed in about 25 to 35 percent of the activated-sludge basin volume in modules with individual strands at 40 to 100 mm apart (see Fig. 9–22). The specific surface area provided ranges from 120 to 500 m^2/m^3 of tank volume. The packing placement location in the aeration tank is important. To provide efficient contact with the wastewater the packing should be placed along one side of the aeration vessel with the aeration equipment providing a spiral roll pattern for flow through the packing (Sen et al., 1993). Spiral roll aeration is usually less efficient than full floor coverage aeration with fine bubble diffusers.

The location along the length of the tank is also important for nitrification and denitrification system operations. Randall and Sen (1996) recommend a location where sufficient BOD remains to develop a biofilm growth, but where the BOD demand is low enough so that ammonia oxidation can occur in the film. However, they noted that the optimal rate can be difficult to achieve as variations in BOD loading can vary the biofilm growth on the packing and the competition between heterotrophic and autotrophic bacteria for surface area. In some applications, the advantages of using a fixed internal packing were negated due to the growth of bristle worms in the biofilm.

Bio-2-Sludge® Process. A schematic of the Bio-2-Sludge® process is illustrated on Fig. 9–23. The PVC packing bundle with a surface area of 90 to 165 m^2/m^3 and a minimum opening of 20 × 20 mm to prevent clogging is positioned along the walls of the aeration tank. The air diffusion system is designed to create a mixed liquid recirculation flow through the packing (WEF, 2000).

Submerged Rotating Biological Contactors. Rotating biological contactor units have been installed in activated sludge. The *submerged rotating biological contactor* (SRBC) is operated at approximately 85 percent submergence (see Fig. 9–11*c*). The SRBC units can be as large as 5.5 m (18 ft) diameter with a surface area of 28,800 m^2. The rotation is driven by aeration and may be mechanically assisted. The submerged operation reduces the load on the packing shaft.

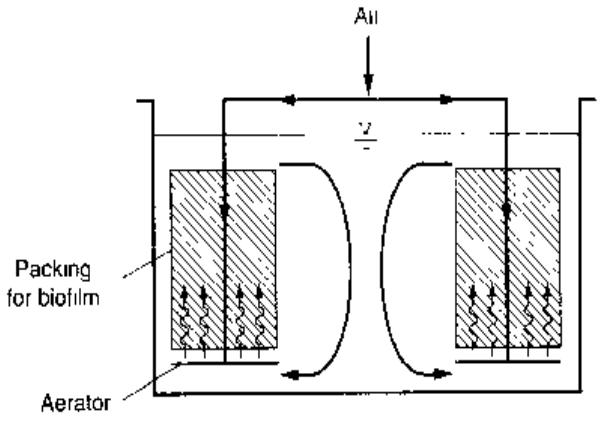

Figure 9-23
Schematic of Bio-2-Sludge® process.

9–6 SUBMERGED ATTACHED GROWTH PROCESSES

Aerobic submerged fixed-film processes consist of three phases: a packing, biofilm, and liquid. The BOD and/or NH_3-N removed from the liquid flowing past the biofilm is oxidized. Oxygen is supplied by diffused aeration into the packing or by being predissolved into the influent wastewater. Aerobic fixed-film processes include downflow packed-bed reactors, upflow packed-bed reactors, and upflow fluidized-bed reactors. The type and size of packing is a major factor that affects the performance and operating characteristics of submerged attached growth processes. Designs differ by their packing configuration and inlet and outlet flow distribution and collection. No clarification is used with aerobic submerged attached growth processes, and excess solids from biomass growth and influent suspended solids are trapped in the system and must be periodically removed. Most designs require a backwashing system much like that used in a water filtration plant to flush out accumulated solids, usually on a daily basis.

The major advantages of submerged attached growth processes are their relatively small space requirement, the ability to effectively treat dilute wastewaters, no sludge settling issues as in activated-sludge process, and aesthetics. Also for many processes solids filtration occurs to produce a high-quality effluent. Such fixed-film systems have equivalent hydraulic retention times of less than 1 to 1.5 h, based on their empty tank volumes. Their disadvantages include a more complex system in terms of instrumentation and controls, limitations of economies of scale for application to larger facilities, and generally a higher capital cost than activated-sludge treatment.

A wide variety of submerged attached growth processes have been used. The purpose of this section is to describe the more common processes used and their design loadings and performance capability. The processes described are the downflow Biocarbone® process, the upflow Biofor® and Biostyr® process, and the aerobic upflow fluidized-bed reactor.

Downflow Submerged Attached Growth Processes

The Biocarbone® process is a typical example of a downflow submerged attached growth process. Over 100 facilities have been constructed worldwide since the development of the process in France in the early 1980s (WEF, 1998). The process has also been termed the biological aerated filter (BAF) (Stensel et al., 1988). Although activated carbon packing was used in the original design, a 3- to 5-mm fired clay material is used in

Figure 9–24
Schematic of Biocarbone® downflow biological process.

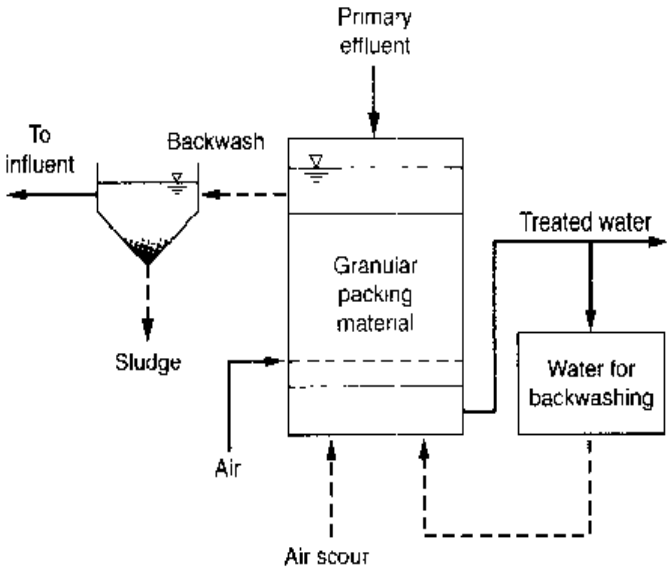

Table 9–17
Typical design loadings for Biocarbone® aerobic submerged attached growth process[a]

Application	Unit	Loading range
BOD removal	kg BOD/m^3·d	3.5–4.5
BOD removal and nitrification	kg BOD/m^3·d	2.0–2.75
Tertiary nitrification	kg N/m^3·d	1.2–1.5

[a] Adapted from Mendoza and Stephenson (1999) and WEF (1998).
Note: kg/m^3·d × 62.4280 = lb/10^3 ft^3·d.

current designs. Plant installations range in size from 2000 to 80,000 m^3/d. A schematic of the Biocarbone® process is shown on Fig. 9–24. The system is designed much like a water filter with the addition of an air header about 300 mm above the underdrain nozzles to sparge air through the packing. The air header is uniformly arranged across the bed to assure that oxygen is provided throughout the entire bed of packing. The actual oxygen transfer efficiency is in the range of 5 to 6 percent, which is comparable to fine bubble diffused aeration performance for that depth (Stensel et al., 1988).

Backwashing is normally done once per day or when the headloss increases to about 1.8 m. The design must consider both organic loading and hydraulic application rate. Hydraulic application rates in the range of 2.4 to 4.8 m^3/m^2·h are recommended to prevent excessive headloss. The Biocarbone® process has been used in aerobic applications for BOD removal only, combined BOD removal and nitrification, and tertiary nitrification. The process has also been used for denitrification as have all the attached growth processes shown here, and these applications are presented in Chap. 10. Typical design loadings for Biocarbone applications are presented in Table 9–17. In combined BOD removal and nitrification systems, the nitrification rate is about 0.45 kg/m^3·d (Stensel et al., 1988). Higher DO concentrations in the range of 3 to 5 mg/L are recommended for efficient nitrification. For BOD removal applications, effluent BOD and TSS concentrations are generally <10 mg/L and for nitrification, effluent NH_4-N concentrations may range from 1 to 4 mg/L. A similar process, but using an expanded shale

Figure 9–25
Schematic of Biofor® upflow biological reactor.

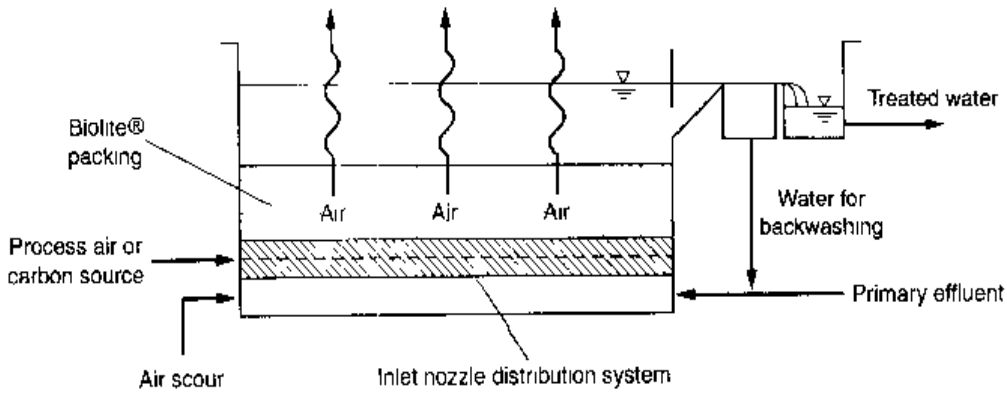

Table 9–18
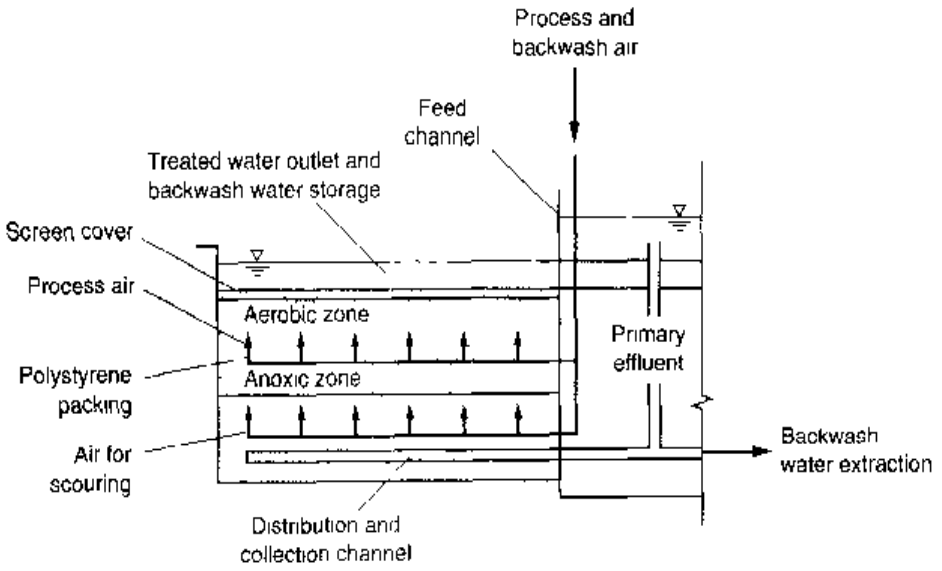
Recommended loading limits for the Biofor® process[a]

Item	Unit	COD removal	Tertiary nitrification
Installed packing porosity	%		~40
Loading	kg COD/m³·d	10–12	
	kg N/m³·d		1.5–1.8
Hydraulic application	m³/m²·h	5.0–6.0	10–12

[a] Adapted from Pujol et al. (1994)
Note: kg/m³·d × 62.4280 = lb/10³ ft³·d.
m³/m²·h × 3.2808 = ft³/ft²·h

packing, has been developed and installed in England by the Thames Water Utilities (Smith and Edwards, 1994).



Upflow Submerged Attached Growth Processes

Two upflow submerged attached growth processes that have been applied with success include the Bifor® and Biostyr® processes. The key features of these processes are described below.

Biofor® Process. The Biofor® process, an upflow submerged aerobic attached growth process (see Fig. 9–25), is being used at more than 100 installations in Europe and North America (Ninassi et al., 1998). The upflow reactor has a typical bed depth of 3 m but designs in the range of 2- to 4-m bed depth have been used (Pujol et al., 1994). The packing, termed Biolite®, is an expanded clay material with a density greater than 1.0 and a 2- to 4-mm size range. Inlet nozzles distribute the influent wastewater up through the bed, and an air header (Oxazur® system) provides process air across the bed area. Backwashing is typically done once per day with a water flush rate of 10 to 30 m/h to expand the bed (Lazarova et al., 2000). Fine screening of the wastewater is needed to protect the inlet nozzles. The Biofor® process has been applied for BOD removal and nitrification, tertiary nitrification, and denitrification. Recommended operating limits for the Biofor® process are shown in Table 9–18. The loadings are similar to that used for the Biocarbone® process. A study of 12 plants by Canler and Perret

Figure 9–26

Schematic of Biostyr® process showing arrangement for nitrification-denitrification.

(1994) showed similar treatment performance results for COD removal as a function of the hydraulic application rate and COD loading for both the Biocarbone® and Biofor® systems.

Biostyr® Process. The Biostyr® process is an upflow process, developed in Denmark, and uses 2- to 4-mm (specific area about 1000 m^2/m^3) polystyrene beads that have a specific density less than water. The installed packing porosity is about 40 percent, providing an effective area of about 400 m^2/m^3 for biofilm growth. Packing depths range from 1.5 to 3 m. A schematic of the Biostyr® process is shown on Fig. 9–26. The bed can be operated entirely aerobic by providing air at the bottom or as an anoxic/aerobic bed by providing air at an intermediate level. Nitrified effluent is recycled for the anoxic/aerobic operation. The floating packing is retained by nozzle plates and is compressed as the wastewater flows upward to provide filtration. Backwash water is stored above the treatment bed. During the backwash cycle treated water flows down through the packing at a very high rate, which results in a downward expansion of the originally compressed packing. The solids retained in the lower portion of the reactor and excess biomass produced on the packing are flushed out into a backwash collection tank. The normal backwash procedure consists of repeated rinse (water flushing) and air scouring steps. Typically four water phases and three air phases are used (Holbrook et al., 1998; Borregaard, 1997).

The Biostyr® process has been used for BOD removal only, combined BOD removal and nitrification, tertiary nitrification, and postdenitrification. Typical loadings possible for the various types of treatment with the Biostyr® process are presented in Table 9–19 (Le Tallec et al, 1997; Borregaard, 1997; Payraudeau et al., 2000). The organic loadings are in the same range as that for the Biocarbone® and Biofor® processes. Nitrification testing work by Payraudeau et al. (2000) suggests that a higher nitrification load is possible for tertiary nitrification. At loadings of 1.5 to 1.8 kg $N/m^3 \cdot d$, 85 to 90 percent nitrogen oxidation was shown. Effluent performance for a number of full-scale facilities was given by Borregaard (1997), but the process loadings were not defined. Average effluent BOD, TSS, and NH_4-N concentrations of 7, 11, and 1.8 mg/L, respectively, were shown for long-term operation.

Table 9–19
Typical design loadings for the Biostyr® process

Application	Unit	Value
BOD only	kg COD/m^3·d	8–10
BOD removal and nitrification	kg COD/m^3·d	4–5
Tertiary nitrification	kg N/m^3·d	1.0–1.7

Note: kg/m^3·d × 62.4280 = lb/10^3 ft^3·d.

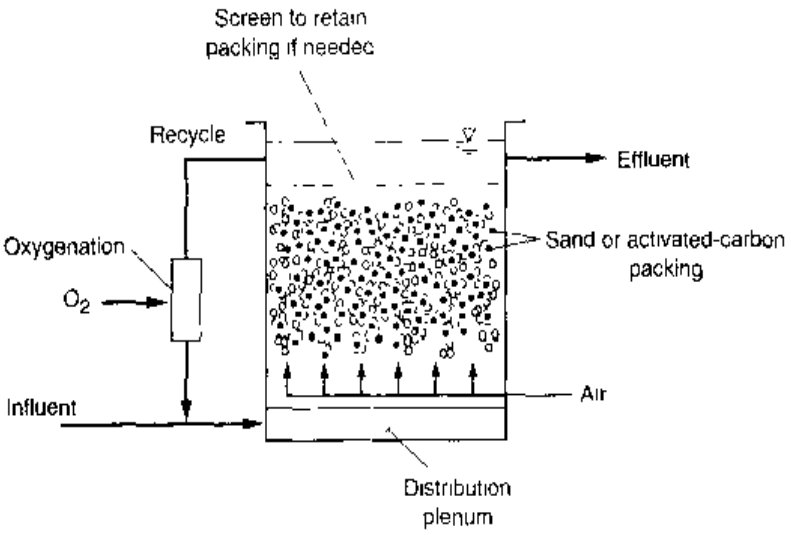


Figure 9–27
Schematic of fluidized-bed biological reactor (FBBR).

Fluidized-Bed Bioreactors (FBBR)

In fluidized-bed bioreactors the wastewater is fed upward to a bed of 0.4- to 0.5-mm sand or activated carbon. Bed depths are in the range of 3 to 4 m. The specific surface area is about 1000 m^2/m^3 of reactor volume, which is greater than any of the other fixed-film packing. Upflow velocities are 30 to 36 m/h. Effluent recirculation is necessary to provide the fluid velocity within the necessary treatment detention times. Hydraulic retention times in FBBRs range from 5 to 20 min. As the biofilm increases in size, the packing becomes lighter and accumulates at the top of the bed where it can be removed and agitated periodically to remove excess solids.

A schematic of an FBBR system is shown on Fig. 9–27. For aerobic applications recirculated effluent is passed through an oxygenation tank to predissolve oxygen. Adding air to the fluidized-bed reactor would discharge packing to the effluent. For municipal wastewater treatment, FBBRs have been used mainly for postdenitrification (see Sec. 9–7). Anaerobic applications of the FBBRs are described in Chap. 10. Aerobic FBBRs are frequently used to treat groundwater contaminated with hazardous substances. In these applications activated carbon is used for the packing to provide both carbon adsorption and biological degradation (Sutton and Mishra, 1994). The main advantages for the FBBR technology in this application are (1) it provides an extraordinarily long SRT for microorganisms necessary to degrade the xenobiotic and toxic compounds; (2) shock loads or nonbiodegradable toxic compounds can be absorbed onto the activated carbon; (3) high-quality effluent is produced low in TSS and COD concentration; (4) the oxygenation method prevents stripping and emission of toxic organic compounds to the atmosphere; and (5) the system operation is simple and reliable.

9–7 ATTACHED GROWTH DENITRIFICATION PROCESSES

Biological denitrification processes have been applied following secondary treatment nitrification processes to reduce the nitrate/nitrite produced. Typically, an exogenous carbon source is added to provide an electron donor that can be oxidized biologically using nitrate or nitrite. Both attached growth and suspended growth processes have been used for postanoxic denitrification with success. Suspended growth processes used for denitrification are discussed in Sec. 8–5 in Chap. 8. The different types of attached growth postanoxic processes, illustrated on Fig. 9–28, include (1) downflow and upflow packed-bed reactors, (2) upflow fluidized-bed reactors, and (3) submerged rotating biological contactors. All of the processes require carbon addition in the form of methanol to the influent. Methanol to NO_3-N dose ratios are in the range of 3.0 to 3.5 kg methanol/kg NO_3-N. The general physical designs of the downflow Biocarbone® and upflow Biofor® and Biostyr® systems have been described in Sec. 9–6. Specific design loadings used for the various systems for attached growth postanoxic denitrification are presented and discussed in this section. Attached growth preanoxic denitrification processes are also considered.

Downflow Packed-Bed Postanoxic Denitrification Processes

Downflow packed-bed denitrification filters (see Fig. 9–28*a*) are deep bed filters [1.2 to 2.0 m (4 to 6.5 ft)] that have been used in many installations (U.S. EPA, 1993) for

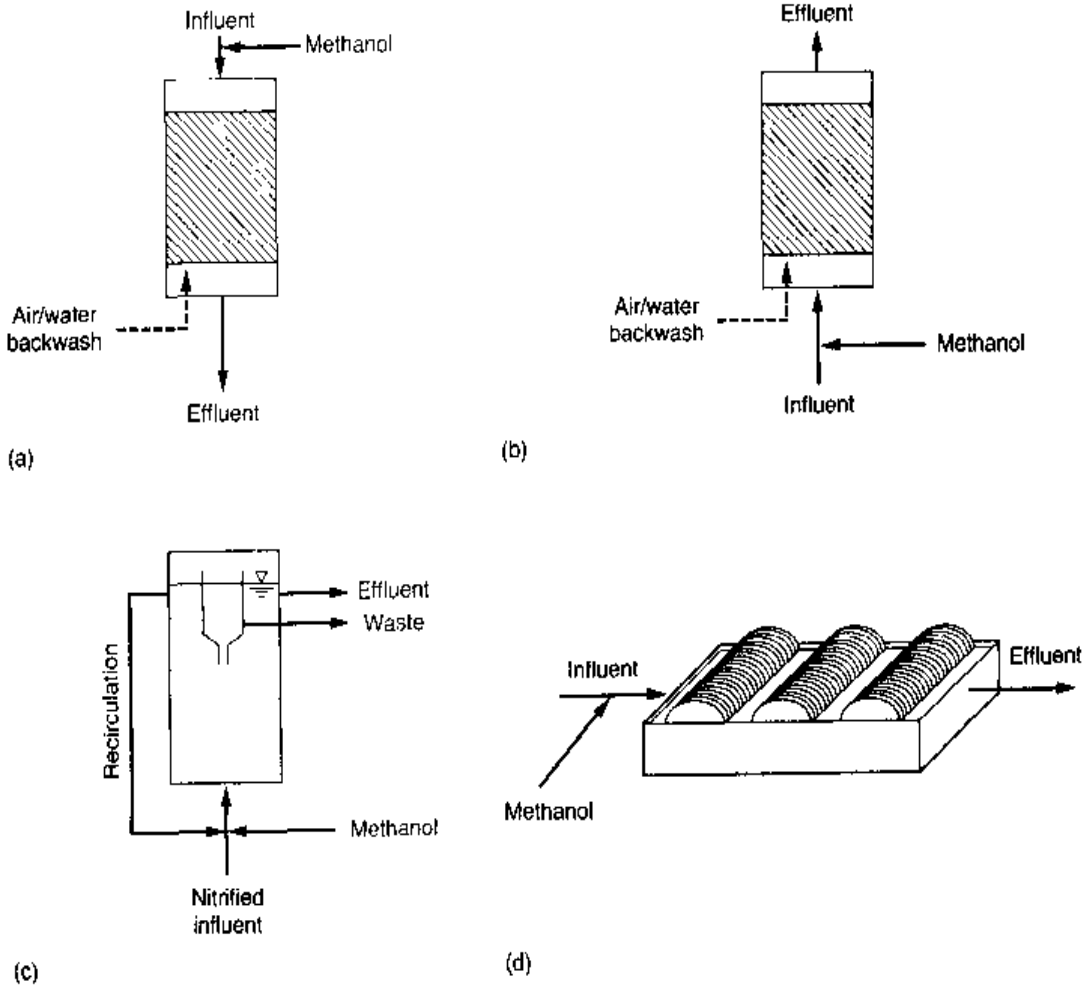

Figure 9–28

Postanoxic attached growth denitrification processes: (*a*) downflow packed-bed reactor, (*b*) upflow packed-bed reactor, (*c*) fluidized-bed denitrification reactor, and (*d*) submerged rotating biological contactor.

Table 9–20
Typical design criteria for downflow denitrification filters[a]

Parameter	Unit	Value	
		Range	Typical
Packing:			
Type		Sand	Sand
Effective size	mm	1.8–6.0	4.0
Sphericity	unitless	0.8–0.9	0.82
Specific gravity	unitless	2.5–2.7	2.6
Depth	m	1.2–1.8	1.6
Hydraulic application rate:			
20°C	$m^3/m^2 \cdot d$	60–120	100
10°C	$m^3/m^2 \cdot d$	30–90	80
NO_3-N loading:			
20°C	$kg/m^3 \cdot d$	1.4–1.8	1.6
10°C	$kg/m^3 \cdot d$	0.8–1.2	1.0
Empty-bed contact time	min	20–30	20
Methanol to NO_3-N ratio	unitless	3.0–3.5	3.2
Air scour before backwash:			
Flowrate	$m^3/m^2 \cdot min$	1.2–1.6	1.5
Duration	s	20–40	30
Backwash:			
Air flowrate	$m^3/m^2 \cdot h$	90–120	110
Water flowrate	$m^3/m^2 \cdot h$	15–25	20
Duration	min	10–20	15
Frequency	times/d	1	1
Water flush (bump):			
Flowrate	$m^3/m^2 \cdot d$	10–14	12
Duration	min	3–5	4
Frequency	times/d	12	12

[a] Adapted from U.S. EPA (1993) and Bailey et al. (1998).

Note: $m^3/m^2 \cdot d \times 24.5424 = gal/ft^2 \cdot d$.

$kg/m^3 \cdot d \times 62.4280 = lb/10^3\ ft^3 \cdot d$.

postanoxic nitrate removal. The denitrification filter used most commonly is a proprietary process of TETRA Technologies. The filters provide both suspended solids removal and denitrification by microbial growth on the filter packing. Typical design criteria are reported in Table 9–20. Sand is the filter packing and the size selected is small enough to provide effective filtration and sufficient surface area for microbial growth but large enough to accommodate solids capture and microbial growth without excessive headloss. At hydraulic application rates of 80 to 100 $m^3/m^2 \cdot d$ (Table 9–20),

effluent TSS concentrations of ≤ 5.0 mg/L are commonly achieved. With proper control of the methanol dose, total effluent nitrogen concentrations of 1 to 3 mg/L are possible. Overdosing of the methanol can lead to odor production, due to biological sulfate reduction in the filter.

During operation of the denitrification filter, headloss gradually increases because of solids accumulation (filtration), biomass growth, and accumulation of nitrogen gas due to denitrification. The filter is "bumped" periodically by a hydraulic surge to remove nitrogen gas and backwashed for solids removal. A water-only flush is used at a rate of 12 m/h for about 3 to 5 min for a "bump" to release the accumulated nitrogen gas. The bump frequency may vary from once every 2 to 4 h. An air and water backwash is required every 24 to 48 h, depending on the solids accumulation and headloss. The solids storage capacity is estimated to be about 4.0 kg TSS/m^3 before high headloss occurs. The backwash typically consists of an air scour followed by an air and water backwash.

EXAMPLE 9–9 Denitrification Filter Design Given the following flow and secondary effluent characteristics for feed to postanoxic denitrification filters, determine the following design parameters to achieve effluent TSS and NO_3-N concentrations of less than 5.0 and 2.0 mg/L, respectively. Use the typical values given in Table 9–20 for the process design.

Design parameters to be determined:

1. Filter dimensions
2. Backwash water rate
3. Backwash air rate
4. Nitrogen release backwash water bump rate
5. Methanol requirements
6. Solids production

Wastewater characteristics

Item	Unit	Value
Flowrate	m^3/d	8000
TSS	g/m^3	20
NO_3-N	g/m^3	25
Temperature	°C	15

Note: g/m^3 = mg/L

Operational parameters and assumptions

1. Filter backwash frequency = 1/d
2. Water backwash flowrate = 20 $m^3/m^2 \cdot h$ (see Table 9–20)
3. Air backwash rate = 110 $m^3/m^2 \cdot h$ (see Table 9–20)
4. Water flush (bump) frequency = once/2 h

5. One filter required for standby
6. Synthesis yield with methanol = 0.18 g VSS/g COD,
7. VSS/TSS = 0.85

Solution

1. Determine the dimensions of the denitrification filter.
   a. Determine filter size based on nitrogen loading.

$$NO_3\text{-N removal} = [(25.0 - 2.0)\ g/m^3]\ (8000\ m^3/d)\ (1\ kg/10^3\ g)$$

$$= 184\ kg/d$$

From Table 9–20, select NO_3-N loading at 15°C of 1.3 kg/m³·d and a depth D of 1.6 m.

$$\text{Volume} = \frac{(184\ kg/d)}{(1.3\ kg/m^3\cdot d)} = 141.5\ m^3$$

$$\text{Area} = V/D = 141.5\ m^3/1.6\ m$$

$$= 88.4\ m^2$$

   b. Determine filter size based on filtration hydraulic loading bases.

From Table 9–20, select hydraulic application rate of 90 m³/m²·d

$$\text{Filter area} = (8000\ m^3/d)/(90\ m^3/m^2\cdot d)$$

$$= 88.9\ m^2$$

Thus, the filter size is controlled by the hydraulic application rate.

Assume 5 filters installed with 1 filter used as standby. Use of the filters should be rotated so that active biofilm is maintained in all of the filters.

$$\text{Area/filter} = \frac{88.9\ m^2}{4} = 22.2\ m^2$$

Use a square configuration.

Filter dimensions = 4.7 × 4.7 × 1.6 m

2. Determine air and water backwash flowrates and percent of product water used as backwash water.
   a. Determine backwash air flowrate at an air backwash application rate of 110 m³/m²·h.

$$\text{Air flowrate} = (110\ m^3/m^2\cdot h)\ (22.2\ m^2/\text{filter}) = 2442\ m^3/h$$

   b. Determine backwash water flowrate at a water backwash application rate of 20 m³/m²·h.

$$\text{Water flowrate} = (20\ m^3/m^2\cdot h)\ (22.2\ m^2/\text{filter}) = 444\ m^3/h$$

$$= 7.4\ m^3/min$$

c. Determine volume of backwash water at 1 backwash/24 h for each filter with a duration of 15 min (Table 9–20)

Backwash water volume = (7.4 m^3/min)(15 min/filter)(4 filters)

= 444 m^3/d

d. Determine percent of product water used as backwash water.

(444 m^3/d)/(8000 m^3/d) = 0.0555

= 5.6%

3. Determine volume of water used to flush (bump) filters at 1 bump/2 h with a duration of 3 min/bump and a flowrate of 12 m/d.

Water volume = (88.9 m^2) (12 m/d) (3 min/bump) (1 bump/2 h·filter) (24 h/d)

(1 h/60 min)

= 640 m^3/d

Percent of product water used for nitrogen release bumping:

= (640 m^3/d) / (8000 m^3/d) = 0.08

= 8.0%

4. Total product water used − 8.0 + 5.6 = 13.6%

Actual filtration rate required including product water used for backwashing and bumping:

(90 m^3/m^2·d)(1.136) = 102 m^3/m^2·d

Note: An iterative calculation can be performed to develop an actual filtration rate approaching 90 m^3/m^2·d by using a lower rate in step 1b.

5. Methanol (CH_3OH) requirements.

Nitrate removal = 184 kg/d

Use 3.2 kg methanol/kg NO_3-N (see Table 9–20)

Methanol = (3.2 kg/kg)(184 kg/d) = 588.8 kg/d

6. Determine the solids production.

Solids = filtered solids + biomass production

Use effluent TSS = 5 mg/L (g/m^3)(given value)

Filter solids = [(20 − 5) g/m^3] (8000 m^3/d) (1 kg/10^3 g)

= 120 kg/d

Biomass production:

Based on the stoichiometric balance for methanol oxidation, there are 1.5 g COD/g CH_3OH ($CH_3OH + 1.5O_2 \rightarrow CO_2 + 2H_2O$)

$$\text{Biomass} = \left(\frac{0.18\text{ g VSS}}{\text{g COD}}\right)\left(\frac{1.5\text{ g COD}}{\text{g CH}_3\text{OH}}\right)\left(\frac{588.8\text{ kg}}{\text{d}}\right)$$

$$= 159\text{ kg VSS/d}$$

TSS = (159 kg VSS/d)/(0.85 g VSS/g TSS) = 187.1 kg TSS/d

Total solids = 120 kg/d + 187.1 kg/d = 307.1 kg/966d

Solids storage assuming 1 backwash/d

Filter volume = (22.2 m^2)(1.6 m)(1 backwash/d) = 36 m^3/filter·d

$$\text{Solids storage} = \left(\frac{307.1\text{ kg}}{\text{d}}\right)\left(\frac{1}{4\text{ filters}}\right)\left[\frac{\text{filter}}{(36\text{ m}^3/\text{d})}\right] = 2.1\text{ kg TSS/m}^3$$

Comment Because the solids storage value is well below 4.0 kg TSS/m^3, backwashing may be required only once every 2 days. However, to maintain the health of the filter, backwashing once per day is recommended (see Sec. 11–4 in Chap. 11).

The downflow packed-bed Biocarbone® process, as described in Sec. 9–6, has been demonstrated at pilot scale for nitrogen removal. An effluent total nitrogen concentration of less than 8 mg/L was achieved with an NO_3-N loading of 4 kg NO_3-N/m^3·d at 10 to 12°C in a postanoxic application (Jepsen and Jansen, 1993). The effective size of the packing was 4 to 6 mm and the packing depth was 2.0 m. Nitrogen gas bumping was not advocated for this system.

Upflow Packed-Bed Postanoxic Denitrification Reactors

As illustrated on Fig. 9–28*b*, upflow packed-bed reactors have been demonstrated for postanoxic denitrification for both the Biostyr® and Biofor® processes. As described previously, the packing used in these processes is a 2.0-m depth of 2- to 5-mm polystyrene beads for the Biostyr® (Jepsen and Jansen, 1993) and a 2-m depth of a 2- to 4-mm expanded clay (Biolite) for the Biofor® process (Aesoy et al., 1998). Reported NO_3-N loading rates for these processes are in the range from 3.0 to 4.0 kg NO_3-N/m^3·d to achieve effluent NO_3-N concentrations below 5.0 mg/L (Pujol et al., 1994; Borregaard, 1997), assuming a sufficient amount of electron donor is supplied. Higher hydraulic application rates of up to 330 m^3/m^2·d have been claimed for these processes. No special backwash "bumping" is provided for nitrogen gas release during backwash as compared to the proprietary Tetra® filter.

Fluidized-Bed Reactors for Postanoxic Denitrification

In the fluidized-bed reactor (FBR), the upward flow to the reactor containing sand or other suitable packing material is at a sufficient velocity to expand and fluidize the sand

Table 9–21
Design criteria for upflow fluidized-bed reactors for postanoxic denitrification[a]

Parameter	Unit	Value	
		Range	Typical
Packing:			
Type		Sand	Sand
Effective size	mm	0.3–0.5	0.4
Sphericity	unitless	0.8–0.9	0.8–0.85
Uniformity coefficient	unitless	1.25–1.50	≤1.4
Specific gravity	unitless	2.4–2.6	2.6
Depth	m	1.5–2.0	2.0
Bed expansion	%	75–150	100
Upflow velocity	m/min	0.60–0.70	0.6
Hydraulic application rate	$m^3/m^2 \cdot d$	400–600	500
Recirculation ratio	unitless	2:1–5:1	2:1–5:1
NO_3-N loading:			
13°C	$kg/m^3 \cdot d$	2.0–4.0	3.0
20°C	$kg/m^3 \cdot d$	3.0–6.0	5.0
Empty-bed contact time	min	10–20	15
Methanol to NO_3-N ratio	unitless	3.0–3.5	3.2

[a] Adapted from U.S. EPA, 1993; Sadick et al., 1994; and Sadick et al., 1996.
Note: $m^3/m^2 \cdot d \times 24.5424 = gal/ft^2 \cdot d$
$kg/m^3 \cdot d \times 62.4280 = lb/10^3\ ft^3 \cdot d$.

particles coated with biofilms (see Fig. 9–28*c*). The intense mixing provides good mass transfer and the dense biofilm that develops results in an equivalent reactor biomass concentration of 20 to 30 g/L for postdenitrification applications (U.S. EPA, 1993).

Design criteria for fluidized-bed reactors for postanoxic denitrification are summarized in Table 9–21. Effluent recirculation ratios of 2:1 to 5:1 are used to maintain the high upflow liquid velocity to fluidize the sand. Volumetric NO_3-N loadings of 2.0 to 6.0 $kg/m^3 \cdot d$ have been shown to be feasible for denitrification applications, depending on the temperature. Empty-bed liquid retention times are only 10 to 20 min, and effluent NO_3-N concentrations of 2 to 4 mg/L have been achieved when treating municipal nitrified wastewaters (Sadick et al. 1996).

The FBR systems are operated without the need of effluent filtration or clarification. The sand packing is removed at the top of the reactor and passed through a high shear pump to separate biomass from the sand. The cleaned packing material is returned to the FBR. Packing with thicker biofilms migrates to the top of the bed due to the lower overall particle density caused by the biofilm growth. The excess biomass is removed from the top of the bed to control the bed packing depth. Various separation techniques including screens with spray washers, external cyclones, and hydraulic separators (U.S. EPA, 1993) are used to separate the sheared biomass from the packing material. In a properly designed and operated system the FBR effluent TSS concentration can be in

Table 9–22
Postanoxic denitrification rates in submerged RBCs[a]

Effluent NO_3-N concentration, mg/L	Specific denitrification rate relative to packing area, kg NO_3-N/10^3 m^2·d
1.0	0.40
6.0	3.25

[a] Adapted from WEF (1998).
Note: kg/10^3 m^2·d × 0.2048 = lb/10^3 ft^2·d.

the range of 15 to 20 mg/L. The influent manifold system is also a critical physical design element of the FBR. The manifold must be designed to distribute the influent flow uniformly across the fluidized bed. The Reno Sparks, NV, wastewater-treatment plant was the first full-scale installation of a FBR for postanoxic denitrification, with operation beginning in the early 1980s.

Submerged Rotating Biological Contactors

Submerged RBCs (see Fig. 9–28*d*) have been proposed for postanoxic denitrification applications and have shown good performance at pilot-plant scale. Denitrification rates for submerged RBCs are reported in Table 9–22.

Attached Growth Preanoxic Denitrification Processes

Preanoxic denitrification, as illustrated on Fig. 9–29*a*, can be used with attached growth processes. In the first case, an attached growth process is used for denitrification using organic material in the influent wastewater for the electron donor to reduce NO_3-N. Nitrate is provided in the recycle stream, which is pumped at a rate that is 3 to 4 times the influent flowrate. Attached growth preanoxic processes that have been used for preanoxic denitrification include: (1) trickling filters (Nasr et al., 2000, and Dorias and Baumenn, 1994), (2) the Biofor® process at pilot scale (Ninassi et al., 1998), and (3) a moving bed fixed film reactor (Lazarova et al., 1998). An important advantage of the preanoxic denitrification treatment scheme is that influent BOD is used for nitrate reduction, and thus the cost of methanol addition is eliminated. A disadvantage is the effect of the nitrate recycle flows on the design and operating cost. Where trickling filters are used for nitrification, the energy required for pumping the recycle and influent flow to the trickling filter increases significantly. The preanoxic loading conditions for 80 percent removal of NO_3-N fed to the preanoxic Biofor® reactor are summarized in Table 9–23.

An alternative approach for preanoxic denitrification is shown on Fig. 9–29*b* for a system with an attached growth process for nitrification. The nitrified trickling filter effluent is recycled to provide nitrate for a suspended growth preanoxic reactor (Melhart, 1994). An intermediate clarifier is used to separate the denitrifying mixed liquor and to provide return activated sludge to the anoxic tank. The recycle flow needed to provide nitrate to the preanoxic zone has a significant effect on the clarifier size and pumping requirements to the trickling filter, and thus the overall system economics.

Part of a full-scale trickling filter facility at Salisbury, MD, was modified to evaluate biological nitrogen removal by converting an existing trickling filter to a preanoxic

Figure 9-29
Preanoxic biological nitrogen removal processes: (a) attached growth denitrification process and (b) suspended growth denitrification process with attached growth nitrification.

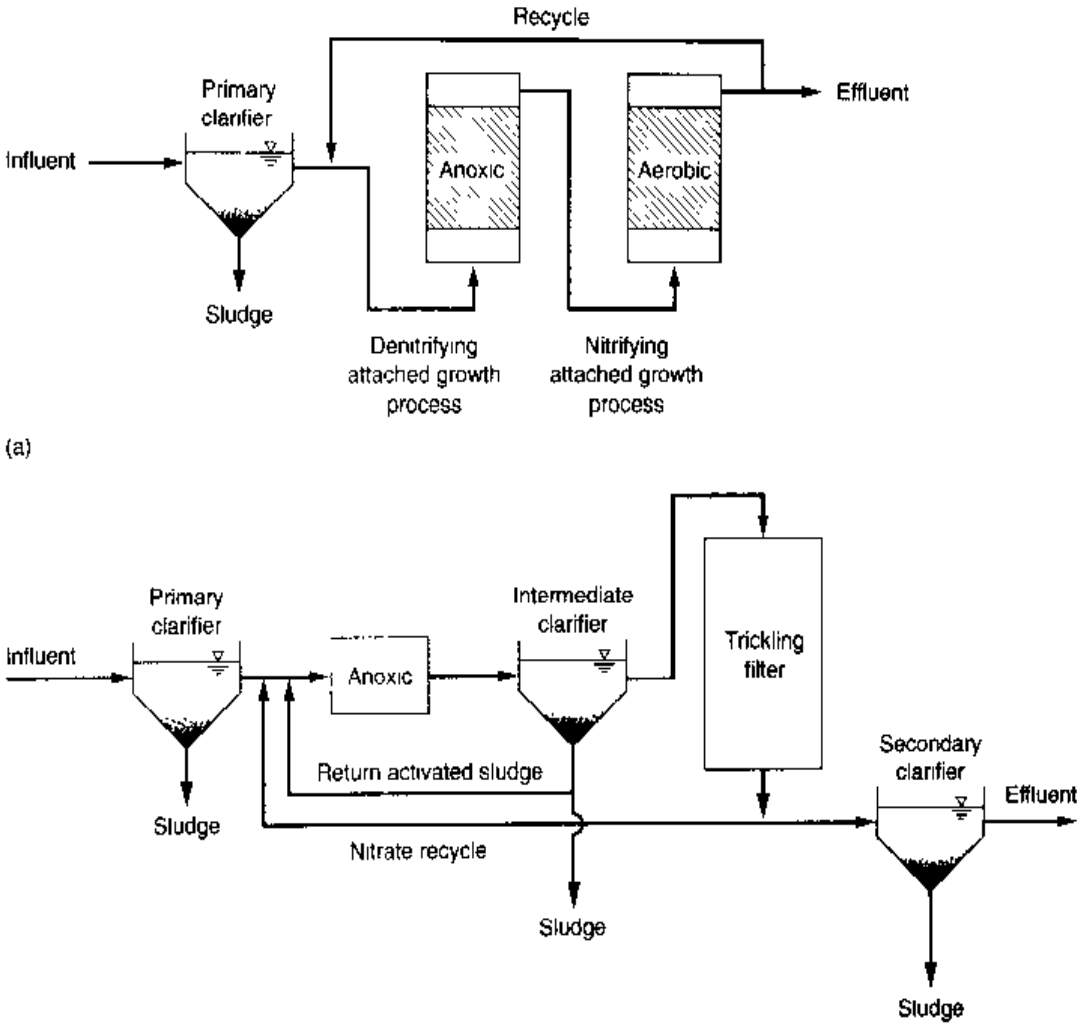

Table 9-23
Preanoxic reactor loading conditions for Biofor® process in attached growth biological nitrogen removal treatment system[a]

Parameter	Unit	Value	
		Range	Typical
Nitrogen loading	kg NO_3-N/m^3·d	1.0–1.5	1.2
Hydraulic application rate including recycle	m^3/m^2·d	480–750	600

[a] Adapted from Ninassi et al. (1998).
Note: kg/m^3·d × 62.4280 = lb/10^3 ft^3·d.
m^3/m^2·d × 24.5424 = gal/ft^2·d.

filter followed by a nitrification trickling filter (Nasr et al., 2000). Both filters were converted from rock to plastic packing with an increase in height and packing depth. The preanoxic filter was operated as a submerged reactor, and the internal recycle ratio from the effluent of the nitrification trickling filter to the preanoxic filter was 5:1 based on the plant influent flowrate. With most of the BOD removal occurring in the preanoxic filter, a higher DO concentration (3 to 6 mg/L) was obtained in the nitrification filter effluent. The trickling filter nitrification rates were on the order of 1.5 to 2.0 g N/m^2·d

and controlled the treatment process flowrate. An effluent total nitrogen concentration of less than 8 mg/L was achieved at temperatures as low as 13°C. Long-term operating data were not sufficient to assess solids inventory and control issues in the preanoxic trickling filter. The high DO concentration in the nitrification trickling filter effluent and its effect on nitrate removal in the preanoxic filter was of concern. In another design using trickling filters, Dorias and Baumenn (1994) used a nonsubmerged preanoxic trickling filter with the recycle and influent feed flows supplied by the trickling filter distributor. A gastight cover over the trickling filter was necessary to develop sustained anoxic conditions, and the preanoxic trickling filter effluent NO_3-N concentrations ranged from 2.0 to 4.0 mg/L with specific NO_3-N removal rates of 70 to 100 g/m^3·d.

The Biofor® attached growth process for preanoxic denitrification and nitrification in series was demonstrated in a pilot plant with municipal wastewater (Ninassi et al, 1998). An internal recycle ratio of 2.5, based on the effluent flowrate, was used and nitrogen removal efficiency was affected by the preanoxic reactor feed bCOD/NO_3-N ratio and internal recycle ratio. A COD/N value greater than 10 was needed to maximize performance.

PROBLEMS AND DISCUSSION TOPICS

9–1 A 20-m-diameter plastic packing trickling filter, containing cross-flow plastic packing at a 6.1-m depth with a specific surface area of 90 m^2/m^3, receives domestic wastewater after primary treatment. The average flowrate is 400, 450, or 480 m^3/hr (value to be selected by instructor) and the BOD concentration is 130 mg/L. Determine and compare the effluent BOD concentration and percent BOD removal at 20°C and 15°C. Assume an n value of 0.5.

9–2 Two 15-m-diameter trickling filters containing conventional cross-flow plastic packing at a 6-m depth are used to treat a pharmaceutical wastewater at an average flowrate of 2120 m^3/d. The influent BOD concentration is 500, 800, or 1000 mg/L (value to be selected by instructor) and the temperature is 20°C. Each tower has a 2-arm distributor. Determine: (a) the operating dose and flushing dose from Table 9–3 and distributor speeds in revolutions/min for each case; and (b) the recirculation ratio and total pumping rate in m^3/h to each filter.

9–3 For Example 9–4, using the same design criteria given for the trickling towers, influent BOD concentration and temperature, and effluent BOD concentration, determine the following using a plastic packing depth of 4.0, 5.0, or 6.0 m (value to be selected by the instructor):

1. Volume of plastic packing, m^3
2. Hydraulic application rate in L/m^2·s
3. Volumetric BOD loading in kg/m^3·d

Compare the results to the values determined for the same design parameters in the example.

9–4 The following data were obtained for a pilot-plant study involving the treatment of a combined domestic-industrial wastewater with a tower trickling filter filled with plastic packing at a depth of 6.1 m. The diameter of the pilot-plant tower was 1 m and the specific surface area of the plastic packing was 90 m^2/m^3. The wastewater temperature at the time of the test was 15, 18, or 22°C (value to be determined by the instructor). During the testing the influent BOD concentration was 350 mg/L. The following table summarizes the average BOD removal efficiency at different flowrates. Using these data, determine the value of the wastewater treatability coefficient, k (assume the value of n is 0.50), at the test temperature and at 20°C.

Pilot-plant test results:

Flowrate, m^3/d	BOD removal efficiency, %
6	88
12	82
18	67
24	63
48	54

9–5 The following design information is given for a domestic wastewater (wastewater A, B, or C to be selected by instructor):

Design information	Wastewater		
	A	B	C
Flow, m^3/d	10,000	10,000	15,000
BOD, mg/L	260	300	220
Minimum temp., °C	15	15	15
TSS, mg/L	240	280	200

Using the above information, and assuming 30 percent BOD removal in primary clarification, a packing depth of 6.1 m, and a value for n of 0.50, determine the following design parameters for a trickling filter treatment system:

1. Primary and secondary clarifier diameters (m)
2. Trickling filter tower diameter (m)
3. Packing volume (m^3)
4. Recirculation ratio, if required
5. Total pumping rate (m^3/h)
6. Flushing and normal dose rates (mm/pass)

9–6 Determine the diameters and packing volume of two 1.5-m deep rock trickling filters, operated in series, for a domestic wastewater treatment application with the following characteristics and requirements using the NRC model.

Parameter	Unit	Value
Flow	m^3/d	5000
Influent BOD	mg/L	(A) 220
		(B) 200
		(C) 180
Temperature	°C	14

(continued)

(*Continued*)

Parameter	Unit	Value
Primary clarifier BOD removal efficiency	%	35
Trickling filter average effluent BOD	mg/L	20

Note: Value A, B, or C to be selected by instructor

9–7 An 18-m-diameter trickling filter tower containing conventional plastic packing at a 6.1-m depth treats a primary effluent flowrate of 7570 m^3/d. The primary effluent BOD is 120, 150, or 160 mg/L (value to be selected by instructor) and the wastewater temperature is 18°C. The air temperature varies from 2 to 23°C. The BOD loading peaking factor is 1.5. Assume a factor of 1.5 for the inlet and outlet pressure losses for the tower. Determine the following:

1. The required oxygen supply rate (kg/hr)
2. The required air flowrate at the warmest temperature (m^3/min)
3. The airflow pressure drop across the packing (Pa).

9–8 Two 20-m-diameter plastic tower trickling filters containing 6.1 m of conventional plastic media (90 m^2 area/m^3 volume) receive a primary clarifier effluent at an average flowrate of 11,200 m^3/d. The TKN concentration is 24 mg/L and the BOD concentration is 150, 130, or 120 mg/L (value to be selected by the instructor) The temperature is 18°C. Evaluate the trickling filter BOD loading and determine the nitrogen removal efficiency due to nitrification.

9–9 Prepare a table to compare the advantages and limitations of a tower trickling filter with plastic packing versus activated-sludge treatment in terms of space, ease of process operation, sludge settling characteristics, energy requirements, maintenance, treatment flexibility, nitrification reliability, potential odors, and potential for future nitrogen or phosphorus removal.

9–10 A 20-m-diameter trickling filter tower containing a 5-m depth of high-density plastic packing (138 m^2 area/m^3 packing volume) is used in a tertiary nitrification application. The influent flowrate is 37,000, 39,000, or 40,000 m^3/d (value to be selected by the instructor) and the NH_4-N concentration is 20 mg/L. Assuming that the nitrification $r_{n,max}$ value is 1.5 g/m^2·d and the K_n value is 1.5 g/m^3, determine the trickling filter effluent NH_4-N concentration (mg/L). Why is no gravity settling tank used for the trickling filter effluent?

9–11 A TF/AS process is used after primary clarification, and the primary effluent wastewater characteristics are given below. For the following design parameters, compare the effect of designing the plastic tower trickling filter step for 40 percent versus 75 percent BOD removal:

1. Trickling filter diameter (m) and hydraulic application rate (L/m^2·s)
2. Oxygen required in the activated-sludge aeration tank (kg/d)
3. The amount of solids wasted per day (kg/d)
4. The volume (m^3) and hydraulic retention time (h) of the aeration tank.

Use the following assumptions for the trickling filter and activated-sludge designs.

Trickling filter:

Plastic packing treatability coefficient, $K_{20} = 0.18(L/s)^{0.5}/m^2$
Packing depth = 6.1 m
Number of towers = 2
50 percent of theoretical effluent BOD is soluble.

Activated sludge:

SRT = 5.0 d (no nitrification)
MLSS = 3000 mg/L
Biomass yield, Y, = 0.6 g VSS/g BOD removed
Endogenous decay, k_d – 0.12 g VSS/g VSS·d
UBOD/BOD = 1.6

Wastewater characteristics:

Item	Unit	Value
Flow	m^3/d	8000
BOD	mg/L	A (150)
		B (140)
		C (110)
sBOD	mg/L	80
TSS	mg/L	65
VSS	mg/L	55
nbVSS	mg/L	22
Temperature	°C	12

Note: Value A, B, or C to be selected by instructor

Which design is preferred? State your reasons.

9–12 An existing activated-sludge facility with primary treatment is operated at an SRT of 12 d and minimal temperature of 12°C so that complete nitrification is maintained. The system is operated with an MLSS concentration of 2200 mg/L, and the SVI is generally in the range of 180 to 200 mL/g. At these conditions, the treatment flow is 8,000 m^3/d. The city engineer requests that your firm design a plastic tower pretreatment system for about 60 percent BOD removal before the activated-sludge unit. You are to list for the city engineer the potential impacts of converting the existing activated-sludge process to a TF/AS process, including flow capacity, solids production, oxygen requirements, energy demand, sludge settling characteristics, and effluent NH_4-N and BOD concentrations. Provide an explanation of the basis of your opinion on the potential impacts.

9–13 Prepare a plot of soluble BOD removal efficiency in percent versus contact time in minutes for a contact tank to be used in a TF/SC process. The operating conditions are:

1. Temperature = 12, 15, or 18° C (value to be selected by instructor)
2. MLVSS = 2000 mg/L
3. $k_{20} = 3.0 \times 10^{-5}$ L/mg·min

9–14 An industrial waste is to be treated with a tower trickling filter followed by an activated-sludge process (TF/AS process). The wastewater flowrate is 20,000 m^3/d and is equalized. Primary settling is not used because the wastewater contains mainly soluble organic substances. The tower trickling filter contains conventional plastic packing medium and the operational SRT for the activated-sludge process is to be 5 d during the critical summer period and vary from 5 to 15 d during the winter. The lowest average sustained winter temperature (at least two weeks) is 5°C and the highest average sustained summer temperature is 26°C. The characteristics of the industrial waste, data derived from pilot-plant studies, and related design data are presented below. Using these data, size the units and determine the following:

1. Concentration of mixed liquor suspended solids to be maintained during summer and winter operation
2. Recycle rates around the filter and activated-sludge process
3. Quantity of sludge to be disposed
4. Effluent BOD concentration from the trickling and activated-sludge processes
5. Quantity of nutrients that must be added.

Wastewater characteristics:

BOD_5 = 1200, 1500, or 1800 mg/L (value to be selected by instructor)
TSS = 100 mg/L
VSS = 0 mg/L
Total nitrogen as N = 10 mg/L.
Total phosphorus as P = 4 mg/L.

Trickling filter pilot-plant results:

$k_{20°C}$ = 0.075 $(L/s)^{0.5}/m^2$
Net solids yield = 0.5 g VSS/g BOD removal
Temperature correction value, θ = 1.06

Activated-sludge pilot-plant results:

Solids synthesis yield, Y = 0.6 g VSS/g BOD removal
Endogenous decay, k_d = 0.12 g VSS/g VSS·d
k = 6.0 g BOD/g VSS·d
K_s = 90 mg BOD/L
θ = 1.035

Design parameters:

Trickling filter hydraulic application rate = 0.10 m^3/m^2·min

Activated-sludge SRT: summer = 5 d; winter = 5–15 d

9–15 The following wastewater is to be treated with an upflow attached growth process for BOD removal only (assume the Biostyr® process) to achieve an effluent BOD concentration of 20 mg/L or less. Assume a media depth of 2 m and maximum surface area of 100 m^2 for the Biostyr® process. Determine (a) the reactor volume and number of Biostyr® units, and (b) the area requirements of a plastic tower trickling filter and secondary clarifier to treat the same wastewater. Compare the area requirements for the two processes. Assume a plastic packing depth of 6.1 m, a packing treatability coefficient of 0.21 $(L/s)^{0.5}/m^2$, and 20°C.

Design wastewater characteristics:

Parameter	Unit	Value
COD	mg/L	400
Flow	m^3/d	A (15,000)
		B (18,000)
		C (20,000)
BOD	mg/L	160
TSS	mg/L	80
Temperature	°C	18

Note. Value A, B, or C to be selected by instructor

9–16 A secondary effluent has the following characteristics:

Parameter	Unit	Value
Flowrate	m^3/d	5000
TSS	mg/L	15
NO_3-N	mg/L	30
Temperature	°C	18

Design a downflow denitrification filter with a sand media depth of 1.6 m to reduce the NO_3-N to an effluent concentration of 4.0, 2.0, or 1.0 mg/L (value to be determined by instructor). Determine the following:

1. Denitrification filter media volume; m^3
2. Filter hydraulic application rate, $m^3/m^2 \cdot d$
3. Number of filters and filter dimensions, assuming square tanks with a maximum dimension of 10 m by 10 m
4. Methanol dose in mg/L and kg/d
5. Amount of solids produced, kg/d

PROBLEMS AND DISCUSSION TOPICS 1027

REFERENCES 1031

Anaerobic treatment processes include anaerobic suspended growth, upflow and downflow anaerobic attached growth, fluidized-bed attached growth, upflow anaerobic sludge blanket (UASB), anaerobic lagoons, and membrane separation anaerobic processes. Anaerobic suspended growth processes associated with biological phosphorus removal are discussed in Chap. 8. The anaerobic digestion of sludge is presented in Chap. 14. The purpose of this chapter is to present process designs for other anaerobic treatment processes used to remove organic material from liquid streams. The various types of processes are described along with their typical design loadings and treatment process capabilities. Before considering the individual anaerobic treatment processes, it will be helpful to consider the rationale for the use of anaerobic treatment processes.

10–1 THE RATIONALE FOR ANAEROBIC TREATMENT

The rationale for and interest in the use of anaerobic treatment processes can be explained by considering the advantages and disadvantages of these processes. The principal advantages and disadvantages of anaerobic treatment are listed in Table 10–1 and are discussed below.

Advantages of Anaerobic Treatment Processes

Of the advantages cited in Table 10–1, energy considerations, lower biomass yield, fewer nutrients required, and higher volumetric loadings are examined further in the following discussion.

Energy Considerations. Anaerobic processes may be net energy producers instead of energy users, as is the case for aerobic processes. An energy balance comparison for a high-strength wastewater at 20°C is presented in Table 10–2. For the con-

Table 10–1
Advantages and disadvantages of anaerobic processes compared to aerobic processes

Advantages	• Less energy required
	• Less biological sludge production
	• Fewer nutrients required
	• Methane production, a potential energy source
	• Smaller reactor volume required
	• Elimination of off-gas air pollution
	• Rapid response to substrate addition after long periods without feeding
Disadvantages	• Longer start-up time to develop necessary biomass inventory
	• May require alkalinity addition
	• May require further treatment with an aerobic treatment process to meet discharge requirements
	• Biological nitrogen and phosphorus removal is not possible
	• Much more sensitive to the adverse effect of lower temperatures on reaction rates
	• May be more susceptible to upsets due to toxic substances
	• Potential for production of odors and corrosive gases

Table 10–2
Comparison of energy balance for aerobic and anaerobic processes for the treatment of a wastewater with the following characteristics: wastewater flowrate = 100 m^3/d; wastewater strength = 10 kg/m^3; and temperature = 20°C

Energy	Value, kJ/d	
	Anaerobic	Aerobic
Aeration[a,b]		-1.9×10^6
Methane produced[c,d]	12.5×10^6	
Increase wastewater temperature to 30°C	-2.1×10^6	
Net energy, kJ/d	10.4×10^6	-1.9×10^6

[a] Oxygen required = 0.8 kg/kg COD removed.
[b] Aeration efficiency = 1.52 kg O_2/kWh and 3600 kJ = 1 kWh.
[c] Methane production = 0.35 m^3/kg COD removed.
[d] Energy content of methane = 35 846 kJ/m^3 (at 0°C and 1 atm).

ditions given in Table 10–2, the aerobic process requires 1.9×10^6 kJ/d. On the other hand, the anaerobic process produces a total of 12.5×10^6 kJ/d. Of the total energy produced anaerobically, about 2.1×10^6 kJ/d is required to raise the temperature of the wastewater from 20 to 30°C, the low end of the mesophilic temperature range, a more desirable temperature for anaerobic treatment. Thus, the potential net energy production that can be achieved with anaerobic treatment is on the order of 10.4×10^6 kJ/d, or about 5 times the energy required for aerobic treatment.

The wastewater strength is important for comparing energy balances for aerobic and anaerobic processes, where the wastewater temperature must be increased. With the same assumptions used to generate the energy balance presented in Table 10–2, both the aerobic and anaerobic processes would require the same amount of energy input if the wastewater biodegradable COD concentration is 1270 mg/L. At lower COD concentrations, the aerobic process requires less energy. However, heat recovery from the anaerobic effluent stream can modify these values. Further, the lower biomass yield discussed below is still a major advantage offered by anaerobic treatment.

Lower Biomass Yield. Because the energetics of anaerobic processes result in lower biomass production by a factor of about 6 to 8 times, sludge processing and disposal costs are reduced greatly. The major environmental and economic issues associated with the reuse and disposal of biomass produced from aerobic processes are discussed in Chap. 14. The fact that less sludge is produced in anaerobic treatment is a significant advantage over aerobic treatment.

Fewer Nutrients Required. Many industrial wastewaters lack sufficient nutrients to support aerobic growth. The cost for nutrient addition is much less for anaerobic processes because less biomass is produced.

Higher Volumetric Loadings. Anaerobic processes generally have higher volumetric organic loads than aerobic processes, so smaller reactor volumes and less space may be required for treatment. Organic loading rates of 3.2 to 32 kg COD/m^3·d may be

used for anaerobic processes, compared to 0.5 to 3.2 kg COD/m^3·d for aerobic processes (Speece, 1996).

Disadvantages of Anaerobic Treatment Processes

Potential disadvantages also exist for anaerobic processes as reported in Table 10–1. Operational considerations, the need for alkalinity addition, and the need for further treatment are highlighted further in the following discussion.

Operational Considerations. The major concerns with anaerobic processes are their longer start-up time (months for anaerobic versus days for aerobic processes), their sensitivity to possible toxic compounds, operational stability, the potential for odor production, and corrosiveness of the digester gas. However, with proper wastewater characterization and process design these problems can be avoided and/or managed.

Need for Alkalinity Addition. The most significant negative factor that can affect the economics of anaerobic versus aerobic treatment is the possible need to add alkalinity. Alkalinity concentrations of 2000 to 3000 mg/L as $CaCO_3$ may be needed in anaerobic processes to maintain an acceptable pH with the high gas phase CO_2 concentration. If this amount of alkalinity is not available in the influent wastewater or cannot be produced by the degradation of proteins and amino acid, a significant cost may be incurred to purchase alkalinity, which can affect the overall economics of the process.

Need for Further Treatment. Anaerobic processes can also be followed by aerobic processes for effluent polishing to utilize the benefits of both processes. Series reactors of anaerobic-aerobic processes have been shown feasible for treating municipal wastewaters in warmer climates resulting in lower energy requirements and less sludge production (Goncalves and Avaujo, 1999; Garuti et al., 1992).

Summary Assessment

In general, for municipal wastewaters with lower concentrations of biodegradable COD, lower temperatures, higher effluent quality needs, and nutrient removal requirements, aerobic processes are favored at present. For industrial wastewaters with much higher biodegradable COD concentrations and elevated temperatures, anaerobic processes may be more economical. In the future, as more is learned about anaerobic treatment processes, it is anticipated that their use will become more widespread in a variety of applications.

10–2 GENERAL DESIGN CONSIDERATIONS FOR ANAEROBIC TREATMENT PROCESSES

The type of wastewater and its characteristics are important in the evaluation and design of anaerobic processes. The characteristics presented here apply to the suspended growth, sludge blanket, attached growth, and membrane separation anaerobic processes presented in subsequent sections. Important factors and wastewater characteristics that need to be considered in the evaluation of anaerobic processes for wastewater treatment are discussed below.

Table 10–3
Examples of types of wastewater treated by anaerobic processes

Alcohol distillation	Landfill leachate
Breweries	Pharmaceuticals
Chemical manufacturing	Pulp and paper
Dairy and cheese processing	Slaughterhouse and meatpacking
Domestic wastewater	Soft drink beverages
Fish and seafood processing	Sugar processing

Characteristics of the Wastewater

A wide variety of wastewaters have been treated by anaerobic processes including those reported in Table 10–3. Anaerobic processes are attractive, especially for high strength and warm temperature wastewaters because: (1) aeration is not required, thus saving energy cost, and (2) the low amount of solids generated. Food processing and distillery wastewaters, for example, can have COD concentrations ranging from 3000 to 30,000 mg/L. Other considerations that may apply to different wastewater sources are the presence of potential toxic streams, flow variations, inorganic concentrations, and seasonal load variations. Anaerobic processes are capable of responding quickly to wastewater feed after long periods without substrate addition. In some cases with warmer climates, anaerobic treatment has also been considered for municipal wastewater treatment.

Flow and Loading Variations. Wide variations in influent flow and organic loads can upset the balance between acid fermentation and methanogenesis in anaerobic processes. For soluble, easily degradable substrates, such as sugars and soluble starches, the acidogenic reactions can be much faster at high loadings and may increase the reactor volatile fatty acids (VFA) and hydrogen concentrations and depress the pH. Higher hydrogen concentrations can inhibit propionic and butyric acid conversion. The lower pH can inhibit methanogenesis. Flow equalization or additional capacity must be provided to meet peak flow and loading conditions.

Organic Concentration and Temperature. As discussed in Sec. 10–1, the wastewater strength and temperature greatly affect the economics and feasibility of anaerobic treatment. Reactor temperatures of 25 to 35°C are generally preferred to support more optimal biological reaction rates and to provide more stable treatment. Generally, COD concentrations greater than 1500 to 2000 mg/L are needed to produce sufficient quantities of methane to heat the wastewater without an external fuel source. At 1300 mg/L COD or less, aerobic treatment may be the preferred selection.

Anaerobic treatment can be applied at lower temperatures and has been sustained at 10 to 20°C in suspended and attached growth reactors. At the lower temperatures, slower reaction rates occur and longer SRTs, larger reactor volumes, and lower organic COD loadings are needed (Banik and Dague, 1996; Collins et al., 1998). Further, at temperatures in the range from 10 to 20°C, the degradation of long chain fatty acids is often rate limiting. If long chain fatty acids accumulate, foaming may occur in the reactor. When higher SRTs are needed, the solids loss in an anaerobic reactor can become a critical limiting factor. Anaerobic reactors generally produce more dispersed, less flocculent solids than aerobic systems, with effluent TSS concentrations for suspended

growth processes in the 100 to 200 mg/L range. For dilute wastewaters, the effluent TSS concentration will limit the possible SRT of the process and treatment potential. Either a lower treatment performance occurs or it is necessary to operate the reactor at a higher temperature. Thus, the method used to retain solids in the anaerobic reactor is important in the overall process design and performance.

Fraction of Nondissolved Organic Material. The composition of the wastewater in terms of its particulate and soluble fractions affects the type of anaerobic reactor selected and its design. Wastewaters with high solids concentrations are treated more appropriately in suspended growth reactors than by upflow or downflow attached growth processes. Where greater conversion of particulate organic matter is required, longer SRT values may be needed if solids hydrolysis is the rate-limiting step as compared to acid fermentation or methanogenesis in anaerobic treatment.

Wastewater Alkalinity. With the high CO_2 content (typically in the range from 30 to 50 percent) in the gas produced in anaerobic treatment, alkalinity concentrations in the range from 2000 to 4000 mg/L as $CaCO_3$ are typically required to maintain the pH at or near neutral. The level of alkalinity needed is seldom available in the influent wastewater, but may be generated in some cases by the degradation of protein and amino acids (e.g., meatpacking wastewaters). The requirement to purchase chemicals for pH control can have a significant impact on the economics of anaerobic treatment.

The relationship between pH and alkalinity as outlined in Appendix F is controlled by the bicarbonate chemistry as follows:

$$\frac{[HCO_3^-][H^+]}{[H_2CO_3]} = K_{a1} \qquad (10\text{–}1)$$

where K_{a1} = first acid dissociation constant, which is a function of ionic strength and temperature

The carbonic acid (H_2CO_3) concentration is determined using Henry's law [Eq. (2–46)] and the partial pressure of the CO_2 in the atmosphere above the water.

$$x_g = \frac{P_T}{H} p_g \qquad (2\text{–}46)$$

where x_g = mole fraction of gas in water, mole gas/mole water

$$= \frac{\text{mole gas } (n_g)}{\text{mole gas } (n_g) + \text{mole water } (n_w)}$$

P_T = total pressure, usually 1.0 atm

H = Henry's law constant, $\dfrac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}$

p_g = mole fraction of gas in air, mole gas /mole of air

Once the carbonic acid concentration is known, the bicarbonate (HCO_3^-) alkalinity needed to maintain the required pH can be estimated. The use of the above equations is illustrated in Example 10–1.

EXAMPLE 10–1 pH and Alkalinity in an Anaerobic Process Determine the alkalinity required in kg $CaCO_3$/d to maintain a pH value of 7.0 in an anaerobic suspended growth process at 35°C, with a 30 percent CO_2 content in the gas above the water. The influent wastewater flowrate is 2000 m^3/d, the alkalinity is 400 mg/L as $CaCO_3$, and no alkalinity producing substances are present. At 35°C, Henry's constant for CO_2, computed using Eq. (2-48) and the data given in Table 2–8, is 2092 atm and the value of K_{a1} is 4.85×10^{-7} mole/L (see Table F–2 in Appendix F).

Solution

1. Determine the concentration of HCO_3^- required to maintain the pH at or near a value of 7.0.
   a. Determine the concentration of H_2CO_3 using Eq. (2–47).

$$x_{H_2CO_3} = \frac{P_g}{H} = \frac{(1 \text{ atm})(0.30)}{2092 \text{ atm}} = 1.434 \times 10^{-4}$$

Because 1 liter of water contains 55.6 mole [1000 g/(18 g/mole)], the mole fraction of H_2CO_3 is equal to

$$x_{H_2CO_3} = \frac{\text{mole gas } (n_g)}{\text{mole gas } (n_g) + \text{mole water } (n_w)}$$

$$1.434 \times 10^{-4} = \frac{[H_2CO_3]}{[H_2CO_3] + [55.6 \text{ mole/L}]}$$

Because the number of moles of dissolved gas in a liter of water is much less than the number of moles of water,

$$[H_2CO_3] \approx (1.434 \times 10^{-4})[55.6 \text{ mole/L}] \approx 7.97 \times 10^{-3} \text{ mole/L}$$

   b. Determine the concentration of HCO_3^- required to maintain the pH at or near a value of 7.0 using Eq. (10–1).

$$[HCO_3^-] = \frac{[4.85 \times 10^{-7} \text{ mole/L}][7.97 \times 10^{-3} \text{ mole/L}]}{[10^{-7} \text{ mole/L}]}$$

$$= 0.0387 \text{ mole/L}$$

$$HCO_3^- = (0.0387 \text{ mole/L})(61 \text{ g/mole})(10^3 \text{ mg/g}) = 2361 \text{ mg/L}$$

2. Determine the amount of alkalinity required per day.

$$\text{Equivalents of } HCO_3^- = \frac{(2.361 \text{ g/L})}{(61 \text{ g/eq})} = 0.0387 \text{ eq/L}$$

$$1 \text{ eq } CaCO_3 = \frac{\text{mw}}{2} = \frac{(100 \text{ g/mole})}{2} = 50 \text{ g } CaCO_3\text{/eq}$$

$$\text{Alkalinity as } CaCO_3 = (0.0387 \text{ eq/L})(50 \text{ g/eq})(10^3 \text{ mg/g})$$

$$= 1925 \text{ mg/L as } CaCO_3$$

$$\text{Alkalinity needed} = (1935 - 400)\ \text{mg/L}$$
$$= 1535\ \text{mg/L as } CaCO_3$$
$$\text{Daily alkalinity addition} = (1535\ \text{g/m}^3)(2000\ \text{m}^3\text{/d})(1\ \text{kg}/10^3\ \text{g})$$
$$= 3070\ \text{kg/d}$$

Comment Based on the results of the above analysis, it is clear that a large quantity of alkalinity may be required and, as a consequence, a significant cost can be incurred. Because the addition of lime for alkalinity can lead to the formation of precipitates, the preferred form of alkalinity to be added is sodium bicarbonate.

The results of similar calculations to those presented in Example 10–1 for different temperatures and gas phase CO_2 concentrations are reported in Table 10–4. The data presented in Table 10–4 were derived using the carbonate equilibrium constants given in Table 6–16 in Chap. 6 and Henry's constants derived from the data given in Table 2–8 in Chap. 2. The values presented in Table 10–4 can be used to estimate the alkalinity requirements. For wastewaters with a higher total dissolved solids concentration and ionic strength, the alkalinity requirements will generally be much greater.

Nutrients. Though anaerobic processes produce less sludge and thus require less nitrogen and phosphorus for biomass growth, many industrial wastewaters may lack sufficient nutrients. Thus, the addition of nitrogen and/or phosphorus may be needed. Depending on the characteristics of the substrate and the SRT value, typical nutrient requirements for nitrogen, phosphorus, and sulfur are in the range from 10 to 13, 2 to 2.6, and 1 to 2 mg per 100 mg of biomass, respectively. The values for nitrogen and phosphorus are consistent with the values for these constituents estimated on the basis of the composition of the cell biomass (see Sec. 8–3 in Chap. 8). Further, to maintain maximum methanogenic activity, liquid phase concentrations of nitrogen, phosphorus, and sulfur on the order of 50, 10, and 5 mg/L, respectively are desirable (Speece, 1996).

Macronutrients. The importance of trace metals to stimulate methanogenic activity has been noted and discussed by Speece (1996). The recommended requirements for iron, cobalt, nickel, and zinc are 0.02, 0.004, 0.003, and 0.02 mg/g acetate produced,

Table 10–4 Estimated minimum alkalinity as $CaCO_3$ required to maintain a pH of 7.0 as a function of temperature and percent carbon dioxide during anaerobic digestion

Temperature, °C	Gas phase CO_2, %			
	25	30	35	40
20	900	1050	1200	1400
25	1100	1300	1500	1700
30	1300	1600	1800	2100
35	1500	1800	2100	2400
40	1700	2100	2400	2800

respectively. Examples of increased anaerobic activity were noted after trace additions of iron, nickel, or cobalt. The exact amounts of trace nutrients needed can vary for different wastewaters, and thus trial approaches are used to assess their benefit for anaerobic processes with high VFA concentrations. A recommended dose of trace metals per liter of reactor volume is 1.0 mg $FeCl_2$, 0.1 mg $CoCl_2$, 0.1 mg $NiCl_2$, and 0.1 $ZnCl_2$.

Inorganic and Organic Toxic Compounds. Proper analysis and treatability studies are needed to assure that a chronic toxicity does not exist for wastewater treated by anaerobic processes. At the same time, the presence of a toxic substance does not mean the process cannot function. Some toxic compounds inhibit anaerobic methanogenic reaction rates, but with a high biomass inventory and low enough loading, the process can be sustained. Toxic and inhibitory inorganic and organic compounds of concern for anaerobic processes are presented in Tables 10–5 and 10–6, respectively.

Acclimatization to toxic concentrations has also been shown (Speece, 1996). Pretreatment steps may be used to remove the toxic constituents, and, in some cases, phase separation can prevent toxicity problems by providing for degradation of the toxic constituents in the acid phase, before exposure of the more sensitive methanogenic bacteria to the toxic constituents (Lettinga and Hulshoff Pol, 1991).

Solids Retention Time

The solids retention time is a fundamental design and operating parameter for all anaerobic processes. In general, SRT values greater than 20 d are needed for anaerobic processes at 30°C for effective treatment performance, with much higher SRT values at lower temperatures.

Table 10–5
Toxic and inhibitory inorganic compounds of concern for anaerobic processes[a]

Substance	Moderately inhibitory concentration, mg/L	Strongly inhibitory concentration, mg/L
Na^+	3500–5500	8,000
K^+	2500–4500	12,000
Ca^{2+}	2500–4500	8,000
Mg^{2+}	1000–1500	3,000
Ammonia-nitrogen NH_4^+	1500–3000	3,000
Sulfide, S^{2-}	200	200
Copper, Cu^{2-}		0.5 (soluble)
		50–70 (total)
Chromium, Cr(VI)		3.0 (soluble)
		200–250 (total)
Chromium, Cr(III)		180–420 (total)
		2.0 (soluble)
Nickel, Ni^{2+}		30.0 (total)
Zinc, Zn^{2-}		1.0 (soluble)

[a]From Parkin and Owen (1986).

Table 10–6
Toxic and inhibitory organic compounds of concern for anaerobic processes[a]

Compound	Concentration resulting in 50 percent reduction in activity, mM[b]

[b] mM = millimole.

Expected Methane Gas Production

Higher-strength wastewaters will produce a greater amount of methane per volume of liquid treated to provide a relatively higher amount of energy to raise the liquid temperature, if needed. As derived in Sec. 7–12 in Chap. 7, the amount of methane (CH_4) produced per unit of COD converted under anaerobic conditions is equal to 0.35 L CH_4/g COD at standard conditions (0°C and 1 atm). The quantity of methane at other than standard conditions is determined by using the universal gas law [Eq. (2–44)] to determine the volume of gas occupied by one mole of CH_4 at the temperature in question.

$$V = \frac{nRT}{P} \tag{2-44}$$

where V = volume occupied by the gas, L
n = moles of gas, mole

R = universal gas law constant, 0.082057 atm·L/mole·K
T = temperature, K (273.15 + °C)
P = absolute pressure, atm

Thus, at 35°C, the volume occupied by one mole of CH_4 is

$$V = \frac{(1 \text{ mole})(0.082057 \text{ atm·L/mole·K})[(273.15 + 35)\text{K}]}{1.0 \text{ atm}} = 25.29 \text{ L}$$

Because the COD of one mole of CH_4 is equal to 64 g, the amount of CH_4 produced per unit of COD converted under anaerobic conditions at 35°C is equal to 0.40 L as determined below.

$(25.29 \text{ L})/(64 \text{ g COD/mole } CH_4) = 0.40 \text{ L } CH_4/\text{g COD}$

If the composition of the waste is known, and neglecting the amount of the constituent used for cell synthesis, the following relationship, first proposed by Buswell and Boruff (1932) and subsequently extended by Sykes (2000), can be used to estimate the amount of methane (CH_4), carbon dioxide (CO_2), ammonia (NH_3), and hydrogen sulfide (H_2S) that will be produced under anaerobic conditions.

$$C_vH_wO_xN_yS_z + \left(v - \frac{w}{4} + \frac{x}{2} + \frac{3y}{4} + \frac{z}{2}\right)H_2O \rightarrow$$

$$\left(\frac{v}{2} + \frac{w}{8} + \frac{x}{4} + \frac{3y}{8} + \frac{z}{4}\right)CH_4 + \left(\frac{v}{2} - \frac{w}{8} + \frac{x}{4} + \frac{3y}{8} + \frac{z}{4}\right)CO_2 + yNH_3 + zH_2S \quad (10\text{–}2)$$

The gaseous ammonia (NH_3) that is formed will react with the carbon dioxide to form the ammonium ion and bicarbonate according to the following relationship.

$$NH_3 + H_2O + CO_2 \rightarrow NH_4^+ + HCO_3^- \quad (10\text{–}3)$$

The reaction given by Eq. (10–3) is representative of the formation of alkalinity under anaerobic conditions, due to the conversion of organic compounds containing proteins (i.e., nitrogen). The expected mole fractions of methane, carbon dioxide, and hydrogen sulfide are given by the following three expressions, respectively. In general, the mole fraction of hydrogen sulfide will be somewhat less because of metal complexation/precipitation.

$$f_{CO_2} = \frac{4v - w + 2x - 5y + 2z}{8(v - y + z)} \quad (10\text{–}4)$$

$$f_{CH_4} = \frac{4v + w - 2x - 5y - 2z}{8(v - y + z)} \quad (10\text{–}5)$$

$$f_{H_2S} = \frac{z}{8(v - y + z)} \quad (10\text{–}6)$$

As noted previously, the percentage of carbon dioxide in the gas can be as high as 50 percent. For carbohydrate and starch wastes, alkalinity will be a problem.

Treatment Efficiency Needed

Anaerobic treatment processes are capable of high COD conversion efficiency to methane with minimal biomass production. At SRT values greater than 20 to 50 d, maximum conversion of solids may occur at temperatures above 25°C. However, high-effluent suspended solids (50 to 200 mg/L) are common for anaerobic processes. Without pilot-plant studies and extreme measures to control effluent suspended solids concentrations, such as chemical flocculation or membrane separation, anaerobic processes alone cannot be depended on to achieve secondary treatment levels. Some form of aerobic treatment would be necessary to provide effluent polishing, either attached growth or suspended growth processes. For high-strength wastewaters the combination of anaerobic and aerobic treatment can be economical (Obayashi et al., 1981).

Sulfide Production

Oxidized sulfur compounds, such as sulfate, sulfite, and thiosulfate, may be present in significant concentrations in various industrial wastewaters and to some degree in municipal wastewaters. These compounds can serve as electron acceptors for sulfate-reducing bacteria, which consume organic compounds in the anaerobic reactor and produce hydrogen sulfide (H_2S). For example, using methanol as the electron donor and an f_s value of 0.05 (see Sec. 7 4 in Chap. 7), the overall reaction for the reduction of sulfate to H_2S can be illustrated by the following expression:

$$0.119SO_4^{2-} + 0.167CH_3OH + 0.010CO_2 + 0.003NH_4^+ + 0.003HCO_3^- + 0.178H^+ = 0.003C_5H_7NO_2 + 0.060H_2S + 0.060HS^- + 0.331H_2O \quad (10\text{–}7)$$

From Eq. (10–7), the amount of COD used for sulfate reduction is 0.89 g COD/g sulfate, which is in the range of 0.67 g COD/g sulfate reduced as reported by Arceivala (1998). The higher value is due to the lower biomass yield coefficient associated with methanol oxidation. Based on the following stoichiometry for H_2S oxidation, 2 moles of oxygen are required per mole of H_2S, as was the case for methane oxidation,

$$H_2S + 2O_2 \rightarrow H_2SO_4 \quad (10\text{–}8)$$

Thus, the amount of H_2S produced per unit COD is the same as that for methane (0.40 L H_2S/g COD used at 35°C).

Hydrogen sulfide is malodorous and corrosive to metals. Combustion products formed from sulfur oxidation are considered air pollutants. In contrast to methane, H_2S is highly soluble in water, with a solubility of 2650 mg/L at 35°C, for example.

The concentration of oxidized sulfur compounds in the influent wastewater to an anaerobic treatment process is important, as high concentrations can have a negative effect on anaerobic treatment. Sulfate-reducing bacteria compete with the methanogenic bacteria for COD and thus can decrease the amount of methane gas production. While low concentrations of sulfide (less than 20 mg/L) are needed for optimal methanogenic activity, higher concentrations can be toxic (Speece, 1996). Methanogenic activity has been decreased by 50 percent or more at H_2S concentrations ranging from 50 to 250 mg/L (Arceivala, 1998). A comprehensive evaluation of the dynamics of competition between sulfate-reducing and methanogenic bacteria and toxicity effects is given in Maillacheruvu et al. (1993).

Because un-ionized H_2S is considered more toxic than ionized sulfide, pH is important in determining H_2S toxicity. The degree of H_2S toxicity is also complicated by the type of anaerobic biomass present (granular versus dispersed), the particular methanogenic population, and the feed COD/SO_4 ratio. With higher COD concentrations, more methane gas is produced to dilute the H_2S and transfer more H_2S to the gas phase. Hydrogen sulfide exists in aqueous solution as either the hydrogen sulfide gas (H_2S), the ion (HS^-), or the sulfide ion (S^{2-}), depending on the pH of the solution, in accordance with the following equilibrium reactions:

$$H_2S \leftrightarrow HS^- + H^+ \tag{10–9}$$

$$HS^- \leftrightarrow S^{2-} + H^+ \tag{10–10}$$

Applying the law of mass action to Eqs. (10–9) to (10–10) yields

$$\frac{[HS^-][H^+]}{[H_2S]} = K_{a1} \quad \text{and} \quad \frac{[S^{2-}][H^+]}{[HS^-]} = K_{a2} \tag{10–11}$$

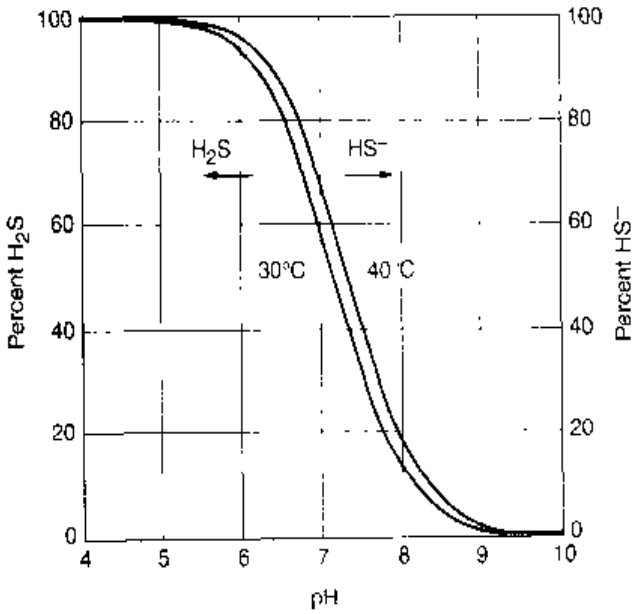
where K_{a1} = first acid dissociation constant at 25°C, 1×10^{-7} mole/L
K_{a2} = second acid dissociation constant 25°C, $\sim 10^{-19}$ mole/L (value uncertain)

The percentage H_2S as a function of the pH can be determined using the following relationship:

$$H_2S, \% = \frac{[H_2S] \times 100}{[H_2S] + [HS^-]} = \frac{100}{1 + [HS^-]/[H_2S]} = \frac{100}{1 + K_{a1}/[H^+]} \tag{10–12}$$

Dissociation constants for hydrogen sulfide as a function of temperature are presented in Table 10–7, along with values for ammonia. As illustrated on Fig. 10–1, at a pH value of 7, at 30°C, about 60 percent of the total H_2S is present as gaseous H_2S.

Ammonia Toxicity



Ammonia toxicity may be of concern for anaerobic treatment of wastewaters containing high concentrations of ammonium or proteins and/or amino acids, which can be degraded to produce ammonium. Free ammonia (NH_3), at high enough concentrations, is considered toxic to methanogenic bacteria. As described in Chap. 2, ammonia is a weak acid and dissociates in water to form ammonium (NH_4^+) and hydroxyl ions. The

Table 10–7
Acid equilibrium constants for hydrogen sulfide (H_2S) and ammonia (NH_3)

Temperature, °C	$K_{a1,H_2S} \times 10^7$, mole/L	$K_{a,NH_3} \times 10^{10}$, mole/L
0	0.262	7.28
10	0.485	6.37
20	0.862	5.84
25	1.000	5.62
30	1.48	5.49
40	2.44	5.37

Figure 10-1

Percent of hydrogen sulfide present as H_2S and HS^- as a function of pH.

amount of free ammonia is a function of temperature and pH. Dissociation constants for NH_3 as a function of temperature are given in Table 10–7. At a pH of 7.5 and at 30 to 35°C, 2 to 4 percent of the ammonium present will be as free ammonia (Speece, 1996). The toxicity threshold for ammonia has been reported to be 100 mg/L as NH_3-N (McCarty and McKinney, 1961), but with acclimatization time, higher concentrations may be tolerated. In batch tests, Lay et al. (1998) found a steady inhibition of methanogenic activity as the NH_3-N concentration was increased from 50 to 500 mg/L, with 500 mg/L being the apparent toxicity threshold level.

In stating the toxicity as total ammonium concentration, McCarty (1964) reported a toxicity concentration range of 1500 to 3000 mg/L as NH_4-N at pH above 7.4, with 3000 mg/L being toxic at any pH. However, after long-term acclimatization, much higher NH_4-N concentrations without toxicity have been observed. Moen (2000) found no inhibition effects for both thermophilic and mesophilic digestion of municipal sludge with NH_4-N concentrations ranging from 1900 to 2400 mg/L. Others (van Velsen, 1977; Parkin and Miller, 1982) have reported no effect of ammonia toxicity with long-term acclimatized cultures at NH_4-N concentrations in the range of 5000 to 8000 mg/L.

Liquid-Solids Separation

Efficient liquid-solids separation can enhance the performance of anaerobic treatment processes. Because of the low solids synthesis yield coefficient associated with anaerobic treatment, most of the solids wasting is via the treated effluent flow, and thus the degree of solids capture affects the SRT value that can be maintained. Good solids capture improves the effluent quality in terms of TSS concentration, and can also result in a longer SRT in the anaerobic reactor to increase the level of COD conversion.

10–3 ANAEROBIC SUSPENDED GROWTH PROCESSES

Early applications of anaerobic treatment of industrial wastewaters were suspended growth processes, which were initially designed in a similar manner as anaerobic sludge digesters. Three types of anaerobic suspended growth treatment processes are

illustrated on Fig. 10–2: (1) the complete-mix suspended growth anaerobic digester, (2) the anaerobic contact process, and (3) the anaerobic sequencing batch reactor, a more recent suspended growth reactor design development. Each of these processes is described below along with general design considerations for suspended growth processes.

Complete-Mix Process

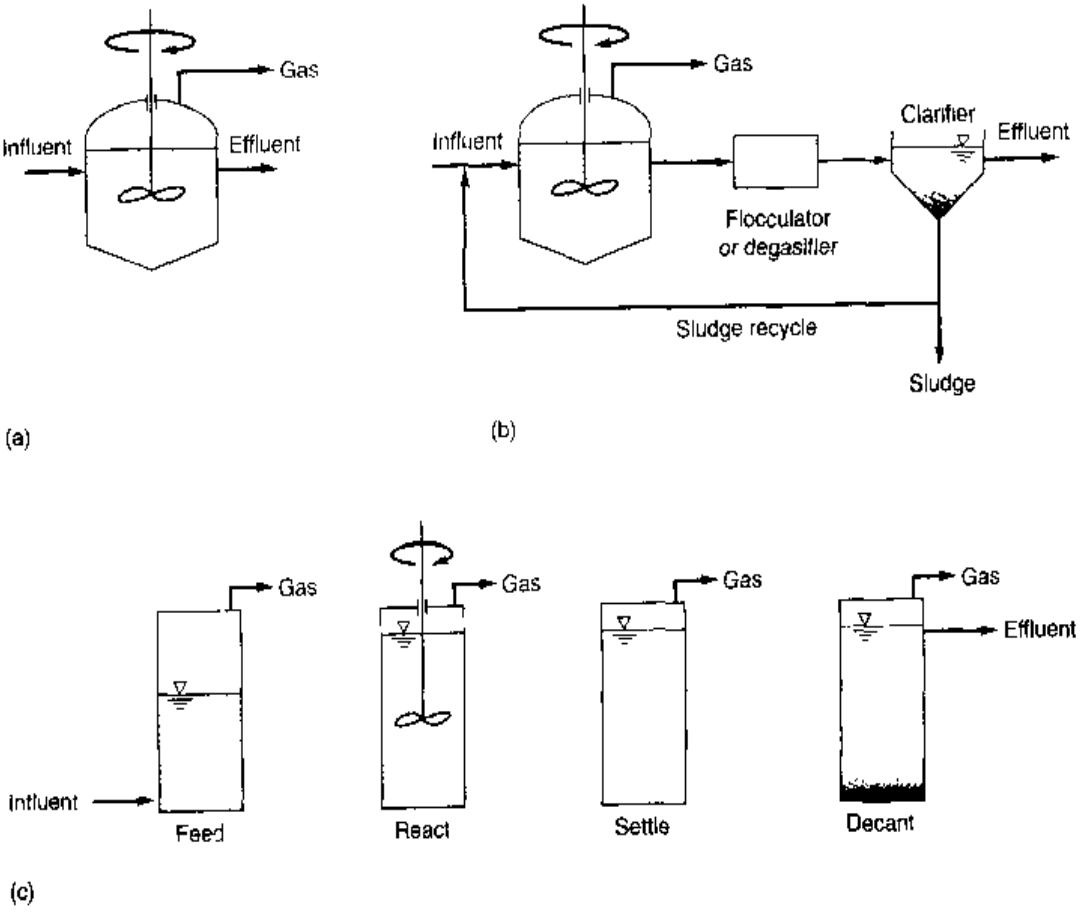
For the complete-mix anaerobic digester (see Fig. 10–2*a*) the hydraulic retention and solids retention times are equal (τ = SRT). The reactor τ may be in the range of 15 to 30 d to provide sufficient safety factors for operation and process stability (Parkin and Owen, 1986). The complete-mix digester without sludge recycle is more suitable for wastes with high concentrations of solids or extremely high dissolved organic concentrations, where thickening the effluent solids is difficult so that it is more practical to operate with τ equal to the SRT. As in anaerobic digestion (see Chap. 14), various methods of mixing may be used to utilize the reactor volume more fully. Typical organic loading rates for the complete-mix process are presented in Table 10–8, along with comparative values for the anaerobic contact and anaerobic sequence reactor processes. Examples of typical pilot plants used to assess the feasibility of anaerobic digestion for specific organic wastes are shown on Fig. 10–3.

Anaerobic Contact Process

The anaerobic contact process (see Fig. 10–2*b*) overcomes the disadvantages of a complete-mix process without recycle. Biomass is separated and returned to the

Figure 10–2

Anaerobic suspended growth treatment processes: (*a*) complete-mix suspended growth anaerobic digester, (*b*) anaerobic contact process, and (*c*) anaerobic sequencing batch reactor (ASBR).



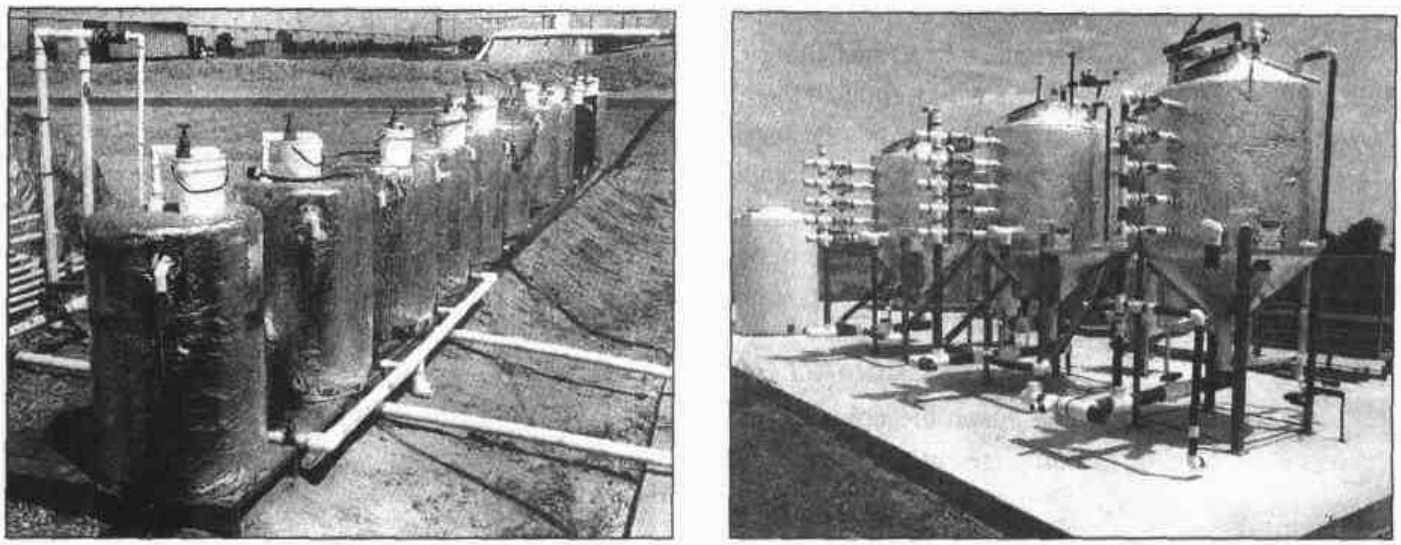


Table 10-8
Typical organic loading rates for anaerobic suspended growth processes at 30°C

Process	Volumetric organic loading, kg COD/m³·d	Hydraulic retention time τ, d
Complete-mix	1.0–5.0	15–30
Anaerobic contact	1.0–8.0	0.5–5
Anaerobic sequence batch reactor	1.2–2.4	0.25–0.50

Note: kg/m³·d × 62.4280 = lb/10³ ft³·d.

(a) (b)

Figure 10-3
View of typical pilot plants used to assess the feasibility of the anaerobic complete-mix treatment process: (a) pilot-scale anaerobic reactors at a food-processing facility and (b) pilot-scale anaerobic reactors (under construction) to be used to assess the treatability of animal wastes.

complete-mix or contact reactor so that the process SRT is longer than τ. By separating τ and SRT values, the anaerobic reactor volume can be reduced. Gravity separation is the most common approach for solids separation and thickening prior to sludge recycle; however, a sludge with poor settling properties is commonly produced and alternative separation processes must be used or other methods must be employed to improve solids capture. Separation of solids using gas flotation by dissolving the process off-gas under pressure has been used in place of gravity separation.

Because the reactor sludge contains gas produced in the anaerobic process and gas production can continue in the separation process, solids-liquid separation can be inefficient and unpredictable. Various methods have been used to minimize the effect of trapped gas bubbles in the sludge-settling step. These include gas stripping by agitation or vacuum degasification, inclined-plate separators, and the use of coagulant chemicals

(Malina and Pohland, 1992). Clarifier hydraulic application rates range from 0.5 to 1.0 m/h. Practical reactor MLVSS concentrations are 4000 to 8000 mg/L (Malina and Pohland, 1992). Volumetric organic loadings that are used for anaerobic contact process are presented in Table 10–8.

Anaerobic Sequencing Batch Reactor

The anaerobic sequencing batch reactor (ASBR) process (see Fig. 10–2*c*) can be considered a suspended growth process with reaction and solids-liquid separation in the same vessel, much like that for aerobic sequencing batch reactors (SBRs) (see Chap. 8). The success of the ASBR depends on the development of a good settling granulated sludge as found in the upflow anaerobic sludge blanket (UASB) processes (Speece, 1996). The operation of ASBRs consists of four steps: (1) feed, (2) react, (3) settle, and (4) decant/effluent withdrawal. During the react period, intermittent mixing for a few minutes each hour is done to provide uniform distribution of substrates and solids (Sung and Dague, 1995). The feasibility of the process was demonstrated in laboratory reactors at temperatures from 5 to 25°C treating a nonfat dry milk synthetic substrate with a 600 mg/L feed COD concentration (Banik and Dague, 1996). The organic loading of the process was changed by selecting hydraulic retention times from 6.0 to 24 h. At 25°C, 92 to 98 percent COD removal was achieved at volumetric organic loadings of 1.2 to 2.4 kg COD/m^3·d. At 5°C, COD removal ranged from 85 to 75 percent for COD loadings from 0.9 to 2.4 kg/m^3·d, respectively.

A critical feature of the ASBR process is the settling velocity of the sludge during the settle period before decanting the effluent. Settling times used are about 30 min. Just before settling, at the end of the react period, organic removal and gas production rates are lower to provide better conditions for solids settling. After sufficient operating time, a dense granulated sludge was developed that improved liquid-solids separation rates. Effluent TSS concentrations ranged from 50 to 100 mg/L over the range of test conditions. Effluent TSS concentrations were higher at lower temperatures. At τ values from 6 to 24 h, the SRT ranged from 50 to 200 d, respectively.

Design of Anaerobic Suspended Growth Processes

Anaerobic suspended growth processes may be designed in a manner similar to completely mixed aerobic activated-sludge processes, because the hydraulic regime and biomass concentration can be reasonably defined. The design procedure is summarized in Table 10–9.

These same design considerations must be used for other anaerobic treatment processes, with the main difference being the need to rely on observed organic loadings to size the reactor volume.

A summary of kinetic coefficients and design values from Chap. 7 is provided in Table 10–10. For temperatures below 25°C, the anaerobic process design is best developed from laboratory treatability studies or pilot-plant test results. A temperature correction value of 1.08 as proposed by Banik and Dague (1996) may be used to develop a preliminary sizing for the treatability studies. The design of an anaerobic suspended growth contact process is presented in Example 10–2.

Table 10-9
Summary of design procedure for anaerobic suspended growth process

Item	Description
1.	Select an SRT to achieve a given effluent concentration and percent COD removal
2.	Determine the daily solids production and mass of solids in the system to maintain the desired SRT
3.	Select the expected solids concentration in the reactor and determine the reactor volume
4.	Determine the gas production rate
5.	Determine the amount of excess sludge wasted and the nutrient needs
6.	Check the volumetric organic loading rate
7.	Determine alkalinity needs

Table 10-10
Summary of design parameters for completely mixed suspended growth reactors treating soluble COD

Parameter	Unit	Value	
		Range	Typical
Solids yield, Y			
Fermentation	g VSS/g COD	0.06–0.12	0.10
Methanogenesis	g VSS/g COD	0.02–0.06	0.04
Overall combined	g VSS/g COD	0.05–0.10	0.08
Decay coefficient, k_d			
Fermentation	g/g·d	0.02–0.06	0.04
Methanogenesis	g/g·d	0.01–0.04	0.02
Overall combined	g/g·d	0.02–0.04	0.03
Maximum specific growth rate, μ_m			
35°C	g/g·d	0.30–0.38	0.35
30°C	g/g·d	0.22–0.28	0.25
25°C	g/g·d	0.18–0.24	0.20
Half-velocity constant, K_S			
35°C	mg/L	60–200	160
30°C	mg/L	300–500	360
25°C	mg/L	800–1100	900
Methane			
Production at 35°C	m^3/kg COD	0.4	0.4
Density at 35°C	kg/m^3	0.6346	0.6346
Content of gas	%	60–70	65
Energy content	kJ/g	50.1	50.1

Note: $m^3/kg \times 16.0185 = ft^3/lb$.
$kg/m^3 \times 62.4280 = lb/10^3\ ft^3$.

EXAMPLE 10–2 Suspended Growth Anaerobic Contact Reactor Process Determine the reactor sizing, the gas production rate, the energy available, the solids production rate, and the alkalinity and nutrient requirements for an anaerobic contact process (see Fig. 10–2*b*) treating the following wastewater to achieve 90 percent COD removal.

Wastewater characteristics

Item	Unit	Value
Flowrate	m^3/d	300
COD	g/m^3	6000
Soluble COD	g/m^3	4000
COD/TSS ratio	g/g	1.8
Degradable fraction of TSS	%	80
Nitrogen	g/m^3	10
Phosphorus	g/m^3	20
Alkalinity	g $CaCO_3/m^3$	500
Temperature	°C	25

Design parameters and assumptions:

1. Effluent TSS concentration = 150 g/m^3
2. Factor of safety for design SRT = 1.5
3. VSS/TSS = 0.85 (from Chap. 7)
4. f_d = 0.15 g VSS cell debris /g VSS biomass decay
5. Use kinetic coefficients from Table 10–10
6. Nutrient requirements based on VSS: N = 12% and P = 2.4%
7. At SRT > 40 d, degradable TSS is transformed
8. MLSS = 6000 g/m^3
9. Settling rate = 24 m/d
10. Gas composition = 65% CH_4 and 35% CO_2

Solution

1. Determine design SRT at 25°C.
   At 90 percent COD removal the effluent COD is

   = (1.0 − 0.90) (6000 g/m^3) = 600 g/m^3

   The assumed effluent TSS concentration equals 150 g/m^3.

   Effluent COD from TSS = (150 mg/L) 1.8 g COD/g TSS = 270 g/m^3

   Allowable effluent soluble COD = (600 − 270) g/m^3 = 330 g/m^3

   Rearrange Eq. (7–39) and substitute μ_m for Yk to determine the SRT:

$$\text{SRT} = \left(\frac{\mu_m S_e}{K_s + S_e} - k_d\right)^{-1}$$

From Table 10–10 the kinetic coefficients are:

$\mu_m = 0.20$ g/g·d

$K_S = 900$ mg/L

$k_d = 0.03$ g/g·d

$$\text{SRT} = \left[\frac{(0.20 \text{ g/g·d})(330 \text{ g/m}^3)}{[(900 + 330) \text{ g/m}^3]} - 0.03 \text{ g/g·d}\right]^{-1}$$

SRT = 42.3 d

The design SRT with a factor of safety of 1.5 is:

Design SRT = 1.5(42.3) = 63.4 d ≈ 63 d

2. Determine sludge production.

Calculate nondegraded TSS concentration.

At SRT values greater than 40 d, degradable TSS is transformed.

Nonsoluble COD = (6000 − 4000) g/m^3

= 2000 g/m^3

Determine the nonsoluble COD as TSS using 1.8 g COD/g TSS (given).

Nonsoluble COD as TSS = (2000 g/m^3 COD)/(1.8 g COD/g TSS)

= 1111 g/m^3 TSS

Degradable fraction of TSS = 0.8(given)

Nondegraded TSS = 0.20(1111) = 222 g/m^3 TSS

Use Eq. (8–16) to determine solids production:

$$P_{X,\text{TSS}} = \frac{QY(S_o - S)}{[1 + (k_d)\text{SRT}](0.85)} + \frac{f_d(k_d)QY(S_o - S)\text{SRT}}{[1 + (k_d)\text{SRT}](0.85)} + Q \text{ (nondegradable TSS)}$$

$S_o - S$ = COD degraded = Influent COD − nondegradable TSS COD − effluent soluble degradable COD

= 6000 g COD/m^3 − [(222 g/m^3 TSS)(1.8 g COD/g TSS)] − 330 g/m^3

= (6000 − 400 − 330) g/m^3

= 5270 g/m^3 COD

Using the following coefficients from Table 10–10 and the given value for f_d, solve for $P_{X,\text{TSS}}$

$Y = 0.08$ g VSS/g COD

$k_d = 0.03$ g/g·d

$$P_{X,TSS} = \frac{(300 \text{ m}^3/\text{d})(0.08 \text{ g VSS/g COD})(5270 \text{ g COD/m}^3)}{[1 + (0.03 \text{ g/g·d})(63 \text{ d})](0.85)}$$

$$+ \frac{0.15 \text{ g/g}(0.03 \text{ g/g·d})(300 \text{ m}^3/\text{d})(0.08 \text{ g/g})(5270 \text{ g/m}^3)(63 \text{ d})}{[1 + (0.03 \text{ g/g·d})(63 \text{ d})](0.85)}$$

$$+ 300 \text{ m}^3/\text{d}\ (222 \text{ g/m}^3)$$

$$= 51{,}488 \text{ g/d} + 14{,}597 \text{ g/d} + 66{,}600 \text{ g/d}$$

$$P_{X,TSS} = 132{,}685 \text{ g/d}$$

3. Determine reactor volume and τ.
   a. Determine the volume using Eq. (7–55).

$$\text{Volume} = \frac{(P_{X,TSS})(\text{SRT})}{X_{TSS}}$$

For $X_{TSS} = 6000$ g/m^3 (given), the volume is:

$$\text{Volume} = \frac{(132{,}685 \text{ g/d})(63 \text{ d})}{(6000 \text{ g/m}^3)} = 1393 \text{ m}^3$$

   b. Determine the hydraulic detention time τ.

$$\tau = \frac{V}{Q} = \frac{1393 \text{ m}^3}{(300 \text{ m}^3/\text{d})} = 4.64 \text{ d}$$

4. Determine the methane and total gas production rate and energy content.
   a. Methane gas production rate
   From Table 10–10 methane volume at 35°C = 0.4 m^3 CH_4/kg COD

   At 25°C, CH_4 the volume of methane is

$$= (0.4)\frac{(273.15 + 25)}{(273.15 + 35)} = 0.39 \text{ m}^3/\text{kg COD}$$

   Total CH_4 production rate = (0.39 m^3/kg)(5270 g COD/m^3)(300 m^3/d)/
   (1 kg/10^3 g)

$$= 616.6 \text{ m}^3/\text{d}$$

   b. Total gas production rate

$$\text{Gas production} = \frac{(616.6 \text{ m}^3 \text{ CH}_4/\text{d})}{(0.65 \text{ m}^3 \text{ CH}_4/\text{m}^3 \text{ gas})} = 948.6 \text{ m}^3/\text{d}$$

c. Energy content of gas

At 25°C, the volume occupied by one mole of gas is

$$V = \frac{(1 \text{ mole})(0.082057 \text{ atm·L/mole·K})[(273.15 + 25)\text{K}]}{1.0 \text{ atm}} = 24.5 \text{ L}$$

The total moles of methane produced per day

$$\text{Mole } CH_4/\text{d} = \frac{(616.6 \text{ m}^3/\text{d})}{(24.5 \text{ L/mole})(1 \text{ m}^3/10^3 \text{ L})} = 25{,}167 \text{ mole/d}$$

Mass of methane = (25,167 mole CH_4/d)(16 g CH_4/mole) = 4.03×10^5 g/d

Energy content = $(4.03 \times 10^5$ g/d)(50.1 kJ/g) = 20.2×10^6 kJ/d

5. Determine nutrient requirements.

Biomass production = first two terms in $P_{X,TSS}$ calculation given in step 2.

= 51,488 g/d + 14,597 g/d

= 66,085 g/d

For N = 12% and P = 2.4% of VSS, the nutrient requirements are:

N required = (66,085 g/d)(0.12 g/g)(0.85) = 6741 g/d

P required = (66,085 g/g)(0.024 g/g)(0.85) = 1348 g/d

Influent nutrients:

N = (10 g/m^3) (300 m^3/d) = 3000 g/d

P = (20 g/m^3) (300 m^3/d) = 6000 g/d

There is sufficient phosphorus in the influent, but nitrogen must be added.

N addition = (6741 − 3000) g/d

= 3741 g/d

= 3.74 kg/d

6. Determine alkalinity requirement.

From Table 10–4, the minimum alkalinity needed at 35% CO_2 = 1500 mg/L as $CaCO_3$

Alkalinity addition = 1500 mg/L − 500 mg/L = 1000 mg/L as $CaCO_3$

$$\text{As } NaHCO_3 = \frac{(84 \text{ g } NaHCO_3/\text{eq})(10^3 \text{ g/m}^3)}{(50 \text{ g/eq } CaCO_3)}$$

$$= 1680 \text{ g } NaHCO_3/\text{m}^3$$

$NaHCO_3$/d = (1680 g/m^3) (300 m^3/d) (1 kg/10^3 g) = 504 kg/d

7. Determine clarifier diameter.
(Assume degasifier used before clarifier)

$$\text{Area} = \frac{(Q, \text{m}^3/\text{d})}{(\text{settling rate, m/d})} = \frac{300 \text{ m}^3}{(24 \text{ m/d})} = 12.5 \text{ m}^2$$

Diameter = 4 m

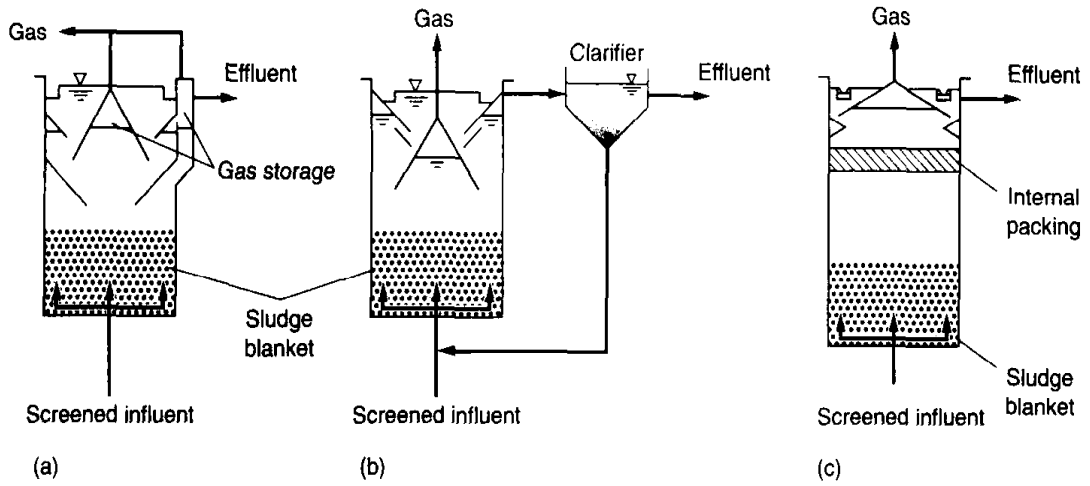
Comments Considerable energy (i.e., 20.2×10^6 kJ/d) is generated by the production of methane (CH_4). The methane could be used to heat the anaerobic reactor, which would provide more rapid degradation and thus reduce the anaerobic bioreactor size.

10–4 ANAEROBIC SLUDGE BLANKET PROCESSES

One of the most notable developments in anaerobic treatment process technology was the upflow anaerobic sludge blanket (UASB) reactor in the late 1970s in the Netherlands by Lettinga and his coworkers (Lettinga and Vinken, 1980; Lettinga et al., 1980). The principal types of anaerobic sludge blanket processes include (1) the original UASB process and modification of the original design, (2) the anaerobic baffled reactor (ABR), and (3) the anaerobic migrating blanket reactor (AMBR®). The ABR process was developed by McCarty and coworkers at Stanford University in the early 1980s (Bachmann et al., 1985). Work in the late 1990s at Iowa State University has led to the development of the AMBR process (Angenent et al., 2000). Of these sludge blanket processes, the UASB process is used most commonly, with over 500 installations treating a wide range of industrial wastewaters. A number of pilot studies have been done with the ABR, with a limited number of full-scale installations (Orozco, 1988). In this section all three types of anaerobic sludge blanket processes are described along with their performance, demonstrated process loadings, and key design considerations. The major emphasis is, however, on the UASB process.

Upflow Sludge Blanket Reactor Process

The basic UASB reactor is illustrated on Fig. 10–4*a*. As shown on Fig. 10–4*a*, influent wastewater is distributed at the bottom of the UASB reactor and travels in an upflow mode through the sludge blanket. Critical elements of the UASB reactor design are the influent distribution system, the gas-solids separator, and the effluent withdrawal design. Modifications to the basic UASB design include adding a settling tank (see Fig. 10–4*b*) or the use of packing material at the top of the reactor (see Fig. 10–4*c*). Both modifications are intended to provide better solids capture in the system and to prevent the loss of large amounts of the UASB reactor solids due to process upsets or changes in the UASB sludge blanket characteristics and density. The use of an external solids capture system to prevent major losses of the system biomass is recommended strongly by Speece (1996). A view of a sludge blanket fixed-film reactor installation is shown on Fig. 10–5.



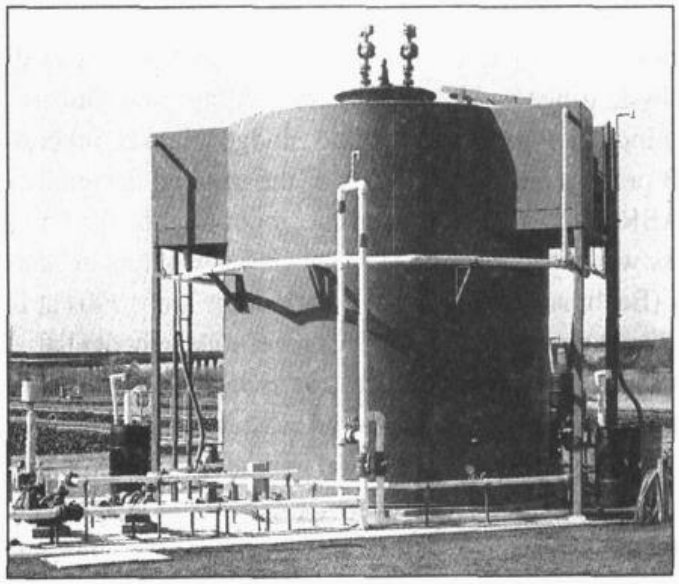


Figure 10–4

Schematic of the UASB process and some modifications: (*a*) original UASB process, (*b*) UASB reactor with sedimentation tank and sludge recycle, and (*c*) UASB reactor with internal packing for fixed-film attached growth, placed above the sludge blanket.

Figure 10–5

View of UASB reactor equipped with internal packing above the sludge blanket. The exterior physical appearance of a UASB reactor without and with internal packing is the same (see Fig. 10–4*c* for location of internal packing).

The key feature of the UASB process that allows the use of high volumetric COD loadings compared to other anaerobic processes is the development of a dense granulated sludge. Because of the granulated sludge floc formation, the solids concentration can range from 50 to 100 g/L at the bottom of the reactor and 5 to 40 g/L in a more diffuse zone at the top of the UASB sludge blanket. The granulated sludge particles have a size range of 1.0 to 3.0 mm and result in excellent sludge-thickening properties with SVI values less than 20 mL/g. Several months may be required to develop the granulated sludge, and seed is often supplied from other facilities to accelerate the system startup. Variations in morphology were observed for anaerobic granulated sludge developed at 30 and 20°C, but both exhibited similar floc size and settling properties (Soto et al., 1997).

The development of granulated sludge solids is affected by the wastewater characteristics. Granulation is very successful with high carbohydrate or sugar wastewaters,

but less so with wastewaters high in protein, resulting in a more fluffy floc instead (Thaveesri et al., 1994). Other factors affecting the development of granulated solids are pH, upflow velocity, and nutrient addition (Annachhatre, 1996). The pH should be maintained near 7.0, and a recommended COD:N:P ratio during startup is 300:5:1, while a lower ratio can be used during steady-state operation at 600:5:1. Control of the upflow velocity is recommended during startup by having it high enough to wash out nonflocculent sludge.

The presence of other suspended solids in the sludge blanket can also inhibit the density and formation of granulated sludge (Lettinga and Hulshoff Pol, 1991). An explanation of the fundamental metabolic conditions associated with granular sludge formation is provided by Speece (1996) based on work by Palns et al. (1987, 1990). The explanation is as follows. The formation of dense granulated sludge floc particles is favored under conditions of near neutral pH, a plug-flow hydraulic regime, a zone of high hydrogen partial pressure, a nonlimiting supply of NH_4-N, and a limited amount of the amino acid cysteine. With a high hydrogen concentration and sufficient NH_4-N, the bacteria responsible for granulation may produce other amino acids, but their synthesis is limited by the cysteine supply. Some of the excess amino acids that are produced are thought to be secreted to form extracellular polypeptides which, in turn, will bind organisms together to form the dense pellets or floc granules.

Design Considerations for UASB Process

A comprehensive review of design considerations for UASB reactors has been provided by Lettinga and Hulshoff Pol (1991). Important design considerations are (1) wastewater characteristics in terms of composition and solids content, (2) volumetric organic load, (3) upflow velocity, (4) reactor volume, (5) physical features including the influent distribution system, and (6) gas collection system.

Wastewater Characteristics. Wastewaters that contain substances that can adversely affect the sludge granulation, cause foaming, or cause scum formation are of concern. Wastewaters with higher concentrations of proteins and/or fats tend to create more of the above problems. The fraction of particulate versus soluble COD is important in determining the design loadings for UASB reactors as well as determining the applicability of the process. As the fraction of solids in the wastewater increases, the ability to form a dense granulated sludge decreases. At a certain solids concentration (greater than 6 g TSS/L) anaerobic digestion and anaerobic contact processes may be more appropriate.

Volumetric Organic Loadings. Typical COD loadings as a function of the wastewater strength, fraction of particulate COD in the wastewater, and TSS concentrations in the effluent are summarized in Table 10–11. Removal efficiencies of 90 to 95 percent for COD have been achieved at COD loadings ranging from 12 to 20 kg COD/m^3·d on a variety of wastes at 30 to 35°C with UASB reactors. Values for τ for high-strength wastewater have been as low as 4 to 8 h at these loadings. Where less than 90 percent COD removal and higher-effluent TSS concentrations are acceptable, higher upflow velocities can be used, which will develop a more dense granulated sludge by flushing out other solids. Thus, the higher volumetric COD loadings are shown for this condition.

Table 10-11
Recommended volumetric COD loading for UASB reactors at 30°C to achieve 85 to 95 percent COD removal[a]

Wastewater COD, mg/L	Fraction as particulate COD	Volumetric loading, kg COD/m³·d		
		Flocculent sludge	Granular sludge with high TSS removal	Granular sludge with little TSS removal
1000–2000	0.10–0.30	2–4	2–4	8–12
	0.30–0.60	2–4	2–4	8–14
	0.60–1.00	na	na	na
2000–6000	0.10–0.30	3–5	3–5	12–18
	0.30–0.60	4–8	2–6	12–24
	0.60–1.00	4–8	2–6	na
6000–9000	0.10–0.30	4–6	4–6	15–20
	0.30–0.60	5–7	3–7	15–24
	0.60–1.00	6–8	3–8	na
9000–18,000	0.10–0.30	5–8	4–6	15–24
	0.30–0.60	na	3–7	na
	0.60–1.00	na	3–7	na

[a]Adapted from Lettinga and Hulshoff Pol (1991).
Note: kg/m³·d × 62.4280 = lb/10³ ft³·d.

Recommended loadings as a function of temperature for wastewaters with mainly soluble COD are presented in Table 10–12. These loadings apply to the sludge blanket volume, and a reactor effectiveness factor of 0.8 to 0.9 as discussed below is used to determine the reactor liquid below the gas collector. The higher loading recommendation for the wastewater containing mainly volatile fatty acids (VFA) is based on the potential of obtaining a more dense granulated sludge. Design τ values are also given for the treatment of domestic wastewater in Table 10–13 based on pilot-plant experience. The τ value needed is longer than that used in aerobic processes for secondary treatment for BOD removal. In addition, an aerobic polishing step would likely be needed. The economic benefits of energy savings and lower sludge production would have to be sufficient to justify the higher capital costs for liquid treatment with a UASB process.

Upflow Velocity. The upflow velocity, based on the flowrate and reactor area, is a critical design parameter. Recommended design velocities are shown in Table 10–14. Temporary peak superficial velocities of 6 m/h and 2 m/h can be allowed for soluble and partially soluble wastewaters, respectively. For weaker wastewaters the allowable velocity and reactor height will determine the UASB reactor volume, and for stronger

Table 10–12
Recommended volumetric organic loadings as a function of temperature for soluble COD substrates for 85 to 95 percent COD removal. Average sludge concentration is 25 g/L[a]

	Volumetric loading, kg sCOD/m³·d			
	VFA wastewater		Non-VFA wastewater	
Temperature, °C	Range	Typical	Range	Typical
15	2–4	3	2–3	2
20	4–6	5	2–4	3
25	6–12	6	4–8	4
30	10–18	12	8–12	10
35	15–24	18	12–18	14
40	20–32	25	15–24	18

Table 10–14
Upflow velocities and reactor heights recommended for UASB reactors[a]

	Upflow velocity, m/h		Reactor height, m	
Wastewater type	Range	Typical	Range	Typical
COD nearly 100% soluble	1.0–3.0	1.5	6–10	8
COD partially soluble	1.0–1.25	1.0	3–7	6
Domestic wastewater	0.8–1.0	0.7	3–5	5

[a] Adapted from Lettinga and Hulshoff Pol (1991).
Note: m × 3.2808 = ft.
m/h × 3.2808 = ft/h.

wastewaters it will be determined by the volumetric COD loading. The upflow velocity is equal to the feed rate divided by the reactor cross-section area:

$$v = \frac{Q}{A} \tag{10–13}$$

where v = design upflow superficial velocity, m/h
A = reactor cross-section area, m^2
Q = influent flowrate, m^3/h

Reactor Volume and Dimensions. To determine the required reactor volume and dimensions, the organic loading, superficial velocity, and effective treatment volume must all be considered. The effective treatment volume is that volume occupied by the sludge blanket and active biomass. An additional volume exists between the effective volume and the gas collection unit where some additional solids separation occurs and the biomass is dilute. The nominal liquid volume of the reactor based on using an acceptable organic loading is given by

$$V_n = \frac{QS_o}{L_{org}} \tag{10–14}$$

where V_n = nominal (effective) liquid volume of reactor, m^3
Q = influent flowrate, m^3/h
S_o = influent COD, kg COD/m^3
L_{org} = organic loading rate, kg COD/$m^3 \cdot d$

To determine the total liquid volume below the gas collectors, an effectiveness factor is used, which is the fraction occupied by the sludge blanket. Taking into account the effectiveness factor, which may vary from 0.8 to 0.9, the required total liquid volume of the reactor exclusive of the gas storage area is given by

$$V_L = \frac{V_n}{E} \tag{10–15}$$

where V_L = total liquid volume of reactor, m^3
V_n = nominal liquid volume of reactor, m^3
E = effectiveness factor, unitless

Rearranging Eq. (10–13), the area of the reactor is

$$A = \frac{Q}{v} \tag{10–16}$$

The liquid height of the reactor is determined using the following relationship:

$$H_L = \frac{V_L}{A} \tag{10–17}$$

where H_L = reactor height based on liquid volume, m
V_L = total liquid reactor volume, m^3
A = cross-sectional area, m^2

The gas collection volume is in addition to the reactor volume and adds an additional height of 2.5 to 3 m. Thus, the total height of the reactor is

$$H_T = H_L + H_G \tag{10–18}$$

where H_T = total reactor height, m
H_L = reactor height based on liquid volume, m
H_G = reactor height to accommodate gas collection and storage, m

Physical Features. The main physical features requiring careful consideration are the feed inlet, gas separation, gas collection, and effluent withdrawal. The inlet and gas separation designs are unique to the UASB reactor. The feed inlet must be designed

to provide uniform distribution and to avoid channeling or the formation of dead zones. The avoidance of channeling is more critical for weaker wastewaters, as there would be less gas production to help mix the sludge blanket. A number of inlet feed pipes are used to direct flow to different areas of the bottom of the UASB reactor from a common feed source. Access must be provided to clean the pipes in the event of clogging. Guidelines for determining the area served by the individual inlet feed pipes as a function of the sludge characteristics and organic loading are provided in Table 10–15.

Gas Collection and Solid Separation. The gas solids separator (GSS) is designed to collect the biogas, prevent washout of solids, encourage separation of gas and solid particles, allow for solids to slide back into the sludge blanket zone, and help improve effluent solids removal. A series of upside-down V-shaped baffles is used next to effluent weirs to accomplish the above objectives. Guidelines for the GSS design are summarized in Table 10–16.

Table 10–15
Guidelines for sizing the area served by inlet feed pipes for UASB reactor[a]

Sludge type	COD loading, $kg/m^3 \cdot d$	Area per feed inlet, m^2
Dense flocculent sludge, >40 kg TSS/m^3	<1.0	0.5–1
	1–2	1–2
	>2	2–3
Medium flocculent sludge, 20–40 kg TSS/m^3	<1–2	1–2
	>3	2–5
Granular sludge	1–2	0.5–1
	2–4	0.5–2
	>4	>2

[a] Adapted from Lettinga and Hulshoff Pol (1991).
Note: $kg/m^3 \cdot d \times 62.4280 = lb/10^3\ ft^3 \cdot d$.

Table 10–16
Recommended design considerations for the gas solids separator for UASB reactors[a]

- The slope of the settler bottom, i.e., the inclined wall of the gas collector, should be between 45 and 60°
- The surface area of the apertures between the gas collectors should not be smaller than 15 to 20 percent of the total reactor surface area
- The height of the gas collector should be between 1.5 and 2 m at reactor heights of 5–7 m
- A liquid-gas interface should be maintained in the gas collector to facilitate the release and collection of gas bubbles and to control scum layer formation
- The overlap of the baffles installed beneath the apertures should be 100 to 200 mm to avoid upward-flowing gas bubbles entering the settler compartment
- Generally scum layer baffles should be installed in front of the effluent weirs
- The diameter of the gas exhaust pipes should be sufficient to guarantee the easy removal of the biogas from the gas collection cap, particularly in the case where foaming occurs
- In the upper part of the gas cap, antifoam spray nozzles should be installed in the case where the treatment of the wastewater is accompanied by heavy foaming

[a] Adapted from Malina and Pohland (1992).

Advantages for the UASB process are the high loadings and relatively low detention times possible for anaerobic treatment and the elimination of the cost of packing material. Another major advantage is that the UASB process is, as noted previously, a proven process with more than 500 full-scale facilities in operation. Limitations of the process are related to those wastewaters that are high in solids content or where their nature prevents the development of the dense granulated sludge. The process design for the UASB process is illustrated in Example 10–3.

EXAMPLE 10–3 UASB Treatment Process Design For a UASB treatment process treating an industrial wastewater, determine the (1) size and dimensions of the reactor, (2) detention time, (3) reactor SRT, (4) average VSS concentration in biomass zone of the reactor, (5) methane gas production, (6) energy available from methane production, and (7) alkalinity requirements for a wastewater with the characteristics given below to achieve greater than 90 percent soluble COD removal. The wastewater is mainly soluble, containing carbohydrate compounds, and a granular sludge is expected. Assume 50 percent of the influent pCOD and VSS is degraded, 90 percent of the influent sulfate is reduced biologically, and the effluent VSS concentration is 150 g/m^3. Assume the design parameters given below and the typical values given in Tables 10–10 and 10–12 are applicable.

Wastewater characteristics

Item	Unit	Value
Flowrate	m^3/d	1000
COD	g/m^3	2300
sCOD	g/m^3	2000
TSS	g/m^3	200
VSS	g/m^3	150
Alkalinity	g/m^3 as $CaCO_3$	500
SO_4	g/m^3	200
Temperature	°C	30

Design parameters and assumptions:

1. From Table 10–10,

   Y = 0.08 g VSS/g COD

   k_d = 0.03 g VSS/g VSS·d

   μ_m = 0.25 g VSS/g VSS·d
2. f_d = 0.15 g VSS cell debris/g VSS biomass decay
3. Methane production at 35°C = 0.40 L CH_4/g COD
4. Reactor volume effectiveness factor = 85 percent
5. Height for gas collection = 2.5 m

Solution

1. Determine the reactor volume based on the design organic loading and the use of Eq. (10–14).
   a. From Table 10–12 select the average organic loading of 10 kg sCOD/m^3·d.

$$V_n = \frac{QS_o}{L_{org}} = \frac{(1000\ \text{m}^3/\text{d})(2\ \text{kg sCOD/m}^3)}{(10\ \text{kg sCOD/m}^3\cdot\text{d})}$$

$$V_n = 200\ \text{m}^3$$

   b. Determine the total reactor liquid volume using Eq. (10–15).

$$V_L = \frac{V_n}{E} = \frac{200\ \text{m}^3}{0.85} = 235\ \text{m}^3$$

2. Determine the reactor dimensions.
   a. First determine the reactor cross-sectional area using Eq. (10–16) based on the design superficial velocity. Use the upflow velocity data given in Table 10–14. Because the wastewater is highly soluble, select a velocity of 1.5 m/h.

$$A = \frac{Q}{v} = \frac{(1000\ \text{m}^3/\text{d})}{(1.5\ \text{m/h})(24\ \text{h/d})} = 27.8\ \text{m}^2$$

$$A = \frac{\pi D^2}{4} = 27.8\ \text{m}^2 \qquad D = 6\ \text{m}$$

   b. Determine the reactor liquid height using Eq. (10–17).

$$H_L = \frac{V_L}{A} = \frac{235\ \text{m}^3}{27.8\ \text{m}^2} = 8.4\ \text{m}$$

   c. Determine the total height of the reactor using Eq. (10–18).

$$H_T = H_L + H_G = 8.4\ \text{m} + 2.5\ \text{m} = 10.9\ \text{m}$$

   d. Reactor dimensions.

   Diameter = 6 m

   Height = 10.9 m

3. Determine the reactor hydraulic detention time τ.

$$\tau = \frac{V_L}{Q} = \frac{(235\ \text{m}^3)(24\ \text{h/d})}{(1000\ \text{m}^3/\text{d})} = 5.64\ \text{h}$$

4. Determine the reactor SRT.
   a. The value of the SRT can be estimated by assuming that all the wasted biological solids are in the effluent flow. A conservative design approach is to assume that the given effluent VSS concentration consists of biomass. Thus, the following relationship applies:

$$QX_e = P_{X,VSS} = \text{solids wasted per day}$$

Both Q and X_e are known. The value of $P_{X,VSS}$ is given by Eq. (7–52):

$$P_{X,VSS} = \frac{Q(Y)(S_o - S)}{1 + (k_d)SRT} + \frac{f_d(k_d)Q(Y)(S_o - S)SRT}{1 + (k_d)SRT} + Q(nbVSS) - QX_e$$

b. Develop the data needed to solve the above equation.

i. The effluent soluble COD concentration at 90% COD removal is

$$S = (1.0 - 0.9)(2000\ g/m^3) = 200\ g/m^3$$

ii. The effluent nbVSS concentration given that 50 percent of the influent VSS is degraded is:

$$nbVSS = 0.50(150\ g/m^3) = 75\ g/m^3$$

iii. The pCOD degraded is

$$pCOD\ degraded = 0.50(2300 - 2000)\ g/m^3 = 150\ g/m^3$$

iv. Total degradable influent COD, S_o

$$S_o = (2000 + 150)\ g/m^3 = 2150\ g/m^3$$

c. Substitute the given parameter values and solve the expression given above for SRT.

$$QX_e = (1000\ m^3/d)(150\ g/m^3)$$

$$= \frac{(1000\ m^3/d)(0.08\ g\ VSS/g\ COD)[(2150 - 200)g/m^3]}{[1 + (0.03\ g\ VSS/g\ VSS{\cdot}d)SRT]}$$

$$+ \frac{(0.15\ g\ VSS/g\ VSS)(0.03\ g\ VSS/g\ VSS{\cdot}d)(1000\ m^3/d)(0.08\ g\ VSS/gCOD)[(2150 - 200)g/m^3]SRT}{[1 + (0.03\ g\ VSS/g\ VSS{\cdot}d)SRT]}$$

$$+ (1000\ m^3/d)(75\ g/m^3)$$

$$150{,}000\ g/d = 156{,}144{,}000/[1 + (0.03)\ SRT] + 702{,}648\ SRT/$$

$$[1 + (0.03)\ SRT] + 75{,}000\ g/d$$

$$SRT = 52\ d$$

5. Estimate the effluent soluble COD at an SRT of 52 d at 30°C using Eq. (7–40) and the given coefficients.

$$S = \frac{K_s[1 + (k_d)SRT]}{SRT(Yk - k_d) - 1}$$

$$k = \frac{\mu_m}{Y} = \frac{(0.25\ g\ VSS/g\ VSS{\cdot}d)}{(0.08\ g\ VSS/g\ COD)} = 3.125\ g\ COD/g\ VSS{\cdot}d$$

$$S = \frac{(360\ mg/L)[1 + (0.03\ g/g{\cdot}d)\ 52\ d]}{[(52\ d)[(0.08\ g/g)(3.125\ g/g{\cdot}d) - (0.03\ g/g{\cdot}d)] - 1]}$$

$$S = 88.3\ mg/L$$

6. Determine if the computed SRT value is adequate.

$$\text{The fraction of the influent sCOD in effluent} = \frac{(88.3\ \text{mg/L})}{(2000\ \text{mg/L})} = 0.044 = 4.4\%\text{S}$$

Because 4.4 percent is less than 10 percent (specified in problem statement), the process SRT is adequate.

7. Determine the average X_{TSS} concentration in biomass zone of the reactor.
   a. The value of the X_{TSS} can be estimated by using Eq. (7–35) developed previously in Chap. 7 for the SRT.

$$\text{SRT} = \frac{V(X_{TSS})}{(Q - Q_w)X_e + Q_w X_R}$$

Because it was assumed that all the wasted solids are in the effluent flow, the term $Q_w = 0$ and the value of X_{TSS} can be estimated as follows:

$$\text{SRT} \approx \frac{VX_{TSS}}{QX_e} \qquad \text{and} \qquad X_{TSS} \approx \frac{QX_e\text{SRT}}{V}$$

   b. Solve for the value of X_{TSS}, with the volume V equal to the effective volume, V_n.

$$X_{TSS} \approx \frac{(1000\ \text{m}^3/\text{d})(150\ \text{g/m}^3)(52\ \text{d})(1\ \text{kg}/10^3\ \text{g})}{200\ \text{m}^3} = 39.0\ \text{kg/m}^3$$

The computed value is within the range of solids concentration values given earlier for the UASB process.

8. Determine the methane gas production and energy produced.
   a. Determine the COD degraded.

$$\text{COD} = (2150 - 200)\ \text{g/m}^3 = 1950\ \text{g/m}^3$$

   b. Determine the COD removed with sulfate as the electron acceptor.
   From Sec. 10–3, 0.67 g COD removed/g SO_4 reduced

$$\text{COD}_{SR} = 0.90(200\ \text{g SO}_4/\text{m}^3)(0.67\ \text{g COD/g SO}_4) = 120.6\ \text{g/m}^3$$

   c. Determine the COD used by methanogenic bacteria.

$$\text{COD}_{MB} = (1950 - 120.6)\ \text{g/m}^3(1000\ \text{m}^3/\text{d}) = 1{,}829{,}400\ \text{g/d}$$

   d. Determine the methane production rate.

$$\text{Methane production at 30°C} = (0.40\ \text{L/g})\left(\frac{273.15 + 30}{273.15 + 35}\right) = 0.3935\ \text{L/g}$$

$$\begin{aligned}\text{Amount of CH}_4\text{ produced/d} &= 0.3935\ \text{L/g}\ (1{,}829{,}400\ \text{g COD/d}) \\ &= 719{,}869\ \text{L/d} \\ &= 719.9\ \text{m}^3/\text{d}\end{aligned}$$

Total gas volume produced (use 65% methane per Table 10–10)
$= (719.9\ \text{m}^3/\text{d})/(0.65) = 1107.5\ \text{m}^3/\text{d}$

9. Determine energy produced from methane.
To determine the energy produced, determine the density of methane at 30°C and use the factor of 50.1 kJ/g methane (Table 10–10).
   a. Determine density.

   Density at 35°C = 0.6346 g/L (Table 10–10)

   $$\text{Methane density at } 30°\text{C} = (0.6346 \text{ g/L})\left(\frac{273.15 + 35}{273.15 + 30}\right) = 0.6451 \text{ g/L}$$

   b. Determine energy produced.

   $$\text{Energy produced} = (719{,}869 \text{ L } CH_4/\text{d})(0.6451 \text{ g/L})(50.1 \text{ kJ/g})$$
   $$= 23.3 \times 10^6 \text{ kJ/d}$$

10. Determine the alkalinity requirements.
From Table 10–9, the estimated alkalinity concentration required at 30°C and 35% CO_2 in the gas phase is 1800 mg/L. Because the alkalinity in the influent is 500 mg/L, the amount of alkalinity that has to be added is

    $$\text{Alkalinity required} = (1800 - 500) \text{ mg/L as } CaCO_3 = 1300 \text{ mg/L as } CaCO_3$$

    $$\text{Daily addition} = (1300 \text{ g/m}^3)(1000 \text{ m}^3/\text{d})(1 \text{ kg}/10^3 \text{ g}) = 1300 \text{ kg/d as } CaCO_3$$

Comments A significant amount of methane gas is produced daily. If the methane can be used for the production of energy by the industrial facility, it could help to offset the cost of adding a considerable amount of alkalinity to maintain the anaerobic reactor pH near 7. Also it is important to note the significance of the effluent solids concentration in determining the system SRT. Anaerobic processes generally produce higher-effluent VSS concentrations compared to aerobic processes. For weak wastewater for which solids production is lower, it may be difficult to maintain long SRT values for high treatment efficiency due to effluent solids loss.

Also, in contrast to the situation presented in this example, manual wasting of sludge may be necessary. If the wastewater had a higher-influent COD concentration, and the effluent VSS concentration remained the same, the concentration of solids (X_{TSS}) in the sludge blanket would have to increase and the blanket level would have to be higher. To avoid a rising sludge blanket, manual wasting of sludge would have to be initiated and the SRT value would have to be less than the computed value of 52 d. For design, it is best to assume that the average VSS concentration of the sludge blanket would be less than 25 to 35 kg/m^3.

Anaerobic Baffled Reactor

In the anaerobic baffled reactor (ABR) process, as shown on Fig. 10-6*a*, baffles are used to direct the flow of wastewater in an upflow mode through a series of sludge blanket reactors. The sludge in the reactor rises and falls with gas production and flow, but moves through the reactor at a slow rate. Various modifications have been made to the ABR to improve performance. The modifications include (1) changes to the baffle

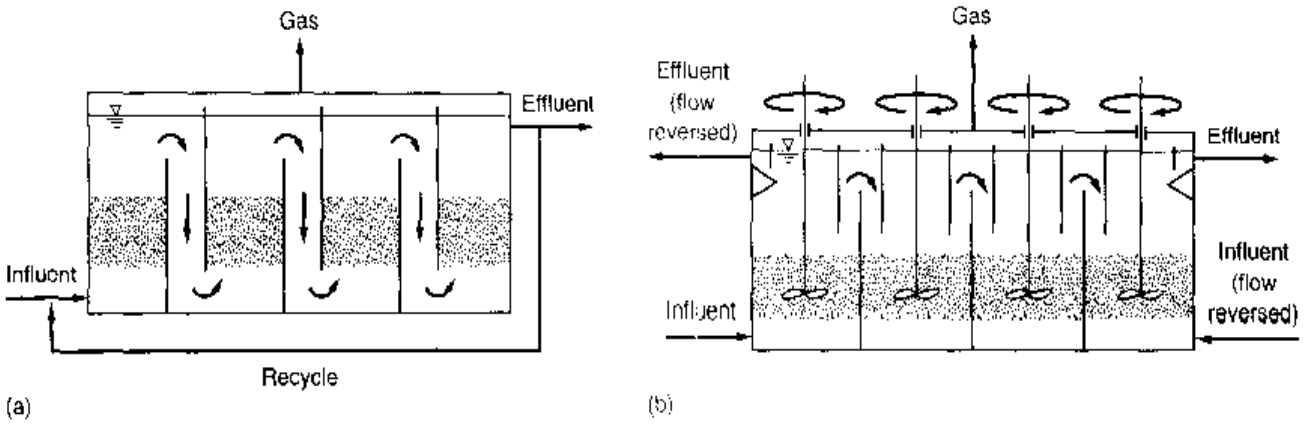

Figure 10–6

Schematic views of alternative sludge blanket processes: (a) anaerobic baffled reactor (ABR) and (b) anaerobic migrating blanket reactor (AMBR).

design, (2) hybrid reactors where a settler has been used to capture and return solids, or (3) packing has been used in the upper portion of each chamber to capture solids (Barber and Stuckey, 1999). Though granulated sludge is not considered essential for the operation and performance of the ABR process, it has been observed in the ABR process (Boopathy and Tilche, 1992).

A number of studies have been done with the ABR process at bench and pilot scale for a wide range of wastewaters and temperatures as low as 13°C. An excellent summary of these studies including organic loading rates, temperature, and percent COD removal is provided by Barber and Stuckey (1999). Typical design loadings for the ABR process are presented in Table 10–17. Many of these studies were operated at τ values in the range of 6 to 24 h. The reactor volatile solids concentrations varied from 4 to 20 g/L.

Advantages claimed for the ABR process include the following:

1. Simplicity, i.e., no packing material, no special gas separation method, no moving parts, no mechanical mixing, and little plugging potential
2. Long SRT possible with low hydraulic retention time τ
3. No special biomass characteristic required
4. Wastewaters with a wide variety of constituent characteristics can be treated
5. Staged operation to improve kinetics
6. Stable to shock loads

The main limitations at this time (2001) with the ABR process are the lack of information based on the operation of full-scale facilities and a full understanding of the system hydraulics.

Anaerobic Migrating Blanket Reactor

The anaerobic migrating blanket reactor (AMBR®) process is similar to the ABR with the added features of mechanical mixing in each stage and an operating approach to maintain the sludge in the system without resorting to packing or settlers for additional

Table 10–17
Design and performance results from bench- and pilot-scale studies on anaerobic treatment of various wastewaters with the ABR process[a]

Wastewater	Temperature, °C	Number of chambers	Influent COD, mg/L	COD loading, kg/m³·d	Percent COD removal
Carbohydrate/protein	35	5	7100–7600	2–10	79–82

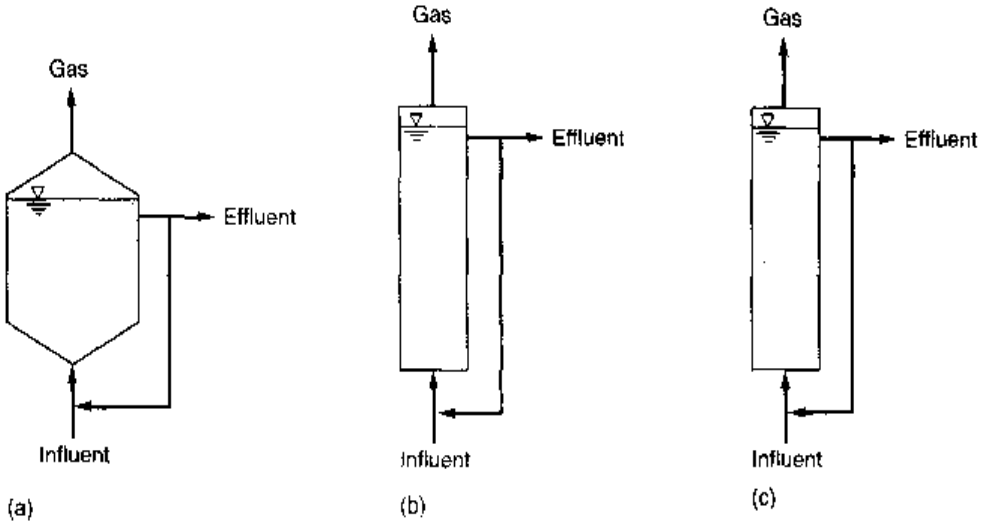
Note: kg/m³·d × 62.4280 = lb/10³ ft³·d.

solids capture (see Fig. 10–6*b*). In the AMBR® process, the influent feed point is changed periodically to the effluent side and the effluent withdrawal point is also changed. In this way the sludge blanket remains more uniform in the anaerobic reactor. The flow is reversed when a significant quantity of solids accumulates in the last stage.



The AMBR® process has been shown to be feasible from bench-scale testing treating nonfat dry milk (Angenent et al., 2000) at 15 and 20°C. The organic loading rate was varied from 1.0 to 3.0 kg COD/m³·d with hydraulic retention times ranging from 4 to 12 h. At the higher COD loading, the COD removal efficiency was 59 percent at 15°C. At 20°C, COD removals ranged from 80 to 95 percent at COD loadings of 1 to 2.0 kg/m³·d.

10–5 ATTACHED GROWTH ANAEROBIC PROCESSES

Upflow attached growth anaerobic treatment reactors differ by the type of packing used and the degree of bed expansion. Three types of upflow attached growth processes are illustrated on Fig. 10–7. In the upflow packed-bed reactor (see Fig. 10–7*a*) the packing is fixed and the wastewater flows up through the interstitial spaces between the packing and biogrowth. Effluent recycle is generally not used for the packed-bed reactor except for high-strength wastewaters. While the first upflow anaerobic packed-bed processes contained rock, a variety of designs employing synthetic plastic packing are used currently. The anaerobic expanded-bed reactor (see Fig. 10–7*b*) uses a fine-grain sand to support biofilm growth. Recycle is used to provide upflow velocities, resulting in 20 percent bed expansion. Higher upflow velocities are used for fluidized-bed anaer-

Figure 10–7

Upflow anaerobic attached growth treatment reactors: (*a*) anaerobic upflow packed-bed reactor, (*b*) anaerobic expanded-bed reactor, and (*c*) anaerobic fluidized-bed reactor.

obic reactors (see Fig. 10–7*c*), which also contain a fine-grain packing. In fluidized-bed systems, both fluidization and mixing of the packing material occurs. The expanded and fluidized-bed reactors have more surface area per reactor volume for biomass growth and better mass transfer than the upflow packed-bed reactor, but have lower solids capture. These different systems are described in more detail in the following paragraphs, along with their typical design conditions and COD loadings.

Upflow Packed-Bed Attached Growth Reactor

Full-scale upflow packed-bed anaerobic filters are used in cylindrical or rectangular tanks at widths and diameters ranging from 2 to 8 m and heights from 3 to 13 m (see Fig. 10–7*a*). Packing material placement may be in the entire depth or, for hybrid designs, only in the upper 50 to 70 percent. The most common packing materials are corrugated plastic cross-flow or tubular modules, similar to that described in Chap. 9 for aerobic attached growth processes, and plastic pall rings. The specific surface area of the packing averages about 100 m^2/m^3 and, based on research results, no performance improvements were observed at higher packing densities (Song and Young, 1986). Cross-flow packing appeared to provide a higher process performance efficiency over randomly packed medium (Young and Yang, 1989). Typical COD loadings used, hydraulic retention times, and COD removal efficiencies for upflow packed-bed anaerobic reactors are reported in Table 10–18. At loadings of 1.0 to 6.0 kg COD/m^3·d, process efficiencies up to 90 percent are shown for high-strength wastewaters.

A large portion of the biomass responsible for treatment in the upflow attached growth anaerobic processes is loosely held in the packing void spaces and not just attached to the packing material (Young and Dehab, 1983). Low upflow velocities are generally used to prevent washing out the biomass. Over time, solids and biomass will accumulate in the packing to cause plugging and flow short circuiting. At this point, solids must be removed by flushing and draining the packing.

Advantages of upflow attached growth anaerobic reactors are high COD loadings, relatively small reactor volumes, and operational simplicity. The main limitations are the cost of the packing material and operational problems and maintenance associated with solids accumulation and possible packing plugging. The process is best suited for wastewaters with low suspended solids concentrations.

Table 10-18
Examples of process operating conditions and performance for upflow attached growth anaerobic reactors[a]

Wastewater	Packing type	Temp., °C	COD loading kg/m³·d	τ, d	Recycle ratio, R/Q	COD removed, %

Upflow Attached Growth Anaerobic Expanded-Bed Reactor

In the upflow attached growth anaerobic expanded-bed reactor (AEBR) process (see Fig. 10–7*b*), the packing material is generally silica sand with a diameter in the range of 0.2 to 0.5 mm and specific gravity of 2.65. For operation with about 20 percent bed expansion, an upflow velocity of about 2 m/h is used. The smaller packing provides a greater surface area per unit volume, theoretically supporting a greater amount of biomass growth. The packing void fraction is about 50 percent when expanded and the specific surface area is in the range of 10,000 m^2/m^3 (Malina and Pohland, 1992). With such a small packing and void volume, the expanded-bed operation is necessary to prevent plugging. Because the expanded-bed system is not fully fluidized, some solids are trapped and some degree of solids degradation occurs (Morris and Jewell, 1981).

Most applications for the AEBR treatment process have been for the treatment of domestic wastewater (Jewell, 1987). More recently, Collins et al. (1998) have investigated the application of the AEBR for treating domestic wastewater at low temperatures. The results of these studies are summarized in Table 10–19, where the data for COD loading and removal efficiency at 20°C are within the same order of magnitude as shown for upflow packed anaerobic bed reactors treating industrial wastewater. The advantages and limitations are similar to those for the fluidized-bed reactor discussed next.

Attached Growth Anaerobic Fluidized-Bed Reactor

The attached growth anaerobic fluidized-bed reactor (FBR) (see Fig. 10–7*c*) is similar in physical design to the upflow expanded-bed reactor. The packing size (~0.3 mm sand) is similar to the expanded-bed reactor, but the FBR is operated at higher upflow liquid velocities of about 20 m/h to provide about 100 percent bed expansion. Effluent recycle is used to provide sufficient upflow velocity. Reactor depth ranges from 4 to 6 m.

Table 10–19
Performance of a bench-scale upflow anaerobic expanded-bed reactor treating domestic wastewater at low temperatures[a]

Temperature, °C	Organic loading, kg COD/m³·d	Percent COD removal
20	4.4	89
15	4.0	80
10	0.4	71
5	0.3	35

Note: kg/m³·d × 62.4280 = lb/10³ ft³·d.

Table 10–20
Benefits of using granular activated carbon (GAC) versus sand as the packing material in anaerobic FBRs

- Higher biomass concentration maintained due to porous structure of GAC
- Adsorption properties help prevent toxic and inhibitory substances from decreasing biological treatment performance
  - Concentration of degradable substrate can be reduced to below toxic levels
  - Other toxic substances can be removed to protect bacteria
- Adsorption properties may minimize shock loads by sorption of increased organics
- Adsorption properties may help acclimate and enhance biomass degradation of toxic compounds by providing more time of exposure

Besides sand, other packing materials have been considered for use in FBRs including diatomaceous earth, anion and cation exchange resins, and activated carbon (Wang et al., 1984; Kindzierski et al., 1992). Though a greater biomass concentration could be developed with the more porous diatomaceous earth packing, better performance did not result when compared to sand. Diffusion limitations into the biomass within the porous packing structure may explain the lack of improved treatment efficiency.

Activated carbon has been used in many anaerobic FBRs for treating industrial and hazardous waste streams (Hickey et al., 1991; Iza, 1991). The mean diameter of the granular activated carbon particles is 0.6 to 0.8 mm and upflow velocities of 20 to 24 m/h are used. Many benefits associated with using activated carbon in the anaerobic FBR (Wang et al., 1986; Fox et al., 1988) are listed in Table 10–20. The main limitation with activated carbon is the higher cost, but for certain types of industrial and hazardous waste streams the use of activated carbon is a necessity.

Solids capture is minimal in the anaerobic FBR due to the high turbulence and thin biofilms developed. With little solids capture, the process is better suited for wastewaters with mainly soluble COD. Solids discharged in the effluent from sloughed biofilm are minimized by controlling the biofilm inventory in the reactor. As biomass accumulates on the FBR packing, the net particle density decreases and the particle migrates to the top of the reactor. Periodic removal of these solids can control biofilm sloughing and minimize effluent TSS concentrations. The removed particles are mechanically processed to separate biomass from the sand, which is returned to the FBR.

Startup of anaerobic FBRs must be done with more care than the other types of high-rate anaerobic reactors. A higher hydraulic application rate is recommended at

first to select for bacteria that more readily attach to the reactor packing under the highly turbulent conditions (Sutton and Huss, 1984; Denac and Dunn, 1988). The startup time can take 3 to 6 months. In a laboratory study by Tay and Zhang (2000) the startup and performance of an aerobic FBR was compared to that for an anaerobic UASB reactor and upflow packed-bed reactor. All three could achieve COD loading of 10 kg COD/m^3·d at 35°C in 3 months with an influent COD concentration of 5000 mg/L (primarily glucose) and a τ of 12 h. The COD removal efficiency was best for the FBR and UASB reactors, about 96 percent compared to 90 percent for the upflow packed-bed reactor.

Process COD loading values of 10 to 20 kg COD/m^3·d are feasible for anaerobic FBRs with greater than 90 percent COD removal, depending on the type of wastewater. Treatment performance is higher for FBRs than upflow packed-bed reactors at higher loadings, most likely due to a greater mass transfer rate due to the turbulent mixing. Reactor biomass concentrations of 15 to 20 g/L can be established in anaerobic FBRs (Malina and Pohland, 1992). Anaerobic FBR loadings and performance data are presented in Table 10–21. Bench-scale or pilot-plant studies are normally done before establishing full-scale design loadings.

The advantages for the anaerobic FBR process include the ability to provide high biomass concentrations and relatively high organic loadings, high mass transfer characteristics, the ability to handle shock loads due to its mixing and dilution with recycle, and minimal space requirements. The process is best suited for soluble wastewaters due to its inability to capture solids. Care must also be taken in the inlet and outlet designs to assure good flow distribution. Other disadvantages include the pumping power required to operate the fluidized bed, the cost of reactor packing, the need to control the packing level and wasting with biogrowth, and the length of startup time.

Downflow Attached Growth Processes

Downflow attached growth anaerobic processes, as illustrated on Fig. 10–8, have been applied for treatment of high-strength wastewaters using a variety of packing materials including cinder block, random plastic, and tubular plastic. Packing heights are in the range of 2 to 4 m, and systems are designed to allow recirculation of the reactor efflu-

ent. Anaerobic downflow attached growth reactors can be operated at loadings in the range of 5 to 10 kg COD/m³·d for easily degradable wastewaters. Operating performance varies for different wastewaters as shown in Table 10–22. Because plugging of the packing can be of concern, the use of a packing material with a high void volume, such as the vertical plastic packing used in tower trickling filters, is recommended.

The major advantages for the downflow attached growth process, where a higher void space packing material is used, are a simpler inlet flow distribution design, no plugging problems, and a simple operation. For systems with aerobic treatment following anaerobic treatment, the solids are captured in the aerobic process and thus do not accumulate in the attached growth process. Similar to the other anaerobic processes used for high-strength industrial wastewater treatment, benefits include the ability to treat high COD loadings with relatively small reactor volume sizes. Disadvantages include the cost of the packing material, and the somewhat lower organic loading rates to achieve the same treatment efficiency as the UASB and FBR processes.

10–6 OTHER ANAEROBIC TREATMENT PROCESSES

In addition to the anaerobic processes considered in Secs. 10–3 through 10–5, numerous other anaerobic processes have been developed and new processes are being developed continuously. Two such processes, the covered anaerobic earthen lagoon process and the membrane separation anaerobic treatment process, are considered briefly in the following discussion.

Covered Anaerobic Lagoon Process

Anaerobic lagoons have been used for high-strength industrial wastewaters, such as meat-processing wastewaters. Detention times ranged from 20 to 50 d with lagoon depths of 5 to 10 m (Crites and Tchobanoglous, 1998). A schematic of a simple nonproprietary covered anaerobic lagoon process is shown on Fig. 10–9*a*. A schematic of a proprietary covered anaerobic lagoon process known as the ADI-BVF® reactor is shown on Fig. 10–9*b* (McMullin et al., 1994). One of the main advantages for the covered lagoon processes is their ability to handle a wide range of waste characteristics including solids and oils and greases. Other advantages include simple and relatively economical construction, the large volume that can provide equalization of loads, the use of a low loading, and a high effluent quality. Disadvantages include the large land area required, potential feed flow distribution inefficiencies, and maintenance of the geomembrane cover.

For the plug-flow covered lagoon process shown on Fig. 10–10*a*, typical τ and SRT values for treating cow manure are on the order of 20 to 24 d, when treating a wastewater with a total solids concentration of about 8 to 10 percent. In general, process performance is best with fresh manure, as opposed to reconstituted manure that has dried for some period of time. The degree of waste conversion achieved will depend on the concentration of biodegradable COD in the manure. Typically, the VSS/TSS ratio of fresh manure will vary from 0.80 to 0.85. Of the VSS, about 30 to 40 percent is

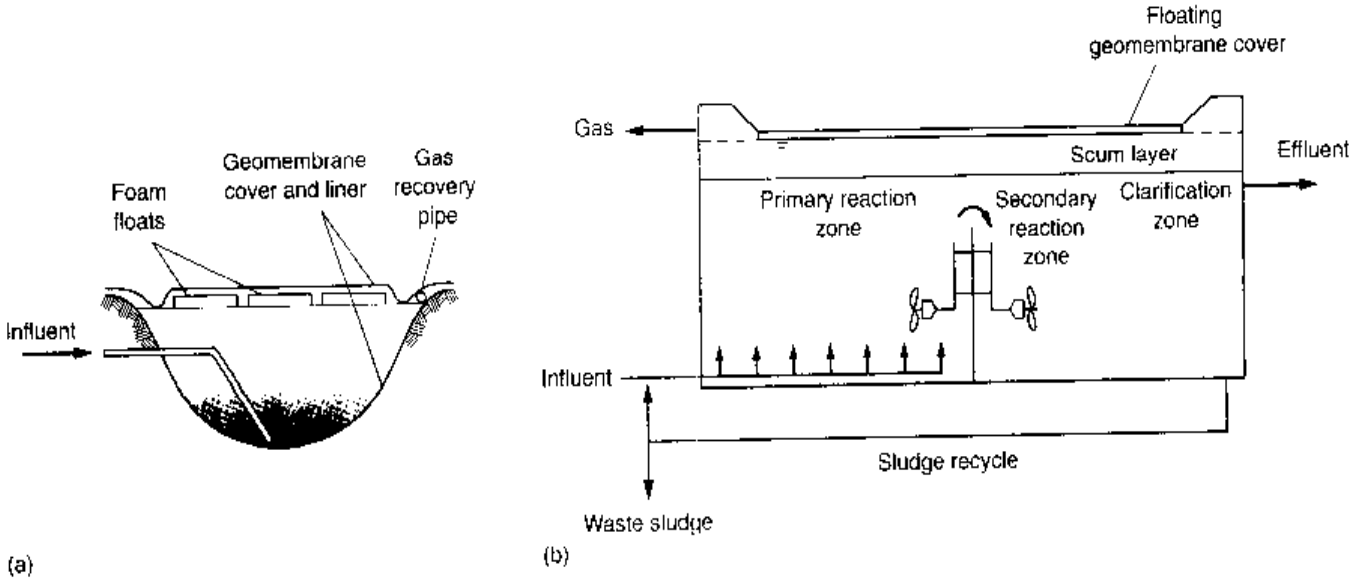

Figure 10–9

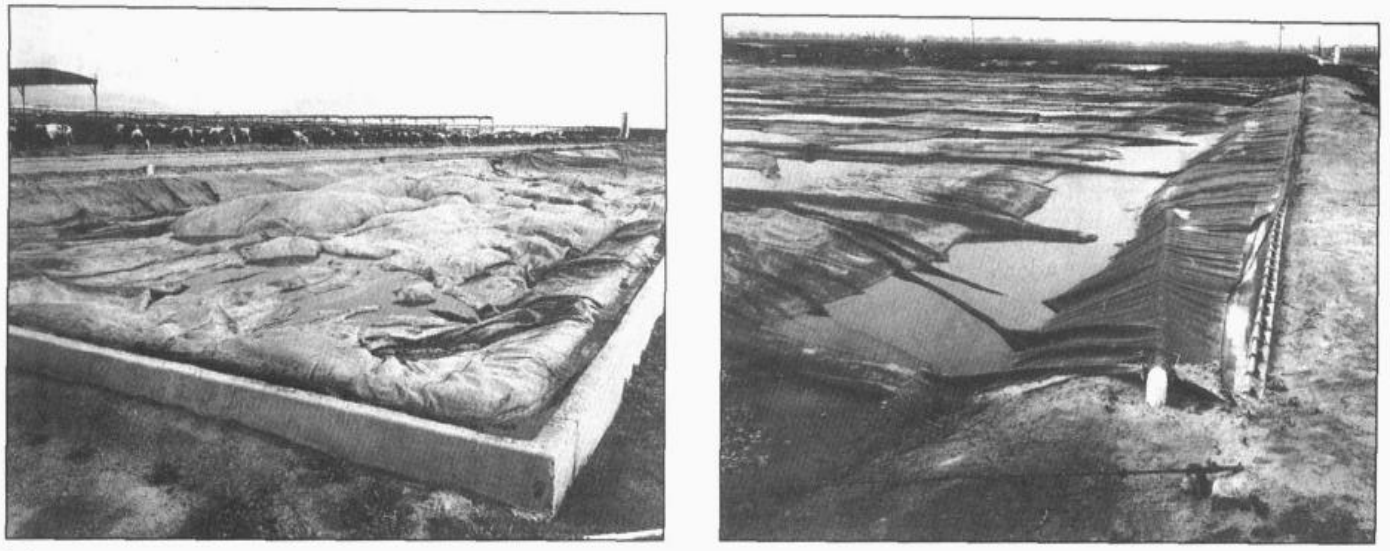

Figure 10–10

Views of covered lagoon treatment process: (*a*) installation used for the treatment of cow manure and (*b*) installation for the treatment of piggery waste.

biodegradable. Detention times for the covered lagoon process shown on Figs. 10–9*a* and 10–10*b* are in the range of 30 to 50 d with solids concentrations varying from 0.5 to 5 percent, although higher values have been used. The SRT value for the covered lagoon process will be higher than the τ value because a large fraction of the influent solids will settle and undergo long-term degradation. It is estimated that the SRT values can vary from about 50 to 100 d. The performance of the covered lagoon process can be improved by building a series of ponds with the same total volume as a single large lagoon. Another consideration for lagoon processes is to separate the acid phase from the methane phase to reduce the total volume required and improve performance.

The ADI-BVF® reactor (see Fig. 10–9*b*) is typically of earthen and concrete construction with about 3- to 4-m vertical concrete sidewalls. A sloping interior floor and exterior earthen berms are used. The maximum liquid depth ranges from 7 to 9 m. The reactor has a floating geomembrane cover with a layer of closed-cell polyethylene insulation attached to its underside. The cover is sealed to the reactor perimeter, thereby allowing for the collection of biogas, temperature control, and positive odor control. The cover material is arranged in panels, with folds or "troughs" designed to allow rainwater collection in controlled locations and subsequent removal from the cover. Influent piping is situated along the bottom of the influent zone of the reactor in a design which provides distribution of influent throughout the sludge blanket. Sludge recirculation is employed and interior baffles are provided to promote retention of sludge within the influent zone. The wastewater flows through a series of gas-liquid-solids separators which act as internal clarifiers to inhibit the movement of solids to the reactor surface. The reactor also contains a low-speed mixer which operates on an intermittent basis for short periods of time. The ADI-BVF® process is normally operated as a low-loaded anaerobic process, with loadings in the range of 1.0 to 2.0 kg COD/m^3·d. The

Table 10–23
Operation and treatment performance for the ADI-BVF® anaerobic covered lagoon process[a]

Wastewater	Temperature, °C	COD loading, kg/m³·d	τ, h	COD removed, %
Potato/pea processing	20–25	0.7	8.0	85
Apple juice	15–30	0.2	17	94

Note: kg/m³·d × 62.4280 = lb/10³ ft³·d.

lagoon is generally not heated so that the temperatures may be 15 to 25°C, depending on the location and time of year. Typical performance data for the ADI-BVF® process are presented in Table 10–23. At very low loads, 80 to 90 percent COD removal is possible.

Membrane Separation Anaerobic Treatment Process

Basic concepts of membrane separation technology are described in detail in Chap. 11. The successful use of membrane separation in activated-sludge treatment is discussed in Chap. 8. Membrane separation has been considered for anaerobic reactors, but the technology is still in a developmental stage. The potential advantages for using membrane separation technology are (1) using higher biomass concentrations in the anaerobic reactor to further reduce its size and increase volumetric COD loadings, (2) allowing much higher SRTs in the anaerobic reactor by almost complete capture of solids that could result in maximum removal of VFAs and degradable soluble COD substances to provide a higher-quality effluent, and (3) maximizing capture of effluent suspended solids to greatly improve the effluent quality from anaerobic treatment. The latter two potential advantages of a longer SRT and low effluent suspended solids concentration should allow anaerobic reactors to produce an effluent quality equal to aerobic secondary treatment processes.

The major design considerations for the application of membrane separation in biological reactors (see Sec. 8–9 in Chap. 8) are (1) the membrane flux rate and (2) the ability to prevent fouling of the membrane to sustain acceptable flux rates. In the submerged membrane reactors used for aerobic suspended growth treatment the membranes are placed in the activated sludge reactor and coarse bubble aeration is used to minimize fouling. For anaerobic processes a similar type of gas agitation system might be possible. In current designs, as shown on Fig. 10–11, an external cross-flow membrane separation unit is used.

To control fouling, high liquid velocities are maintained across the membrane. The solids in the reject stream are recycled back to the anaerobic reactor, while clear permeate is removed for effluent discharge. Fouling problems and loss of active cells have been reported (Choo and Lee, 1998). Organic fouling problems are typically caused by the accumulation of colloidal material and bacteria on the membrane surface. High pumping flowrates across the membrane may lead to the loss of viable bacteria due to cell lysis. Inorganic fouling is due to the formation of struvite ($MgNH_4PO_4$), which precipitates because of a rise in the pH as the flow passes through the membranes and CO_2 escapes from the liquid. Observed performance data derived from a limited number of membrane reactor studies are summarized in Table 10–24. In general, the process

Figure 10–11
Anaerobic bioreactor with external membrane separation of solids in effluent stream.

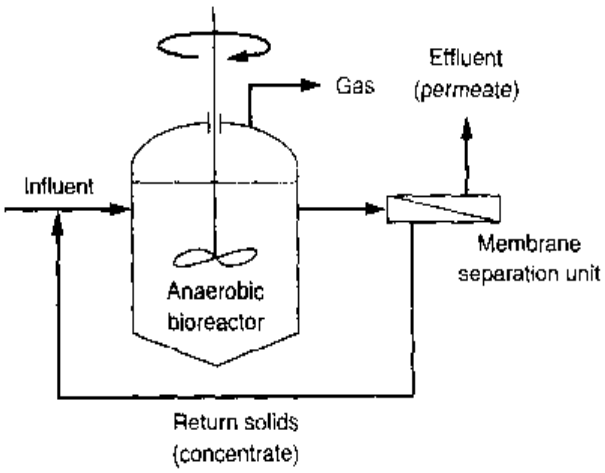

Table 10–24
Summary of operating conditions from a limited number of membrane separation anaerobic reactor studies

Parameter	Unit	Value	
		Range	Typical
COD loading	kg COD/m³·d	2–22	8
τ	d	0.5–15.0	8
SRT	d	30–160	50
MLSS	g/L	8–50	20–25
Solids yield	g VSS/g COD	0.04–0.12	0.08
Final flux	L/m²·h	5–26	18
Specific flux	L/m²·h·bar	2.5–21	14

Note: kg/m³·d × 62.4280 = lb/10³ ft³·d.
L/m²·h × 0.0245 = gal/ft²·h.

organic loading rates are in the range of those used with the sludge blanket and attached growth processes. Further developments in membrane design and fouling control measures could make membrane separation anaerobic reactors a viable technology in the future.

PROBLEMS AND DISCUSSION TOPICS

10-1 The alkalinity and pH are measured in an anaerobic suspended growth reactor operated at 30°C. The alkalinity values are 1800, 2000, or 2200 mg as $CaCO_3$/L (value to be selected by instructor) and the pH is 7.2. Assuming equilibrium between the liquid and gas phases, determine the approximate CO_2 content of the gas phase in percent.

10-2 An industrial wastewater with a flow of 4000 m³/d has a soluble degradable COD concentration of 1800, 2200, or 3000 mg/L (value to be selected by instructor), a temperature of 20°C and an alkalinity concentration of 200 mg/L as $CaCO_3$. Determine and compare the net operating costs or revenue for anaerobic versus aerobic treatment based on the following key parameters and assumptions (labor and maintenance costs are omitted here) for each:

Anaerobic process

Anaerobic operating cost items are related to raising the liquid temperature, and adding alkalinity, versus the revenue from methane production. The following assumptions apply:

1. Reactor temperature = 35°C
2. Heat exchanger recovery efficiency for raising liquid temperature = 80%
3. COD removal efficiency = 95 percent
4. Percent CO_2 of gas phase = 35 percent and pH = 7.0
5. Value of methane = \$5/10^6 kJ
6. Alkalinity is provided as $NaHCO_3$ at \$0.90/kg

Aerobic

Major aerobic treatment operating cost items are energy for aeration and sludge processing and disposal. The following assumptions apply:

1. COD removal efficiency = 99 percent
2. g O_2/g COD removal = 1.2
3. Actual aeration efficiency = 1.2 kg O_2/kw-hr
4. Electricity costs = \$0.08/kWh
5. Net sludge production = 0.3 g TSS/g COD removed
6. Sludge processing/disposal cost = \$0.10/kg dry solids

10-3 A wastewater has a daily average flowrate of 1000, 2000, or 3000 m^3/d (value to be selected by instructor) and 4000 mg/L of an organic substance with the following approximate composition: $C_{50}H_{75}O_{20}N_5S$. For anaerobic treatment at 95 percent degradation determine: (a) the alkalinity production in mg/L as $CaCO_3$; and (b) the approximate mole fraction of CO_2, CH_4, and H_2S in the gas phase.

10-4 An industrial wastewater has an average flowrate of 2000 m^3/d, an influent COD concentration of 4000, 6000, or 8000 mg/L (value to be selected by instructor), and influent sulfate concentration of 500 mg/L. The percent of COD degraded in an anaerobic treatment process at 35°C is 95 percent, and 98 percent of the sulfate reduced. Determine: (a) the amount of methane produced in m^3/d; (b) the amount of methane produced in m^3/d, if the sulfate reduction is not accounted for; and (c) the amount of H_2S in the gas phase at a reactor pH value of 7.0.

10-5 A suspended growth anaerobic reactor is operated at an SRT of 30 days at a temperature of 30°C. On a given day, the methane gas production rate (m^3/d) decreases by 30 percent. List at least four possible causes that should be investigated and briefly explain the mechanism behind each one.

10-6 A 100 percent soluble industrial wastewater is to be treated by an anaerobic suspended growth process consisting of a mixed covered reactor, a degasifier, and gravity settling. The effluent TSS concentration from the clarifier is 120 mg/L. For the following wastewater characteristics and design assumptions determine and compare the following design parameters for treatment at 25°C and 35°C:

1. The design SRT, d
2. The reactor volume, m^3
3. The reactor hydraulic detention time τ, d
4. The methane gas production rate, m^3/d
5. The total gas production rate, m^3/d

6. The amount of solids to be manually wasted daily, kg/d
7. The nitrogen and phosphorus requirements, kg/d

Wastewater characteristics:

Parameter	Unit	Value
Flow	m^3/d	2000
Degradable COD	mg/L	A (4000)
		B (6000)
		C (8000)
Percent sCOD	%	100
Alkalinity	mg/L as CaCO	500

Note: value A, B, or C to be selected by instructor

Other design assumptions:

1. Reactor MLSS concentration = 5000 mg/L
2. Factor of safety for SRT = 1.5
3. VSS/TSS ratio = 0.85
4. f_d = 0.15 g VSS cell debris/g VSS biomass decay
5. Gas phase percent methane = 65 percent
6. Nitrogen content of biomass = 0.12 g N/g VSS5
7. Phosphorus content of biomass = 0.02 g P/g VSS
8. Use the appropriate kinetic coefficients and design information provided in Table 10–10

10-7 An anaerobic process is being considered for the treatment of a soluble industrial wastewater at 30°C. A design SRT of 30 d is required to provide the desired level of 95 percent soluble COD degradation. An effluent VSS concentration of 100, 150, or 200 mg/L (value to be selected by instructor) from biomass growth is assumed. Using the appropriate kinetic coefficient values from Table 10–10, determine the influent sCOD concentration that must be present to allow operation at a 30-d SRT, if all the biomass wasted is via the effluent solids losses.

10-8 Design a single UASB reactor to treat an industrial wastewater at 30°C with the following wastewater characteristics and using the assumptions given below. Design for 97 percent degradation of the soluble COD, and assume 50 percent particulate COD degradation and an effluent VSS concentration of 200 mg/L. Using the given information, determine:

1. The reactor liquid volume, m^3
2. The reactor area (assume a circular reactor will be used), m^2
3. The reactor area diameter, liquid depth, and total height, m
4. The hydraulic retention time, d
5. The average SRT, d
6. The amount of solids to be manually wasted daily, kg/d
7. The average MLVSS and MLSS concentration in the UASB reactor, mg/L
8. The methane gas production rate, m^3/d
9. The energy value of the gas, kJ/d
10. The alkalinity requirement, kg as $CaCO_3/d$

Design Assumptions:

1. Kinetic coefficients from Table 10–10.
2. Reactor effectiveness factor (E) = 0.85
3. f_d = 0.15 g VSS/g VSS biomass decayed
4. pH = 7.0
5. Percent CO_2 in gas phase = 35 percent
6. Maximum reactor liquid height = 8 m

Wastewater characteristics:

Parameter	Unit	Value
Flow	m^3/d	500
Total bCOD	mg/L	A (6000)
		B (7000)
		C (8000)
Particulate COD	Percent	40
Particulate COD/VSS ratio	g/g	1.8
Particulate VSS/TSS ratio	g/g	0.85
Alkalinity	mg/L as $CaCO_3$	300

Note: value A, B, or C to be selected by instructor

10-9 A domestic wastewater is to be treated using the UASB process at 25°C. The wastewater characteristics are given in the following table. Determine: (a) the reactor hydraulic retention time (hours); (b) the COD loading rate (kg COD/m^3·d); and (c) the reactor liquid height (m) and diameter (m). What effluent BOD and TSS concentration may be expected from the UASB reactor? Describe an aerobic secondary treatment process you would select to add after the UASB process to meet an effluent BOD concentration of 20 mg/L or less. Would alkalinity have to be added to the UASB reactor to maintain the pH near 7.0? Explain the basis for your answer.

Wastewater characteristics:

Parameter	Unit	Value
Flow	m^3/d	A (3000)
		B (4000)
		C (5000)
COD	mg/L	450
BOD	mg/L	180
TSS	mg/L	180
Alkalinity	mg/L as $CaCO_3$	150

Note: value A, B, or C to be selected by instructor

10-10 A brewery wastewater with a flow of 1000 m^3/d and COD (mainly soluble) of 4000 mg/L is to be treated at 35°C in an upflow attached growth anaerobic reactor, which contains cross-flow plastic packing, with the aim of 90 percent COD removal. Assume that the attached growth SRT is 30 days. Determine: (a) the reactor volume (m^3) and dimensions; (b) the methane gas production rate (m^3/d); and (c) the effluent TSS concentration (mg/L).

10-11 An industrial wastewater has a degradable COD concentration of 8000 mg/L and 4000 mg/L VSS concentration with 50 percent of the VSS degradable. Briefly critique the compatibility of the following processes for treatment of this wastewater and describe the potential impact of the influent solids on the reactor operation and performance.

Processes:

UASB
Anaerobic fluidized-bed reactor
Anaerobic baffled reactor
Upflow packed-bed reactor
Downflow attached growth reactor
Anaerobic covered lagoon

10-12 From the literature within the past three years, identify and summarize an application of a membrane separation anaerobic treatment process. Include a description of the wastewater treated, the reactor design, the organic loading rate, the temperature, the membrane fouling control strategy, the membrane flux rate over time, the reactor solids concentration, the membrane cleaning method or restoration method, and any significant operating and performance issues.

REFERENCES 1212

Advanced wastewater treatment is defined as the additional treatment needed to remove suspended, colloidal, and dissolved constituents remaining after conventional secondary treatment. Dissolved constituents may range from relatively simple inorganic ions, such as calcium, potassium, sulfate, nitrate, and phosphate, to an ever-increasing number of highly complex synthetic organic compounds. In recent years, the effects of many of these substances on the environment have become understood more clearly. Research is ongoing to determine (1) the environmental effects of potential toxic and biologically active substances found in wastewater and (2) how these substances can be removed by both conventional and advanced wastewater-treatment processes. As a result, wastewater-treatment requirements are becoming more stringent in terms of both limiting concentrations of many of these substances in the treatment plant effluent and establishing whole effluent toxicity limits, as outlined in Chap. 2. To meet these new requirements, many of the existing secondary treatment facilities will have to be retrofitted and new advanced wastewater-treatment facilities will have to be constructed. Therefore, the purpose of this chapter is to present an introduction to the subject of advanced wastewater treatment. The chapter contains an expanded discussion of the need for advanced wastewater treatment, an overview of the available technologies used for the removal of the constituents of concern, identified previously in Chap. 2, and an introduction to the more important of these technologies as applied to the removal of specific constituents found in wastewater. The ultimate disposal of residuals from advanced wastewater treatment is considered in Chap. 14.

11-1 NEED FOR ADVANCED WASTEWATER TREATMENT

The need for advanced wastewater treatment is based on a consideration of one or more of the following factors.

1. The need to remove organic matter and total suspended solids beyond what can be accomplished by conventional secondary treatment processes to meet more stringent discharge and reuse requirements.
2. The need to remove residual total suspended solids to condition the treated wastewater for more effective disinfection.
3. The need to remove nutrients beyond what can be accomplished by conventional secondary treatment processes to limit eutrophication of sensitive water bodies.
4. The need to remove specific inorganic (e.g., heavy metals) and organic constituents (e.g., MBTE and NDMA) to meet more stringent discharge and reuse requirements for both surface water and land-based effluent dispersal and for indirect potable reuse applications (e.g., groundwater recharge).
5. The need to remove specific inorganic (e.g., heavy metals, silica) and organic constituents for industrial reuse (e.g., cooling water, process water, low-pressure boiler makeup water, and high-pressure boiler water).

With increased scientific knowledge derived from laboratory studies and environmental monitoring concerning the impacts of the residual constituents found in secondary effluent, it is anticipated that many of the methods now classified as advanced will become conventional within the next 5 to 10 years.

Compounds containing available nitrogen and phosphorus have received considerable attention since the mid-1960s. Initially, nitrogen and phosphorus in wastewater

discharges became important because of their effects in accelerating eutrophication of lakes and promoting aquatic growths. More recently, nutrient control has become a routine part of treating wastewaters used for the recharge of groundwater supplies. Nitrification of wastewater discharges is also required in many cases to reduce ammonia toxicity or to lessen the impact on the oxygen resources in flowing streams or estuaries. As a result of the many concerns over nutrients, nutrient removal has become, for all practical purposes, an integral part of conventional wastewater treatment. Thus, the removal of nitrogen and phosphorus by biological processes is considered in Chaps. 8 and 9. The removal of phosphorus by chemical methods is discussed in Chap. 6.

11–2 TECHNOLOGIES USED FOR ADVANCED TREATMENT

Over the past 20 years, a wide variety of treatment technologies have been studied, developed, and applied for the removal of the residual constituents found in treated effluent. The residual constituents found in treated wastewater are reviewed and the technologies used for the advanced treatment of wastewater are introduced in this section.

Residual Constituents in Treated Wastewater

The typical composition of domestic wastewater was reported previously in Table 3-15. In addition to the constituents reported in Table 3–15, most domestic wastewaters also contain a wide variety of trace compounds and elements, although they are not measured routinely. The potential effects of residual constituents contained in treated effluents may vary considerably. Some of the effects of specific constituents are listed in Table 11–1. The list presented in Table 11–1 is not meant to be exhaustive; rather, it is meant to highlight that a wide variety of substances must be considered in establishing and meeting discharge requirements.

Classification of Technologies

Advanced wastewater-treatment systems may be classified by the type of unit operation or process or by the principal removal function performed. To facilitate a general comparison of the various operations and processes, information on (1) the principal residual constituent removal function and (2) the types of operations or processes that can be used to perform this function are presented in Table 11–2. As will be noted in reviewing Table 11–2, many of the operations and processes can be used for the removal of a number of constituents. The individual constituents listed in Table 11–2 can be grouped into four broad categories requiring removal: (1) residual organic and inorganic colloidal and suspended solids, (2) dissolved organic constituents, (3) dissolved inorganic constituents, and (4) biological constituents. Typical advanced treatment process flow diagrams incorporating many of the technologies listed in Table 11–2 are illustrated on Fig. 11–1.

Removal of Organic and Inorganic Colloidal and Suspended Solids

Removal of organic and inorganic colloidal and suspended solids is typically accomplished by filtration. A general classification of the filtration processes commonly used in wastewater engineering is presented on Fig. 11–2. As illustrated on Fig. 11–2, the fil-

Table 11–1
Typical residual constituents found in treated wastewater effluents and their impacts

Residual constituent	Effect
Inorganic and organic colloidal and suspended solids	
Suspended solids	• May cause sludge deposits or interfere with receiving water clarity
	• Can impact disinfection by shielding organisms
Colloidal solids	• May affect effluent turbidity
Organic matter (particulate)	• May shield bacteria during disinfection, may deplete oxygen resources
Dissolved organic matter	
Total organic carbon	• May deplete oxygen resources
Refractory organics	• Toxic to humans; carcinogenic
Volatile organic compounds	• Toxic to humans; carcinogenic; form photochemical oxidants
Pharmaceutical compounds	• Impact aquatic species (e.g., endocrine disruption, sex reversal)
Surfactants	• Cause foaming and may interfere with coagulation
Dissolved inorganic matter	
Ammonia	• Increases chlorine demand
	• Can be converted to nitrates and, in the process, can deplete oxygen resources
	• With phosphorus, can lead to the development of undesirable aquatic growths
	• Toxic to fish
Nitrate	• Stimulates algal and aquatic growth
	• Can cause methemoglobinemia in infants (blue babies)
Phosphorus	• Stimulates algal and aquatic growth
	• Interferes with coagulation
	• Interferes with lime-soda softening
Calcium and magnesium	• Increase hardness and total dissolved solids
Chloride	• Imparts salty taste
Total dissolved solids	• Interfere with agricultural and industrial processes
Biological	
Bacteria	• May cause disease
Protozoan cysts and oocysts	• May cause disease
Viruses	• May cause disease

ters used for wastewater fall into three general classifications: (1) depth filtration, (2) surface filtration, and (3) membrane filtration. In depth filtration, the removal of suspended material occurs within and on the surface of the filter bed (see Fig. 11–3*a*). In surface and membrane filtration, the suspended material is removed by straining through a straining surface (e.g., filter cloth) or a thin supported membrane (see Fig. 11–3*b*). An automobile oil filter and a kitchen colander are diverse examples of surface filters.

[a] The biological removal of nitrogen and phosphorus is considered in Chaps. 7 through 10.

[b] Phosphorous removal is accomplished in a two-stage filtration process.

[c] Some carryover can occur.

Removal of Dissolved Organic Constituents

Many treatment methods can be used for the removal of dissolved organic constituents. Because of the complex nature of the dissolved organic constituents, the treatment methods must consider the specific characteristics of the wastewater and the nature of the constituents. Treatment processes used to remove some of the specific dissolved organic constituents include (1) carbon adsorption, (2) reverse osmosis, (3) chemical precipitation, (4) chemical oxidation, (5) advanced chemical oxidation, (6) electrodialysis, and (7) distillation. Chemical precipitation and chemical oxidation are discussed in Chap. 6. Biological treatment for nutrient removal is discussed in Chaps. 7 through 10.

Removal of Dissolved Inorganic Constituents

As reported in Table 11-2, a number of different unit operations and processes have been investigated in various advanced wastewater-treatment applications. Although many of them have proved to be technically feasible, other factors, such as cost, operational requirements, and aesthetic considerations, have not been favorable in some cases. Nevertheless, it is important that environmental engineers be familiar with the more important operations and processes so that in any given situation they can consider all treatment possibilities. Removal of dissolved inorganic constituents is accomplished by chemical processes or membrane filtration. The principal unit operations and processes are (1) chemical precipitation (discussed in Chap. 6), (2) ion exchange, (3) ultrafiltration, (4) reverse osmosis, (5) electrodialysis, and (6) distillation. As noted previously, chemical precipitation is discussed in Chap. 6.

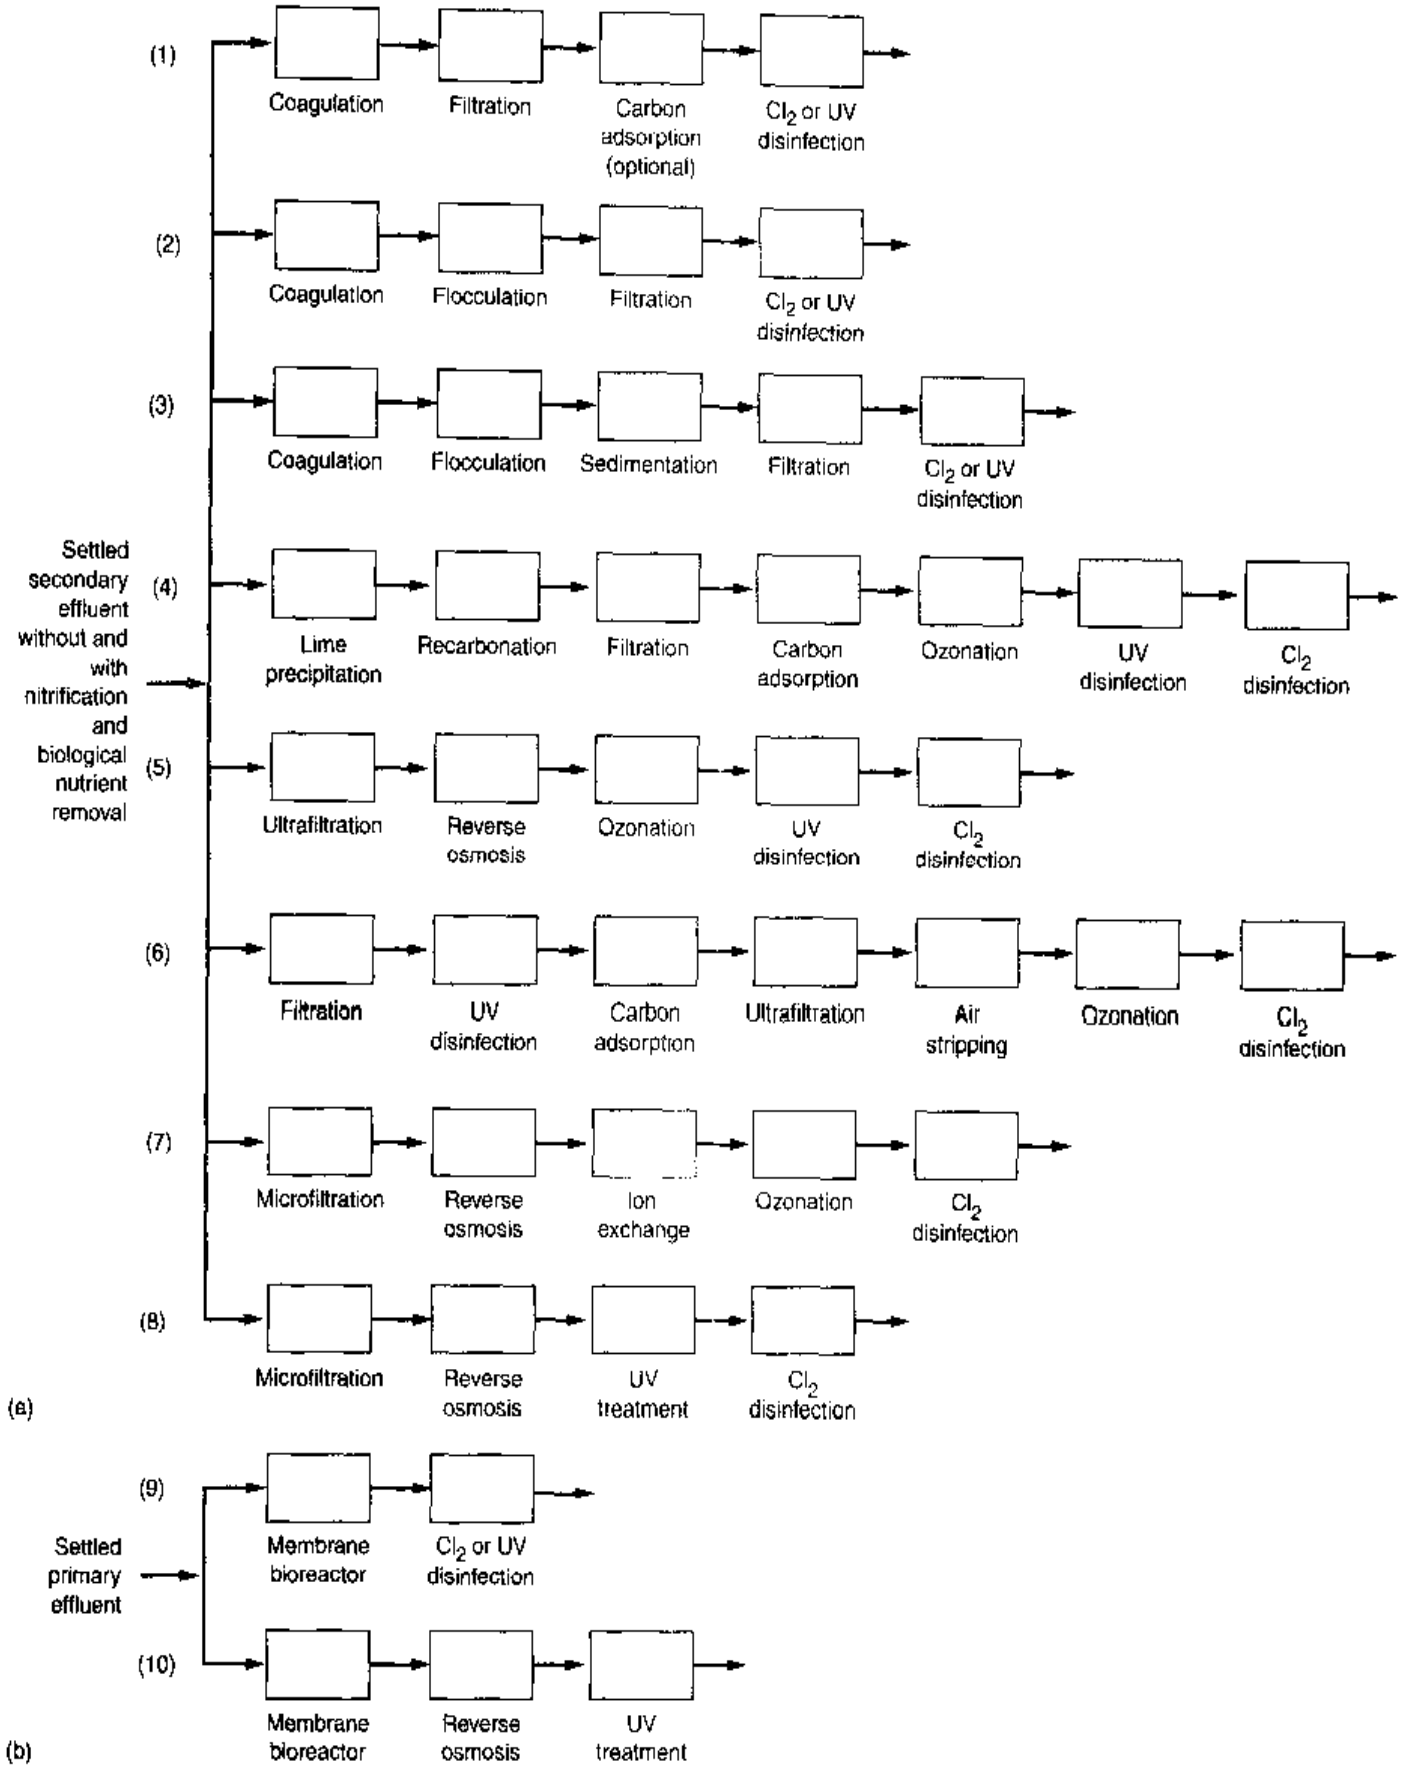

Figure 11–1

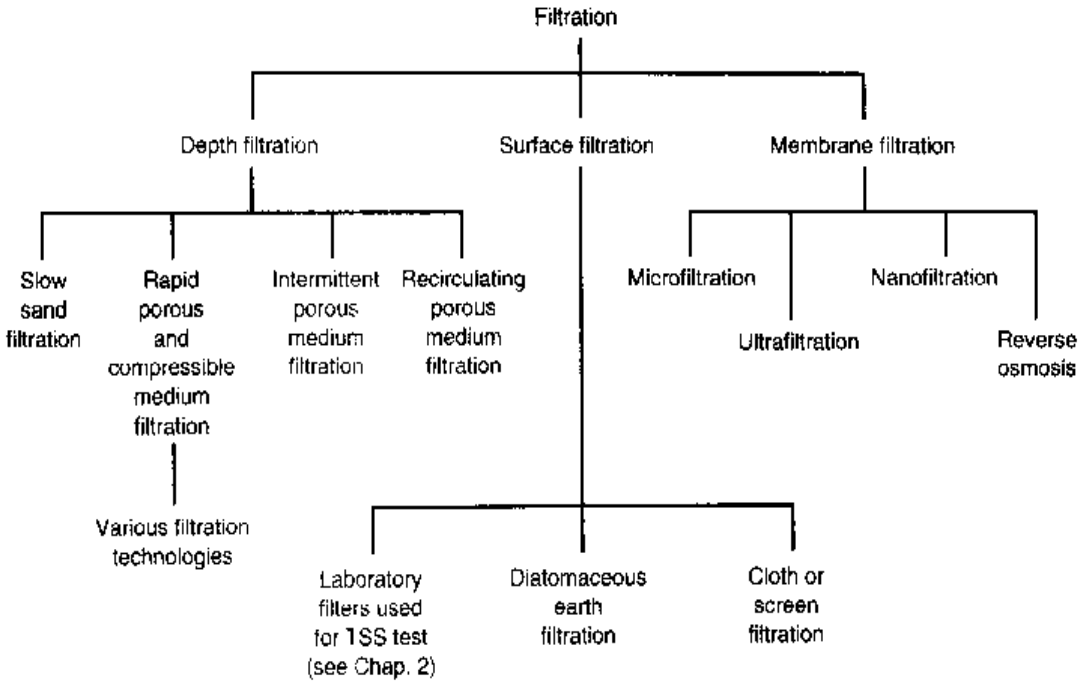
Typical process flow diagrams for wastewater treatment employing advanced treatment processes with (a) settled secondary effluent and (b) settled primary effluent. All of the flow diagrams have been used at one time or another. For example, in flow diagram 7, ion exchange is used for the removal of nitrate. In flow diagram 10, UV can be used for both disinfection and the destruction of NDMA.

Figure 11–2

Classification of filtration processes used in wastewater management. Note: Intermittent and recirculating porous medium filters are used for small systems and are not considered in this text.



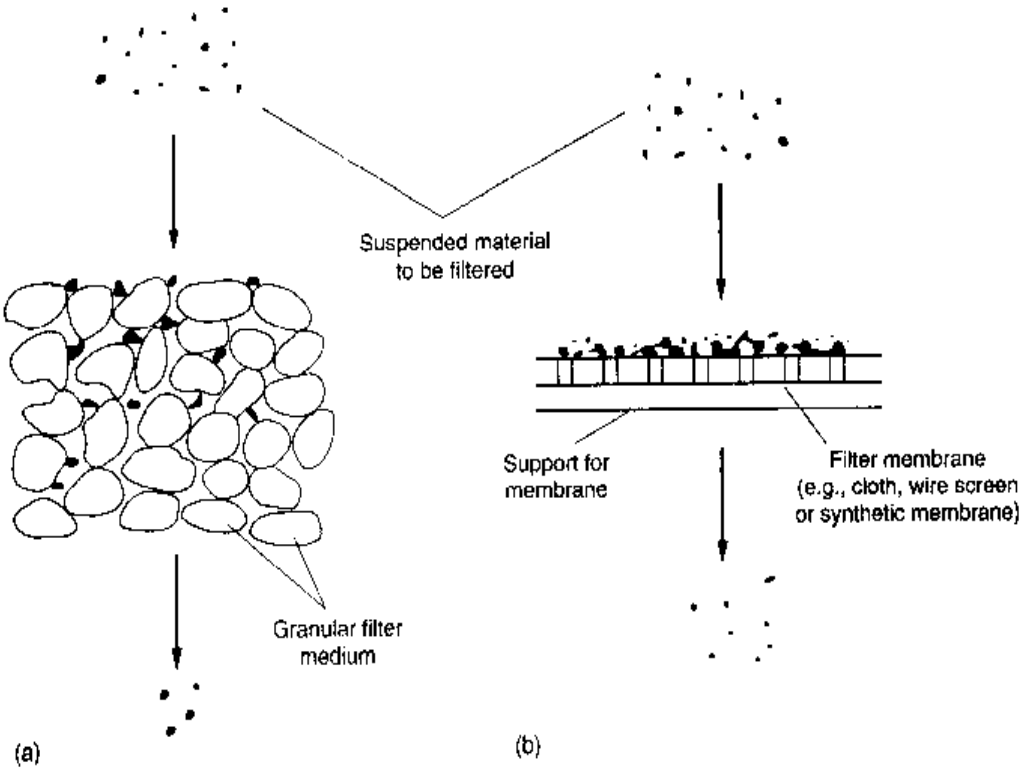


Figure 11–3

Definition sketch for filtration processes: (*a*) depth filtration and (*b*) surface filtration.

Removal of Biological Constituents

In addition to the constituents discussed above, the removal of biological constituents is also of interest. The unit operations and processes that are useful for the removal of biological constituents including bacteria, protozoan cysts and oocysts, and viruses are reported in Table 11–2. Because the effectiveness of the unit operations and processes listed in Table 11–2 is variable, disinfection of the treated effluent is required for most applications.

Process Selection and Performance Data

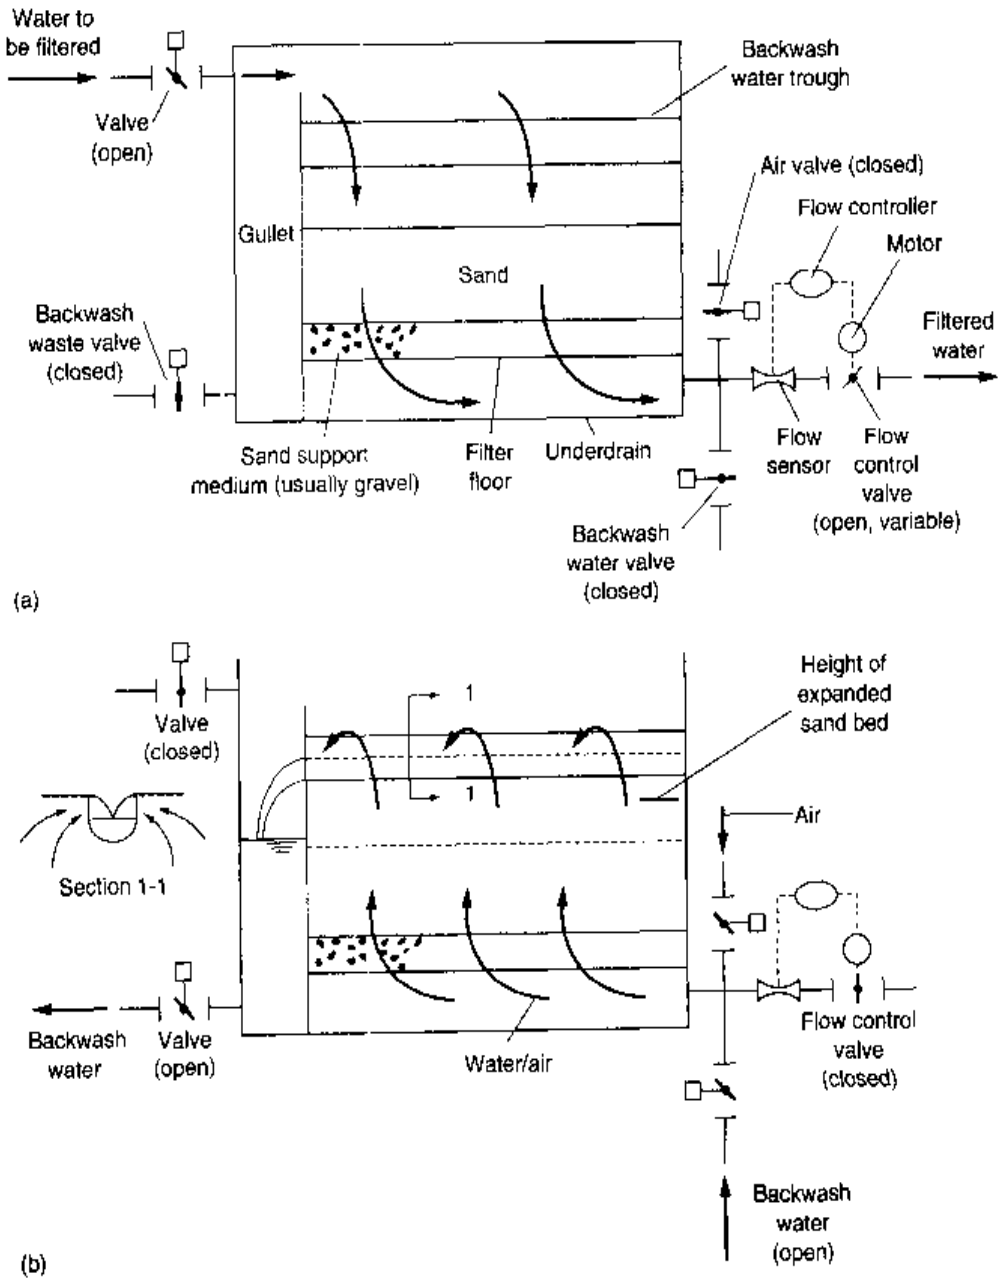
Selection of a given operation, process, or combination thereof depends on (1) the use to be made of the treated effluent, (2) the nature of the wastewater, (3) the compatibility of the various operations and processes, (4) the available means to dispose of the ultimate contaminants, and (5) the environmental and economic feasibility of the various systems. Specific factors that should be considered in the selection of treatment processes may be found in Table 4–11 in Chap. 4. It should be noted that in some situations economic feasibility may not be a controlling factor in the design of advanced wastewater-treatment systems, especially where specific constituents must be removed to protect the environment. Based on the variations in performance observed in the field, pilot-plant testing is recommended for the development of treatment performance data and design criteria. Representative performance data are presented in the discussion of the individual technologies.

11–3 INTRODUCTION TO DEPTH FILTRATION

Depth filtration involves the removal of particulate material suspended in a liquid by passing the liquid through a filter bed comprised of a granular or compressible filter medium (see Fig. 11–3*a*). Although depth filtration is one of the principal unit operations used in the treatment of potable water, the filtration of effluents from wastewater-treatment processes is becoming more common. Depth filtration is now used to achieve supplemental removals of suspended solids (including particulate BOD) from wastewater effluents of biological and chemical treatment processes to reduce the mass discharge of solids and, perhaps more importantly, as a conditioning step that will allow for the effective disinfection of the filtered effluent. Depth filtration is also used as a pretreatment step for membrane filtration (see Sec. 11–6). Single- and two-stage filtration is also used to remove chemically precipitated phosphorus.

Historically, the first depth filtration process developed for the treatment of wastewater was the slow sand filter [typical filtration rates of 30 to 60 L/m^2·d (0.75 to 1.5 gal/ft^2·d), Frankland (1870), and Dunbar (1908)]. The rapid sand filter (typical filtration rates of 80 to 200 L/m^2·min (2.0 to 5.0 gal/ft^2·min), the subject of this section, was developed to treat larger volumes of water in a facility with a smaller footprint. To introduce the subject of depth filtration, the purpose of this section is to present (1) a general introduction to the depth filtration process, (2) an introduction to filter clean-water hydraulics, and (3) an analysis of the filtration process. The types of filters that are available and issues associated with their selection and design, including a discussion of the need for pilot-plant studies, are considered in the following section.

Description of the Filtration Process



Before discussing the available filter technologies, it will be useful to first describe the basics of the depth filtration including (1) the physical features of a conventional granular medium-depth filter, (2) filter-medium characteristics, (3) the *filtration process* in which suspended material is removed from the liquid, (4) the operative particle-removal mechanisms that bring about the removal of suspended material within the filter, and (5) the *backwash process*, in which the material that has been retained within the filter is removed.

Physical Features of a Depth Filter. The general features of a conventional rapid granular medium-depth filter are illustrated on Fig. 11–4. As shown, the filtering medium (sand in this case) is supported on a gravel layer, which, in turn, rests on the filter underdrain system. The water to be filtered enters the filter from an inlet channel. Filtered water is collected in the underdrain system, which is also used to reverse the flow to backwash the filter. Filtered water typically is disinfected before being discharged to the environment. If the filtered water is to be reused, it can be discharged to a storage reservoir or to the reclaimed water distribution system. The hydraulic control of the filter is described in a subsequent section.

Filter-Medium Characteristics. Grain size is the principal filter-medium characteristic that affects the filtration operation. Grain size affects both the clear-water headloss and the buildup of headloss during the filter run. If too small a filtering medium is

Figure 11–4

General features and operation of a conventional rapid granular medium-depth filter: (a) flow during filtration cycle, and (b) flow during backwash cycle. *(From Tchobanoglous and Schroeder, 1985.)*

selected, much of the driving force will be wasted in overcoming the frictional resistance of the filter bed. On the other hand, if the size of the medium is too large, many of the small particles in the influent will pass directly through the bed. The size distribution of the filter material is usually determined by sieve analysis using a series of decreasing sieve sizes. The designation and size of opening for U.S. sieve sizes are given in Table 11–3. The results of a sieve analysis are usually analyzed by plotting the cumulative percent passing a given sieve size on arithmetic-log or probability-log paper (see Example 11–1 and Fig. 11–23).

The effective size of a filtering medium is defined as the 10 percent size based on mass and is designated as d_{10}. For sand, it has been found that the 10 percent size by weight corresponds to the 50 percent size by count. The uniformity coefficient (UC) is defined as the ratio of the 60 percent size to the 10 percent size ($UC = d_{60}/d_{10}$). Sometimes it is advantageous to specify the 99 percent passing size and the 1 percent passing size to define the gradation curve for each filter medium more accurately. Addi-

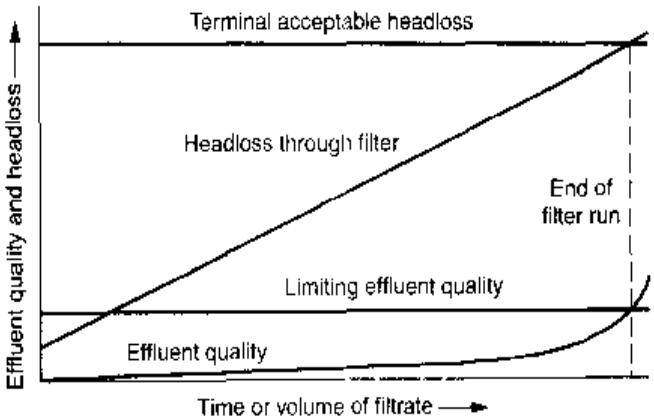

Figure 11–5
Definition sketch for length of filter run based on headloss and effluent turbidity.

tional information on filter-medium characteristics is presented in the following section dealing with the design of filters.

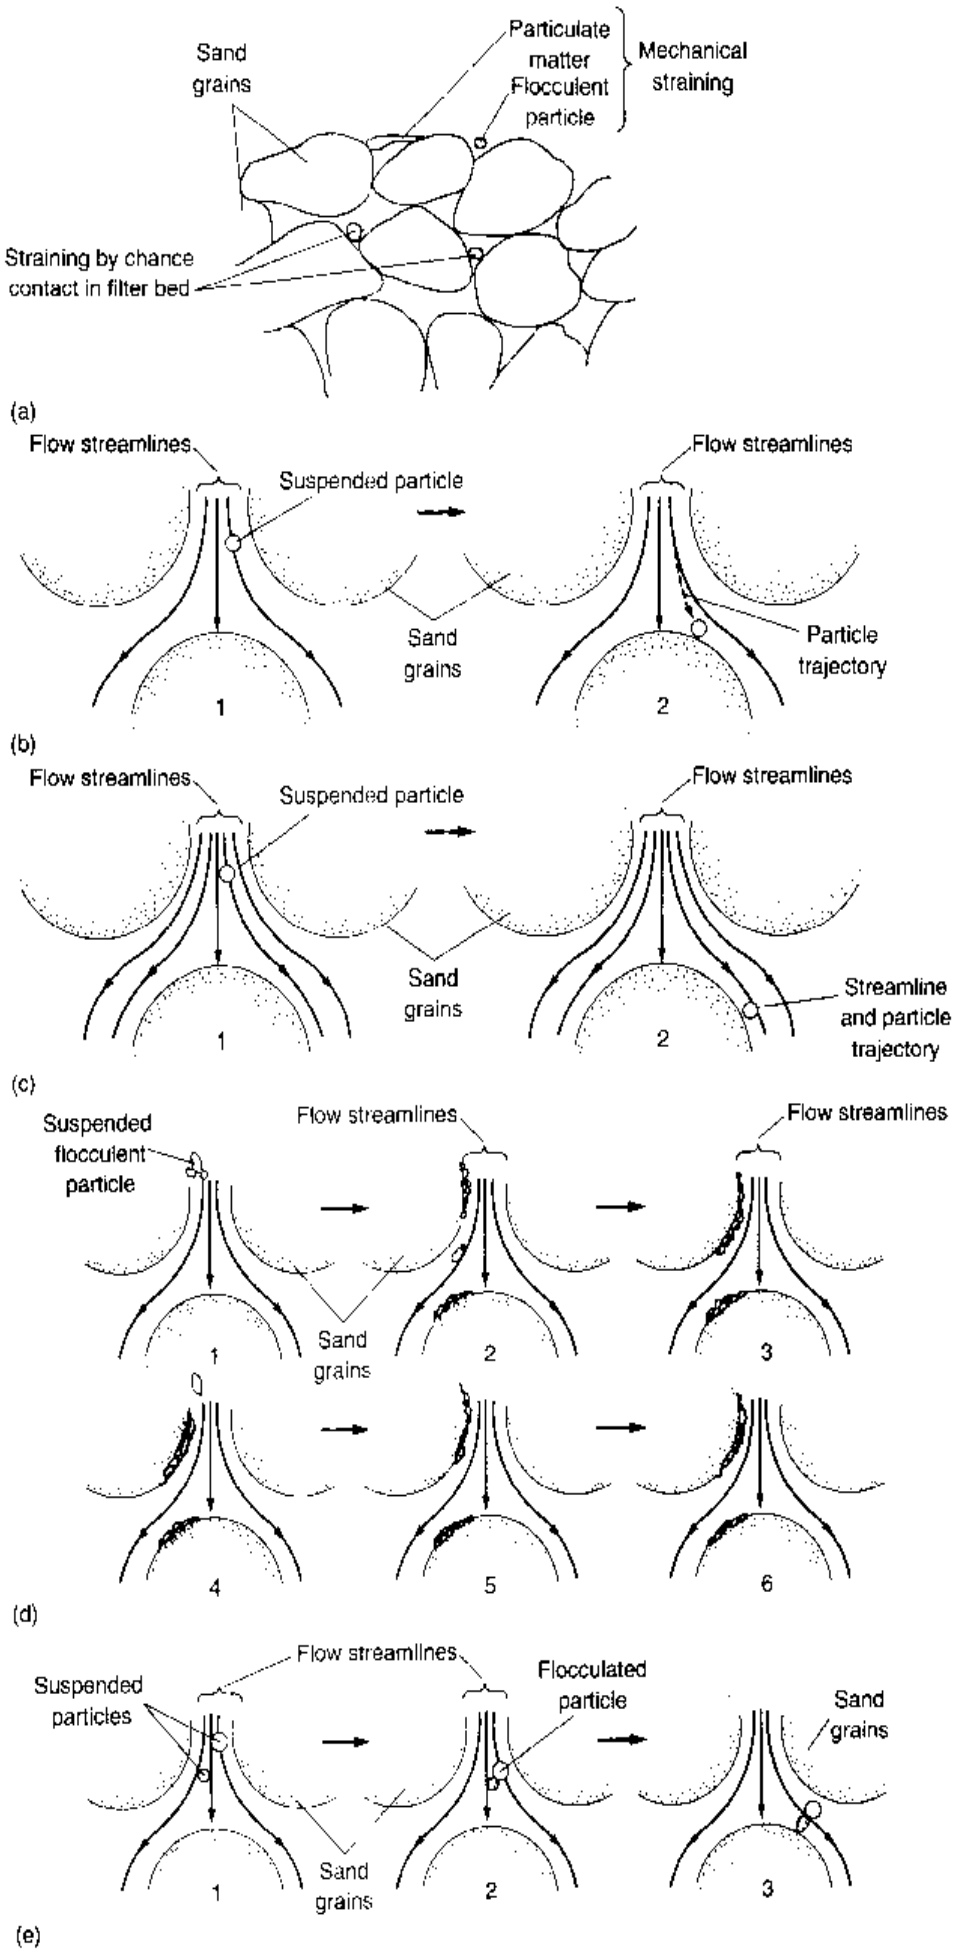
The Filtration Process. During filtration in a conventional downflow depth filter, wastewater containing suspended matter is applied to the top of the filter bed (Fig. 11–4*a*). As the water passes through the filter bed, the suspended matter in the wastewater is removed by a variety of removal mechanisms as described below. With the passage of time, as material accumulates within the interstices of the granular medium, the headloss through the filter starts to build up beyond the initial value, as shown on Fig. 11–5. After some period of time, the operating headloss or effluent turbidity reaches a predetermined headloss or turbidity value, and the filter must be cleaned. Under ideal conditions, the time required for the headloss buildup to reach the preselected terminal value should correspond to the time when the suspended solids in the effluent reach the preselected terminal value for acceptable quality. In actual practice, one or the other event will govern the backwash cycle.

Particle Removal Mechanisms. The principal particle removal mechanisms, believed to contribute to the removal of material within a granular-medium filter, are identified and described in Table 11–4. The major removal mechanisms (the first six listed in Table 11–4) are illustrated pictorially on Fig. 11–6. Straining has been identified as the principal mechanism that is operative in the removal of suspended solids during the filtration of settled secondary effluent from biological treatment processes (Tchobanoglous and Eliassen, 1970). Other mechanisms including impaction, interception, and adhesion are also operative even though their effects are small and, for the most part, masked by the straining action.

The removal of the smaller particles found in wastewater (see Fig. 11–6) must be accomplished in two steps involving (1) the transport of the particles to or near the surface where they will be removed and (2) the removal of particles by one or more of the operative removal mechanisms. This two-step process has been identified as transport and attachment (O'Melia and Stumm, 1967).

Backwash Process. The end of the filter run (filtration phase) is reached when the suspended solids in the effluent start to increase (break through) beyond an acceptable level, or when a limiting headloss occurs across the filter bed (see Fig. 11–5). Once

Table 11–4
Principal mechanisms and phenomena contributing to removal of material within a granular medium-depth filter



Mechanism/ phenomenon	Description
1. Straining	
a. Mechanical	Particles larger than the pore space of the filtering medium are strained out mechanically
b. Chance contact	Particles smaller than the pore space are trapped within the filter by chance contact
2. Sedimentation	Particles settle on the filtering medium within the filter
3. Impaction	Heavy particles will not follow the flow streamlines
4. Interception	Many particles that move along in the streamline are removed when they come in contact with the surface of the filtering medium
5. Adhesion	Particles become attached to the surface of the filtering medium as they pass by. Because of the force of the flowing water, some material is sheared away before it becomes firmly attached and is pushed deeper into the filter bed. As the bed becomes clogged, the surface shear force increases to a point at which no additional material can be removed. Some material may break through the bottom of the filter, causing the sudden appearance of turbidity in the effluent
6. Flocculation	Flocculation can occur within the interstices of the filter medium. The larger particles formed by the velocity gradients within the filter are then removed by one or more of the above removal mechanisms
7. Chemical adsorption	Once a particle has been brought in contact with the surface of the filtering medium or with other particles, either one of these mechanisms, chemical or physical adsorption or both, may be responsible for holding it there
a. Bonding	
b. Chemical interaction	
8. Physical adsorption	
a. Electrostatic forces	
b. Electrokinetic forces	
c. van der Waals forces	
9. Biological growth	Biological growth within the filter will reduce the pore volume and may enhance the removal of particles with any of the above removal mechanisms (1 through 5)

either of these conditions is reached, the filtration phase is terminated, and the filter must be cleaned (backwashed) to remove the material (suspended solids) that has accumulated within the granular filter bed. Backwashing is accomplished by reversing the flow through the filter (see Fig. 11–4*b*). A sufficient flow of washwater is applied until the granular filtering medium is fluidized (expanded), causing the particles of the filtering medium to abrade against each other.

The suspended matter arrested within the filter is removed by the shear forces created by backwash water as it moves up through the expanded bed. The material that has accumulated within the bed is then washed away. Surface washing with water and air

Figure 11-6

Removal of suspended particulate matter within a granular filter (*a*) by straining, (*b*) by sedimentation or inertial impaction, (*c*) by interception, (*d*) by adhesion, (*e*) by flocculation. (*Adapted from Tchobanoglous and Schroeder, 1985.*)

scouring are often used in conjunction with the water backwash to enhance the cleaning of the filter bed. In most wastewater-treatment plant flow diagrams, the washwater containing the suspended solids that are removed from the filter is returned either to the primary settling facilities or to the biological treatment process. Backwash hydraulics are considered in the section dealing with filter hydraulics.

Filter Hydraulics

During the past 60 years considerable effort has been devoted to the modeling of the filtration process. The models fall into two general categories: those models used to predict the clean-water headloss through a filter bed and the filter backwash expansion and those models used to predict the performance of filters for the removal of suspended solids. Filter hydraulics are considered in the following discussion.

Clean-Water Headloss. Over the years several equations have been developed to describe the flow of clean water through a porous medium (Carman, 1937; Fair and Hatch, 1933; Hazen, 1905; Kozeny, 1927; Rose, 1945); these equations are summarized in Table 11–5. In most cases, the equations for the flow of clean water through a porous medium are derived from a consideration of the Darcy-Weisbach equation for flow in a closed conduit and dimensional analysis. The summation term in Eqs. (11–2), (11–6), and (11–8) is included to account for the stratification that occurs in filters. To account for stratification, the mean size of the material retained between successive sieve sizes is assumed to correspond to the mean size of the successive sieves (see Table 11–9 in the following section for sieve sizes), assuming that the particles retained between sieve sizes are substantially uniform (Fair and Hatch, 1933).

In applying the equations given in Table 11–5, some confusion exists over the definition of the shape factor. The definition of the shape factor will depend on whether particle surface, volume, or a linear dimension is of importance in the application (Trussell and Chang, 1999). In Chap. 5, the shape factor for a particle ϕ_p is defined as the ratio of the surface area of an equivalent sphere to the surface area of the particle, for particles of the same volume. For spherical-shaped particles the specific surface area is

$$\frac{A_p}{v_p} = \frac{\pi d^2}{(\pi d^3/6)} = \frac{6}{d} \tag{11-11}$$

where A_p = area of filter-medium particle, m^2, mm^2
v_p = volume of filter-medium particle, m^3, mm^3
d = diameter of filter-medium particle, m, mm

For irregularly shaped particles of the same volume the specific surface area is:

$$\frac{A_p}{v_p} = \frac{6}{\phi d} = \frac{S}{d} \tag{11-12}$$

where ϕ = approximate shape factor
S = approximate area to volume shape factor

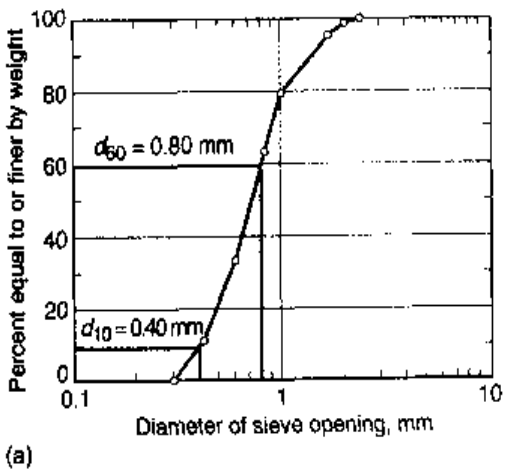
In the literature S has been identified as a shape factor (Fair et al., 1968). The area to volume shape factor is used in the Fair-Hatch equation [(Eq. 11–5)]. Computation of the clean-water headloss through a filter is illustrated in Example 11–1.

Table 11–5
Formulas used to compute the clean-water headloss through a granular porous medium

Equation	No.
Carman-Kozeny (Carman, 1937)	
$h = \frac{f}{\phi}\frac{1-\alpha}{\alpha^3}\frac{L}{d}\frac{v_s^2}{g}$	(11–1)
$h = \frac{1}{\phi}\frac{1-\alpha}{\alpha^3}\frac{Lv_s^2}{g}\sum f\frac{p}{d_g}$	(11–2)
$f = 150\frac{1-\alpha}{N_R} + 1.75$	(11–3)
$N_R = \frac{\phi d v_s \rho}{\mu}$	(11–4)
Fair-Hatch (Fair and Hatch, 1933)	
$h = kvS^2\frac{(1-\alpha)^2}{\alpha^3}\frac{L}{d^2}\frac{v_s}{g}$	(11–5)
$h = kv\frac{(1-\alpha)^2}{\alpha^3}\frac{Lv_s}{g}\left(\frac{6}{\phi}\right)^2\sum\frac{p}{d_g^2}$	(11–6)
Rose (Rose, 1945)	
$h = \frac{1.067}{\phi}C_d\frac{1}{\alpha^4}\frac{L}{d}\frac{v_s^2}{g}$	(11–7)
$h = \frac{1.067}{\phi}\frac{Lv_s^2}{\alpha^4 g}\sum C_d\frac{p}{d_g}$	(11–8)
$C_d = \frac{24}{N_R} + \frac{3}{\sqrt{N_R}} + 0.34$	(11–9)
Hazen (Hazen, 1905)	
$h = \frac{1}{C}\frac{60}{T+10}\frac{L}{(d_{10})^2}v_h$	(11–10)

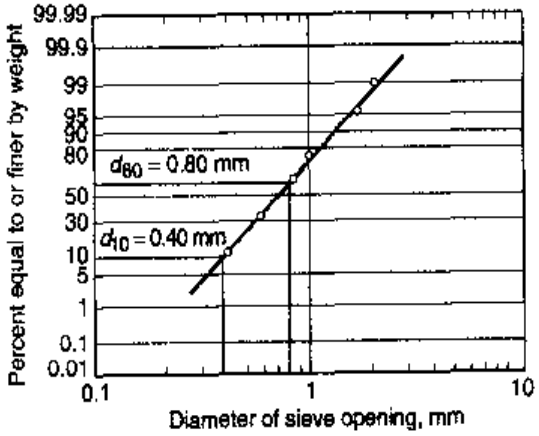
Definition of terms

- C = coefficient of compactness (varies from 600 for very closely packed sands that are not quite clean to 1200 for very uniform clean sand)
- C_d = coefficient of drag
- d = grain size diameter, m (ft)
- d_g = geometric mean diameter between sieve sizes d_1 and d_2, $\sqrt{d_1 d_2}$, mm (in)
- d_{10} = effective grain size diameter, mm
- f = friction factor
- g = acceleration due to gravity, 9.81 m/s² (32.2 ft/s²)
- h = headloss, m (ft)
- k = filtration constant, 5 based on sieve openings, 6 based on size of separation
- L = depth of filter bed or layer, m (ft)
- N_R = Reynolds number
- p = fraction of particles (based on mass) within adjacent sieve sizes
- S = shape factor (varies between 6.0 for spherical particles and 8.5 for crushed materials)
- T = temperature, °C (°F)
- v_h = superficial (approach) filtration velocity, m/d (ft/d)
- v_s = superficial (approach) filtration velocity, m/s (ft/d)
- α = porosity
- μ = viscosity, N·s/m² (lb·s/ft²)
- ν = kinematic viscosity, m²/s (ft²/s)
- ρ = density = kg/m³ (lb·s²/ft⁴)
- ϕ = particle shape factor (1.0 for spheres, 0.82 for rounded sand, 0.75 for average sand, 0.73 for crushed coal and angular sand)



EXAMPLE 11–1 Determination of Clean-Water Headloss in a Granular-Medium Filter Determine the effective size, the uniformity coefficient, and the clean-water headloss in a filter bed composed of 0.75 m of uniform sand with the size distribution given below for a filtration rate of 160 L/m²·min. Assume that the operating temperature is 20°C. Use the Rose equation [Eq. (11–8)] given in Table 11–5 for computing the headloss. Assume the porosity of the sand in the various layers is 0.40 and use a value of 0.85 for the shape factor for sand.

Sieve size or number	Percent of sand retained	Cumulative percent passing	Geometric mean size[a], mm
6–8	0	100	
8–10	1	99	2.18
10–12	3	96	1.83
12–18	16	80	1.30
18–20	16	64	0.92
20–30	30	34	0.71
30–40	22	12	0.50
40–50	12		0.35



[a]Using sieve size data from Table 11–3, the geometric mean size $d_g = \sqrt{d_1 d_2}$.

Solution

1. Determine the effective size and the uniformity coefficient of the sand. Plot the cumulative percent passing versus the corresponding sieve size. Two different methods of plotting the data are presented below.

(a)

(b)

   a. The effective size d_{10} read from the graphs is 0.40 mm.
   b. The uniformity coefficient is

$$\text{UC} = \frac{d_{60}}{d_{10}} = \frac{0.80\text{ mm}}{0.40\text{ mm}} = 2.0$$

2. Determine the clean-water headloss using Eq. (11–8).

$$h = \frac{1.067}{\phi}\,\frac{Lv_s^2}{\alpha^4 g}\,\Sigma C_d\,\frac{p}{d_g}$$

   a. Set up computation table to determine the summation term in Eq. (11–8).

Sieve size or number	Fraction of sand retained	Geometric mean size, $d_g \times 10^3$ m	Reynolds number, N_R	C_d	$C_d(p/d)$, m^{-1}
8–10	0.01	2.18	4.93	6.56	30
10–12	0.03	1.83	4.15	7.60	124
12–18	0.16	1.30	2.93	10.28	1,268
18–20	0.16	0.92	2.08	13.99	2,441
20–30	0.30	0.71	1.60	17.71	7,509
30–40	0.22	0.50	1.13	24.38	10,729
40–50	0.12	0.35	0.80	33.73	11,459
Sum					33,560

i. Determine the C_d value for each geometric mean as illustrated below.

$$C_d = \frac{24}{N_R} + \frac{3}{\sqrt{N_R}} + 0.34$$

$$N_R = \frac{\phi d v_s \rho}{\mu} = \frac{\phi d v_s}{\nu}$$

$d = 2.18$ mm

$$v_s = \frac{(60\ \text{L/m}^2\cdot\text{min})}{(10^3\ \text{L/m}^3)(60\ \text{s/min})} = 0.00267\ \text{m/s}$$

$\nu = 1.003 \times 10^{-6}$ m^2/s (see Appendix C)

$$N_R = \frac{(0.85)(0.00218\ \text{m})(0.00267\ \text{m/s})}{(1.003 \times 10^{-6}\ \text{m}^2/\text{s})}$$

$N_R = 4.93$

ii. Determine C_d.

$$C_d = \frac{24}{4.93} + \frac{3}{\sqrt{4.93}} + 0.34 = 6.56$$

b. Determine the headloss through the stratified filter bed using Eq. (11–8).

$L = 0.75$ m

$v_s = 0.00267$ m/s

$\phi = 0.85$

$\alpha = 0.40$

$$g = 9.81 \text{ m/s}^2$$

$$h = \frac{1.067}{(0.85)} \frac{(0.75 \text{ m})(0.00267 \text{ m/s})^2}{(0.40)^4(9.81 \text{ m/s}^2)} (33{,}500/\text{m})$$

$$h = 0.90 \text{ m}$$

Backwash Hydraulics. To understand what happens during the backwash operation it will be helpful to refer to Fig. 11–7 in which the pressure drop across a packed bed is illustrated as the backwash velocity through it increases. Between points *A* and *B*, the bed is stable, and the pressure drop and Reynolds number N_R are related linearly. At point *B*, the pressure drop essentially balances the weight of the filter. Between points *B* and *C* the filter bed is unstable, and the particles comprising the filter medium adjust their position to present as little resistance to flow as possible. At point *C*, the loosest possible arrangement is obtained in which the particles are still in contact. Beyond point *C*, the particles begin to move freely but collide frequently so that the motion is similar to that of particles in hindered settling. Point *C* is referred to as the "point of fluidization." By the time point *D* is reached, the particles are all in motion, and, beyond this point, increases in N_R result in very small increases in ΔP as the bed continues to expand and the particles move in more rapid and more independent motion. Ultimately, the particles will stream with the fluid, and the bed will cease to exist at point *E*.

To expand a filter bed comprised of a uniform filter medium hydraulically, the headloss must equal the buoyant mass of the granular medium in the fluid. Mathematically this relationship can be expressed as

$$h = L_e(1 - \alpha_e)\left(\frac{\rho_s - \rho_w}{\rho_w}\right) \tag{11-13}$$

where h = headloss required to expand the bed
L_e = depth of the expanded bed
α_e = expanded porosity

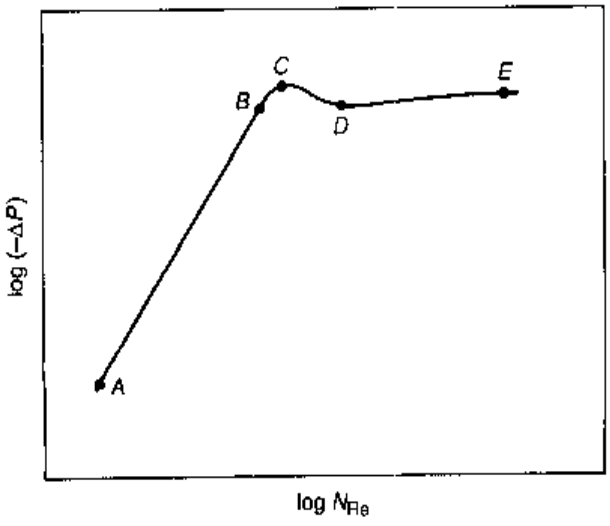


Figure 11–7
Schematic diagram illustrating the fluidization of a filter bed. *(Adapted from Foust et al. 1960.)*

ρ_s = density of the medium
ρ_w = density of water

Because the individual particles are kept in suspension by the drag force exerted by the rising fluid, it can be shown from settling theory (see Sec. 5–5) that

$$C_D A_p \rho_w \frac{v^2}{2} \phi(\alpha_e) = (\rho_s - \rho_w) g v_p \tag{11–14}$$

where v = face velocity of backwash water, m/s
$\phi(\alpha_e)$ = correction factor to account for the fact that v is the velocity of the backwash water and not the particle-settling velocity v_p

and other terms are as defined previously.

From experimental studies (Fair, 1951; Richardson and Zaki, 1954) it has been found that the expanded-bed porosity can be approximated using the following relationships, assuming the Reynolds number is approximately 1.

$$\phi(\alpha_e) = \left(\frac{v_s}{v}\right)^2 = \left(\frac{1}{\alpha_e}\right)^9 \tag{11–15}$$

Thus

$$\alpha_e = \left(\frac{v}{v_s}\right)^{0.22} \tag{11–16}$$

or

$$v = v_s \alpha_e^{4.5} \tag{11–17}$$

where v_s = settling velocity of particle, m/s

However, because the volume of the filtering medium per unit area remains constant, $(1 - \alpha)L$ must be equal to $(1 - \alpha_e)L_e$ so that

$$\frac{L_e}{L} = \frac{1 - \alpha}{1 - \alpha_e} = \frac{1 - \alpha}{1 - (v/v_s)^{0.22}} \tag{11–18}$$

Where the filter medium is stratified, the smaller particles in the upper layers expand first. To expand the entire bed, the backwash velocity must be sufficient to lift the largest particle. To account for filter-bed stratification, Eq. (11–18) is modified assuming that particles retained between sieve sizes are substantially uniform (Fair and Hatch, 1933).

$$\frac{L_e}{L} = (1 - \alpha) \Sigma \frac{p}{(1 - \alpha_e)} \tag{11–19}$$

where p = fraction of filter medium retained between sieve sizes.

Thus, the required backwash velocity and expanded depth can be estimated using Eqs. (11–18) and (11–19), respectively, as illustrated in Example 11–2. Additional details on filter-bed expansion may be found in Amirtharajah (1978), Cleasby and Fan (1982), and Dharmarajah and Cleasby (1986); Kawamura (2000), Leva (1959); and Richardson and Zaki (1954).

EXAMPLE 11-2 Determination of Required Backwash Velocities for Filter Cleaning A stratified sand bed with the size distribution given below is to be backwashed at a rate of 0.75 m/min. Determine the degree of expansion and whether the proposed backwash rate will expand all of the bed. Assume the following data are applicable:

Sieve size or number	Percent of sand retained	Geometric mean size[a], mm
6–8	0	2.83
8–10	1	2.18[b]
10–12	3	1.83
12–18	16	1.30
18–20	16	0.92
20–30	30	0.71
30–40	22	0.50
40–50	12	0.35

[a]Based on sieve sizes given in Table 11–3.

[b]2.18 $\sqrt{2.38 \times 2.0}$

1. Granular medium = sand
2. Specific gravity of sand = 2.65
3. Depth of filter bed = 0.90 m
4. Temperature = 20°C

Solution

1. Set up computation table to determine the summation term in Eq. (11–19).

$$\frac{L_e}{L} = (1 - \alpha)\Sigma \frac{p}{(1 - \alpha_e)}$$

Sieve size or number	Fraction of sand retained	Geometric mean size d_g, mm	v_s, m/s	v/v_s	α_e	$p/(1 - \alpha_e)$
8–10	0.01	2.18	0.304	0.041	0.496	0.020
10–12	0.03	1.83	0.270	0.046	0.509	0.061
12–18	0.16	1.30	0.210	0.060	0.538	0.346
18–20	0.16	0.92	0.157	0.080	0.573	0.351
20–30	0.30	0.71	0.123	0.102	0.605	0.760
30–40	0.22	0.50	0.085	0.146	0.655	0.638
40–50	0.12	0.35	0.055	0.227	0.722	0.432
Summation						2.632

a. Determine the particle settling velocity as illustrated in Example 5–6. Alternatively, the settling velocities can be estimated using Fig. 5–21 in Chap. 5. The computed settling velocity values are entered in the computation table.
b. Determine the values of v/v_s and enter the computed values in the computation table. The backwash velocity is $v = 0.75$ m/min $= 0.0125$ m/s.
c. Determine the values of α_e and enter the computed values in the computation table.

$$\alpha_e = \left(\frac{v}{v_s}\right)^{0.22} = \left(\frac{0.0125}{0.304}\right)^{0.22} = 0.496$$

d. Determine the values for column 7 and enter the computed values in the computation table.

$$\frac{p}{1 - \alpha_e} = \frac{1}{1 - 0.496} = 1.98$$

2. Determine the expanded-bed depth using Eq. (11–19).

$$\frac{L_e}{L} = (1 - \alpha)\Sigma \frac{p}{(1 - \alpha_e)}$$

$$L_e = (0.9 \text{ m})\,(1 - 0.4)\,(2.63) = 1.42 \text{ m}$$

3. Because the expanded porosity of the largest size fraction (0.496) is greater than the normal porosity of the filter material, the entire filter bed will be expanded.

Comment The expanded depth needs to be known to establish the minimum height of the washwater troughs above the surface of the filter bed. In practice, the bottom of the backwash-water troughs is set from 50 to 150 mm (2 to 6 in) above the expanded filter bed. The width and depth of the troughs should be sufficient to handle the volume of backwash water used to clean the bed, with a minimum freeboard of 600 mm (24 in) at the upper end of the trough.

Analysis of the Filtration Process

In general, the mathematical characterization of the time-space removal of particulate matter within the filter is based on a consideration of the equation of continuity, together with an auxiliary rate equation.

Equation of Continuity. The equation of continuity for the filtration operation may be developed by considering a suspended-solids mass balance for a section of filter of cross-sectional area A and of thickness Δz, measured in the direction of flow (see Fig. 11–8). Following the approach delineated in Chap. 4, the mass balance would be as follows:

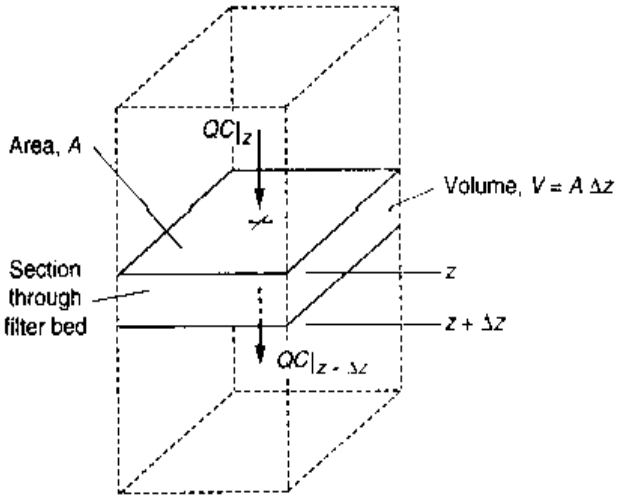

Figure 11–8
Definition sketch for the analysis of the filtration process. *(From Tchobanoglous and Schroeder, 1985.)*

1. General word statement:

$$\begin{pmatrix}\text{Rate of accumulation}\\ \text{of solids within the}\\ \text{volume element}\end{pmatrix} = \begin{pmatrix}\text{rate of}\\ \text{flow into the}\\ \text{volume element}\end{pmatrix} - \begin{pmatrix}\text{rate of}\\ \text{flow out of the}\\ \text{volume element}\end{pmatrix} \qquad (11\text{–}20)$$

2. Simplified word statement:

Accumulation = inflow − outflow

3. Symbolic representation:

$$\left(\frac{\partial q}{\partial t} + \alpha(t)\frac{\partial \bar{C}}{\partial t}\right)\Delta V = QC + Q\left(C + \frac{\Delta C}{\Delta z}\Delta z\right) \qquad (11\text{–}21)$$

where $\partial q/\partial t$ = change in quantity of solids deposited within the filter time, g/m^3·min
$\alpha(t)$ = average porosity as a function of time
$\partial \bar{C}/\partial t$ = change in average concentration of solids in pore space with time, g/m^3·min
ΔV = differential volume, m^3
Q = volumetric flowrate, L/min (the unit L/min is used for convenience)
C = concentration of suspended solids, g/m^3
$\Delta C/\Delta z$ = change in concentration of suspended solids in fluid stream with distance, g/m^3·m

Substituting $A\,\Delta z$ for ΔV and Av for Q where v is the filtration velocity, simplifying, and taking the limit as Δz approaches zero, Eq. (11–21) becomes

$$-v\frac{\partial C}{\partial z} = \frac{\partial q}{\partial t} + \alpha(t)\frac{\partial \bar{C}}{\partial t} \qquad (11\text{–}22)$$

In Eq. (11–22), the first term represents the difference between the mass of suspended solids entering and leaving the section; the second term represents the time rate of change in the mass of suspended solids accumulated within the interstices of the filter medium; and the third term represents the time rate of change in the suspended-solids concentration in the pore space within the filter volume.

In a flowing process, the quantity of fluid contained within the bed is usually small compared with the volume of liquid passing through the bed. In this case, the materials balance equation can be written as

$$-v\frac{\partial C}{\partial z} = \frac{\partial q}{\partial t} \tag{11-23}$$

Equation (11–23) is the one most commonly found in the literature dealing with filtration theory.

If the shape of the removal curve within the filter does not vary with time, the equation of continuity [Eq. (11–23)] may be written as an ordinary differential equation:

$$-v\frac{dC}{dz} = \frac{dq}{dt} \tag{11-24}$$

Rate Equation. To solve Eq. (11–24), an additional independent equation is required. The most direct approach is to derive a relationship that can be used to describe the change in concentration of suspended matter with distance, such as

$$\frac{\partial C}{\partial z} = \phi(V_1, V_2, V_3, \ldots) \tag{11-25}$$

in which V_1, V_2, and V_3 are the variables governing the removal of suspended matter from solution.

An alternative approach is to develop a complementary equation in which the pertinent process variables are related to the amount of material retained (accumulated) within the filter at various depths. In equation form, this may be written as

$$\frac{\partial q}{\partial t} = \phi(V_1, V_2, V_3, \ldots) \tag{11-26}$$

As noted previously, the principal removal mechanism for the residual suspended solids found in settled secondary effluent from biological treatment processes is straining. The removal of suspended material by straining can be identified by noting (1) the variation in the normalized concentration-removal curves through the filter as a function of time, and (2) the shape of the headloss curve for the entire filter or an individual layer within the filter. If straining is the principal removal mechanism, the shape of the normalized removal curve will not vary significantly with time (see Fig. 11–9*a*), and the headloss curves will be curvilinear (Tchobanoglous and Eliassen, 1970). If the floc particles that are being filtered are easily broken apart, the normalized removal curves will vary with time as shown on Fig. 11–9*b*.

From the size and distribution of the influent particles (see Fig. 2–9, Chap. 2) and the shape of the normalized curves (see Fig. 11–9*a*), it can be concluded that the rate of change of concentration with distance must be proportional to some removal coefficient that is changing with the degree of treatment or removal achieved in the filter. For example, the entire particle-size distribution in the influent is passed through the first layer. The probability of removing particles from the waste stream is p_1. In the second layer, the probability of removing particles is p_2; p_2 is less than p_1, assuming that some of the larger particles will be removed by the first layer. Continuing this argument, it

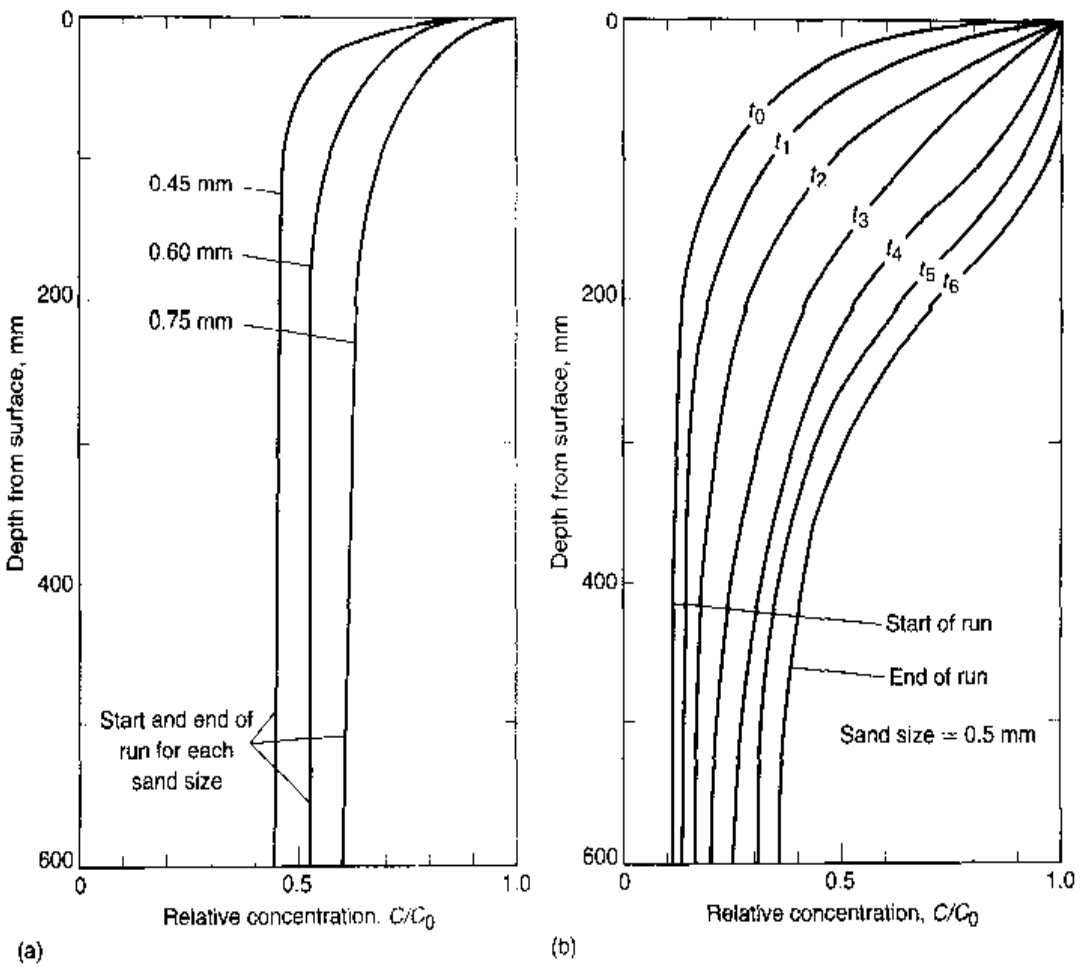

Figure 11-9

Normalized suspended-solids removal curves as a function of depth and time as observed during (*a*) the filtration of settled effluent from an activated-sludge treatment process and (*b*) the filtration of pretreated wastewater (coagulation/flocculation/sedimentation) with a weak floc. When the removal curves do not vary significantly with time as shown on Fig. 11–9*a*, straining is the predominant removal mechanism.

can be reasoned that the rate of removal must always be changing as a function of the degree of treatment. This phenomenon can be expressed mathematically using the following equation:

$$\frac{dC}{dz} = \left[\frac{1}{(1 + az)^n}\right] r_o C \tag{11–27}$$

where C = concentration, mg/L
z = distance from top of filter bed, cm
r_o = initial removal rate, cm^{-1}
a, n = constants

In Eq. (11–27), the term within brackets is a retardation factor as described in Chap. 4. When the exponent n is equal to zero, the term within the brackets is equal to 1; under these conditions, Eq. (11–27) represents a logarithmic curve. When n equals 1, the value of the term within brackets drops off rapidly in the first 125 mm (5 in) and then more gradually as a function of distance. Therefore, it appears that the exponent n may be related to the distribution of particle sizes in the influent. For example, when dealing with a uniform filter medium and filtering particles of one size, it would be expected that the value of the exponent n would be equal to zero and that the initial removal could be described as a first-order removal function. It should be noted that this equation was verified only for filtration rates up to 400 $L/m^2 \cdot min$ (10 $gal/ft^2 \cdot min$).

The value of r_o, the initial removal rate constant, is obtained by computing the slope of the removal curve at near zero depth, because $[1/(1 + az)^n] \approx 1$. The easiest way to determine the slope is to rewrite Eq. (11–27) as follows:

$$\left(\frac{Cr_o}{dC/dz}\right)^{1/n} = 1 + az \tag{11–28}$$

If Eq. (11–28) is plotted functionally, the valve of n is equal to the value that results in a straight-line plot. The slope of the line describing the experimental data will be equal to the constant a.

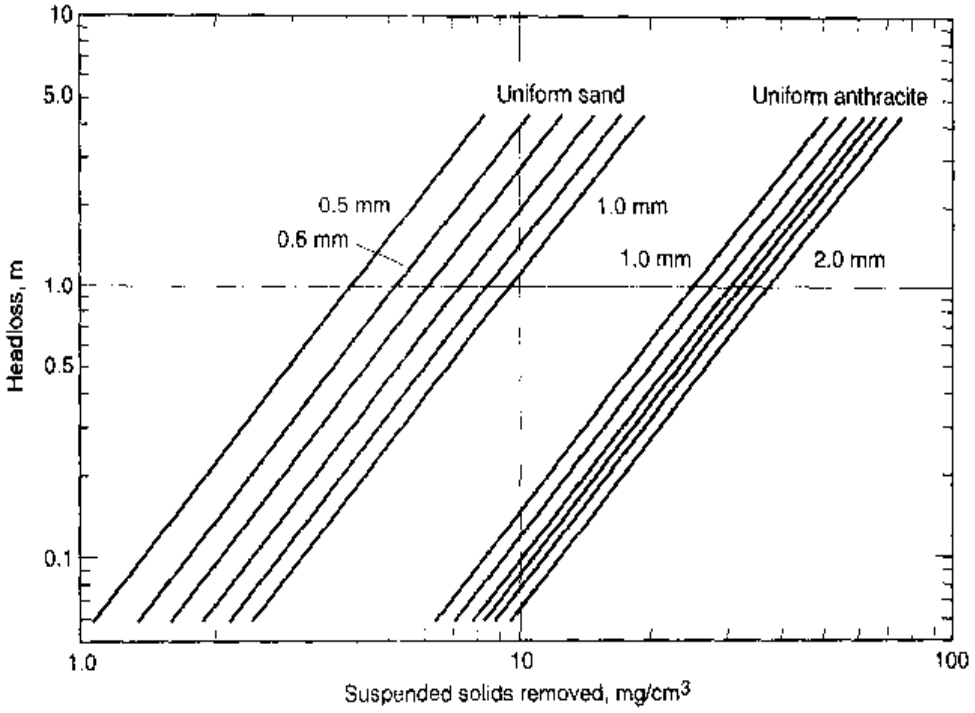
Generalized Rate Equation. On the basis of experimental results derived from pilot testing and data reported in the literature, there appear to be five major factors that affect the time-space removal of the residual suspended matter from a biological treatment process within a granular filter for a given temperature. These factors are the size of the filter medium, the rate of filtration, the influent particle size and size distribution, the floc strength, and the amount of material removed within the filter. Although a number of different formulations are possible, a generalized rate equation in which all five factors are considered can be developed by multiplying Eq. (11–27) by a factor that takes into account the effect of the material accumulated in the filter. The proposed equation is

$$\frac{dC}{dz} = -\frac{1}{(1 + az)^n} r_o C\left(1 - \frac{q}{q_u}\right)^m \tag{11–29}$$

where q = quantity of suspended solids deposited in the filter
q_u = ultimate quantity of solids that can be deposited in the filter
m = a constant related to floc strength

Initially, when the amount of material removed by the filter is low, $q = 0$; $(1 - q/q_u)^m = 1$, and Eq. (11–29) is equivalent to Eq. (11–27). As the upper layers begin to clog, the term $(1 - q/q_u)^m$ approaches zero, and the rate of change in concentration with distance is equal to zero. At the lower depths, the amount of material removed is essentially zero, and the previous analysis applies.

Headloss Development. In the past, the most commonly used approach to determine headloss in a clogged filter was to compute it with a modified form of the equations used to evaluate the clear-water headloss (see Table 11–5). In all cases, the difficulty encountered in using these equations is that the porosity must be estimated for various degrees of clogging. Unfortunately, the complexity of this approach renders most of these formulations useless or, at best, extremely difficult to use.



An alternative approach is to relate the development of headloss to the amount of material removed by the filter. The headloss would then be computed using the expression

$$H_t = H_o + \sum_{i=1}^{n} (h_i)_t \tag{11–30}$$

where H_t = total headloss at time t, m (ft)
H_o = total initial clear-water headloss, m (ft)
$(h_i)_t$ = headloss in the ith layer of the filter at time t, m (ft)

Figure 11–10

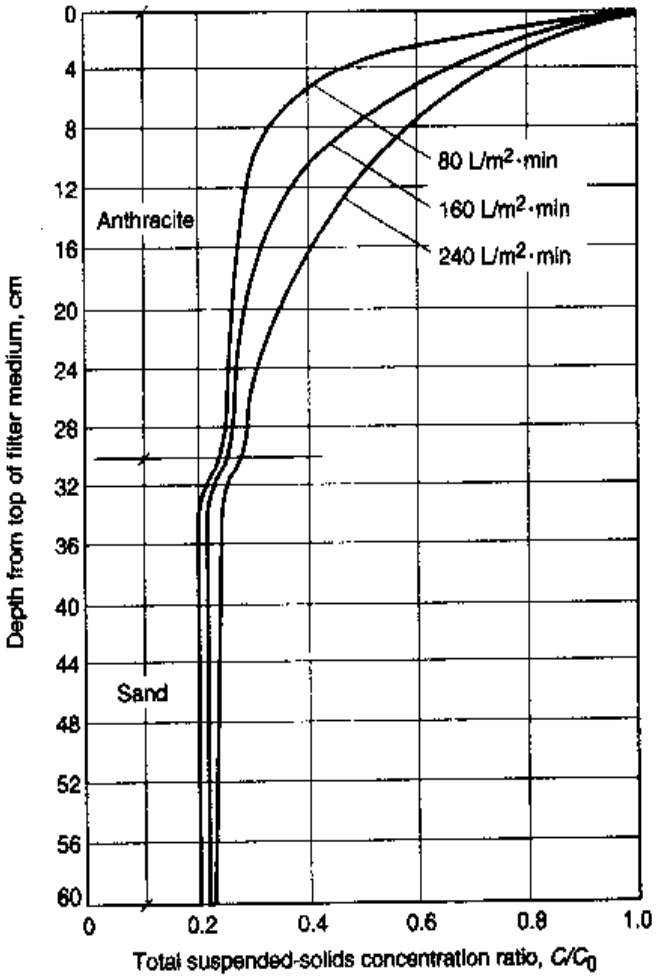
Headloss versus suspended solids removed for various sizes of uniform sand and anthracite. *(Adapted from Tchobanoglous and Eliassen, 1970.)*

From an evaluation of the incremental headloss curves for uniform sand and anthracite, the buildup of headloss in an individual layer of the filter was found to be related to the amount of material contained within the layer (see Fig. 11–10). The form of the resulting equation for headloss in the *i*th layer is

$$(h_i)_t = a(q_i)_t^b \tag{11-31}$$

where $(q_i)_t$ = amount of material deposited in the *i*th layer at time *t*, mg/cm^3
a, b = constants

In Eq. (11–31), it is assumed that the buildup of headloss is only a function of the amount of material removed. Determination of the buildup of headloss during the filtration process using the data presented on Fig. 11–10 is illustrated in Example 11–3.



EXAMPLE 11–3 Analysis of Filtration Data from a Pilot Plant used to Filter Settled Effluent from an Activated-Sludge Process The normalized suspended-solids-removal-ratio curves shown below were derived from a filtration pilot-plant study conducted at an activated-sludge wastewater-treatment plant. Using these curves and the following data, develop curves that can be used to estimate (1) the headloss buildup as a function of the length of run and (2) the length of run to a terminal headloss of 3.0 m (10 ft) as a function of the filtration rate.

Biological treatment process

1. Solids retention time SRT = 15 d
2. Average suspended-solids concentration in effluent from secondary settling tank = 20 mg/L

Pilot plant

1. Type of filter bed = dual-medium
2. Filter media = graded anthracite and sand
3. Filter-medium characteristics
   a. Anthracite, d_{10} = 1.4 mm, $UC \approx 1.4$
   b. Sand, d_{10} = 0.6 mm, $UC \approx 1.4$
4. Filter-bed depth = 0.3 m
   a. Anthracite = 0.3 m
   b. Sand = 0.3 m
5. Filtration rates = 80, 160, and 240 L/m^2·min
6. Temperature = 20°C
7. General observation: average concentration-ratio curves given in the following figure did not vary significantly with time

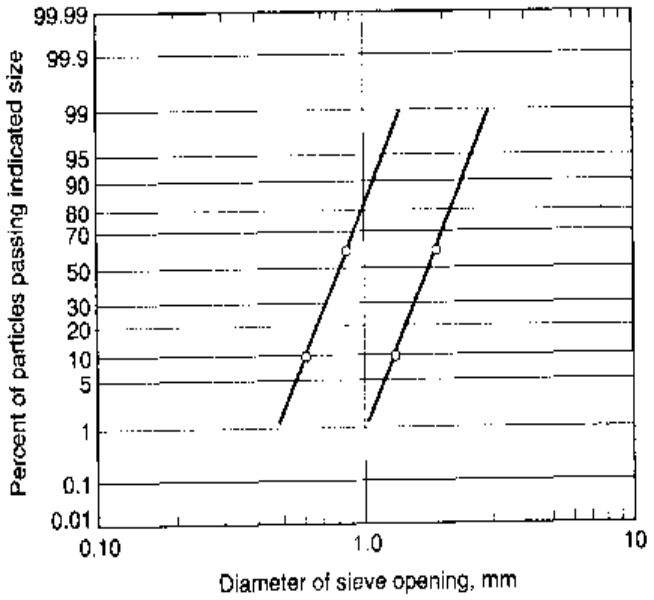
Average suspended-solids concentration-ratio curves versus filter depth for various filtration rates.

Solution

1. To analyze the concentration-ratio curves, rewrite Eq. (11–24) in a form suitable for numerical analysis:

$$-v\frac{\Delta C}{\Delta z} = \frac{\Delta q}{\Delta t}$$

$$-v\frac{C_{z-1} - C_z}{z_{z-1} - z_z} = \frac{q_2 - q_1}{t_2 - t_1}$$



2. Set up a computation table and determine the values of ΔC ($C_{z-1} - C_z$) and the mean grain size for various depth intervals throughout the filter. The required computations are summarized in the following table. The entries in the table are explained below the table.

Depth, cm (1)	Geometric mean grain size, d_g, mm (2)	Filtration rate, L/m²·min: 80 C_z/C_o (3)	80 C_z (4)	80 ΔC (5)	160 C_z/C_o (6)	160 C_z (7)	160 ΔC (8)	240 C_z/C_o (9)	240 C_z (10)	240 ΔC (11)

38		0.20	4.0		0.22	4.4		0.24	4.8	
	0.72			0.0			0.0			0.0
40		0.20	4.0		0.22	4.4		0.24	4.8	

a. As shown in the computation table, the filter depth intervals are entered in col. 1.

b. The mean anthracite and sand particle size associated with each depth interval is entered in col. 2. The mean particle size for each interval can be estimated using the effective size and uniformity coefficient for each medium. For example, at a depth of 4 cm, 4/30ths of the total depth of 30 cm has been passed. Therefore, the particle size associated with a depth of 4 cm corresponds to the sieve size that 13.3 percent [(4/30) × 100] of the anthracite will pass. By plotting the particle size distributions on probability-log paper, and obtaining the equation of the line passing through the plotted points, the 13.3 percent passing anthracite particle size is estimated to be 1.29 mm (see figure below). Assuming the 1 percent size as the cutoff size (1.08 mm), the geometric mean particle size for the interval from zero and 4 cm is, as shown below, 1.18 mm. Following the same procedure, the remaining particle sizes for the anthracite and sand are entered in col. 2.

$$d_g = \sqrt{d_1 d_2} = \sqrt{1.08 \text{ mm} \times 1.29 \text{ mm}} = 1.18 \text{ mm}$$

c. The values of C/C_0 taken from the normalized removal ratio curves corresponding to the depths given in col. 1 are entered in cols. 3, 6, and 9 for each filtration rate.

d. The value of the concentration at each depth is entered in cols. 4, 7, and 10 for each filtration rate.

e. The concentration difference ΔC ($C_{z-1} - C_z$) between the depths given in col. 1 is entered in cols. 5, 8, and 11 for each filtration rate.

3. Set up a computation table and determine the buildup of suspended solids and headloss within each layer of the filter for filter runs of various lengths. The necessary computations for a filtration rate of 160 L/m^2·min (4 gal/ft^2·min) are summarized in the following table.

Depth, cm (1)	ΔC, mg/L (2)	Run length, h: 10 Δq, mg/cm³ (3)	10 Δh, m (4)	15 Δq, mg/cm³ (5)	15 Δh, m (6)	20 Δq, mg/cm³ (7)	20 Δh, m (8)

40							
Σ Δh, m			1.00		2.41		4.55

Although the required computations for the other filtration rates are not shown, they are the same. The values of ΔC given in col. 2 are taken from col. 8 of the table prepared in Step 2. The values of q shown in cols. 3, 5, and 7 are determined by using the difference equation given in Step 1. To illustrate, for the anthracite layer between 4 and 8 cm from the top of the filter bed, the value of Δq after 20 h is as follows:

$$-v\frac{\Delta C}{\Delta z}=\frac{\Delta q}{\Delta t}$$

where $v = 160\ \text{L/m}^2\cdot\text{min} = 0.016\ \text{L/cm}^2\cdot\text{min}$

$\Delta C = 3.2\ \text{mg/L}$

$\Delta z = 4\ \text{cm} - 8\ \text{cm} = -4\ \text{cm}$

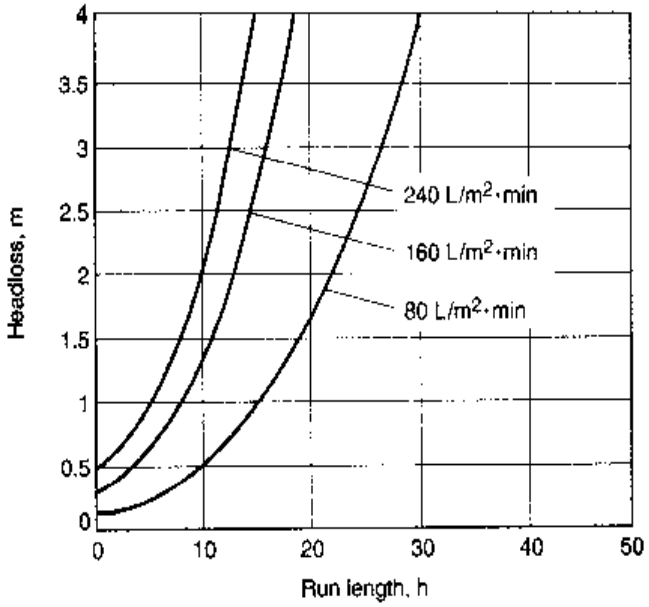
$\Delta t = (20\ \text{h} \times 60\ \text{min/h} - 0) = 1200\ \text{min}$

$$\Delta q = \left(-\frac{0.016\ \text{L}}{\text{cm}^2\cdot\text{min}}\right)\left(\frac{3.2\ \text{mg/L}}{-4\ \text{cm}}\right) 1200\ \text{min}$$

$$= 15.36\ \text{mg/cm}^3$$

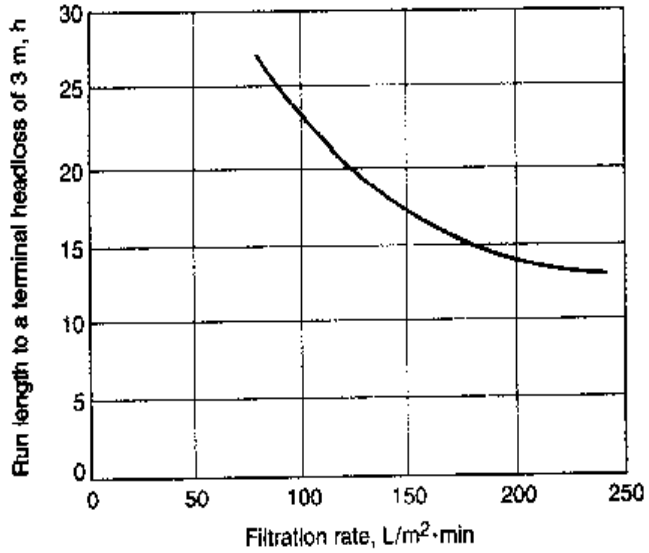
The value of incremental headloss buildup Δh (col. 8) for the anthracite layer between 4 and 8 cm is obtained from Fig. 11–10 by entering with the value of Δq for this layer. The value of the headloss in the sand layers is determined in a similar manner. To simplify the computations, it is assumed that no intermixing occurs between the anthracite and sand. Once all of the Δh headloss values are entered, the entire column is summed to obtain the total headloss in the filter bed. The total headloss for other time periods and filtration rates is determined in exactly the same manner. Summary data for the other flowrates are as follows:

Run length, h	Headloss, m		
	80 L/m²·min	160 L/m²·min	240 L/m²·min
10	0.34	1.00	1.51
15	—	2.41	3.70
20	1.56	4.55	6.96
30	3.82		



4. The clean-water headloss at the three filtration rates, computed as illustrated previously in Example 11–1, is

Filtration rate, L/m²·min	Clean-water headloss, m
80	0.15
160	0.31
240	0.49



5. The total headloss including the clean-water headloss and the headloss due to the accumulation of material within the filter for each of the filtration rates is summarized below.

Run length, h	Headloss, m		
	80 L/m²·min	160 L/m²·min	240 L/m²·min
0	0.15	0.31	0.49
10	0.49	1.31	2.00
15	—	2.72	4.18
20	1.71		
30	3.97		

6. Plot curves of headloss versus run length for the three flowrates. The required curves, which are plotted using the data given in Step 5, are shown in the following figure.

7. Plot the curve of run length to reach a headloss of 3 m versus filtration rate. The required curve is shown below. The data needed to plot this curve are obtained from the headloss curve developed in Step 6 by finding the time required to reach a headloss of 3 m for each filtration rate.

Comment The use of unstratified filter beds for the filtration of treated effluents has been studied by Dahab and Young (1977). They found that unstratified filter beds having the same effective size as that used in the top layer of a dual-medium filter were essentially equivalent to dual-medium filters in terms of effluent quality and length of run.

11–4 SELECTION AND DESIGN CONSIDERATIONS FOR DEPTH FILTERS

The ability to select and design filter technologies must be based on (1) knowledge of the types of filters that are available, (2) a general understanding of their performance characteristics, and (3) an appreciation of the process variables controlling depth filtration. Important design considerations for effluent filtration systems include (1) influent wastewater characteristics, (2) design and operation of the biological treatment process, (3) type of filtration technology to be used, (4) available flow-control options, (5) type of filter backwashing system to be employed, (6) necessary filter appurtenances, and (7) filter control systems and instrumentation. An understanding of issues related to effluent filtration with chemical addition, the type of filter problems encountered in the field, and the importance of pilot-plant studies is also necessary. These subjects are presented and discussed in this section.

Available Filtration Technologies

Historically, the granular-medium filter in which the complete filtration cycle (filtration and backwashing) occurs sequentially, as described in Sec. 11–3, has been used most commonly. However, during the past 20 years, a number of new types of filter technologies have been developed and are now available for the filtration of treated wastewater. The principal types of depth filters that have been used for the filtration of wastewater are identified in Table 11–6 and illustrated on Fig. 11–11. As shown in Table 11–6, the filters can be classified in terms of their operation as semicontinuous or continuous. Filters that must be taken off-line periodically to be backwashed are classified operationally as semicontinuous. Filters in which the filtration and backwash operations occur simultaneously are classified as continuous. Within each of these two classifications there are a number of different types of filters depending on bed depth (e.g., shallow, conventional, and deep bed), the type of filtering medium used (mono-, dual-, and multimedium), whether the filtering medium is stratified or unstratified, the type of operation (downflow or upflow), and the method used for the management of solids (i.e., surface or internal storage). For the mono- and dual-medium semicontinuous filters, a further classification can be made based on the driving force (e.g., gravity or pressure). Another important distinction that must be noted for the filters identified in Table 11–6 is whether they are proprietary or individually designed.

The five types of depth filters used most commonly for wastewater filtration are (1) conventional downflow filters, (2) deep-bed downflow filters, (3) deep-bed upflow continuous-backwash filters, (4) the pulsed-bed filter, and (5) traveling-bridge filters. These filter technologies are described briefly in this section. In addition a new filter employing a synthetic filter medium and a two-stage filtration system which incorporates phosphorus removal are also discussed. Intermittent and recirculating sand and textile filters, usually limited to small systems, are not considered in this text. Information on these filters may be found in Crites and Tchobanoglous (1998). It should be noted that many of the filters to be considered in the following discussion are proprietary and are supplied by the manufacturer as a complete unit. Thus, many of the design details presented in the following section apply only to filters that are designed individually.

Table 11–6
Comparison of principal types of granular-medium filters

Type of filter (common name)	Type of filter operation	Filter-bed details			Typical direction of fluid flow
		Type of filter bed	Filtering medium	Typical bed depth, mm	
Conventional	Semicontinuous	Mono-medium (stratified or unstratified)	Sand or anthracite	760	Downward
Conventional	Semicontinuous	Dual-medium (stratified)	Sand and anthracite	920	Downward
Conventional	Semicontinuous	Multimedium (stratified)	Sand, anthracite, and garnet	920	Downward
Deep-bed	Semicontinuous	Mono-medium (stratified or unstratified)	Sand or anthracite	1830	Downward
Deep-bed	Semicontinuous	Mono-medium (stratified)	Sand or anthracite	1830	Upward
Deep-bed	Continuous	Mono-medium (unstratified)	Sand	1830	Upward
Pulsed-bed	Semicontinuous	Mono-medium (stratified)	Sand	280	Downward
Fuzzy filter	Semicontinuous	Mono-medium (unstratified)	Synthetic fiber	610[a]	Upward
Traveling-bridge	Continuous	Mono-medium (stratified)	Sand	610	Downward
Traveling-bridge	Continuous	Dual-medium (stratified)	Sand and anthracite	410	Downward

[a]Compressed depth.

Conventional Downflow Filters. Single-, dual-, or multimedium filter materials are utilized in conventional downflow depth filters. Typically sand or anthracite is used as the filtering material in single-medium filters (see Fig. 11–11*a*). Dual-medium filters usually consist of a layer of anthracite over a layer of sand (see Fig. 11–11*b*). Other combinations include (1) activated carbon and sand, (2) resin beads and sand, and (3) resin beads and anthracite. Multimedium filters typically consist of a layer of anthracite over a layer of sand over a layer of garnet or ilmenite. Other combinations include (1) activated carbon, anthracite, and sand, (2) weighted, spherical resin beads, anthracite, and sand, and (3) activated carbon, sand, and garnet.

Dual- and multimedium and deep-bed mono-medium depth filters were developed to allow the suspended solids in the liquid to be filtered to penetrate farther into the filter bed, and thus use more of the solids-storage capacity available within the filter bed (see Fig. 11–12). The deeper penetration of the solids into the filter bed also permits longer filter runs because the buildup of headloss is reduced. By comparison, in shal-

Table 11–6 (*Continued*)

Backwash operation	Flowrate through filter	Solids storage location	Remarks	Type of design

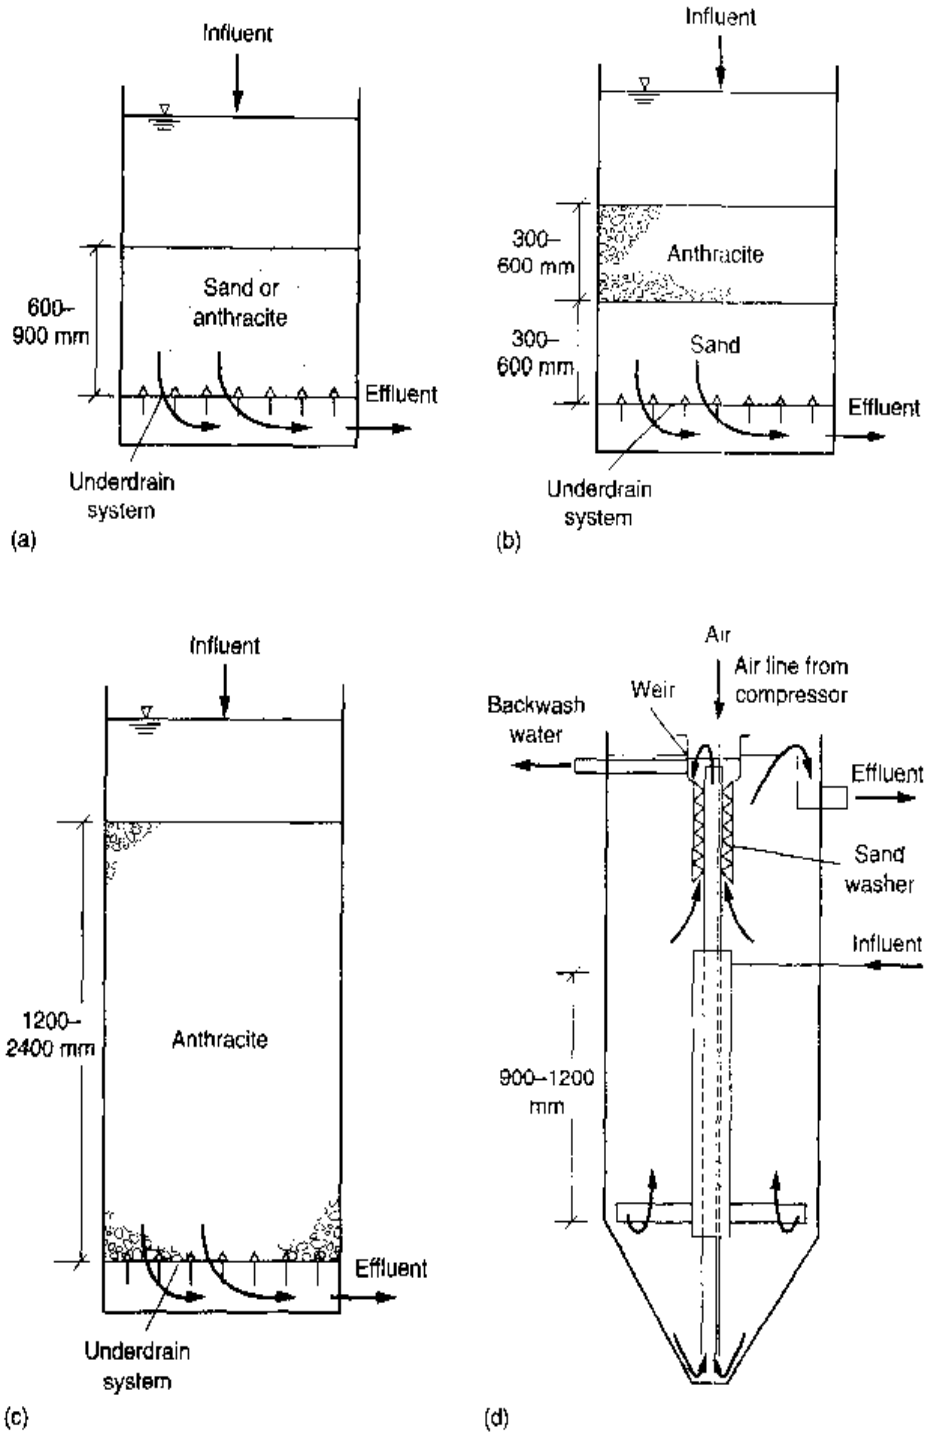
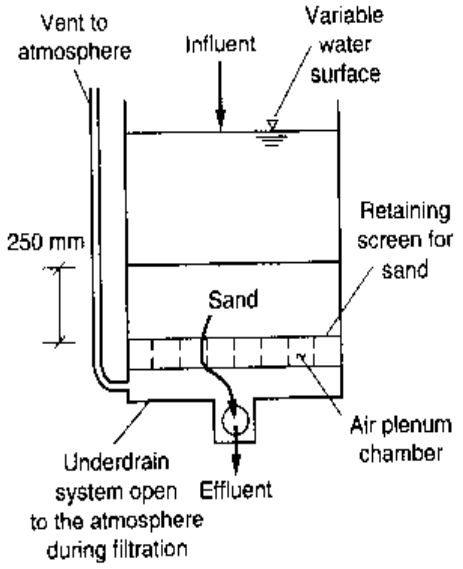
low mono-medium beds, most of the removal occurs in the upper few millimeters of the bed (Tchobanoglous and Eliassen, 1970). The operation of conventional downflow filters has been described previously (see Fig. 11–4). Typically, water wash plus surface water and water wash plus air scour are the principal methods used in backwashing mono-, dual-, and multimedium filter beds. With either of these backwashing methods, the filter mediums are fluidized.

Deep-Bed Downflow Filters. The deep-bed downflow filter (see Fig. 11–11*c*) is similar to the conventional downflow filter with the exception that the depth of the filter bed and the size of the filtering medium (usually anthracite) are greater than the corresponding values in a conventional filter. Because of the greater depth and larger medium size (i.e., sand or anthracite), more solids can be stored within the filter bed and the run length can be extended. The maximum size of the filter medium used in these filters will depend on the ability to backwash the filter. In general, deep-bed filters are not fluidized completely during backwashing. To achieve effective cleaning, air scour plus water is used in the backwash operation.





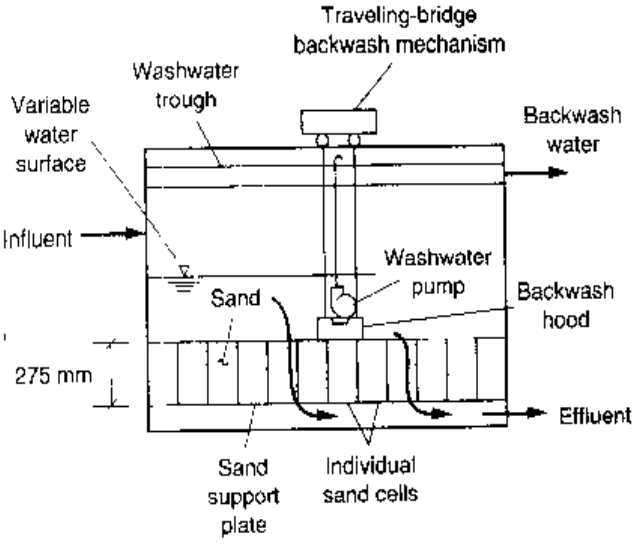


Figure 11–11

Deep-Bed Upflow Continuous Backwash Filters. In this filter, shown schematically (see Fig. 11–11*d*) and pictorially on Fig. 11–13, the wastewater to be filtered is introduced into the bottom of the filter where it flows upward through a series of riser tubes and is distributed evenly into the sand bed through the open bottom of an inlet distribution hood. The water then flows upward through the downward-moving

sand. The clean filtrate exits from the sand bed, overflows a weir, and is discharged from the filter. At the same time sand particles, along with trapped solids, are drawn downward into the suction of an airlift pipe that is positioned in the center of the filter. A small volume of compressed air, introduced into the bottom of the airlift, draws sand, solids, and water upward through the pipe by creating a fluid with a density less than 1.

Impurities are scoured (abraded) from the sand particles during the turbulent upward flow. Upon reaching the top of the airlift, the dirty slurry spills over into the central reject compartment. By setting the filtrate weir above the reject weir, a steady stream of clean filtrate flows upward, countercurrent to the movement of sand, through the washer section. The upflow liquid carries away the solids and reject water. Because the sand has a higher settling velocity than the removed solids, the sand is not carried out of the filter. The sand is cleaned further as it moves down through the washer. The cleaned sand is redistributed onto the top of the sand bed, allowing for a continuous uninterrupted flow of filtrate and reject water.

Pulsed-Bed Filters. The pulsed-bed filter (see Figs. 11–11*e* and 11–14) is a proprietary downflow gravity filter with an unstratified shallow layer of fine sand as the fil-

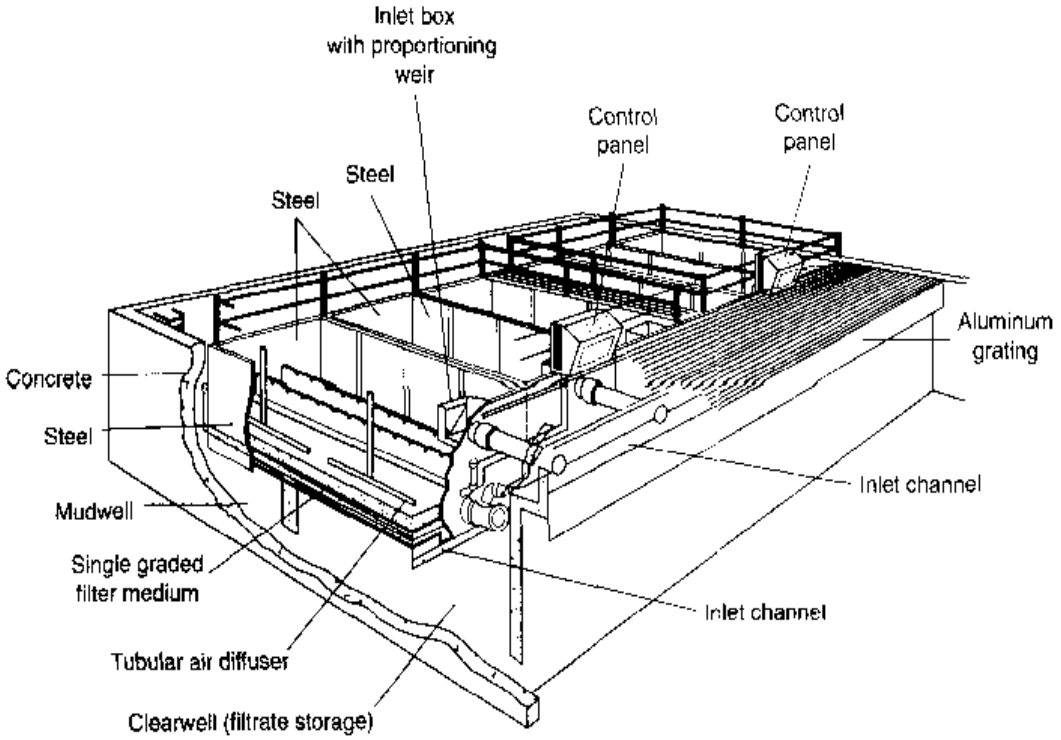
tering medium. The shallow bed is used for solids storage, as opposed to other shallow-bed filters where solids are principally stored on the sand surface. An unusual feature of this filter is the use of an air pulse to disrupt the sand surface and thus allow penetration of suspended solids into the bed. The air pulse process involves forcing a volume of air, trapped in the underdrain system, up through the shallow filter bed to break up the surface mat of solids and renew the sand surface. When the solids mat is disturbed, some of the trapped material is suspended into the admixture over the sand, but the majority of solids are entrapped within the filter bed. The intermittent air pulse causes a folding over the sand surface, burying solids within the medium and regenerating the filter bed surface. The filter continues to operate with intermittent pulsing until a terminal headloss limit is reached. The filter then operates in a conventional backwash cycle to remove solids from the sand. It should be noted that during normal operation the filter underdrain is not flooded as it is in a conventional filter.

Traveling-Bridge Filters. The traveling-bridge filter (see Figs. 11-1*f* and 11-15) is a proprietary continuous downflow, automatic backwash, low-head, granular medium-depth filter. The bed of the filter is divided horizontally into long independent



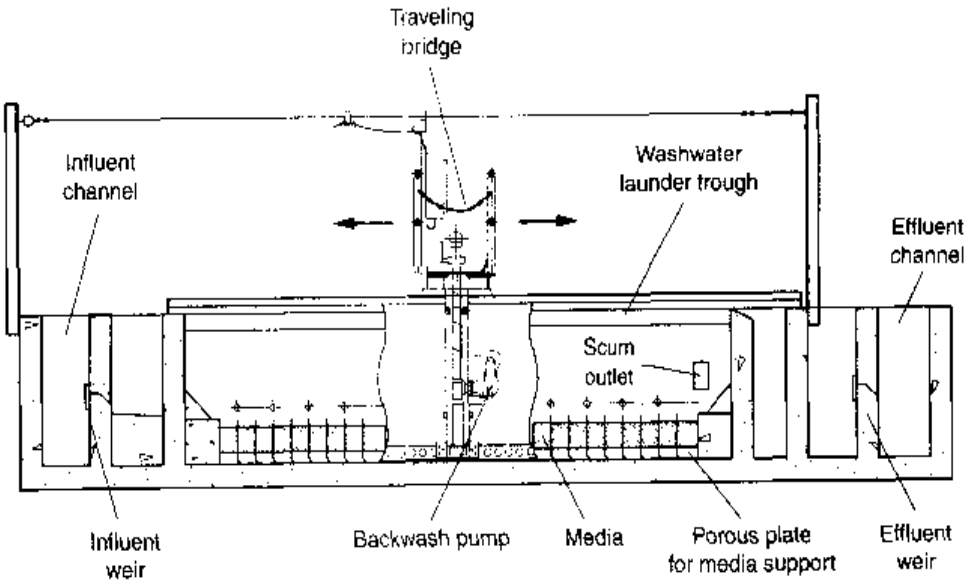


Figure 11-14

Schematic view of pulsed-bed filter. *(Courtesy of U.S. Filter.)*

Figure 11-15

Traveling-bridge filter. *(Courtesy: Aqua Aerobic, Inc.)*

filter cells. Each filter cell contains approximately 280 mm (11 in) of medium. Treated wastewater flows through the medium by gravity and exits to the clearwell plenum via a porous-plate, polyethylene underdrain. Each cell is backwashed individually by an overhead, traveling-bridge assembly, while all other cells remain in service. Water used for backwashing is pumped directly from the clearwell plenum up through the medium and deposited in a backwash trough. During the backwash cycle, wastewater is filtered continuously through the cells that are not being backwashed. The backwash mechanism includes a surface wash pump to assist in breaking up of the surface matting and

"mudballing" in the medium. Because the backwashing operation is performed on an "as needed" basis, the backwash cycle is termed semicontinuous (see Table 11–6).

Synthetic-Medium Filters. A synthetic-medium filter, developed originally in Japan, is now being used for the filtration wastewater. The highly porous synthetic filter medium, made of polyvaniladene, has a diameter of approximately 30 mm (1.25 in). Based on displacement tests, the porosity of the uncompacted quasi-spherical filter medium itself is estimated to be about 88 to 90 percent, and the porosity of the filter bed made up of the filter medium is approximately 94 percent. Unusual features of the filter are: (1) the porosity of the filter bed can be modified by compressing the filter medium and (2) the size of the filter bed is increased mechanically to backwash the filter (see Figs. 11–11*g* and 11–16). The filter medium also represents a departure from conventional filter media in that the fluid to be filtered flows through the medium as opposed to flowing around the filtering medium, as in sand and anthracite filters. As a result of the high porosity, filtration rates of 400 to 1200 L/m^2·min (10 to 30 gal/ft^2·min) have been pilot-tested (Caliskaner and Tchobanoglous, 2000).

In the filtering mode, secondary effluent is introduced in the bottom of the filter. The influent wastewater flows upward through the filter medium, retained by two porous plates, and is discharged from the top of the filter. To backwash the filter, the upper porous plate is raised mechanically. While flow to the filter continues, air is introduced sequentially from the left and right sides of the filter below the lower porous plate, causing the filter medium to move in a rolling motion. The filter medium is cleaned by the shearing forces as the wastewater moves past the filter and by abrasion as the filter medium rubs against itself. Wastewater containing the solids removed from

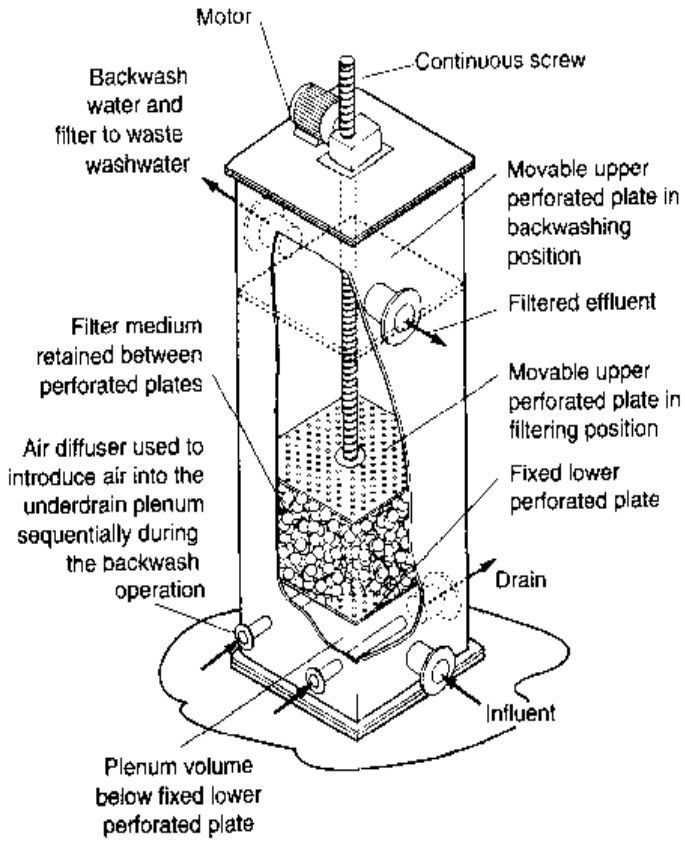

Figure 11–16

the filter is diverted for subsequent processing. To put the filter back into operation after the backwash cycle has been completed, the raised porous plate is returned to its original position. After a short flushing cycle, the filtered effluent valve is opened, and filtered effluent is discharged.

Two-Stage Filtration. A schematic flow diagram for a proprietary two-stage filtration process for the removal of turbidity, total suspended solids, and phosphorus is shown on Fig. 11–17. As shown, two deep-bed upflow continuous backwash filters are used in series to produce a high-quality effluent. A large-size sand diameter is used in the first filter to increase the contact time and to minimize clogging. A smaller sand size is used in the second filter to remove residual particles from the first-stage filter. The backwash water from the second filter which contains small particles and residual coagulant is recycled to the first filter to improve floc formation within the first-stage filter and the influent to waste ratio. Based on full-scale installations the reject rate has been found to be less than 5 percent. Phosphorus levels equal to or less than 0.02 mg/L have been achieved in the final filter effluent.

Performance of Different Types of Filter Technologies

The critical question associated with the selection of any granular-medium depth filter is whether it will perform as anticipated. Insight into the performance of granular-medium filters can be gained from a review of the turbidity, total suspended solids, and particle-removal data for depth filters.

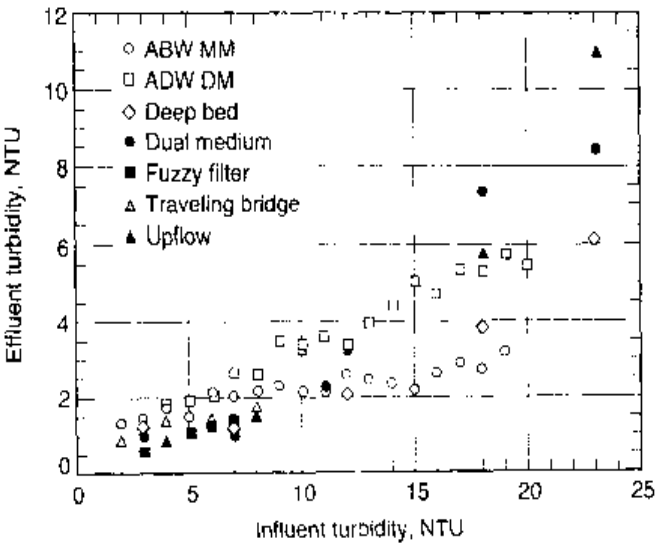

Figure 11-18

Performance data for seven different types of depth filters used for wastewater applications tested using the effluent from the same activated-sludge plant at filtration rate 160 L/m^2·min (4 gal/ft^2·min) with the exception of the Fuzzy filter, which was operated at 800 L/m^2·min (20 gal/ft^2·min).

Removal of Turbidity. The results of long-term testing of seven different types of pilot-scale filters on the effluent from the same activated-sludge process (SRT > 10 d), without chemical addition, are shown on Fig. 11–18. Long-term data from other large-scale wastewater reclamation plants are also shown. The principal conclusions to be reached from an analysis of the data presented on Fig. 11–18 are that (1) given a high-quality filter influent (turbidity less than 5 to 7 NTU) all of the filters tested including the large-scale plant are capable of producing an effluent with an average turbidity of 2 NTU or less, and (2) when the influent turbidity is greater than about 5 to 7 NTU, chemical addition will be required with all of the filters to achieve an effluent turbidity of 2 NTU or less.

Removal of Total Suspended Solids. Using the following two relationships between turbidity and suspended solids as given in Chap. 2 [see Eq. (2–16)], influent turbidity values of 5 to 7 NTU correspond to a total suspended solids concentration varying from about 10 to 17 mg/L, and an effluent turbidity of 2 NTU corresponds to a total suspended solids concentration varying from 2.8 to 3.2 mg/L.

Settled secondary effluent

$$\text{TSS, mg/L} = (2.0 \text{ to } 2.4) \times (\text{turbidity, NTU}) \tag{11-32}$$

Filter effluent

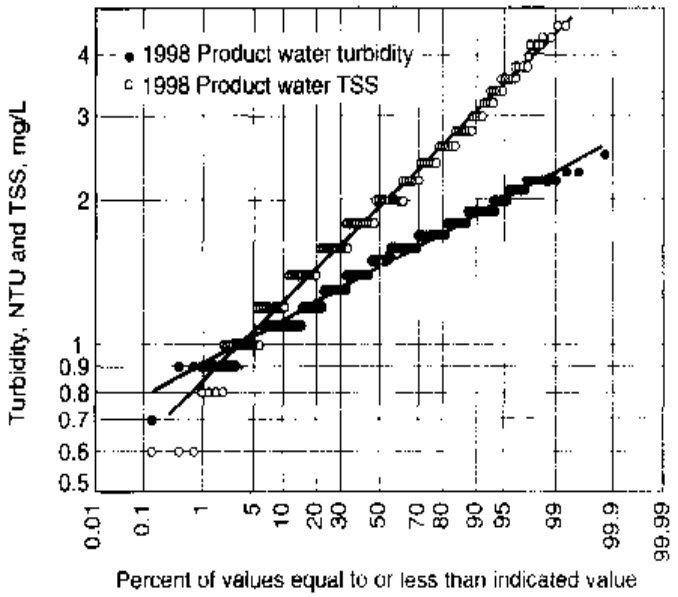
$$\text{TSS, mg/L} = (1.3 \text{ to } 1.5) \times (\text{turbidity, NTU}) \tag{11-33}$$

Long-term total suspended-solids performance data for the depth filters at the Donald C. Tillman Wastewater Reclamation Plant in Los Angeles, CA, are shown on Fig. 11–19. For the data shown on Fig. 11–19, the ratio of TSS to turbidity is about 1.33.

Removal of Particle Size. Typical data on the removal of particle sizes found in settled wastewater are shown on Fig. 11–20. As shown, the particle-removal rate is essentially independent of the filtration rate up to about 240 L/m^2·min (6 gal/ft^2·min).

Figure 11-19

Probability distribution of product water turbidity and TSS for 1998 for the Donald C. Tillman Wastewater Reclamation Plant, Los Angeles, CA.



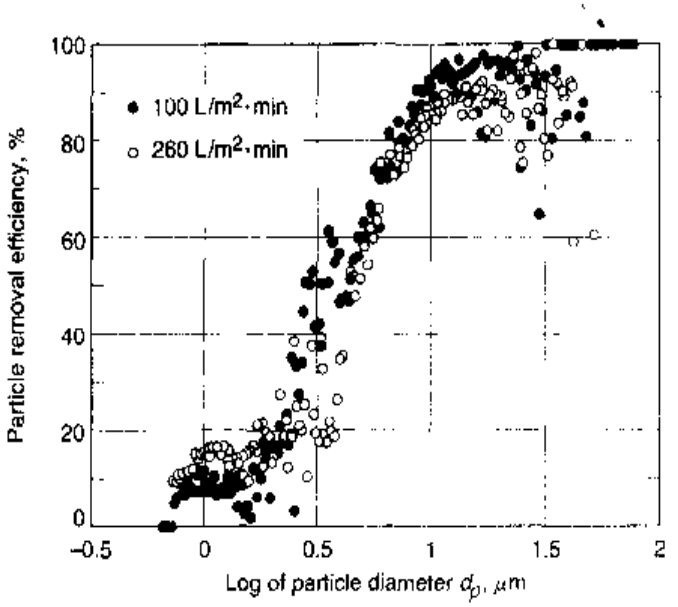


Figure 11-20

Particle-size removal efficiency for a depth filter for effluent from an activated-sludge plant.

It is significant that most depth filters will pass some particles with diameters up to 20 μm. Particles in the size range from 10 to 20 μm are of importance with respect to disinfection because they are of sufficient size to shield microorganisms (see Chap. 12).

Issues Related to Design and Operation of Treatment Facilities

For new wastewater-treatment plants, extra care should be devoted to the design of the secondary settling facilities. With properly designed settling facilities resulting in an effluent with low TSS (typically 5 mg/L), the decision on what type of filtration system is to be used is often based on plant-related variables, such as the space available, duration of filtration period (seasonal versus year-round), the time available for construction, and costs. For existing plants that have variable suspended solids concentrations in the treated effluent and must be retrofitted with effluent filtration, it may be appropriate to consider the type of a filter that can continue to function even when heavily loaded. The pulsed-bed filter and both downflow and upflow deep-bed coarse-medium filters have been used in such applications.

Importance of Influent Wastewater Characteristics

The most important influent characteristics in the filtration of treated secondary effluents are the suspended-solids concentration, particle size and distribution, and floc strength.

Suspended Solids/Turbidity. Typically, the TSS concentration in the effluent from activated-sludge and trickling-filter plants varies between 6 and 30 mg/L. Because this concentration usually is the principal parameter of concern, turbidity is often used as a means of monitoring the filtration process. Corresponding turbidity values can vary from 3 to 15 NTU.

Particle Size and Distribution. Typical data on the particle size and distribution in the effluent from two activated-sludge plants were presented previously on Fig. 2–9 in Chap. 2. As illustrated, the particles fell into two distinct size ranges, small particles varying in areal size (equivalent circular diameter) from 0.8 to 1.2 μm and large particles varying in size from about 5 to 100 μm. In addition, a few particles larger than about 500 μm are almost always found in settled treated effluent. These particles are light and amorphous and do not settle readily (see discussion of hindered settling in Sec. 5–5). The weight fraction of the smaller particles was estimated to be approximately 40 to 60 percent of the total. This percentage will vary, however, depending on the operating conditions of the biological process and the degree of flocculation achieved in the secondary settling facilities.

The most significant observation related to particle size is that the distribution of sizes is bimodal. This observation is important because it will influence the removal mechanisms that may be operative during the filtration process. For example, it seems reasonable to assume that the removal mechanism for particles 1.0 μm in size would be different from that for particles in the size range from 10 to 100 μm. The bimodal particle-size distribution has also been observed in water-treatment plants.

Floc Strength. Floc strength, which will vary with the type of process and the mode of operation, is also important. For example, the residual floc from the chemical precipitation of biologically processed wastewater may be considerably weaker than the residual biological floc before precipitation. Further, the strength of the biological floc will vary with the mean cell-residence time, increasing with longer mean cell-residence time. The increased strength derives in part from the production of extracellular polymers as the mean cell-residence time is lengthened. At extremely long mean cell-residence times (15 days and longer), it has been observed that the floc strength will decrease due to floc breakup.

Selection of Filtration Technology

In selecting a filter technology, important issues that must be considered include (1) type of filter to be used: proprietary or individually designed, (2) the filtration rate, (3) filtration driving force, (4) number and size of filter units, and (5) the backwash-water requirements.

Type of Filter: Proprietary or Individually Designed. As noted in Table 11–6, the currently available filter technologies are either proprietary or individually designed. With proprietary filters, the manufacturer is responsible for providing

the complete filter unit and its controls, based on basic design criteria and performance specifications. In individually designed filters, the designer is responsible for working with several suppliers in developing the design of the system components. Contractors and suppliers then furnish the materials and equipment in accordance with the engineer's design.

Filtration Rate. The rate of filtration is important because it affects the real size of the filters that will be required. For a given filter application, the rate of filtration will depend primarily on the strength of the floc and the size of the filtering medium. For example, if the strength of the floc is weak, high filtration rates will tend to shear the floc particles and carry much of the material through the filter. It has been observed that filtration rates in the range of 80 to 320 L/m^2·min (2 to 8 gal/ft^2·min) will not affect the effluent quality when filtering settled activated-sludge effluents.

Filtration Driving Force. Either the force of gravity or an applied pressure force can be used to overcome the frictional resistance to flow offered by the filter bed. Gravity filters of the type discussed above are used most commonly for the filtration of treated effluent at large plants. Pressure filters of the type shown on Fig. 11–21 operate in the same manner as gravity filters and are used at smaller plants. The only difference is that, in pressure filters, the filtration operation is carried out in a closed vessel under

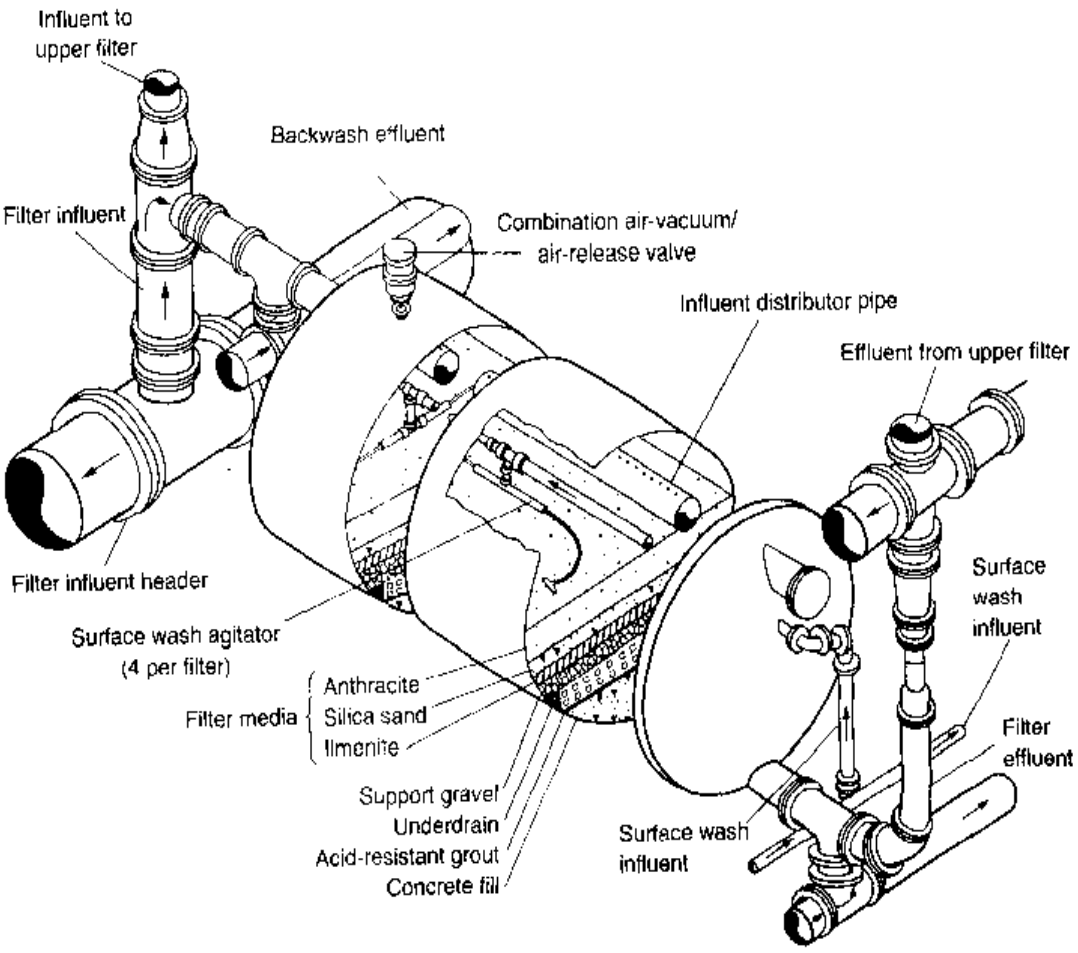

Figure 11–21
Typical pressure filter with multimedium filter bed and surface wash used for wastewater filtration.

pressurized conditions achieved by pumping. Pressure filters normally are operated at higher terminal headlosses, resulting in longer filter runs and reduced backwash requirements.

Number and Size of Filter Units. One of the early decisions to be made in the design of a depth filtration system is determining the number and size of filter units that will be required. The surface area required is based on the peak filtration and peak plant flowrates. The allowable peak filtration rate is usually established on the basis of regulatory requirements. Operating ranges for a given filter type are based on past experience, the results of pilot-plant studies, manufacturers' recommendations, and regulatory constraints. The number of units generally should be kept to a minimum to reduce the cost of piping and construction, but it should be sufficient to assure (1) that backwash flowrates do not become excessively large and (2) that when one filter unit is taken out of service for backwashing, the transient loading on the remaining units will not be so high that material contained in the filters will be dislodged. Transient loadings due to backwashing are not an issue with filters that backwash continuously. To meet redundancy requirements, a minimum of two filters will generally be required.

The sizes of the individual units should be consistent with the sizes of equipment available for use as underdrains, washwater troughs, and surface washers. Typically, width-to-length ratios for individually designed gravity filters vary from 1:1 to 1:4. A practical limit for the surface area on an individual depth filter (or filter cell) is about 100 m^2 (1100 ft^2), although larger filters units have been built. The layout of a bank of deep-bed upflow continuous-backwash filters is shown on Fig. 11–22. For proprietary

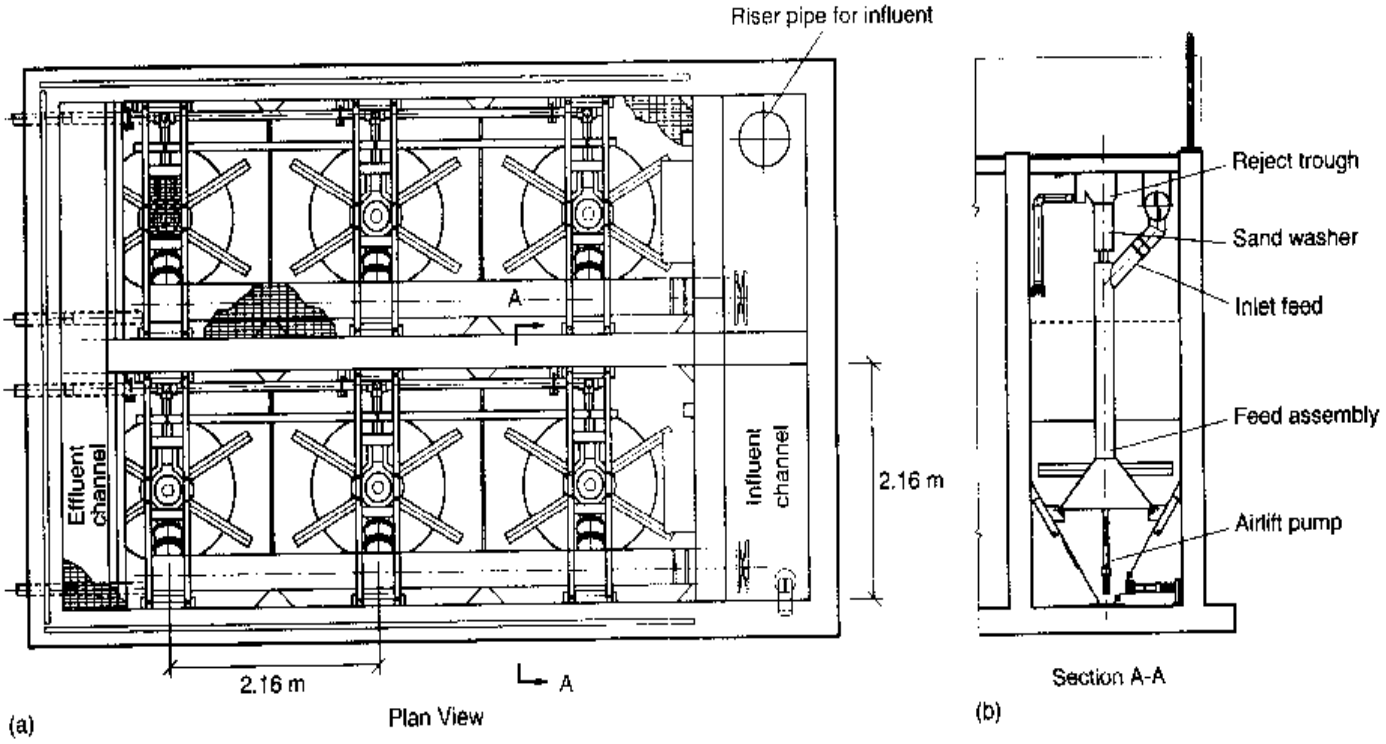

Figure 11–22

Layout of a bank of six deep-bed upflow continuous backwash filters. *(Courtesy Parkson Corp.)*

and pressure filters, it is common practice to use standard sizes that are available from manufacturers. Depending on the manufacturing method, shipping constraints will also limit the size of pressure filters. The maximum diameter of vertical pressure filters is about 3.7 m (12 ft). The maximum diameter and length of horizontal pressure filters is about 3.7 m (12 ft) and 12 m (40 ft), respectively.

Backwash-Water Requirements. As noted in Table 11–6, depth filters operate in either a semicontinuous or continuous mode. In semicontinuous operation, the filter is operated until the effluent quality starts to deteriorate or the headloss becomes excessive, at which point the filter is taken out of service and backwashed to remove the accumulated solids. With filters operated in the semicontinuous mode, provision must be made for the backwash water needed to clean the filters. Typically, the backwash water is pumped from a filtered water clearwell or obtained by gravity from an elevated storage tank. For filters that operate continuously, such as the upflow filter (see Figs. 11–11*d* and 11–13) and the traveling-bridge filter (see Figs 11–11*f* and 11–15), the filtering and cleaning (backwashing) phases take place simultaneously. In the traveling-bridge filter, the backwash operation can be either continuous or semicontinuous as required. It should be noted that with filters that operate continuously, there is no turbidity breakthrough or terminal headloss.

Filter-Bed Characteristics

The principal variables that must be considered in the design of filters are identified in Table 11–7. In the application of filtration to the removal of residual suspended solids, it has been found that the nature of the particulate matter in the influent to be filtered, the filter-bed configuration, the size of the filter material or materials, and the filtration flowrate are perhaps the most important of the process variables.

Filter-Bed Configuration. The principal types of nonproprietary filter-bed configurations now used for wastewater filtration may be classified according to the number of filtering mediums that are used as mono-medium, dual-medium, or multimedium beds (see Fig. 11–12). In conventional downflow filters, the distribution of grain sizes for each medium after backwashing is from small to large. Typical design data for monomedium filters and dual- and multimedium filters are presented in Tables 11–8 and 11–9, respectively.

Selection of Filter Medium. Once the type of filter to be used has been selected, the next step is to specify the characteristics of the filtering medium, or media if more than one is used. Typically, this process involves the selection of the grain size as specified by the effective size d_{10}, uniformity coefficient UC, the 90 percent size, the specific gravity, solubility, hardness, and depth of the various materials used in the filter bed. Typical particle-size distribution ranges for sand and anthracite filtering material are shown on Fig. 11–23. The 90 percent size designated d_{90}, as read from a grain-size analysis, is commonly used to determine the required backwash rate for depth filters. Typical physical properties of filter materials used in depth filters are summarized in Table 11–10. The sizes of filter materials were given previously in Tables 11–7 and 11–8.

Table 11–7
Principal variables in the design of granular-medium filters[a]

Variable	Significance
1. Required effluent quality	Usually fixed regulatory requirement
2. Influent wastewater characteristics	Affect the removal characteristics of a given filter-bed configuration. To a limited extent the listed influent characteristics can be controlled by the designer
a. Suspended-solids concentration	
b. Floc or particle size and distribution	
c. Floc strength	
d. Floc or particle charge	
e. Fluid properties	
3. Filter-medium characteristics	Affect particle-removal efficiency and headloss buildup
a. Effective size, d_{10}	
b. Uniformity coefficient, UC	
c. Type, grain shape, density, and composition	
4. Filter-bed characteristics	Porosity affects the amount of solids that can be stored within the filter. Bed depth affects initial headloss, length of run. Degree of intermixing will affect performance of filter bed
a. Bed depth	
b. Stratification	
c. Degree of medium intermixing	
d. Porosity	
5. Filtration rate	Used in conjunction with variables 2, 3, and 4 to compute clear-water headloss
6. Chemical usage	
7. Allowable headloss	Design variable
8. Backwash requirements	Affects size of filter piping and pipe gallery

[a] Adapted in part from Tchobanoglous and Eliassen (1970) and Tchobanoglous and Schroeder (1985).

The degree of intermixing in the dual-medium and multimedium beds depends on the density and size differences of the various media. To avoid extensive intermixing the settling rate of the filter mediums comprising the dual- and multimedium filters must have essentially the same settling velocity. The following relationship can be used to establish the appropriate sizes (Kawamura, 2000).

$$\frac{d_1}{d_2} = \left(\frac{\rho_2 - \rho_w}{\rho_1 - \rho_w}\right)^{0.667} \tag{11-34}$$

where d_1, d_2 = effective size of filter mediums
ρ_1, ρ_2 = density of filter mediums
ρ_w = density of water

The application of Eq. (11-34) is illustrated in Example 11–4.

[b] Anthracite, sand, and garnet sizes selected to limit the degree of intermixing. Use Eq. (11–34) for other values of density ρ.

Figure 11–23

Typical particle-size distribution ranges for sand and anthracite used in dual-medium depth filters. Note that for sand the 10 percent size by weight corresponds to the 50 percent size by count.

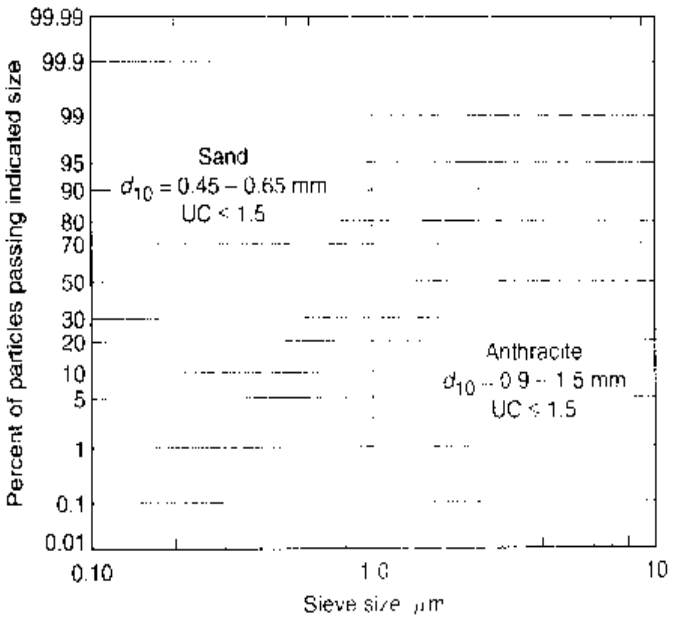

Table 11–10
Typical properties of filter materials used in depth filtration[a]

Filter material	Specific gravity	Porosity, α	Sphericity[b]
Anthracite	1.4–1.75	0.56–0.60	0.40–0.60
Sand	2.55–2.65	0.40–0.46	0.75–0.85
Garnet	3.8–4.3	0.42–0.55	0.60–0.80
Ilmenite	4.5	0.40–0.55	
Fuzzy filter medium		0.87–0.89	

[a]Adapted in part from Cleasby and Logsdon (1999).

[b]Sphericity is defined as ratio of the surface area of an equal volume sphere to the surface area of the filter medium particle.

EXAMPLE 11–4 **Determination of Filter-Medium Sizes** A dual-medium filter bed composed of sand and anthracite is to be used for the filtration of settled secondary effluent. If the effective size of the sand in the dual-medium filter is to be 0.55 mm, determine the effective size of the anthracite to avoid significant intermixing.

Solution

1. Summarize the properties of the filter mediums
   a. For sand
      i. Effective size = 0.55 mm
      ii. Specific gravity = 2.65 (see Table 11–10)
   b. For anthracite
      i. Effective size = to be determined, mm
      ii. Specific gravity = 1.7 (see Table 11–10)

2. Compute the effective size of the anthracite using Eq. (11–34)

$$d_1 = d_2\left(\frac{\rho_2 - \rho_w}{\rho_1 - \rho_w}\right)^{1.667}$$

$$d_1 = 0.55\text{ mm}\left(\frac{2.65 - 1}{1.7 - 1}\right)^{1.667}$$

$$d_1 = 0.97\text{ mm}$$

Comment Another approach that can be used to assess whether intermixing will occur is to compare the fluidized bulk densities of the two adjacent layers (e.g., upper 450 mm of sand and lower 100 mm of anthracite).

Filter Flowrate Control

The principal methods now used to control the rate of flow through downflow gravity filters may be classified as (1) constant-rate filtration with fixed head, (2) constant-rate filtration with variable head, and (3) variable declining-rate filtration. A variety of other control methods are also in use (Cleasby and Logsdon, 1999; Kawamura, 2000).

Constant-Rate Filtration with Fixed Head. In constant-rate filtration with fixed head (see Fig. 11-24*a*), the flow through the filter is maintained at a constant rate. Constant-rate filtration systems are either influent controlled or effluent controlled. Pumps or weirs are used for influent control whereas an effluent modulating valve that can be operated manually or mechanically is used for effluent control. In effluent control systems, at the beginning of the run, a large portion of the available driving force is dissipated at the valve, which is almost closed. The valve is opened as the headloss builds up within the filter during the run. Because the required control valves are expensive and because they have malfunctioned on a number of occasions, alternative methods of flowrate control involving pumps and weirs have been developed and are coming into wider use.

Constant-Rate Filtration with Variable Head. In constant-rate variable filtration head (see Fig. 11-24*b*), the flow through the filter is maintained at a constant rate. Pumps or weirs are used for influent control. When the head or effluent turbidity reaches a preset value, the filter is backwashed.

Variable-Rate Filtration with Fixed or Variable Head. In variable-declining-rate filtration (see Fig. 11-24*c*), the rate of flow through the filter is allowed to decline as the rate of headloss builds up with time. Declining-rate filtration systems are either influent controlled or effluent controlled. When the rate of flow is reduced to the minimum design rate, the filter is removed from service and backwashed.

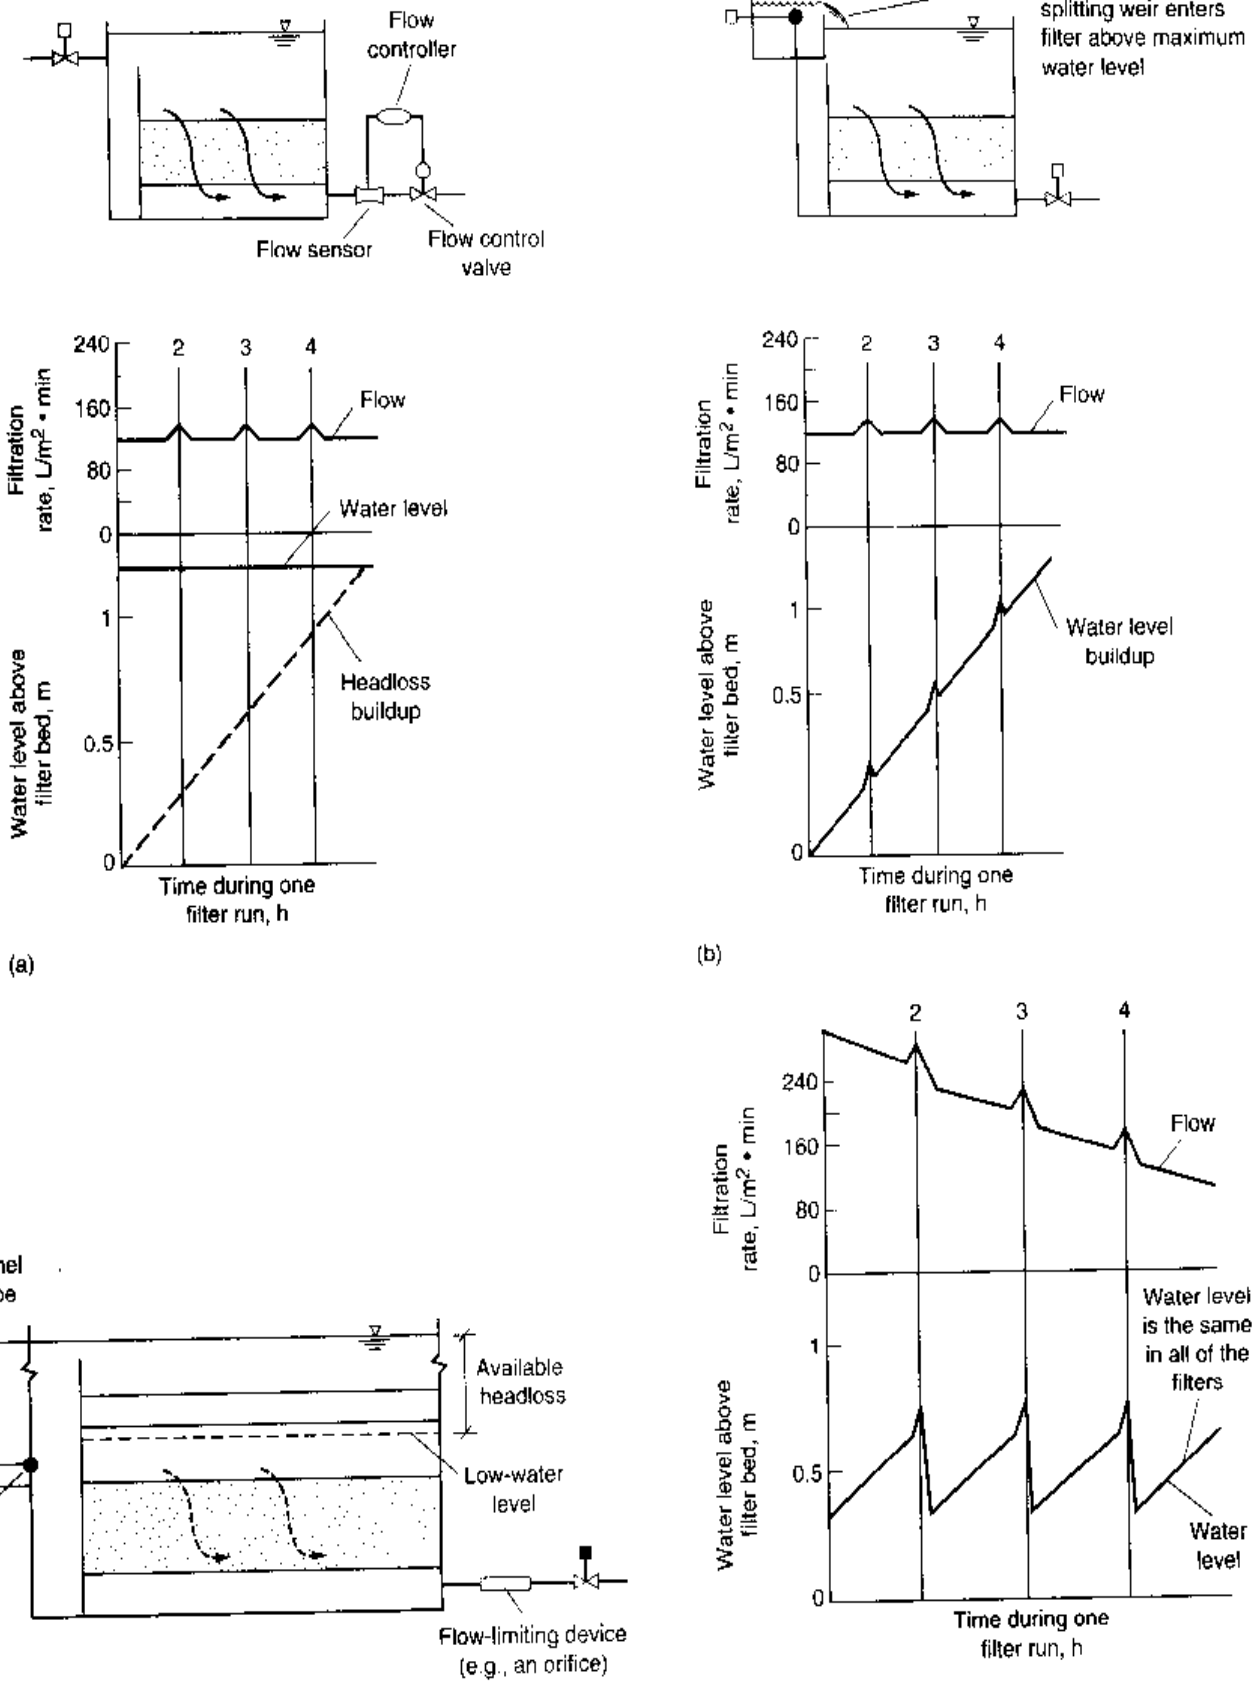

Figure 11-24

Definition sketch for filter operation: (a) fixed head, (b) variable head, and62 (c) variable-flow variable-head. Curves for filters in (a), (b), and (c) are for the operation of one filter in a bank of four filters. The numbers represent the filter that is backwashing during the filter run. In practice, the time before backwashing will not be the same for all of the filters. *(Adapted from Tchobanoglous and Schroeder, 1985.)*

Filter Backwashing Systems

A filter bed can function properly only if the backwashing system cleans the material removed within the filter effectively. The methods commonly used for backwashing granular-medium filter beds operated in the semicontinuous mode include (1) water backwash with auxiliary surface water-wash agitation, (2) water backwash with auxiliary air scour, and (3) combined air-water backwashing. With the first two methods, fluidization of the granular medium is necessary to achieve effective cleaning of the filter bed at the end of the run. With the third method, fluidization is not necessary. Typical backwash flowrates required to fluidize various filter beds are reported in Table 11–11.

Water Backwash with Auxiliary Surface Wash. Surface washers (see Fig. 11–25) are often used to provide the shearing force required to clean the grains of the filtering medium used for wastewater filtration. Operationally, the surface washing cycle is started about 1 or 2 min before the water backwashing cycle is started. Both cycles are continued for about 2 min, at which time the surface wash is terminated. Water usage is as follows: for a single-sweep surface backwashing system, from 20 to 40 L/m^2·min (0.5 to 1.0 gal/ft^2·min); for a dual-sweep surface backwashing system, from 60 to 80 L/m^2·min (1.5 to 2.0 gal/ft^2·min).

Water Backwash with Auxiliary Air Scour. The use of air to scour the filter provides a more vigorous washing action than water alone. Operationally, air is usually applied for 3 to 4 min before the water backwashing cycle begins. In some systems, air is also injected during the first part of the water-washing cycle. Typical air flowrates range from 0.9 to 1.5 m^3/ m^2·min (3 to 5 ft^3/ft^2·min).

Combined Air-Water Backwash. The combined air-water backwash system is used in conjunction with the single-medium unstratified filter bed. Operationally, air and water are applied simultaneously for several minutes. The specific duration of the combined backwash varies with the design of the filter bed. Ideally, during the backwash operation, the filter bed should be agitated sufficiently so that the grains of the filter

Table 11–11
Typical backwash flowrates required to fluidize various filter beds

Type of filter	Size of critical granular medium	Minimum backwash velocity needed to fluidize bed[a]	
		m^3/m^2·min	m/h
Single medium (sand)	2 mm	1.8–2.0	110–120
Dual-media (anthracite and sand)	See Table 11–9	0.8–1.2	48–72

[b] In a combined airi-water backwash process, the water backwash rates are typically less than 50 percent of the rates required to fluidize the bed.

[c] Air at 21°C (70°F) and 1.0 atm.

Note: $m^3/m^2 \cdot min \times 24.5424 = gal/ft^2 \cdot min$

$m^3/m^2 \cdot min \times 3.2808 = ft^3/ft^2 \cdot min$

medium move in a circular pattern from the top to the bottom of the filter as the air and water rise up through the bed. Some typical data on the quantity of water and air required are reported in Table 11–12. The reduced washwater requirements for the air-water backwash system can be appreciated by comparing the values given in Table 11–11 with those given in Table 11–12. At the end of the combined air-water backwash, a 2- to 3-min water backwash at subfluidization velocities is used to remove any air bubbles that

may remain in the filter bed. This last step is required to eliminate the possibility of air binding within the filter.

Filter Appurtenances

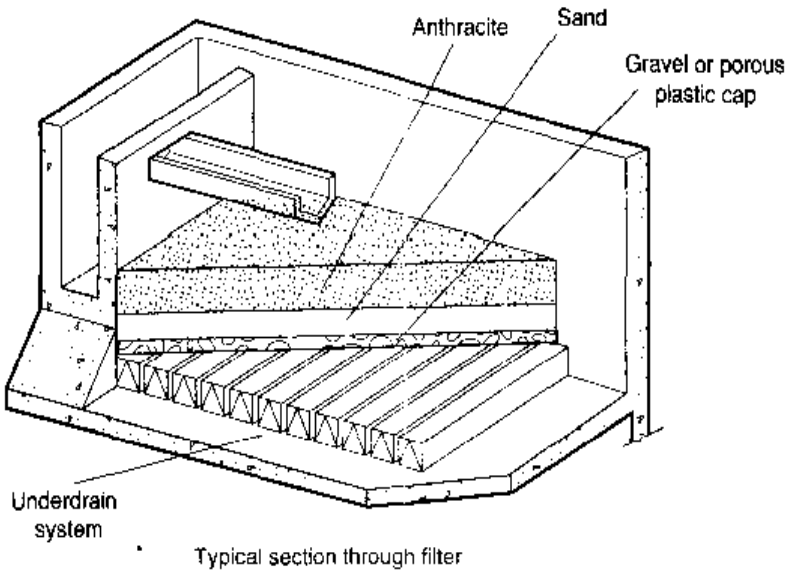
The principal filter appurtenances are as follows: (1) the underdrain system used to support the filtering materials, collect the filtered effluent, and distribute the backwash water and air (where used); (2) the washwater troughs used to remove the spent backwash water from the filter; and (3) the surface washing systems used to help remove attached material from the filter medium.

Underdrain Systems. The type of underdrain system to be used depends on the type of backwash system. In conventional water-backwashed filters without air scour, it is common practice to place the filtering medium on a support consisting of several layers of graded gravel. The design of a gravel support for a granular medium is delineated in the AWWA Standard for Filtering Material B100-96. Typical underdrain systems are shown on Fig. 11–26.

Washwater Troughs. Washwater troughs are constructed of fiberglass, plastic, or sheet metal or of concrete with adjustable weir plates. The particular design of the trough will depend to some extent on the other equipment to be used in the design and construction of the filter. Loss of filter material during backwashing is a common operating problem. To reduce this problem, baffles can be placed on the underside of the washwater troughs as shown on Fig. 11–27.

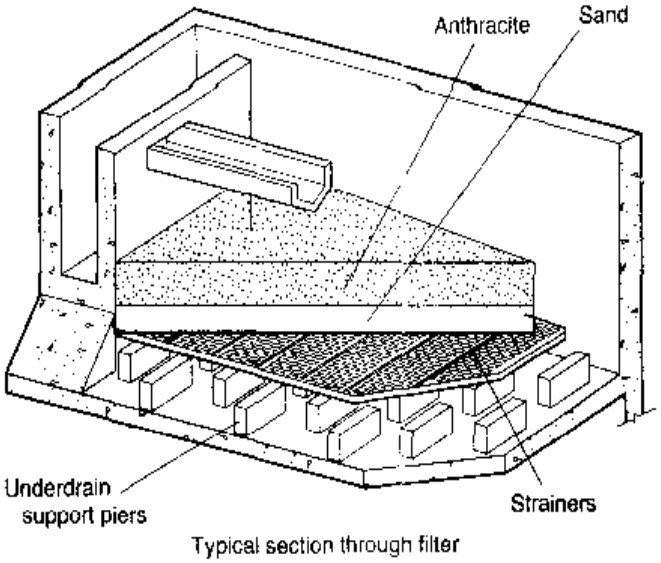
Surface Washers. Surface washers for filters can be fixed or mounted on rotary sweeps, as shown on Fig. 11–25. According to data on a number of systems, rotary-sweep washers appear to be the most effective.

Filter Instrumentation and Control Systems



The supervisory control facilities for wastewater filtration include instrumentation systems for the control and monitoring of the filters. The control systems are similar to those used for water treatment; however, full automation of gravity wastewater filters is not required. Although full automation is not required, fully automatic control systems using programmed logic controllers (PLCs) are used routinely.

Flow through the filters may be controlled from a water level upstream of the filters or from the water level in each filter. These water levels are used in conjunction with rate-of-flow controllers or a control valve to limit or regulate the flowrate through a filter. Filter hydraulic operating parameters requiring monitoring include filtered water flowrate, total headloss across each filter, surface wash and backwash water flowrates, and air flowrate if an air/water backwash system is employed. Water-quality parameters in filtered water that are monitored usually include BOD, TSS, phosphorus, and nitrogen. Turbidity may also be monitored in systems where chemical addition is used. Signals from effluent turbidity monitors and effluent flowrate are often used to pace the chemical-feed system.



The sequencing of the backwash cycle for a conventional gravity filter should be semiautomatic preferably, incorporating manual start, followed by automatic operation to carry the backwash cycle through its various steps. The design of backwash systems

must recognize the impact of maximum wastewater temperatures experienced at treatment plants. Local control units should be provided at the filters to allow for local operation and backwashing by plant operators.

Effluent Filtration with Chemical Addition

Depending on the quality of the settled secondary effluent, chemical addition has been used to improve the performance of effluent filters. Chemical addition has also been used to achieve specific treatment objectives including the removal of specific contaminants such as phosphorus, metal ions, and humic substances. The removal of phosphorus by chemical addition is considered in Chap. 6. To control eutrophication, the contact filtration process is used in many parts of the country to remove phosphorus from wastewater-treatment plant effluents which are discharged to sensitive water bodies. The two-stage filtration process discussed previously (see Fig.11–17) has proved to be very effective, achieving phosphorus levels of 0.2 mg/L in the filtered effluent. Chemicals commonly used in effluent filtration include a variety of organic polymers, alum, and ferric chloride. Use of organic polymers and the effects of the chemical characteristics of the wastewater on alum addition are considered in the following discussion.

Use of Organic Polymers. Organic polymers are typically classified as long-chain organic molecules with molecular weights varying from 10^4 to 10^6. With respect to charge, organic polymers can be cationic (positively charged), anionic (negatively charged), or nonionic (no charge). Polymers are added to settled effluent to bring about the formation of larger particles by bridging as described in Chap. 6. Because the chemistry of the wastewater has a significant effect on the performance of a polymer, the selection of a given type of polymer for use as a filter aid generally requires experimental testing. Common test procedures for polymers involve adding an initial dosage (usually 1.0 mg/L) of a given polymer and observing the effects. Depending upon the effects observed, the dosage should be increased by 0.5 mg/L increments or decreased

by 0.25 mg/L increments (with accompanying observation of effects) to obtain an operating range. After the operating range is established, additional testing can be done to establish the optimum dosage.

A recent development is the use of lower-molecular-weight polymers that are intended to serve as alum substitutes. When these polymers are used, the dosage is considerably higher (≥10 mg/L) than with higher-molecular-weight polymers (0.25 to 1.25 mg/L). As with the mixing of alum, the initial mixing step is critical in achieving maximum effectiveness of a given polymer. In general, mixing times of less than 1 s with G values of $>3500\ s^{-1}$ are recommended (see Table 5–10 in Chap. 5). It should be noted that, as a practical matter, as treatment plants get larger it is difficult to achieve mixing times less than 1 s unless multiple mixing devices are used.

Effects of Chemical Characteristics of Wastewater on Alum Addition. As with polymers, the chemical characteristics of the treated wastewater effluent can have a significant impact on the effectiveness of aluminum sulfate (alum) when it is used as an aid to filtration. For example, the effectiveness of alum is dependent on pH (see Fig. 6–9 in Chap. 6). Although Fig. 6–9 was developed for water-treatment applications, it has been found to apply to most wastewater effluent filtration uses with minor variations. As shown on Fig. 6–9, the approximate regions in which the different phenomena associated with particle removal in conventional sedimentation and filtration processes are operative are plotted as a function of the alum dose and the pH of the treated effluent after alum has been added. For example, optimum particle removal by sweep floc occurs in the pH range of 7 to 8 with an alum dose of 20 to 60 mg/L. Generally, for many wastewater effluents that have high pH values (e.g., 7.3 to 8.5), low alum dosages in the range of 5 to 10 mg/L will not be effective. To operate with low alum dosages, pH control will generally be required.

Filter Problems

The principal problems encountered in wastewater filtration and the control measures that have proved to be effective are reported in Table 11–13. Because these problems can affect both the performance and operation of a filter system, care should be taken in the design phase to provide the necessary facilities that will minimize their impact. When filtering secondary effluent containing residual biological floc, semicontinuous filters should be backwashed at least once every 24 h to avoid the formation of mudballs and the buildup of grease. In most cases, the frequency of backwashing will be more often.

Need for Pilot-Plant Studies

Although the information presented earlier in this section and previously in Sec. 11–3 will help the reader understand the nature of the filtration operation as it is applied to the filtration of treated wastewater, it must be stressed that there is no generalized approach to the design of full-scale filters. The principal reason is the inherent variability in the characteristics of the influent suspended solids to be filtered. For example, changes in the degree of flocculation of the suspended solids in the secondary settling facilities will significantly affect the particle sizes and their distribution in the effluent. This in turn will affect the performance of the filter. Further, because the characteristics of the effluent suspended solids will also vary with the organic loading on the process as well as with the time of day, filters must be designed to function under a rather wide range of oper-

Table 11–13 Summary of commonly encountered problems in depth filtration of wastewater and control measures for those problems

Problem	Description/control
Turbidity breakthrough[a]	Unacceptable levels of turbidity are recorded in the effluent from the filter, even though the terminal headloss has not been reached. To control the buildup of effluent turbidity levels, chemicals and polymers have been added to the filter. The point of chemical or polymer addition must be determined by testing
Mudball formation	Mudballs are an agglomeration of biological floc, dirt, and the filtering medium or media. If the mudballs are not removed, they will grow into large masses that often sink into the filter bed and ultimately reduce the effectiveness of the filtering and backwashing operations. The formation of mudballs can be controlled by auxiliary washing processes such as air scour or water surface wash concurrent with, or followed by, water wash.
Buildup of emulsified grease	The buildup of emulsified grease within the filter bed increases the headloss and thus reduces the length of filter run. Both air scour and water surface wash systems help control the buildup of grease. In extreme cases, it may be necessary to steam clean the bed or to install a special washing system
Development of cracks and contraction of filter bed	If the filter bed is not cleaned properly, the grains of the filter-bed filtering medium become coated. As the filter compresses, cracks develop, especially at the sidewalls of the filter. Ultimately, mudballs may develop. This problem can be controlled by adequately backwashing and scouring
Loss of filter medium or media (mechanical)	In time, some of the filter material may be lost during backwashing and through the underdrain system (where the gravel support has been upset or the underdrain system has been installed improperly). The loss of the filter material can be minimized through the proper placement of washwater troughs and underdrain systems. Special baffles have also proved effective
Loss of filter medium or media (operational)	Depending on the characteristics of the biological floc, grains of the filter material can become attached to it, forming aggregates light enough to be floated away during the backwashing operations. The problem can be minimized by the addition of an auxiliary air and/or water scouring system
Gravel mounding	Gravel mounding occurs when the various layers of the support gravel are disrupted by the application of excessive rates of flow during the backwashing operation. A gravel support with an additional 50- to 75-mm (2- to 3-in) layer of high-density material, such as ilmenite or garnet, can be used to overcome this problem

[a] Turbidity breakthrough does not occur with filters that operate continuously.

ating conditions. The best way to ensure that the filter configuration selected for a given application will function properly is to conduct pilot-plant studies (see Fig. 11–28).

Because of the many variables that can be analyzed, care must be taken not to change more than one variable at a time so as to confound the results in a statistical sense. Testing should be carried out at several intervals, ideally throughout a full year, to assess seasonal variations in the characteristics of the effluent to be filtered. All test

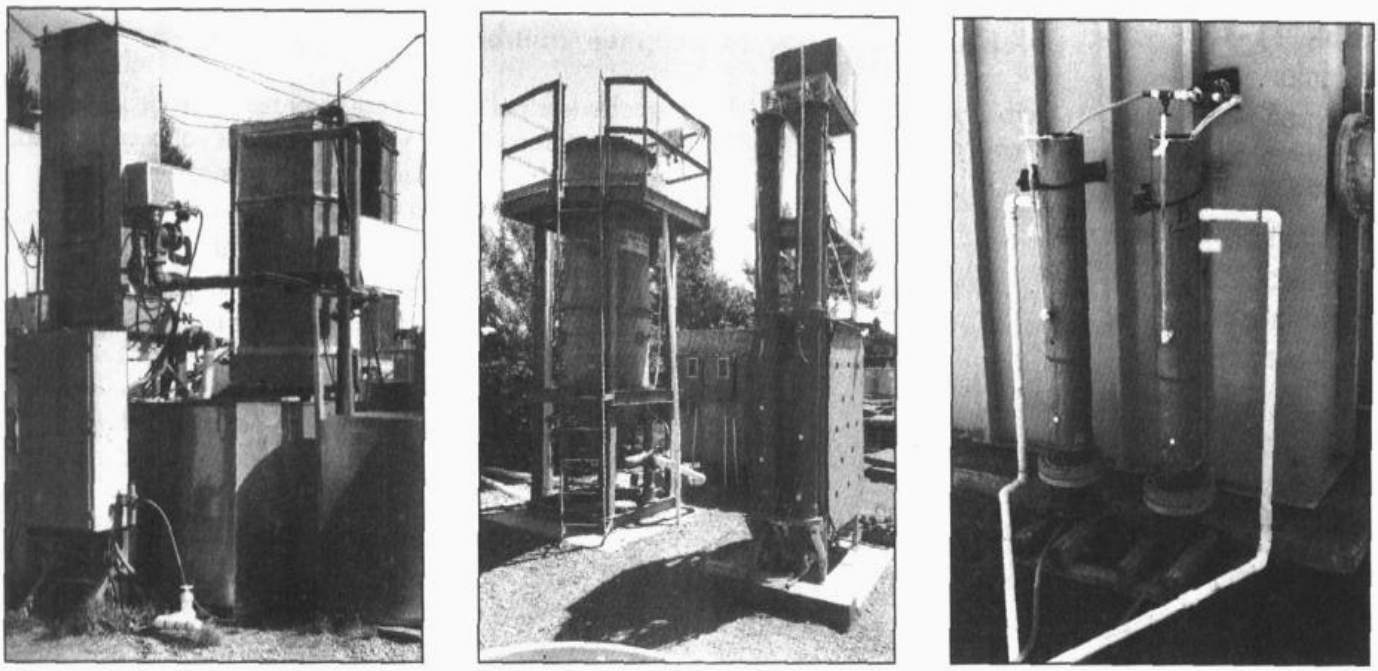

Figure 11-28

Typical pilot-plant facilities used to conduct filtration studies: (a) pulsed-bed filter, (b) continuous backwash upflow filter and dual-medium and deep bed monomedium filter columns, and (c) shallow bed monomedium.

results should be summarized and evaluated in several different ways to ensure their proper analysis. Because the specific details of each test program will be different, no generalization on the best method of analysis can be given.

11-5 SURFACE FILTRATION

Surface filtration, as shown on Fig. 11–3*b*, involves the removal of particulate material suspended in a liquid by mechanical sieving by passing the liquid through a thin septum (i.e., filter material). The mechanical sieving action is similar to a kitchen colander. Materials that have been used as filter septums include woven metal fabrics, cloth fabrics of different weaves, and a variety of synthetic materials. Membrane filters, discussed in the following section, are also surface filtration devices but are differentiated on the basis of the size of the pores in the filter medium. Cloth-medium surface filters have openings in the size range from 10 to 30 μm or larger. In membrane filters the pore size can vary from 0.0001 to 1.0 μm. Surface filtration has been used to remove the residual suspended solids from secondary effluents and from stabilization pond effluents. The focus of this section is on the removal of residual suspended solids from secondary and pond effluents discussed in the previous chapters. In this application, surface filtration is used as a replacement for depth filtration. The two principal types of cloth-medium surface filtration devices are described below.

Discfilter®

The Discfilter® (DF) consists of a series of disks composed of two vertically mounted parallel disks that are used to support the filter cloth. Each disk is connected to a cen-

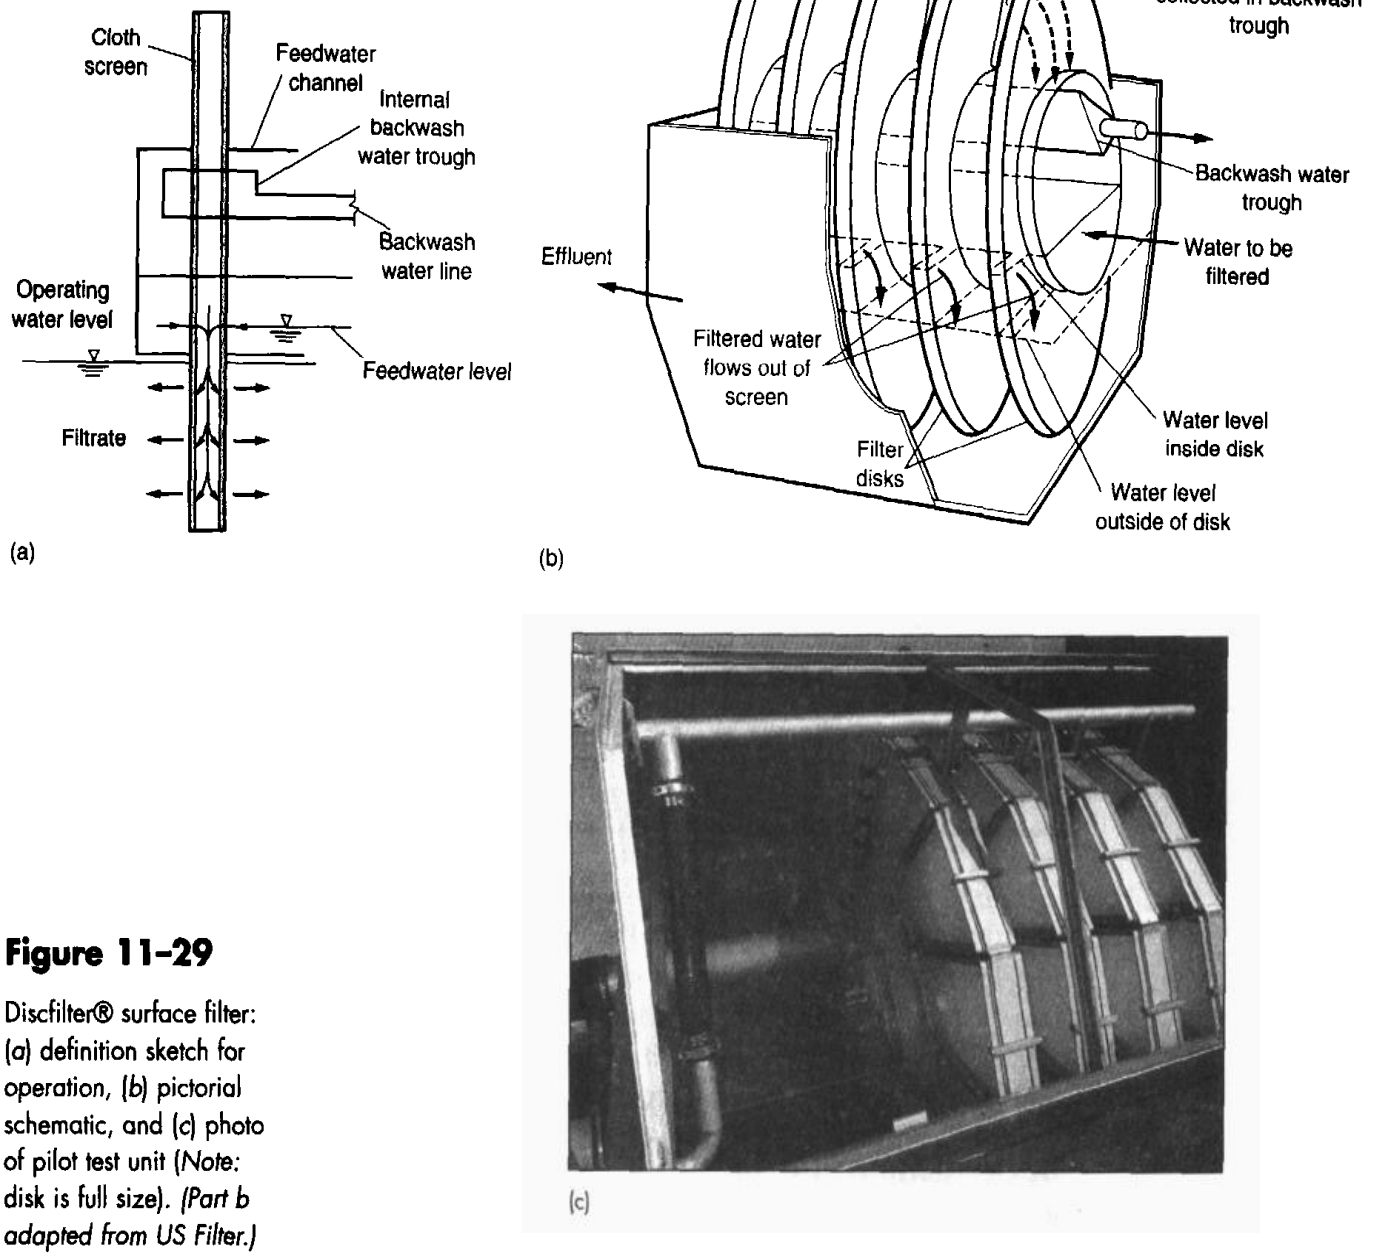

Figure 11-29

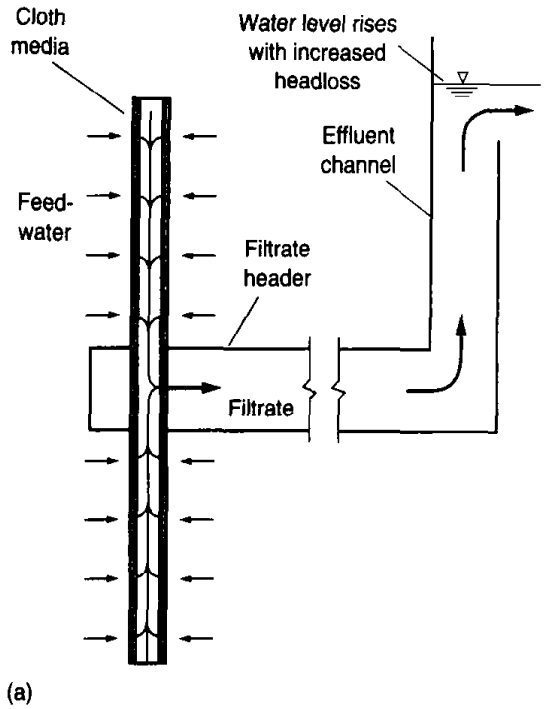
Discfilter® surface filter: (*a*) definition sketch for operation, (*b*) pictorial schematic, and (*c*) photo of pilot test unit (*Note:* disk is full size). *(Part b adapted from US Filter.)*

tral feed tube (see Fig. 11–29). The two-dimensional cloth screen material used with the DF can be of either polyester or Type 316 stainless steel. Typical design information for a DF can be found in Table 11–14.

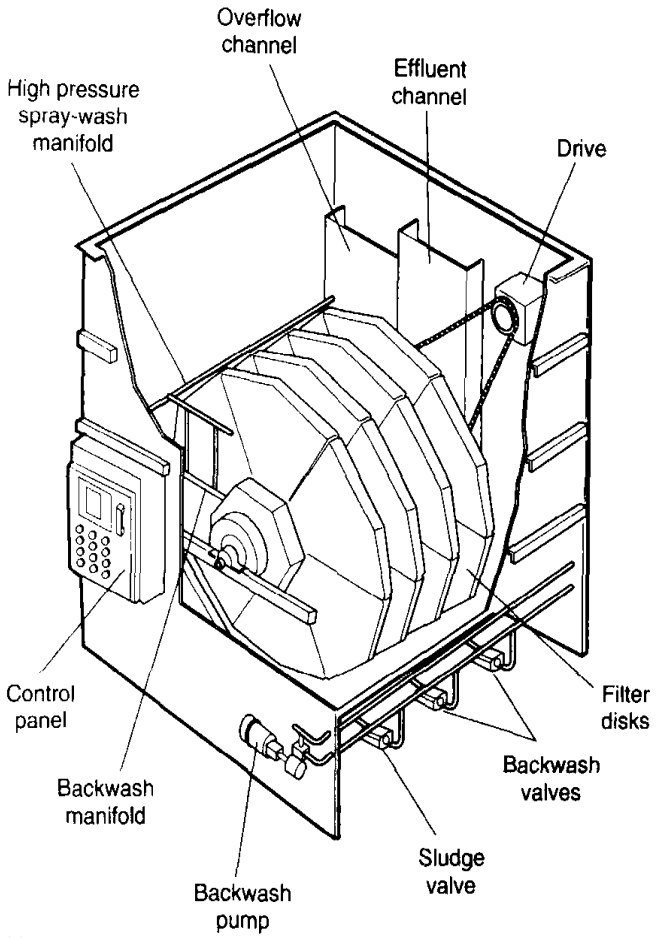
Operation of DF. Operationally, as shown on Fig. 11–29*a*, water enters through a central channel and flows outward through the filter cloth. During normal operation 60 to 70 percent of the surface area of the DF is submerged and the disk rotates, depending on the headloss, from 1 to 8.5 r/min. The DF has the ability to operate in an intermittent or a continuous-backwash mode. When operating in a continuous-backwash mode, the disks of the DF will both produce filtered water and be backwashed simultaneously. The

Table 11-14 Typical design information for surface filtration of secondary settled effluent using a Discfilter®



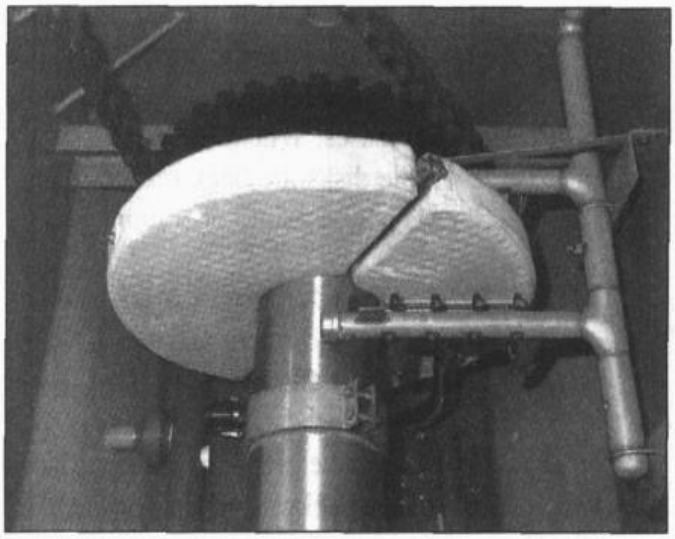
Item	Unit	Typical value	Remarks
Size of opening in screen material	μm	20–35	Two-dimensional stainless-steel or polyester screen cloths are available in sizes ranging from 10 to 60 μm
Hydraulic loading rate	$m^3/m^2 \cdot min$	0.25–0.83	Depends on characteristics of suspended solids that must be removed
Headloss through screen	mm	75–150	Based on submerged surface area of drum
Drum submergence	% height % area	70–75 60–70	Bypass should be provided when headloss exceeds 200 mm
Drum diameter	m	0.75–1.50	Varies depending on screen design; 3 m (10 ft) is most commonly used size; smaller sizes increase backwash requirements
Drum speed	m/min	4.5 at 50 mm headloss	Maximum rotational speed is limited
		30–40 at 150 mm headloss	
Backwash requirements	% throughput	2 at 350 kPa 5 at 100 kPa	

different stages the disk filter passes through during each rotation are identified on Fig. 11–29*b*. At the start of a rotation feedwater enters the central feed tube from where it is distributed into the disks. While the disk filter is submerged, water and particles smaller than openings in the cloth screen pass through the filter to the effluent collection channel. Those particles larger than the screen are retained.



Backwashing the DF. As the disk continues to rotate past the effluent water level, the remaining feedwater passes through the cloth screen until no water remains in the disk. The screen containing the captured wastewater solids continues to rotate until it passes the backwash spray jets. As the disk rotates past the backwash spray jets, the particles that have been retained on the cloth screen are flushed from the surface of the screen. The mixture of backwash water and solids falls from the disk and is collected in the backwash water trough. After passing by the backwash nozzles, the cleaned screens are ready to begin filtering water again. When the DF is operating in an intermittent backwash mode, the backwash spray jets are activated only when headloss through the filter reaches a preset level.

Cloth-Media Disk Filter®



The Cloth-Media Disk Filter (CMDF), as illustrated on Fig. 11–30, also consists of several disks mounted vertically in a tank. Two different types of cloths can be used in the CMDF: (1) a needle felt cloth, made of polyester or (2) a synthetic pile fabric cloth. The

(a)

(b)

(c)

Figure 11-30

Cloth-Media Disk Filter® surface filter: (*a*) definition sketch for operation, (*b*) pictorial schematic, and (*c*) photo of pilot test unit looking down into the filter housing (*Note:* disk is full size). *(Part b adapted from Aqua Aerobic Systems, Inc.)*

needle felt cloth has a random three-dimensional weave to facilitate particle removal. In addition to the normal backwashing, the felt cloth must be cleaned periodically with a high-pressure spray. The pile fabric does not require the use of a high-pressure spray wash and can be cleaned completely by use of a backwash alone. Typical design information for the CMDF can be found in Table 11–15.

Table 11–15
Typical design information for surface filtration of secondary settled effluent using a Cloth-Media Disk Filter®

Item	Unit	Typical value	Remarks
Nominal pore size	μm	10	Polyester three-dimensional needle felt cloths are employed as the filter material
Hydraulic loading rate	$m^3/m^2 \cdot min$	0.1–0.27	Depends on characteristics of suspended solids that must be removed
Headloss through screen	mm	50–300	Based on solids accumulation on or within the cloth
Disk submergence	% height % area	100 100	
Disk diameter	m	0.90 or 1.80	Two sizes are available
Disk speed	r/min	Stationary during normal operation 1 during backwash	
Backwash and sludge wasting requirements	% throughput	4.5 at 0.1 $m^3/m^2 \cdot min$ 7.2 at 0.27 $m^3/m^2 \cdot min$	Is a function of hydraulic loading rate and feedwater quality

Operation of the CMDF. Operationally, as shown on Fig. 11–30*a*, water enters the feed tank and flows through the filter cloth into a central collection tube or header. The resulting CMDF filtrate is collected in a central tube or a filtrate header (see Fig. 11–30*a*), where it flows to final discharge over an overflow weir in the effluent channel. As solids accumulate on and in the cloth medium, resistance to flow or headloss increases. When the headloss through the cloth medium reaches a predetermined level, the disks are backwashed. After filtering to waste after the backwash cycle, the filter is put back into operation.

Backwashing the CMDF. When a backwash cycle is initiated, the disks remain submerged and rotate at 1 r/min. Vacuum suction heads, located on either side of the CMDF, draw filtrate water from the filtrate header back through the cloth media into the vacuum heads while the disk is rotating. This reversal of flow removes particles that have become entrapped on the surface and within the cloth medium. The normal duration of the backwash cycle for the CMDF is 1 min.

Over time, particles will accumulate in the cloth medium that cannot be removed by a typical backwash. This accumulation of particles leads to increased headloss across the filter, an increase in the backwash suction pressure, and shorter run times between backwashes. When the backwash suction pressure reaches 124 kPa (18 lb/in^2), or the time exceeds the desired preset time interval, a high-pressure spray wash is initiated automatically. Prior to the high-pressure spray wash, the tank inlet valve is closed and the influent flow is stopped. A standard backwash is initiated to remove the outer layer of solids from the cloth. The filter-to-waste valve is opened, the water level is lowered to below the midline of the disks, and then a high-pressure spray wash is initiated.

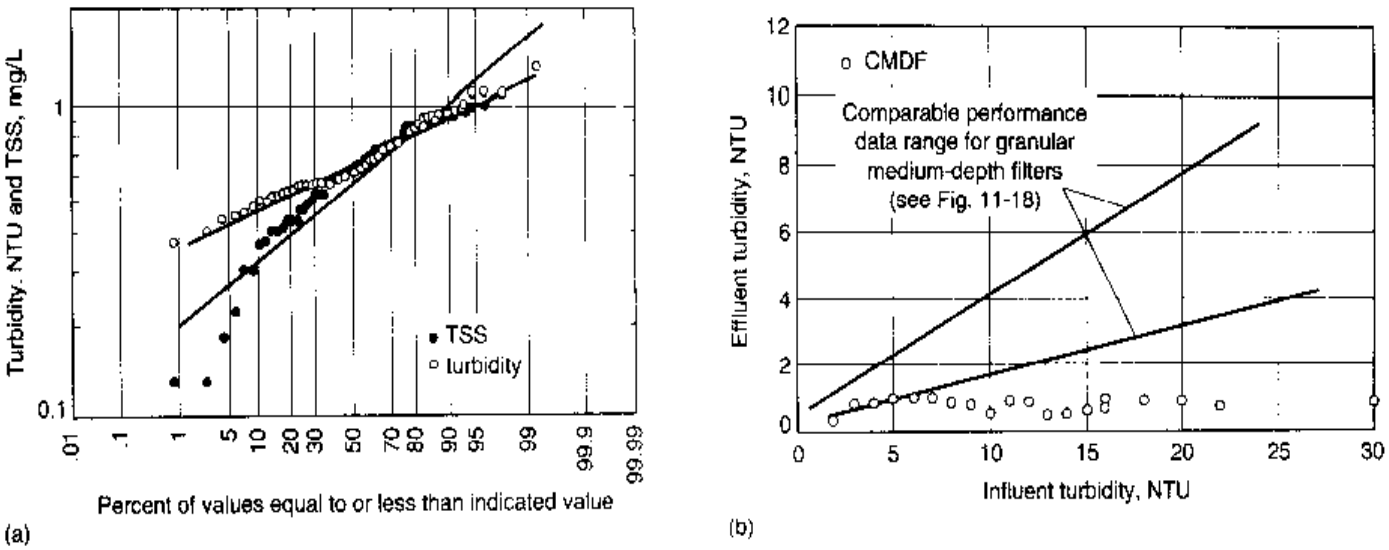


Figure 11-31

Performance data for the Cloth-Media Disk Filter® for secondary effluent: (*a*) effluent probability distributions for turbidity and TSS and (*b*) effluent turbidity as function of the influent turbidity at a filtration rate of 176 L/m²·min (4.4 gal/ft²·min).

During the high-pressure spray wash, the disks rotate slowly at 1 r/min, while filtrate water is sprayed at a high pressure from the outside of the filter cloth. The high-pressure spray wash flushes the particles that have become lodged inside the cloth filter medium effectively in two revolutions of the disk. After the end of the high-pressure spray wash, the inlet valve to the CMDF opens to allow the wastewater to flow to the filter. The disks continue to rotate and the filter-to-waste valve remains open until the solids that were flushed from the filter cloth to the filtrate side of the CMDF are removed from the filtrate header and the effluent line. The time interval between high-pressure spray washes is a function of the feedwater quality.

Performance Characteristics

To evaluate the performance capabilities of CMDF, a pilot unit employing a full-size disk (0.9 m, 3 ft, see Table 11–15) was used to treat secondary effluent from an activated-sludge process that had TSS and turbidity values ranging from 3.9 to 30 mg/L and 2 to 30 NTU, respectively. Based on a long-term study, it was found, as shown on Fig. 11–31*a*, that both the TSS and turbidity values of the filtered effluent were less than 1, 92 percent of the time (Riess et al., 2001). The performance of the CMDF as compared to depth filters all tested with effluent from a previous activated-sludge plant treating the same wastewater is shown on Fig. 11–31*b*. As shown, the effluent from the CMDF remained constant over all of the influent turbidity values tested up to 30 NTU. The DF has not been tested. Based on observations of the cloth surface, it appears that the material removed on the filter also acts as a filter (autofiltration). The percentage of backwash water used ranged between 4 and 10.

In reviewing the data presented on Fig. 11–31*b*, it is important to note the activated-sludge treatment process is operated as an extended aeration treatment process (SRT > 15 *d*). If either of the cloth filters is to be used to filter effluent from activated-sludge

processes operated with extremely low SRT values (i.e., 1 to 2 *d*), pilot testing should be undertaken, as the characteristics of the residual solids to be filtered are significantly different.

11–6 MEMBRANE FILTRATION PROCESSES

Filtration, as defined in Secs. 11–3 and 11–5, involves the separation (removal) of particulate and colloidal matter from a liquid. In membrane filtration the range of particle sizes is extended to include dissolved constituents (typically 0.0001 to 1.0 μm). The role of the membrane, as shown on Fig. 11–32, is to serve as a selective barrier that will allow the passage of certain constituents and will retain other constituents found in the liquid (Cheryan, 1998). To introduce membrane technologies and their application, the following subjects are considered in this section: (1) membrane process terminology, (2) membrane classification, (3) membrane configurations, (4) application of membrane technologies, (5) electrodialysis, (6) the need for pilot-plant studies, and (7) the disposal of concentrated waste streams, which is considered at the end of this section.

Membrane Process Terminology

Terms commonly encountered when considering the application of membrane processes are summarized in Table 11–16. Referring to Fig. 11–32 and Table 11–16, the influent to the membrane module is known as the *feed stream* (also known as feedwater). The liquid that passes through the semipermeable membrane is known as *permeate* (also known as the product stream or permeating stream) and the liquid containing the retained constituents is known as the *concentrate* (also known as the retentate, reject, retained phase, or waste stream). The rate at which the permeate flows through the membrane is known as the rate of *flux*, typically expressed as kg/m^2·d (gal/ft^2·d).

Membrane Process Classification

Membrane processes include microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), reverse osmosis (RO), dialysis, and electrodialysis (ED). Membrane processes can be classified in a number of different ways including (1) the type of material from which the membrane is made, (2) the nature of the driving force, (3) the separation mechanism, and (4) the nominal size of the separation achieved. Each of these methods

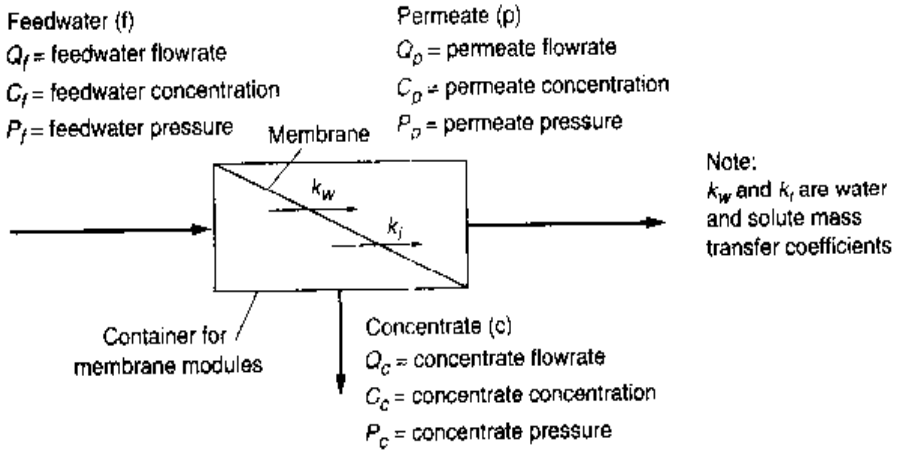

Figure 11–32
Definition sketch for a membrane process.

Table 11-16 Terminology used to describe membrane processes[a]

Term	Description
Array or train	Multiple interconnected stages in series
Brine	Concentrate stream containing total dissolved solids greater than 36,000 mg/L.
Concentrate, retentate, retained phase, reject, residual stream	The portion of the feed stream that does not pass through the membrane that contains higher TDS than the feed stream
Feed stream, feedwater	Input stream to the membrane array
Flux	Mass or volume rate of transfer through the membrane surface
Fouling	Deposition of existing solid material in the element on the feed stream of the membrane. Fouling can be either reversible or irreversible
Lumen	The interior of a hollow fiber membrane
Mass transfer coefficient (MTC)	Mass or volume unit transfer through membrane based on driving force
Membrane element	A single membrane unit containing a bound group of spiral-wound or hollow fine-fiber membranes to provide a nominal surface area
Module	A complete unit comprised of the membranes, the pressure support structure for the membranes, the feed inlet and outlet permeate and retentate ports, and an overall support structure
Molecular weight cutoff (MWCO)	The molecular weight of the smallest material rejected by the membrane, usually expressed in Daltons (D)
Permeate, product, permeating stream	The portion of the feed stream that passes through the membrane that contains lower TDS than the feed stream
Reject ion	Percent solute concentration reduction of permeate stream relative to feed stream
Pressure vessel	A single tube that contains several membrane elements in series
Scaling	Precipitation of solids in the element due to solute concentration on the feed stream of the membrane
Size exclusion	Removal of particles by sieving
Solvent	Liquid containing dissolved constituents (TDS), usually water
Solute	Dissolved constituents (TDS) in raw, feed, permeate, and concentrate streams
Stage or bank	Pressure vessels arranged in parallel
System arrays	Number of arrays needed to produce the required plant flow
Train or array	Multiple interconnected stages in series

[a] Adapted in part from AWWA (1996), Cheryan (1998), and Taylor and Wiesner (1999).

of classifying membrane processes is considered in the following discussion. The general characteristics of membrane processes including typical operating ranges are reported in Table 11–17. The focus of the following discussion is on pressure-driven membrane processes. Electrodialysis is considered separately following the discussion of the application of pressure-driven membranes.

Table 11-17
General characteristics of membrane processes

Membrane process	Membrane driving force	Typical separation mechanism	Operating structure (pore size)	Typical operating range, μm	Permeate description	Typical constituents removed
Microfiltration	Hydrostatic pressure difference	Sieve	Macropores (>50 nm)	0.08–2.0	Water + dissolved solutes	TSS, turbidity, protozoan oocysts and cysts, some bacteria and viruses
Ultrafiltration	Hydrostatic pressure difference	Sieve	Mesopores (2–50 nm)	0.005–0.2	Water + small molecules	Macromolecules, colloids, most bacteria, some viruses, proteins
Nanofiltration	Hydrostatic pressure difference	Sieve + solution/ diffusion + exclusion	Micropores (<2 nm)	0.001–0.01	Water + very small molecules, ionic solutes	Small molecules, some harness, viruses
Reverse osmosis	Hydrostatic pressure difference	Solution/ diffusion + exclusion	Dense (<2 nm)	0.0001–0.001	Water, very small molecules, ionic solutes	Very small molecules, color, hardness, sulfates, nitrate, sodium, other ions
Dialysis	Concentration difference	Diffusion	Mesopores (2–50 nm)	—	Water + small molecules	Macromolecules, colloids, most bacteria, some viruses, proteins
Electrodialysis	Electromotive force	Ion exchange with selective membranes	Micropores (<2 nm)	—	Water + ionic solutes	Ionized salt ions

Membrane Materials. Membranes used for the treatment of water and wastewater typically consist of a thin skin having a thickness of about 0.20 to 0.25 μm supported by a more porous structure of about 100 μm in thickness. Most commercial membranes are produced as flat sheets, fine hollow fibers, or in tubular form. The flat sheets are of two types, asymmetric and composite. Asymmetric membranes are cast in one process and consist of a very thin (less than 1 μm) layer and a thicker (up to 100 μm) porous layer that adds support and is capable of high water flux. Thin-film composite (TFC) membranes are made by bonding a thin cellulose acetate, polyamide, or other active layer (typically 0.15 to 0.25 μm thick) to a thicker porous substrate, which provides stability. Membranes can be made from a number of different organic and inorganic materials. The membranes used for wastewater treatment are typically organic. The principal types of membranes used include polypropylene, cellulose acetate, aromatic polyamides, and thin-film composite (TFC). The choice of membrane and system configuration is based on minimizing membrane clogging and deterioration, typically based on pilot-plant studies.

Driving Force. The distinguishing characteristic of the first four membrane processes considered in Table 11–17 (MF, UF, NF, and RO) is the application of hydraulic pressure to bring about the desired separation. Dialysis involves the transport of constituents through a semipermeable membrane on the basis of concentration differences. Electrodialysis involves the use of an electromotive force and ion-selective membranes to accomplish the separation of charged ionic species.

Removal Mechanisms. The separation of particles in MF and UF is accomplished primarily by straining (sieving), as shown on Fig. 11–33*a*. In NF and RO, small particles are rejected by the water layer adsorbed on the surface of the membrane which is known as a *dense* membrane (see Fig. 11–33*b*). Ionic species are transported across the membrane by diffusion through the pores of the macromolecule comprising the membrane. Typically NF can be used to reject constituents as small as 0.001 μm whereas RO can reject particles as small as 0.0001 μm. Straining is also important in NF membranes, especially at the larger pore size openings.

Size of Separation. The pore sizes in membranes are identified as macropores (>50 nm), mesopores (2 to 50 nm), and micropores (< 2 nm). Because the pore sizes in RO membranes are so small, the membranes are defined as dense. The classification of membrane processes on the basis of the size of separation is shown on Fig. 11–34 and in Table 11–17. Referring to Fig.11–34, it can be seen that there is considerable overlap in the sizes of particles removed, especially between NF and RO. Nanofiltration is used most commonly in water-softening operations in place of chemical precipitation.

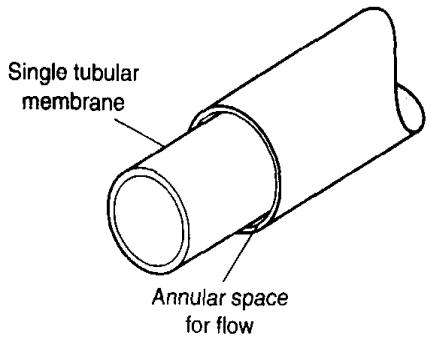
Membrane Configurations

In the membrane field, the term *module* is used to describe a complete unit comprised of the membranes, the pressure support structure for the membranes, the feed inlet and outlet permeate and retentate ports, and an overall support structure. The principal types of membrane modules used for wastewater treatment are (1) tubular, (2) hollow fiber, and (3) spiral wound (AWWA, 1996). Plate and frame and pleated cartridge filters are also available but are used more commonly in industrial applications. The various membranes, described below, are illustrated on Fig. 11–35.

Tubular Modules. In the tubular configuration the membrane is cast on the inside of a support tube. A number of tubes (either singly or in a bundle) are then placed in an appropriate pressure vessel. The feedwater is pumped through the feed tube and the product water is collected on the outside of the tubes (see Fig. 11–35*a*). The concentrate continues to flow through the feed tube. These units are generally used for water with high suspended solids or plugging potential. Tubular units are the easiest to clean, which is accomplished by circulating chemicals and pumping a "foamball" or "sponge-ball" through to mechanically wipe the membrane. Tubular units produce at a low product rate relative to their volume, and the membranes are generally expensive.



Hollow Fiber. The hollow-fiber membrane module, as shown on Fig. 11–35*b*, consists of a bundle of hundreds to thousands of hollow fibers. The entire assembly is inserted into a pressure vessel. The feed can be applied to the inside of the fiber (inside-out flow) or the outside of the fiber (outside-in flow).

Spiral Wound. In the spiral-wound membrane, a flexible permeate spacer is placed between two flat membrane sheets. The membranes are sealed on three sides.

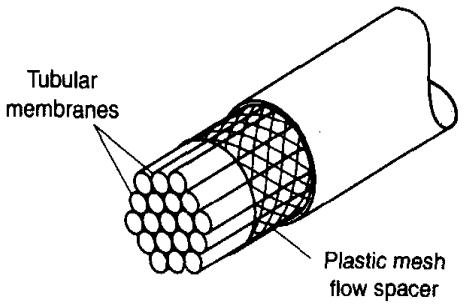


Figure 11-35

Typical membrane elements and modules used in membrane applications: (*a*) single tubular hollow fiber membrane, (*b*) bundle of tubular hollow fiber membranes, (*c*) bundle of hollow fine fiber membranes with flow from the outside to the inside of the fiber, (*d*) view of an exposed bundle of hollow fine fiber membranes, (*e*) bundle of hollow fine fiber membranes with flow from the inside to the outside of the fiber, (*f*) bundles of hollow fine fiber membranes placed in a pressure vessel. *(Figs. c, e, g, h, and k from Crites and Tchobanoglous, 1998.)*

Typical membrane elements and modules used in membrane applications: (*g*) cutaway of spiral-wound thin-film composite membrane module, (*h*) section through spiral-wound thin-film composite membrane module, (*i*) pressure vessel containing 3 spiral-wound thin-film composite membrane modules in series, (*j*) typical installation of reverse osmosis pressure vessels containing 6 spiral-wound thin-film composite membrane modules in series, and (*k*) parallel plate and frame membrane. *(Figs. c, e, g, h, and k from Crites and Tchobanoglous, 1998.)*

The open side is attached to a perforated pipe. A flexible feed spacer is added and the flat sheets are rolled into a tight circular configuration (see Figs. 11–35*g* and *h*). Thin-film composites are used most commonly in spiral-wound membrane modules. The term spiral derives from the fact that the flow in the rolled-up arrangement of membranes and support sheets follows a spiral flow pattern.

Plate and Frame. Plate and frame membrane modules (see Fig. 11–35*k*) are comprised of a series of flat membrane sheets and support plates. The water to be treated passes between the membranes of two adjacent membrane assemblies. The plate supports the membranes and provides a channel for the permeate to flow out of the unit. The plate and frame configuration is used most commonly for electrodialysis modules (sometimes identified as stacks).

Pleated-Cartridge Filters. Pleated-cartridge filters are used most commonly in microfiltration applications and usually are designed as disposable units. Pleated-cartridge filters are used almost exclusively to concentrate virus from treated wastewater for analysis (see Chap. 2).

Pressure Vessels. With the exception of the pressure vessels, which need to be manufactured specially, most of the equipment used for membrane filtration is standard to the chemical and process industry. The primary purpose of the pressure vessel (or tube) is to support the membrane and keep the feedwater and product streams isolated. The vessel must also be designed to prevent leaks and pressure losses to the outside, minimize the buildup of salt or fouling, and permit easy replacement of the membranes. Depending on the operating pressure and the characteristic of the feedwater, a variety of materials have been used, including plastic and fiberglass tubes and plumbing components. Steel pressure tubes are required for some reverse-osmosis applications, and stainless steel is required for seawater and brackish water having high TDS. Centrifugal pumps can be used for MF, UF, and NF; positive-displacement pumps or high-pressure turbine pumps are necessary for RO.

Membrane Operation

The operation of membrane processes is quite simple. A pump is used to pressurize the feed solution and to circulate it through the module. A valve is used to maintain the pressure of retentate. The permeate is withdrawn, typically at atmospheric pressure. As constituents in the feedwater accumulate on the membranes (often termed membrane fouling), the pressure builds up on the feed side, the membrane flux (i.e., flow through membrane) starts to decrease, and the percent rejection also starts to decrease (see Fig. 11–36). When the performance has deteriorated to a given level, the membrane modules are taken out of service and backwashed and/or cleaned chemically. The operational configurations and parameters for the various membrane processes are considered in the following discussion.

Microfiltration and Ultrafiltration. Three different process configurations are used with microfiltration and ultrafiltration units as illustrated on Fig. 11–37. In the first configuration known as *cross flow* (Fig. 11–37*a*) the feedwater is pumped with cross flow tangential to the membrane. Water that does not pass through the membrane

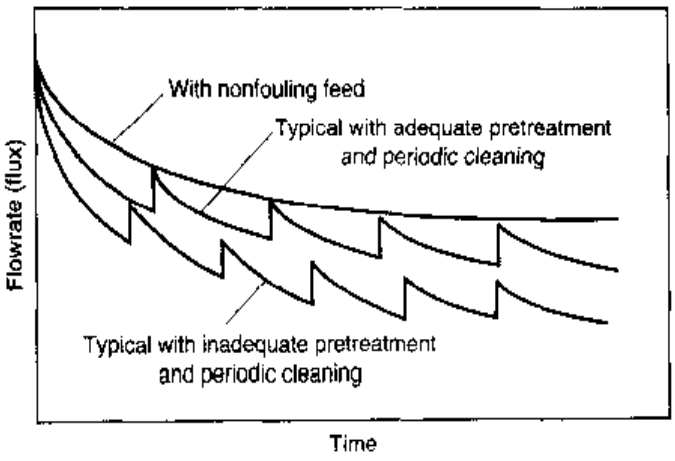

Figure 11–36

Definition sketch for the performance of a membrane filtration system.

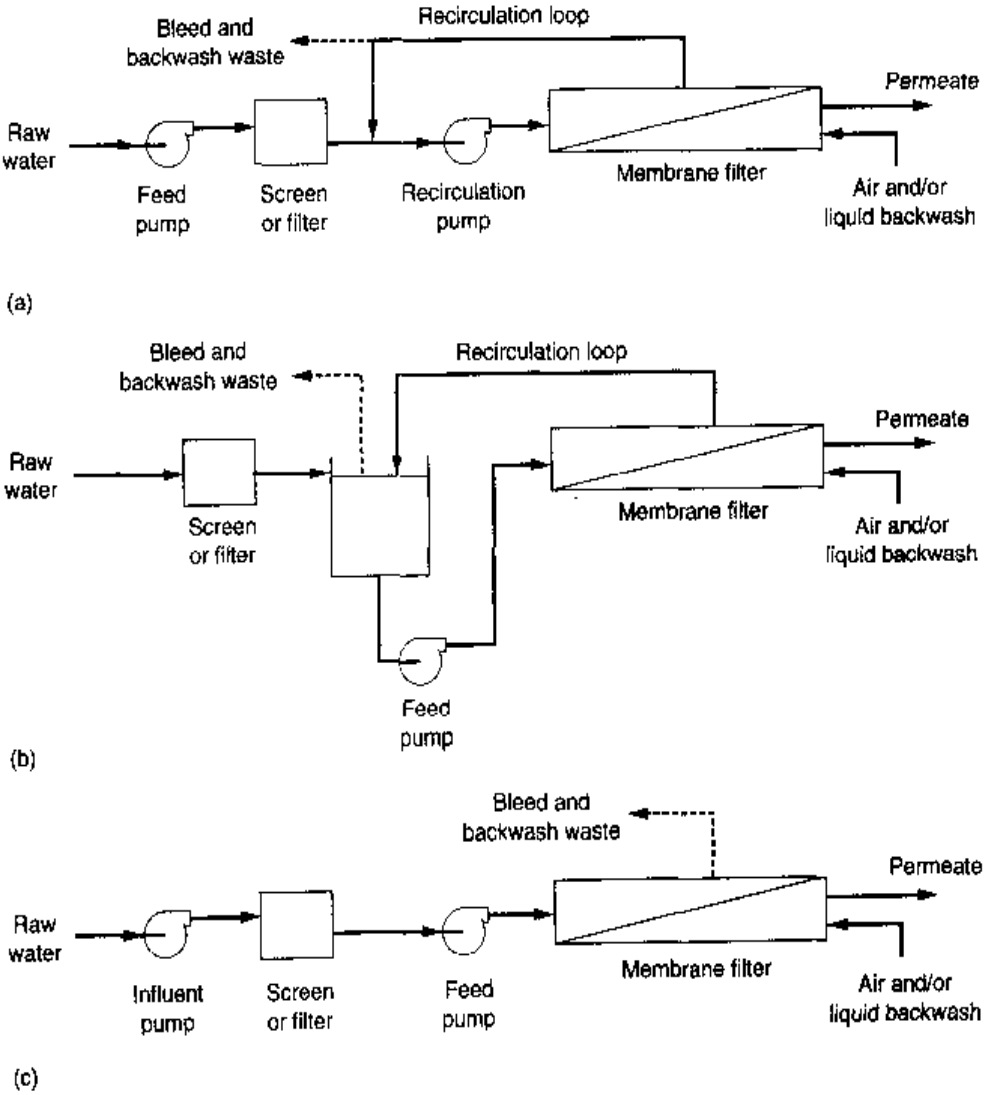

Figure 11–37

Typical operational modes for MF and UF membrane processes: (a) cross flow, (b) cross flow with reservoir, and (c) direct feed. *(Adapted from Jacangelo and Buckley, 1996.)*

is recirculated through the membrane after blending with additional feedwater. The second configuration, also known as cross flow (Fig. 11–37*b*), is similar to the first with the exception that the water that does not pass through the membrane is recirculated to a storage reservoir. The third configuration is known as direct feed (also *dead-end*) (Fig. 11–37*c*) in that there is no cross flow. All of the water applied to the membrane

passes through the membrane. Raw feedwater is used periodically to flush the accumulated material from the membrane surface.

For the cross-flow mode of operation (see Fig. 11–37*a* and *b*), the transmembrane pressure is given by the following expression:

$$P_{tm} = \left[\frac{P_f + P_c}{2}\right] - P_p \tag{11–35}$$

where P_{tm} = transmembrane pressure gradient, kPa
P_f = inlet pressure of feed stream, kPa
P_c = pressure of concentrate stream, kPa
P_p = pressure of permeate stream, kPa

The overall pressure drop across the filter module for the cross-flow mode of operation is given by

$$P = P_f - P_p \tag{11–36}$$

where P = pressure drop across module, kPa
P_f and P_P as defined above

For the direct-feed mode of operation (see Fig. 11–37*c*) the transmembrane pressure is given by the following expression:

$$P_{tm} = P_f - P_p \tag{11–37}$$

where P_{tm} = transmembrane pressure gradient, kPa
P_f and P_P as defined above

The total permeate flow from a membrane system is given by

$$Q_p = F_w A \tag{11–38}$$

where Q_p = permeate stream flowrate, kg/s
F_w = transmembrane water flux rate, kg/m^2·s
A = membrane area, m^2

As would be expected, the transmembrane water flux rate is a function of the quality of the feed stream, the degree of pretreatment, the characteristics of the membrane, and the system operating parameters.

The recovery rate r is defined as

$$r, \% = \frac{Q_p}{Q_f} \times 100 \tag{11–39}$$

where Q_p = permeate stream flow, kg/s
Q_f = feed stream flow, kg/s

It should be noted that there is a difference in the recovery rate (which refers to the water) and the rate of rejection (which refers to the solute) as given below:

$$R, \% = \frac{C_f - C_p}{C_f} \times 100 = 1 - \frac{C_p}{C_f} \times 100 \tag{11–40}$$

The corresponding mass balance equations are

$$Q_f = Q_p + Q_c \tag{11-41}$$

$$Q_f C_f = Q_p C_p + Q_c C_c \tag{11-42}$$

Three different operating modes can be used to control the operation of a membrane process with respect to flux and the transmembrane pressure (TMP). The three modes, illustrated on Fig. 11–38, are (1) constant flux in which the flux rate is fixed and the TMP is allowed to vary (increase) with time; (2) constant TMP in which the TMP is fixed and the flux rate is allowed to vary (decrease) with time, and (3) both the flux rate and the TMP are allowed to vary with time. Traditionally, the constant-flux mode of operation has been used. However, based on the results of a recent study with various wastewater effluents (Bourgeous et al., 1999), it appears the mode in which both the flux rate and the TMP are allowed to vary with time may be the most effective mode of operation.

Reverse Osmosis. When two solutions having different solute concentrations are separated by a semipermeable membrane, a difference in chemical potential will exist across the membrane (Fig. 11–39). Water will tend to diffuse through the membrane from the lower-concentration (higher-potential) side to the higher-concentration (lower-potential) side. In a system having a finite volume, flow continues until the pressure dif-

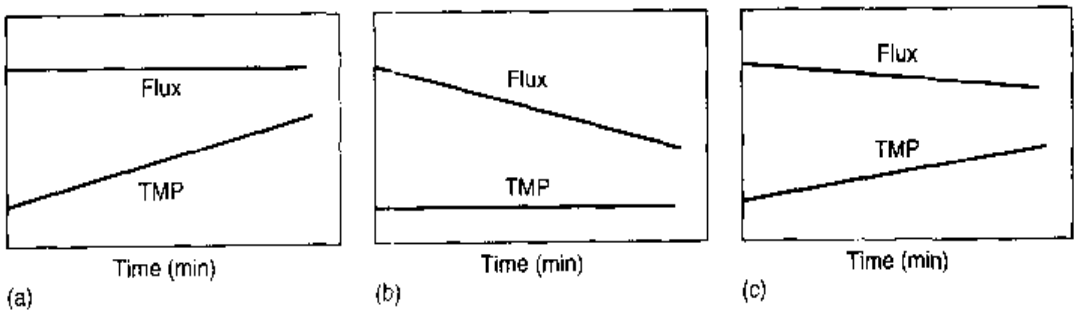

Figure 11-38
Three modes of membrane operation: (a) constant flux, (b) constant pressure, and (c) nonrestricted flux and pressure. *(Adapted from Bourgeous et al., 1999.)*

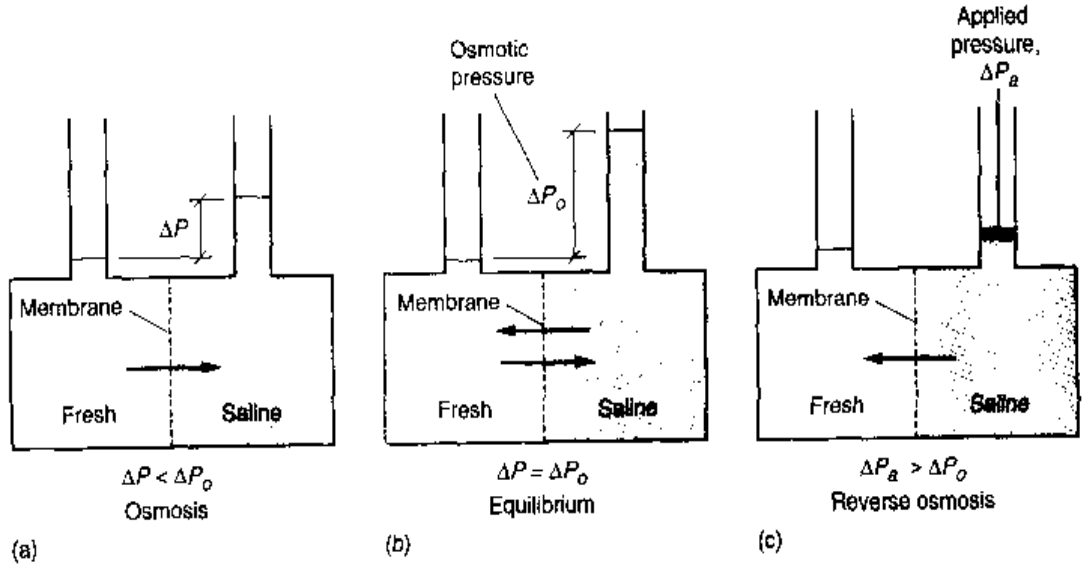

Figure 11-39
Definition sketch of osmotic flow: (a) osmotic flow, (b) osmotic equilibrium, and (c) reverse osmosis.

ference balances the chemical potential difference. This balancing pressure difference is termed the *osmotic pressure* and is a function of the solute characteristics and concentration and temperature. If a pressure gradient opposite in direction and greater than the osmotic pressure is imposed across the membrane, flow from the more concentrated to the less concentrated region will occur and is termed *reverse osmosis* (see Fig. 11–39*c*).

A number of different models have been developed to determine the surface area of membrane and the number of arrays required (see Fig. 11–40). The basic equations used to develop the various models are as follows (Taylor and Wiesner, 1999). Referring to Fig. 11–32, the flux of water through the membrane is a function of the pressure gradient:

$$F_w = k_w(\Delta P_a - \Delta\Pi) = \frac{Q_p}{A} \tag{11–43}$$

where F_w = water flux rate, kg/m^2·s
k_w = water mass transfer coefficient involving temperature, membrane characteristics, and solute characteristics, s/m
ΔP_a = average imposed pressure gradient, kPa
$= \left[\frac{P_f + P_c}{2}\right] - P_p$
$\Delta\Pi$ = osmotic pressure gradient, kPa
$= \left[\frac{\Pi_f + \Pi_c}{2}\right] - \Pi_p$
Q_p = permeate stream flow, kg/s
A = membrane area, m^2

Some solute passes through the membrane in all cases. Solute flux can be described adequately by an expression of the form

$$F_i = k_i\,\Delta C_i = \frac{Q_p C_p}{A} \tag{11–44}$$

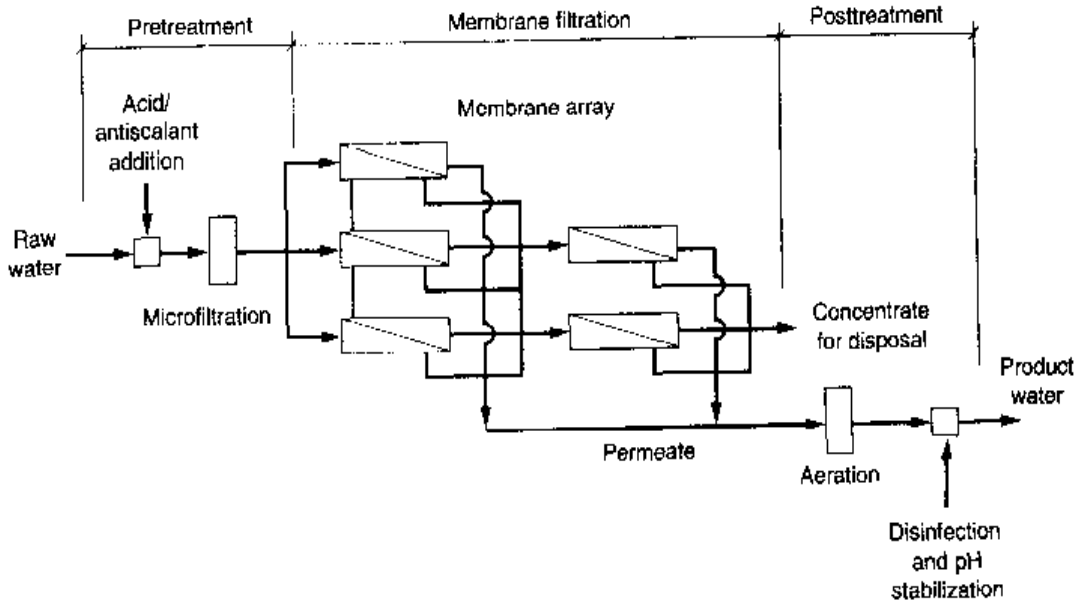

Figure 11–40
Typical flow diagram for reverse osmosis membrane process with pre- and posttreatment.

where F_i = flux of solute species i, kg/m²·s
k_i = solute mass transfer coefficient, m/s
ΔC_i = solute concentration gradient, kg/m³

$$= \left[\frac{C_f + C_c}{2}\right] - C_p$$

C_f = solute concentration in feed stream, kg/m³
C_c = solute concentration in concentrate stream, kg/m³
C_p = solute concentration in permeate stream, kg/m³

The recovery rate and the rate of rejection are as described above for the micro- and ultrafiltration membranes. Use of the above equations to estimate the required surface area for desalination is illustrated in Example 11–5.

EXAMPLE 11–5 Determination of Membrane Area Required for Demineralization A brackish water having a TDS concentration of 3000 g/m³ is to be desalinized using a thin-film composite membrane having a flux rate coefficient k_w of 1.5×10^{-6} s/m and a mass transfer rate coefficient k_i of 1.8×10^{-6} m/s. The product water is to have a TDS of no more than 200 g/m³. The flowrate is to be 0.010 m³/s. The net operating pressure ($\Delta P_a - \Delta\Pi$) will be 2500 kPa. Assume the recovery rate will be 90 percent. Estimate the rejection rate and the concentration of the concentrate stream.

Solution

1. The problem involves determination of the membrane area required to produce 0.010 m³/s of water and the TDS concentration of the permeate. If the permeate TDS concentration is well below 200 g/m³, blending of feed and permeate will reduce the required membrane area.
2. Estimate membrane area using Eq. (11–43).

$$F_w = k_w(\Delta P_a - \Delta\Pi)$$
$$= (1.5 \times 10^{-6}\ \text{s/m})(2500\ \text{kg/m}^2) = 3.75 \times 10^{-3}\ \text{kg/m}^2\cdot\text{s}$$
$$Q_p = F_w \times A$$
$$A = \frac{(0.010\ \text{m}^3/\text{s})(10^3\ \text{kg/m}^3)}{(3.75 \times 10^{-3}\ \text{kg/m}^2\cdot\text{s})} = 2667\ \text{m}^2$$

3. Estimate permeate TDS concentration using Eq. (11–44).

$$F_i = k_i\,\Delta C_i = \frac{Q_p C_p}{A}$$
$$Q_p C_p = k_i\left(\left[\frac{C_f + C_c}{2}\right] - C_p\right)A$$

Assume $C_c \approx C_f$ and solve for C_p

$$C_p = \frac{k_i A C_f}{Q_p + k_i A}$$

Assume $Q_p = r\,Q_f$

$$C_p = \frac{(1.8 \times 10^{-6}\ \text{m/s})(2667\ \text{m}^2)(3.0\ \text{kg/m}^3)}{(0.01)(0.9) + (1.8 \times 10^{-6}\ \text{m/s})(2667\ \text{m}^3)} = 0.152\ \text{kg/m}^3$$

The permeate solute concentration is lower than necessary. It may be possible to reduce the area by blending.

4. Estimate the rejection rate using Eq. (11–40)

$$R, \% = \frac{C_f - C_p}{C_f} \times 100$$

$$R = \frac{(3.0\ \text{kg/m}^3 - 0.152\ \text{kg/m}^3)}{(3.0\ \text{kg/m}^3)} \times 100 = 95\%$$

5. Estimate the concentrate stream TDS using Eq. (11–42)

$$C_c = \frac{Q_f C_f - Q_p C_p}{Q_c}$$

$$C_c = \frac{(0.1\ \text{L})(3.0\ \text{kg/m}^3) - (0.9\ \text{L})(0.152\ \text{kg/m}^3)}{0.1\ \text{L}} = 31.4\ \text{kg/m}^3$$

Membrane Fouling

The term *fouling* is used to describe the potential deposition and accumulation of constituents in the feed stream on the membrane. Membrane fouling is an important consideration in the design and operation of membrane systems as it affects pretreatment needs, cleaning requirements, operating conditions, cost, and performance. Constituents in wastewater that can bring about membrane fouling are identified in Table 11–18. Fouling of the membrane, as reported in Table 11–18, can occur in three general forms: (1) a buildup of the constituents in the feedwater on the membrane surface, (2) the formation of chemical precipitates due to the chemistry of the feedwater, and (3) damage to the membrane due to the presence of chemical substances that can react with the membrane or biological agents that can colonize the membrane.

Membrane Fouling Caused by Buildup of Solids. Three accepted mechanisms resulting in resistance to flow due to the accumulation of material within a lumen (see Fig. 11–41) are (1) pore narrowing, (2) pore plugging, and (3) gel/cake formation caused by concentration polarization (Ahn et al., 1998). Gel/cake formation, caused by concentration polarization, occurs when the majority of the solid matter in the feed is larger than the pore sizes or molecular weight cutoff of the membrane. Concentration polarization can be described as the buildup of matter close to or on the membrane surface that causes an increase in resistance to solvent transport across the membrane. Some degree of concentration polarization will always occur in the operation of a membrane system. The formation of a gel or cake layer, however, is an extreme

Table 11-18
Constituents in wastewater that can affect the performance of membranes through the mechanism of fouling

Type of membrane fouling	Responsible constituents	Remarks
Fouling (cake formation sometimes identified as biofilm formation)	Metal oxides Organic and inorganic colloids Bacteria Microorganisms Concentration polarization	Damage to membranes can be limited by controlling these substances (for example, by the use of microfiltration before reverse osmosis)
Scaling (precipitation)	Calcium sulfate Calcium carbonate Calcium fluoride Barium sulfate Metal oxide formation Silica	Scaling can be reduced by limiting salt content, by adding acid to limit the formation of calcium carbonate, and by other chemical treatments (e.g., the addition of antiscalants)
Damage to membrane	Acids Bases pH extremes Free chlorine Bacteria Free oxygen	Damage to membranes can be limited by controlling these substances. Extent of damage depends on the nature of the membrane

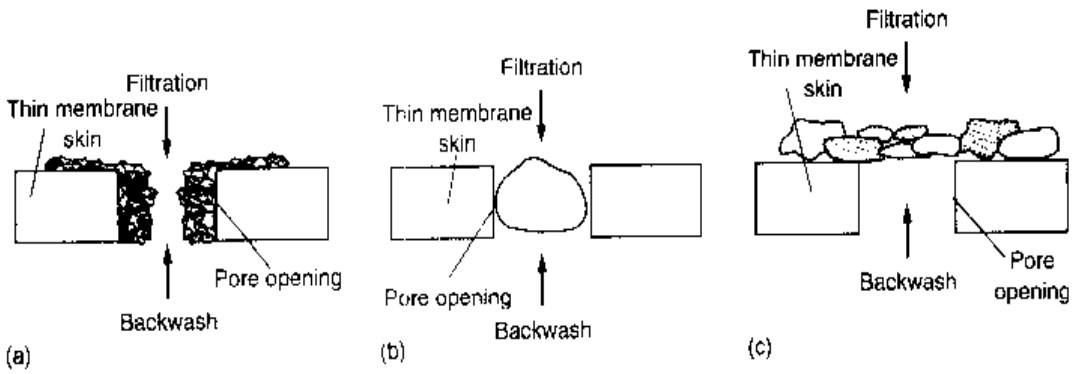

Figure 11-41
Modes of membrane fouling: (a) pore narrowing, (b) pore plugging, and (c) gel/cake formation caused by concentration polarization. *(Adapted from Bourgeous et al., 1999.)*

case of concentration polarization where a large amount of matter has actually accumulated on the membrane surface, forming a gel or cake layer. The mechanisms of pore plugging and pore narrowing will occur only when the solid matter in the feedwater is smaller than the pore size or the molecular weight cutoff. As the name describes, pore plugging occurs when particles the size of the pores become stuck in the pores of the membrane. Pore narrowing consists of solid material attaching to the interior surface of the pores, which results in a narrowing of the pores. It has been hypothesized that once the pore size is reduced, concentration polarization is amplified further, causing an increase in fouling (Crozes et al.,1997).

Control of Membrane Fouling. Typically, three approaches are used to control membrane fouling: (1) pretreatment of the feedwater, (2) membrane backflushing, and (3) chemical cleaning of the membranes. Pretreatment is used to reduce the TSS and bacterial content of the feedwater. Often the feedwater will be conditioned chemi-

cally to limit chemical precipitation within the units. The most commonly used method of eliminating the accumulated material from the membrane surface is backflushing with water and/or air. Chemical treatment is used to remove constituents that are not removed during conventional backwashing. Chemical precipitates can be removed by altering the chemistry of the feedwater and by chemical treatment. Damage of the membrane due to deleterious constituents typically cannot be reversed.

Pretreatment for Nanofiltration and Reverse Osmosis. A very high-quality feed is required for efficient operation of a nanofiltration or reverse osmosis unit. Membrane elements in the reverse osmosis unit can be fouled by colloidal matter and constituents in the feed stream. The following pretreatment options have been used singly and/or in combination.

1. Pretreatment of a secondary effluent by chemical clarification and multimedia filtration or by multimedia filtration and ultrafiltration is usually necessary (see Fig. 11–40) to remove colloidal material.
2. Cartridge filters with a pore size of 5- to 10-μm have also been used to reduce residual suspended solids.
3. To limit bacterial activity it may be necessary to disinfect the feedwater using either chlorine, ozone, or UV radiation.
4. The exclusion of oxygen may be necessary to prevent oxidation of iron, manganese, and hydrogen sulfide.
5. Depending on the type of membrane, removal of chlorine (with sodium bisulfite) and ozone may be necessary.
6. The removal of iron and manganese may also be necessary to decrease scaling potential.
7. To inhibit scale formation, the pH of the feed should be adjusted (usually with sulfuric acid) within the range from 4.0 to 7.5.

Regular chemical cleaning of the membrane elements (about once a month) is necessary to restore the membrane flux.

Assessing Need for Pretreatment for NF and RO. To assess the treatability of a given wastewater with NF and RO membranes, a variety of fouling indexes have been developed over the years. The three principal indexes are the silt density index (SDI), the modified fouling index (MFI), and the mini plugging factor index (MPFI). Fouling indexes are determined from simple membrane tests. The sample must be passed through a 0.45 μm Millipore filter with a 47 mm internal diameter at 210 kPa (30 lb/in^2) gage to determine any of the indexes. The time to complete data collection for these tests varies from 15 min to 2 h, depending on the fouling nature of the water.

The most widely used index is the SDI. The SDI is defined as follows:

$$\text{SDI} = \frac{100\left[1 - (t_i/t_f)\right]}{t} \tag{11–45}$$

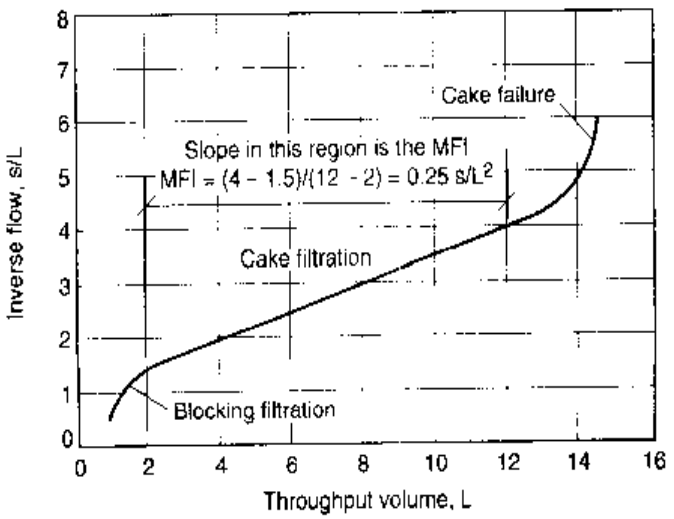
where t_i = time to collect initial sample of 500 mL
t_f = time to collect final sample of 500 mL
t = total time for running the test

The silt density index is a static measurement of resistance that is determined by samples taken at the beginning and end of the test. The SDI does not measure the rate of change of resistance during the test. Recommended SDI values are reported in Table 11–19. The calculation of the SDI is demonstrated in Example 11–6.

The modified fouling index (MFI) is determined using the same equipment and procedure used for the SDI, but the volume is recorded every 30 s over a 15-min filtration period. Derived from a consideration of cake filtration, the MFI is defined as follows:

$$\frac{1}{Q} = a + \text{MFI} \times V \qquad (11\text{–}46)$$

where Q = average flow, L/s
a = constant
MFI = modified fouling index, s/L^2
V = volume, L



The value of the MFI is obtained as the slope of the straight-line portion of the curve obtained by plotting the inverse flow versus the cumulative volume (see Fig. 11–42). Recommended MFI values are reported in Table 11–19.

Table 11–19
Approximate values for fouling indexes[a]

Membrane process	Fouling index	
	SDI	MFI, s/L^2
Nanofiltration	0–2	0–10
Reverse osmosis hollow fiber	0–2	0–2
Reverse osmosis spiral wound	0–3	0–2

[a] Adapted in part from Taylor and Wiesner (1999) and AWWA (1996).

Figure 11–42
Typical plot to determine the modified fouling factor.

EXAMPLE 11–6 Silt Density Index for Reverse Osmosis Determine the silt density index for a proposed feedwater from the following test data. If a spiral-wound RO membrane is to be used, will pretreatment be required?

Test run time = 30 min

Initial 500 mL = 2 min

Final 500 mL = 10 min

Solution

1. Calculate the SDI using Eq. (11–45).

$$SDI = \frac{100[1 - (t_i/t_f)]}{t}$$

$$SDI = \frac{100[1 - (2/10)]}{30} = 2.67$$

2. Compare the SDI to the acceptable criteria.

Comment Calculated SDI value of 2.67 is less than 3 (see Table 11–19); therefore, no further pretreatment would be needed normally. As a practical matter, because the SDI value is close to 3.0 it may be prudent to consider some form of pretreatment to prolong the filtration cycle.

Application of Membranes

With evolving health concerns (see Chap. 2) and the development of new and lower-cost membranes, the application of membrane technologies in the field of environmental engineering has increased dramatically within the past 5 years. The increased use of membranes is expected to continue well into the future. In fact, the use of conventional filtration technology, such as described in Secs. 11–3 and 11–4, may be a thing of the past within 10 to 15 years, especially in light of the need to remove resistant organic constituents of concern (see Chap. 13). Typical applications of membrane technologies for wastewater treatment are reported in Table 11–20. The principal applications of the various membrane technologies for the removal of specific constituents found in wastewater are summarized in Table 11–21. A comparison of the constituents found in wastewater and the operating ranges for the various membrane technologies was presented previously on Fig. 11–34. Typical operating ranges in terms of operating pressures and flux rates, along with the types of membranes used, are reported in Table 11–22.

Typical energy consumption and product recovery values for various membrane systems are presented in Table 11–23. In reviewing the information presented in Table 11–23, it is important to note that the reported operating pressure values for all of the membrane processes, excluding electrodialysis, are considerably lower than comparable values of 5 years ago. It is anticipated that operating pressures will continue to go down as new membranes are developed. At the present time where the use of membranes is being considered, special attention must be devoted to the characteristics of the wastewater to be

Table 11-20
Typical applications for membrane technologies in wastewater treatment[a]

Applications	Description
	Microfiltration and ultrafiltration
Aerobic biological treatment	Membrane is used to separate the treated wastewater from the active biomass in an activated-sludge process. The membrane separation unit can be internal immersed in the bioreactor or external to the bioreactor (see Fig. 11-45). Such processes are known as membrane bioreactor (MBR) processes
Anaerobic biological treatment	Membrane is used to separate the treated wastewater from the active biomass in an anaerobic complete-mix reactor
Membrane aeration biological treatment	Plate and frame, tubular, and hollow membranes are used to transfer pure oxygen to the biomass attached to the outside of the membrane (see Fig. 11-47*a*). Such processes are known as membrane aeration bioreactor (MABR) processes
Membrane extraction biological treatment	Membranes are used to extract degradable organic molecules from inorganic constituents such as acids, bases, and salts from the waste stream for subsequent biological treatment (see Fig. 11-47*b*). Such processes are known as extractive membrane bioreactor (EMBR) processes
Pretreatment for effective disinfection	Used to remove residual suspended solids from settled secondary effluent or from the effluent from depth or surface filters to achieve effective disinfection with either chlorine or UV radiation for reuse applications
Pretreatment for nanofiltration and reverse osmosis	Microfilters are used to remove residual colloidal and suspended solids as a pretreatment step for additional processing
	Nanofiltration
Effluent reuse	Used to treat prefiltered effluent (typically with microfiltration) for indirect potable reuse applications such as groundwater injection. Credit is also given for disinfection when using nanofiltration
Wastewater softening	Used to reduce the concentration of multivalent ion contributing to hardness for specific reuse applications
	Reverse osmosis
Effluent reuse	Used to treat prefiltered effluent (typically with microfiltration) for indirect potable reuse applications such as groundwater injection. Credit is also given for disinfection when using reverse osmosis
Effluent dispersal	Reverse osmosis processes have proved capable of removing sizable amounts of selected compounds such as NDMA
Two-stage treatment for boiler use	Two stages of reverse osmosis are used to produce water suitable for high-pressure boilers

processed. Advantages and disadvantages of MF and UF and RO membrane technology are compared in Table 11–24.

Microfiltration. Microfiltration membranes are the most numerous on the market, are the least expensive, and as reported in Table 11–22, are commonly made of polypropylene, acrylonitrile, nylon, and polytetrafluoroethylene. Typical operating information for microfiltration and ultrafiltration membrane technologies used for wastewater including operating pressures and flux rates is also presented in Table 11–22. Microfiltration technologies, as discussed below, can be used in a variety of ways in wastewater-treatment and water reuse systems.

In advanced treatment applications, microfiltration has been used, most commonly as a replacement for depth filtration to reduce turbidity, remove residual suspended solids, and reduce bacteria to condition the water for effective disinfection (see Fig. 11–43*a*) and as a pretreatment step for reverse osmosis (see Figs. 11–40 and 11–43*a*). The MF units at Dublin San Ramon Sanitary District, used to produce treated water for specific reuse applications or as a pretreatment step for RO, are shown on Fig. 11–44. Corresponding performance data are presented in Table 11–25. Typical

Electrodialysis			2.5	9.5	75–85

Table 11-24
Advantages and disadvantages of membrane treatment technologies

Advantages	Disadvantages
Microfiltration and ultrafiltration	
• Can reduce the amount of treatment chemicals	• Uses more electricity; high-pressure systems can be energy-intensive
• Smaller space requirements (footprint); membrane equipment requires 50 to 80 percent less space than conventional plants	• May need pretreatment to prevent fouling; pretreatment facilities increase space needs and overall costs
• Reduced labor requirements; can be automated easily	• May require residuals handling and disposal of concentrate
• New membrane design allows use of lower pressures; system cost may be competitive with conventional wastewater-treatment processes	• Requires replacement of membranes about every 3 to 5 years
• Removes protozoan cysts, oocysts, and helminth ova; may also remove limited amounts of bacteria and viruses	• Scale formation can be a serious problem. Scale-forming potential difficult to predict without field testing
	• Flux rate (the rate of feedwater flow through the membrane) gradually declines over time. Recovery rates may be considerably less than 100 percent
	• Lack of a reliable low-cost method of monitoring performance
Reverse osmosis	
• Can remove dissolved constituents	• Works best on groundwater or low solids surface water or pretreated wastewater effluent
• Can disinfect treated water	• Lack of a reliable low-cost method of monitoring performance
• Can remove NDMA and other related organic compounds	• May require residuals handling and disposal of concentrate
• Can remove natural organic matter (a disinfection by-product precursor) and inorganic matter	• Expensive compared to conventional treatment

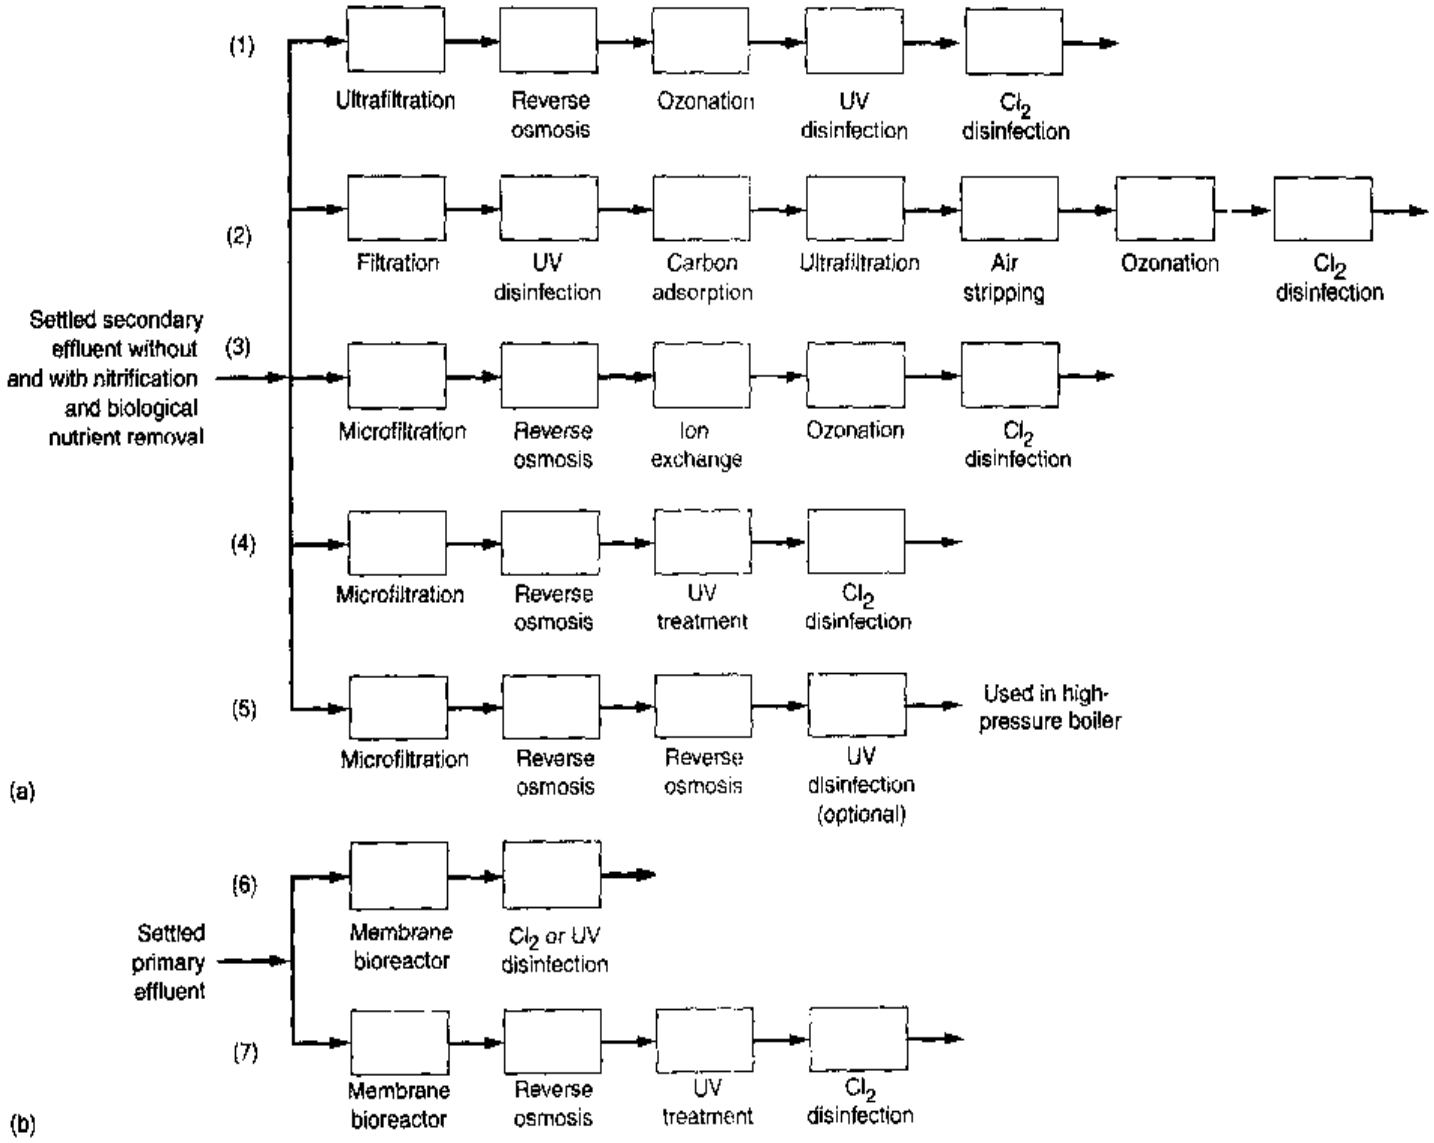

Figure 11–43

Typical flow diagrams employing membranes for advanced wastewater treatment with (a) settled secondary effluent and (b) settled primary effluent. Within the past 5 years, the use of membranes has essentially replaced the use of chemical precipitation in advanced wastewater-treatment applications. In flow diagram 5, two stages of reverse osmosis are used to produce an extremely low TDS water suitable for use in high-pressure boilers. In flow diagram 7, UV can be used for both disinfection and the destruction of NDMA. Chlorine is added in flow diagrams 1 through 4 and 7 to limit the growth of microorganisms in the distribution or conveyance system.

performance data reported in the literature are also included in Table 11–25 for the purpose of comparison. Care should be used in applying the performance data reported in Table 11–25 as it has been found that the performance of MF is to a large extent site-specific, especially with respect to fouling.

A relatively recent development, the use of membranes for biological treatment, promises to be one of the most important uses of membranes in wastewater treatment. As reported in Table 11–20, membranes have been used for both aerobic and anaerobic treatment of wastewaters. Typical membrane bioreactors (MBRs) are illustrated on Fig. 11–45. On Fig. 11–45*a*, the membrane separation unit is internal, immersed in the bioreactor. Treated effluent is withdrawn from the bioreactor with the application of a

vacuum (on the order of 50 kPa). On Fig. 11–45*b*, the membrane separation unit is external to the bioreactor. A photograph of a typical membrane separation unit installed in a test reactor is shown on Fig. 11–46. The aeration system installed below the membrane separation unit is used to clean the hollow fibers continuously by the shearing action of the air bubbles as they rise through the liquid (Stephenson et al., 2000).

Typical performance data for the MBR activated-sludge process are presented in Table 11–26. As reported in Table 11–26, the quality of the effluent is ideal for a number of reuse application or for further processing by nanofiltration or reverse osmosis. In addition to offering excellent performance, MBRs require a considerably smaller aerial footprint. It is also interesting to note that MBRs have also been used for the anaerobic treatment of wastewater. The current literature abounds with articles delineating the use of membranes in a variety of wastewater-treatment applications. The biological characteristics of membrane bioreactors are discussed in greater detail in Chap. 8.

In addition to the MBR process, plate and frame, tubular, and hollow membranes have been used to transfer pure oxygen to the biomass attached to the outside of the membrane (see Fig. 11–47*a*). Such processes are known as membrane aeration bioreactor (MABR) processes. In another application, membranes are used to extract degradable soluble organic molecules from inorganic constituents in a waste stream (see Fig. 11–47*b*). The extracted organic constituents are treated in an external bioreactor. Such processes are known as extractive membrane bioreactor (EMBR) processes.

Additional details on aeration and extractive membrane bioreactors applications may be found in Stephenson et al. (2000).

Ultrafiltration. Ultrafiltration (UF) membranes are used for many of the same applications as described above for microfiltration. Some UF membranes with small pore sizes have also been used to remove dissolved compounds with high molecular weight, such as colloids, proteins, and carbohydrates. The membranes do not remove sugar or salt. Ultrafiltration is used typically in industrial applications for the production of high-purity process rinse water. Typical operating data are presented in Table 11–22.

Nanofiltration. Nanofiltration, also known as "loose" RO, can reject particles as small as 0.001 μm. Nanofiltration is used for the removal of selected dissolved constituents from wastewater such as the multivalent metallic ions responsible for hardness. The advantages of nanofiltration over lime softening include the production of a product water that meets the most stringent reuse water quality requirements. Because both inorganic and organic constituents and bacteria and viruses are removed, disinfection requirements are minimized. Although most NF facilities use polyamide TFC membranes in a spiral-wound configuration, more than ten different types of membranes are available. Other membranes include polyamide hollow fiber, polyvinyl acetate spiral wound, and asymmetric cellulose acetate in a tubular configuration.

Reverse Osmosis. Worldwide, reverse osmosis (RO) is used primarily for desalination. In wastewater treatment, RO is used for the removal of dissolved constituents from wastewater remaining after advanced treatment with depth filtration or microfiltration. The membranes exclude ions, but require high pressures to produce the deionized water. Typical flow diagrams involving the use of reverse osmosis are shown on Figs. 11–40 and 11–43. Typical operating information for reverse osmosis used for wastewater including

operating pressures and flux rate rates is reported in Table 11–22. Typical RO units used for the repurification of pretreated water (with MF) are shown on Fig. 11–48. Corresponding performance data are presented in Table 11–27. Typical performance data reported in the literature are also included in Table 11–27. As noted above, care should be used in applying the performance data reported in Table 11–27 as it has been found that the performance of RO is also site-specific, especially with respect to fouling. Disinfection of the RO feedwater is usually practiced to minimize or limit the bacterial growth on the membrane. Care must be taken with polyamide and TFC membranes because they are sensitive to chemical oxidants. The need for cleaning depends on how long the flux rate is maintained.

[b] Typical flux rate during test period was 348 L/m^2·d.

Electrodialysis

In the electrodialysis process, ionic components of a solution are separated through the use of semipermeable ion-selective membranes. Because the electrodialysis process is being evaluated for a variety of reuse applications, the purpose of the following discussion is (1) to introduce the theory of electrodialysis and (2) to consider some applications.

Theory of Electrodialysis. Application of an electrical potential between the two electrodes causes an electric current to pass through the solution, which in turn causes a migration of cations toward the negative electrode and a migration of anions toward the positive electrode (see Fig. 11–49). Because of the alternate spacing of cation- and anion-permeable membranes, cells of concentrated and dilute salts are formed. Wastewater is pumped through the membranes, which are separated by spacers and assembled into stacks. The wastewater is usually retained for about 10 to 20 days in a single stack or stage. Dissolved solids removals vary with the (1) wastewater temperature, (2) amounts of electrical current passed, (3) type and amount of ions, (4) permselectivity of the membrane, (5) fouling and scaling potential of the wastewater, (6) wastewater flowrates, and (7) number and configuration of stages.

The current required for electrodialysis can be estimated using Faraday's laws of electrolysis. Because one Faraday of electricity will cause one gram equivalent of a substance to migrate from one electrode to another, the number of gram equivalents removed per unit time is given by

$$\text{Gram eq/unit time} = QN\eta \tag{11–47}$$

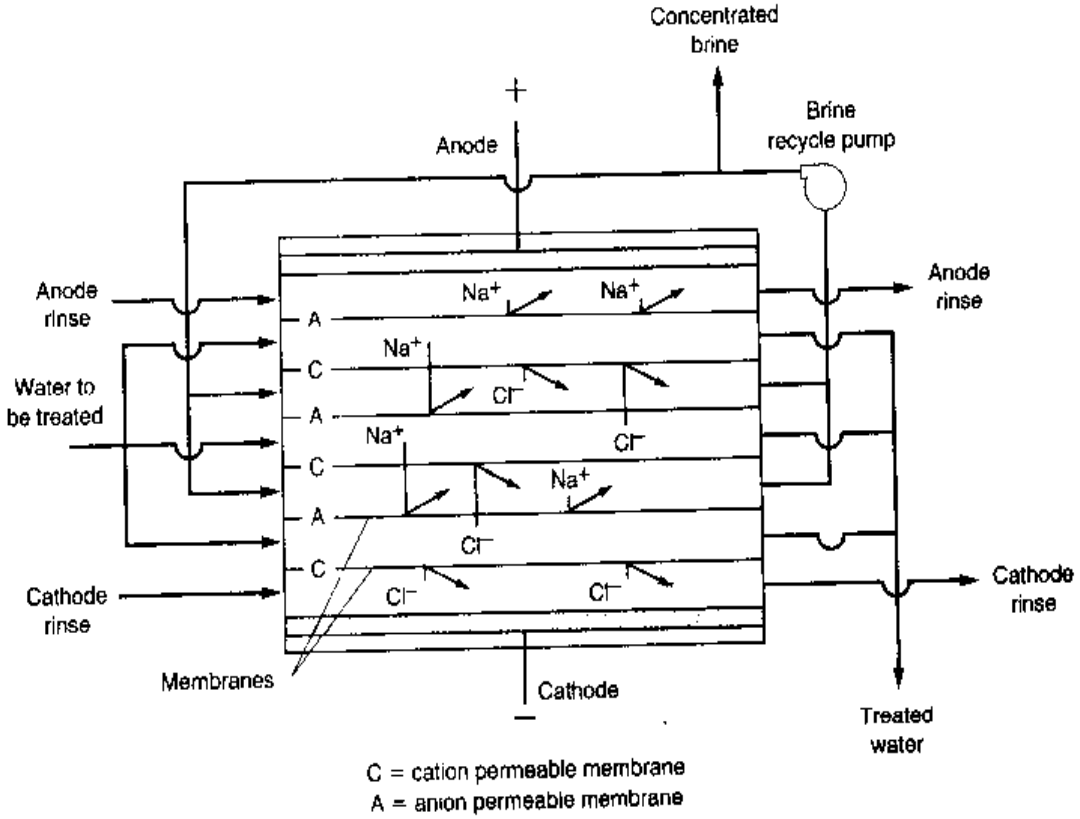

Figure 11–49
Schematic of electrodialysis unit.

where Q = flowrate, L/s
N = normality of solution, eq/L
η = electrolyte removal as a fraction

The corresponding expression for the current for a stack of membranes is given by

$$I = \frac{FQN\eta}{nE_c} \tag{11-48}$$

where I = current, amp
F = Faraday's constant
= 96,485 amp·s/gram equivalent = 96,485 A·s/eq
n = number of cells in the stack
E_c = current efficiency expressed as a fraction

In the analysis of the electrodialysis process, it has been found that the capacity of the membrane to pass an electrical current is related to the current density (*CD*) and the normality (*N*) of the feed solution. Current density is defined as the current in milliamperes that flows through a square centimeter of membrane perpendicular to the current direction. The relationship between current density and the solution normality is known as the *current density to normality* (*CD/N*) ratio. High values of the ratio are indicative that there is insufficient charge to carry the current. When high ratios exist, a localized deficiency of ions may occur on the surface of the membrane, causing a condition called *polarization*. Polarization should be avoided, as it results in high electrical resistance leading to excessive power consumption. In practice, *CD/N* ratios will vary from 500 to 800 when the current density is expressed as mA/cm^2. The resistance of an electrodialysis unit used to treat a particular water must be determined experimentally. Once the resistance R and the current flow I are known, the power required can be computed using Ohm's law as follows:

$$P = E \times I = R(I)^2 \tag{11-49}$$

where P = power, W
E = voltage, V
$= R \times I$
R = resistance, Ω
I = current, A

The application of these relationships is considered in Example 11–7.

EXAMPLE 11–7 Area and Power Requirements for Electrodialysis Determine the area and power required to demineralize 4000 m^3/d of treated wastewater to be used for industrial cooling water using an electrodialysis unit comprised of 240 cells. Assume the following data apply:

1. TDS concentration = 2500 mg/L
2. Cation and anion concentration = 0.010 g-eq/L

3. Efficiency of salt removal = 50 percent
4. The current efficiency = 90 percent
5. The *CD/N* ratio = 500 mA/cm^2
6. Resistance = 5.0 Ω

Solution

1. Calculate the current using Eq. (11–48).

$$I = \frac{FQN\eta}{nE_c}$$

$$Q = (4000 \text{ m}^3/\text{d})(10^3 \text{ L/m}^3)/(86{,}400 \text{ s/d}) = 46.3 \text{ L/s}$$

$$I = \frac{(96{,}485 \text{ A·s/g eq})(46.3 \text{ L/s})(0.010 \text{ g eq/L})(0.50)}{240 \times 0.90}$$

$$I = 103.4 \text{ A}$$

2. Determine the power required using Eq. (11–49).

$$P = R(I)^2$$

$$P = (5.0\ \Omega)(103.4 \text{ A})^2 = 53{,}477 \text{ W} = 53.5 \text{ kW}$$

3. Determine the required surface area.
   a. Determine the current density:

$$CD = (500)(\text{normality}) = 500 \text{ mA/cm}^2 \times 0.010 = 50 \text{ mA/cm}^2$$

   b. The required area is

$$\text{Area} = \frac{(103.4 \text{ A})(10^3 \text{ mA/A})}{(50 \text{ mA/cm}^2)} = 2068 \text{ cm}^2$$

   c. Determine area of membrane assuming a square configuration will be used.

$$\text{Area per membrane} = \sqrt{2068 \text{ cm}^2} \approx 45 \text{ cm}^2$$

Comment The actual performance will have to be determined from pilot tests.

Application. The electrodialysis process may be operated in either a continuous or a batch mode. The units can be arranged either in parallel to provide the necessary hydraulic capacity or in series to effect the desired degree of demineralization. A typical flow diagram for electrodialysis membrane process with pretreatment is shown on Fig. 11–50. Makeup water, usually about 10 percent of the feed volume, is required to wash the membranes continuously. A portion of the concentrate stream is recycled to maintain nearly

Figure 11–50
Typical flow diagram for electrodialysis membrane process with pretreatment.

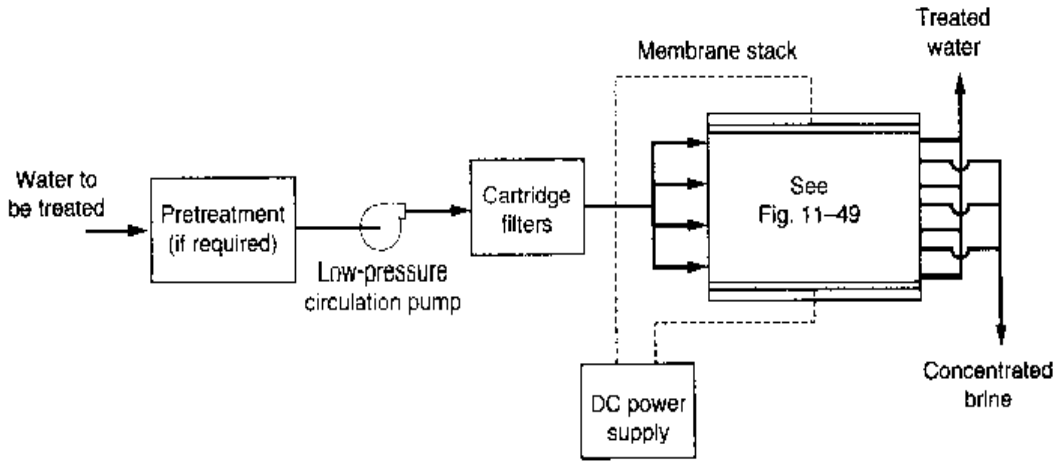

Table 11–28
Typical operating parameters for electrodialysis units

Parameter	Unit	Range
Detention time in stack	d	10–20
CD/N ratio	mA/cm^2	500–800
Membrane resistance, Ω	ohms	4–8
Salt-removal efficiency	%	40–60
Current efficiency	%	85–95
Concentrate stream flow	% of feed	10–20

equal flowrates and pressures on both sides of each membrane. Sulfuric acid is fed to the concentrate stream to maintain a low pH and thus minimize scaling. Typical operating parameters for the electrodialysis process are reported in Table 11–28.

Problems associated with the electrodialysis process for wastewater renovation include chemical precipitation of salts with low solubility on the membrane surface and clogging of the membrane by the residual colloidal organic matter in wastewater-treatment plant effluents. To reduce membrane fouling, activated carbon pretreatment, possibly preceded by chemical precipitation and some form of multimedia filtration, may be necessary.

Pilot Studies for Membrane Applications

Because every wastewater is unique with respect to its chemistry, it is difficult to predict a priori how a given membrane process will perform. As a result, the selection of the best membrane for a given application is usually based on the results of pilot studies. Membrane fouling indexes can be used to assess the need for pretreatment. In some

situations, manufacturers of membranes will provide a testing service to identify the most appropriate membrane for a specific water or wastewater.

The elements that comprise a pilot plant include (1) the pretreatment system, (2) tankage for flow equalization and cleaning, (3) pumps for pressurizing the membrane, recirculation, and backflushing with appropriate controls (e.g., variable-frequency drives), (4) the membrane test module, (5) adequate facilities for monitoring the performance of the test module, and (6) an appropriate system for backflushing the membranes. The information collected should be sufficient to allow for the design of the full-scale system and should include as a minimum the following items:

Membrane operating parameters
- Pretreatment requirements including chemical dosages
- Transmembrane flux rate correlated to operating time
- Transmembrane pressure
- Washwater requirements
- Recirculation ratio
- Cleaning frequency including protocol and chemical requirements
- Posttreatment requirements

Typical water quality measurements may include:
- Turbidity
- Particle counts
- Total organic carbon
- Nutrients
- Heavy metals
- Organic priority pollutants
- Total dissolved solids
- pH
- Temperature
- Heterotrophic plate count (see Chap. 2)
- Other bacterial indicators
- The specific constituents that can limit recovery such as silica, barium, calcium, and sulfate
- Biotoxicity

Additional specific parameters selected for evaluation will depend on the final use to be made of the repurified water. Typical pilot scale test facilities used to evaluate various membrane treatment options in connection with the production of repurified water for indirect potable reuse are shown on Fig. 11–51.

Disposal of Concentrated Waste Streams

Disposal of the concentrated waste streams produced by membrane processes represents the major problem that must be dealt with in their applications. The principal methods now used for the disposal of the concentrated waste streams are reported in Table 11–29. While small facilities can dispose of small concentrated waste streams by blending with other wastewater flows, this approach is not suitable for large facilities. The concentrate from NF and RO facilities will contain hardness, heavy metals, high-molecular-weight organics, microorganisms, and often hydrogen sulfide gas. The pH is usually high due to the concentration of alkalinity, which increases the likelihood of metal precipitation in disposal wells. As a result, most of the large-scale desalination facilities are located along coastal regions, both in the United States and in other parts of the world. For inland

locations, long transmission lines to coastal regions are being considered. While controlled evaporation is technically feasible, because of high operating and maintenance costs this approach is used where no other alternatives are available, and the value of product water is high. The quality and quantity of the concentrated waste stream produced from nanofiltration, reverse osmosis, and electrodialysis can be estimated using simplified recovery and rejection computations as illustrated in Example 11–8.

Figure 11–51
Typical pilot-plant facilities used to test membranes: (*a*) nanofiltration and (*b*) reverse osmosis.

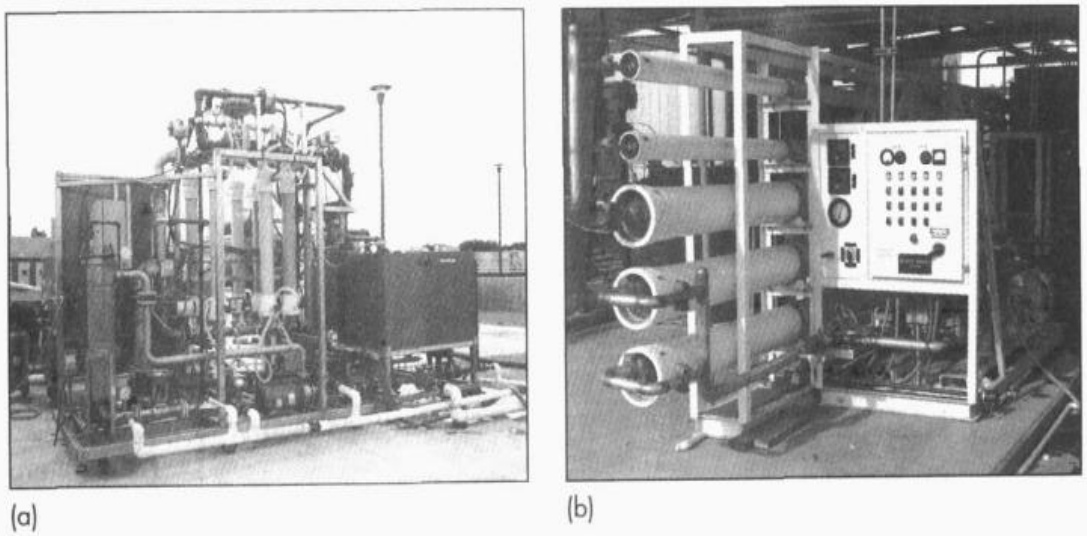

Table 11–29
Disposal options for concentrated brine solutions from membrane processes

Disposal option	Description
Ocean discharge	The disposal option of choice for facilities located in the coastal regions of the United States. Typically, a brine line, with a deep ocean discharge, is used by a number of dischargers. Combined discharge with power-plant cooling water has been used in Florida. For inland locations truck, rail hauling, or pipeline is needed for transportation
Surface water discharge	Discharge of brines to surface waters is the most common method of disposal for concentrated brine solutions
Land application	Land application has been used for some low-concentration brine solutions
Discharge to wastewater-collection system	This option is suitable only for very small discharges such that the increase in TDS is not significant (e.g., less than 20 mg/L)
Deep-well injection	Depends on whether subsurface aquifer is brackish water or is otherwise unsuitable for domestic uses
Evaporation ponds	Large surface area required in most areas with the exception of some southern and western states
Controlled thermal evaporation	Although energy-intensive, thermal evaporation may be the only option available in many areas

EXAMPLE 11–8 Estimate Quantity and Quality of Waste Streams from a Reverse Osmosis Facility Estimate quantity and quality of the waste stream, and the total quantity of water that must be processed, from a reverse osmosis facility that is to produce 4000 m^3/d of water to be used for industrial cooling operations. Assume that both the recovery and rejection rates are equal to 90 percent and that the concentration of the feed stream is 400 g/m^3.

Solution

1. Determine the flowrate of the concentrated waste stream and the total amount of water that must be processed.
   a. Combining Eqs. (11–41) and (11–39) results in the following expression for the concentrate stream flowrate:

$$Q_c = \frac{Q_p(1 - r)}{r}$$

   b. Determine the concentrate stream flowrate.

$$Q_c = \frac{(4000\ m^3/d)(1 - 0.9)}{0.9} = 444\ m^3/d$$

   c. Determine the total amount of water that must be processed to produce 4000 m^3/d of RO water. Using Eq. (11–41), the required amount of water is

$$Q_f = Q_p + Q_c = 4000\ m^3/d + 444\ m^3/d = 4444\ m^3/d$$

2. Determine the concentration of the permeate stream. The permeate concentration is obtained by writing Eq. (11–40) as follows:

$$C_p = C_f(1 - R) = 400\ g/m^3\ (1 - 0.9) = 40\ g/m^3$$

3. Determine the concentration of the concentrated waste stream. The required value is obtained by solving Eq. (11–42):

$$C_c = \frac{Q_f C_f - Q_p C_p}{Q_c}$$

$$C_c = \frac{(4444\ m^3/d)(400\ g/m^3) - (4000\ m^3/d)(40\ g/m^3)}{(444\ m^3/d)}$$

$$C_c = 3643\ g/m^3$$

Comment To reduce the volume of the waste stream that must be treated, a variety of concentration methods are currently under investigation.

11-7 ADSORPTION

Adsorption is the process of accumulating substances that are in solution on a suitable interface. Adsorption, as noted in Chap. 4, is a mass transfer operation in that a constituent in the liquid phase is transferred to the solid phase. The *adsorbate* is the substance that is being removed from the liquid phase at the interface. The *adsorbent* is the solid, liquid, or gas phase onto which the adsorbate accumulates. Although adsorption is used at the air-liquid interface in the flotation process, only the case of adsorption at the liquid-solid interface will be considered in this discussion. The adsorption process has not been used extensively in wastewater treatment, but demands for a better quality of treated wastewater effluent, including toxicity reduction, have led to an intensive examination and use of the process of adsorption on activated carbon. Activated carbon treatment of wastewater is usually thought of as a polishing process for water that has already received normal biological treatment. The carbon in this case is used to remove a portion of the remaining dissolved organic matter. The purpose of this section is to introduce the basic concepts of adsorption and to consider carbon adsorption.

Types of Adsorbents

The principal types of adsorbents include activated carbon, synthetic polymeric, and silica-based adsorbents, although synthetic polymeric and silica-based adsorbents are seldom used for wastewater adsorption because of their high cost. Because activated carbon is used most commonly in advanced wastewater-treatment applications, the focus of the following discussion is on activated carbon. The nature of activated carbon, the use of granular carbon and powdered carbon for wastewater treatment, and carbon regeneration and reactivation are discussed below.

Activated Carbon. Activated carbon is prepared by first making a char from organic materials such as almond, coconut, and walnut hulls; other materials including woods, bone, and coal have also been used. The char is produced by heating the base material to a red heat (less than about 700°C) in a retort to drive off the hydrocarbons, but with an insufficient supply of oxygen to sustain combustion. The carbonization or char-producing process is essentially a pyrolysis process. The char particle is then *activated* by exposure to oxidizing gases such as steam and CO_2 at high temperatures, in the range from 800 to 900°C. These gases develop a porous structure, as illustrated previously on Fig. 4–32 in Chap. 4, in the char and thus creates a large internal surface area. The resulting pore sizes are defined as follows:

Macropores	>25 nm
Mesopores	>1 nm and <25 nm
Micropores	<1 nm

The surface properties that result are a function of both the initial material used and the preparation procedure, so that many variations are possible. The type of base material from which the activated carbon is derived may also affect the pore-size distribution and the regeneration characteristics. After activation, the carbon can be separated into, or prepared in, different sizes with different adsorption capacity. The two size classifications are *powdered activated carbon* (PAC), which typically has a diameter of less than 0.074 mm (200 sieve), and *granular activated carbon* (GAC), which has a diame-

Table 11-30 Comparison of granular and powdered activated carbon

Parameter	Unit	Type of activated carbon[a] GAC	PAC
Total surface area	m^2/g	700–1300	800–1800
Bulk density	kg/m^3	400–500	360–740
Particle density, wetted in water	kg/L	1.0–1.5	1.3–1.4
Particle size range	mm (μm)	0.1–2.36	(5–50)
Effective size	mm	0.6–0.9	na
Uniformity coefficient	UC	≤1.9	na
Mean pore radius		16–30	20–40

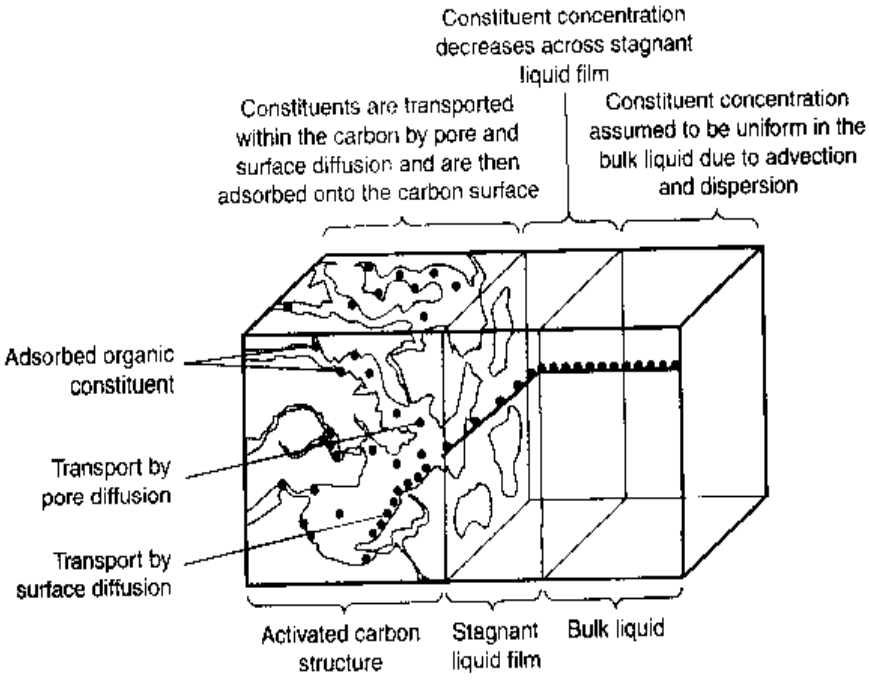
Ash	%	≤8	≤6
Moisture as packed	%	2–8	3–10

[a]Specific values will depend on the source material used for the production of the activated carbon.

ter greater than 0.1 mm (~140 sieve). The characteristics of granular and powdered activated carbon are summarized in Table 11–30.

Carbon Regeneration and Reactivation. Economical application of activated carbon depends on an efficient means of regenerating and reactivating the carbon after its adsorptive capacity has been reached. *Regeneration* is the term used to describe all of the processes that are used to recover the adsorptive capacity of the spent carbon, exclusive of reactivation, including: (1) chemicals to oxidize the adsorbed material, (2) steam to drive off the adsorbed material, (3) solvents, and (4) biological conversion processes. Typically some of the adsorptive capacity of the carbon (about 4 to 10 percent) is also lost in the regeneration process, depending on the compounds being adsorbed and the regeneration method used (Crittenden, 2000). In some applications, the capacity of the carbon following regeneration has remained essentially the same for years. A major problem with the use of powdered activated carbon is that the methodology for its regeneration is not well defined. The use of powdered activated carbon produced from recycled solid wastes may obviate the need to regenerate the spent carbon, and may be more economical. Additional details on carbon reactivation and regeneration may be found in Sontheimer et al. (1988).

Reactivation of granular carbon involves essentially the same process used to create the activated carbon from virgin material. Spent carbon is reactivated in a furnace by oxidizing the adsorbed organic material and, thus, removing it from the carbon surface. The following series of events occurs in the reactivation of spent activated carbon: (1) the carbon is heated to drive off the absorbed organic material (i.e., absorbate), (2) in the process of driving off the absorbed material some new compounds are formed that remain on the surface of the carbon, and (3) the final step in the reactivation process is to burn off the new compounds that were formed when the absorbed material was burned off. With effective process control, the adsorptive capacity of reactivated carbon



will be essentially the same as that of the virgin carbon (Crittenden, 2000). For planning purposes, it is often assumed that a loss of 2 to 5 percent will occur in the reactivation process. It is important to note that most other losses of carbon occur through attrition due to mishandling. For example, right angle bends in piping cause attrition through abrasion and impact. The type of pumping facilities used will also affect the amount of attrition. In general, a 4 to 8 percent loss of carbon is assumed, due to handling. Replacement carbon must be available to make up the loss.

Fundamentals of Adsorption

The adsorption process, as illustrated on Fig. 11–52, takes place in four more or less definable steps: (1) bulk solution transport, (2) film diffusion transport, (3) pore transport, and (4) adsorption (or sorption). *Bulk solution transport* involves the movement of the organic material to be adsorbed through the bulk liquid to the boundary layer of fixed film of liquid surrounding the adsorbent, typically by advection and dispersion in carbon contactors. *Film diffusion transport* involves the transport by diffusion of the organic material through the stagnant liquid film to the entrance of the pores of the adsorbent. *Pore transport* involves the transport of the material to be adsorbed through the pores by a combination of molecular diffusion through the pore liquid and/or by diffusion along the surface of the adsorbent. *Adsorption* involves the attachment of the material to be adsorbed to adsorbent at an available adsorption site (Snoeyink and Summers, 1999). Adsorption can occur on the outer surface of the adsorbent and in the macropores, mesopores, micropores, and submicropores, but the surface area of the macro- and mesopores is small compared with the surface area of the micropores and submicropores and the amount of material adsorbed there is usually considered negligible. Adsorption forces include (Crittenden, 1999):

- Coulombic-unlike charges
- Point charge and a dipole
- Dipole-dipole interactions

Figure 11–52
Definition sketch for the adsorption of an organic constituent with activated carbon.

- Point charge neutral species
- London or van der Waals forces
- Covalent bonding with reaction
- Hydrogen bonding

Additional details on the above adsorption forces may be found in Crittenden (1992). Because it is difficult to differentiate between chemical and physical adsorption, the term *sorption* is often used to describe the attachment of the organic material to the activated carbon.

Because the adsorption process occurs in a series of steps, the slowest step in the series is identified as the *rate limiting step*. In general, if physical adsorption is the principal method of adsorption, one of the diffusion transport steps will be the rate limiting, because the rate of physical adsorption is rapid. Where chemical adsorption is the principal method of adsorption, the adsorption step has often been observed to be rate limiting. When the rate of sorption equals the rate of desorption, equilibrium has been achieved and the capacity of the carbon has been reached. The theoretical adsorption capacity of the carbon for a particular contaminant can be determined by developing its adsorption isotherm as described below.

Development of Adsorption Isotherms. The quantity of adsorbate that can be taken up by an adsorbent is a function of both the characteristics and concentration of adsorbate and the temperature. The characteristics of the adsorbate that are of importance include: solubility, molecular structure, molecular weight, polarity, and hydrocarbon saturation (see Table 11–31). Generally, the amount of material adsorbed is determined as a function of the concentration at a constant temperature, and the resulting function is called an adsorption isotherm. Adsorption isotherms are developed by exposing a given amount of absorbate in a fixed volume of liquid to varying amounts of activated carbon. Typically, more than ten containers are used, and the minimum time allowed for the samples to equilibrate where powdered activated carbon is used is seven days. If granular activated carbon is used, it is usually powdered to minimize adsorption times. The test is illustrated previously on Fig. 4–34 in Chap. 4. At the end of the test period, the amount of absorbate remaining in solution is measured. The absorbent phase concentration after equilibrium is computed using Eq. (11–50). The absorbent phase concentration data computed using Eq. (11–50) are then used to develop adsorption isotherms as described below.

$$q_e = \frac{(C_o - C_e)V}{m} \tag{11–50}$$

where q_e = adsorbent (i.e., solid) phase concentration after equilibrium, mg adsorbate/g adsorbent
C_o = initial concentration of adsorbate, mg/L
C_e = final equilibrium concentration of adsorbate after absorption has occurred, mg/L
V = volume of liquid in the reactor, L
m = mass of adsorbent, g

Freundlich Isotherm. Equations that are often used to describe the experimental isotherm data were developed by Freundlich, Langmuir, and Brunauer, Emmet, and

Teller (BET isotherm) (Shaw, 1966). Of the three, the Freundlich isotherm is used most commonly to describe the adsorption characteristics of the activated carbon used in water and wastewater treatment. Derived empirically in 1912, the Freundlich isotherm is defined as follows:

$$\frac{x}{m} - K_f C_e^{1/n} \tag{11–51}$$

where x/m = mass of adsorbate adsorbed per unit mass of adsorbent, mg adsorbate/g activated carbon
K_f = Freundlich capacity factor, (mg absorbate/g activated carbon)(L water/mg adsorbate)$^{1/n}$
C_e = equilibrium concentration of adsorbate in solution after adsorption, mg/L
$1/n$ = Freundlich intensity parameter

The constants in the Freundlich isotherm can be determined by plotting log (x/m) versus log C_e and making use of Eq. (11–51) rewritten as:

$$\log\left(\frac{x}{m}\right) = \log K_f + \frac{1}{n} \log C_e \tag{11–52}$$

The U.S. EPA has developed adsorption isotherms for a variety of toxic compounds, some of which are presented in Table 11–32 for reference (Dobbs and Cohen, 1980). As shown in Table 11–32, the variation in the Freundlich capacity factor for the various compounds is extremely wide (e.g., 14,000 for PCB to 6.8×10^{-5} for N-Dimethylnitrosamine). Because of the wide variation, the Freundlich capacity factor must be determined for each new compound. Application of the Freundlich adsorption isotherm is illustrated in Example 11–9.

Table 11–32
Freundlich adsorption isotherm constants for selected organic compounds[a,b]

Compound	pH	K_f (mg/g)(L/mg)$^{1/n}$	1/n
Benzene	5.3	1.0	1.6–2.9
Bromoform	5.3	19.6	0.52
Carbon tetrachloride	5.3	11	0.83
Chlorobenzene	7.4	91	0.99
Chloroethane	5.3	0.59	0.95

[a] Adapted from Dobbs and Cohen (1980) and LaGrega et al. (2001).

[b] The adsorption isotherm constants reported in this table are meant to be illustrative of the wide range of values that will be encountered for various organic compounds. It is important to note that the characteristics of the activated carbon used as well as the analytical technique used for the analysis of the residual concentrations of the individual compounds will have a significant effect on the coefficient values obtained for specific organic compounds.

Langmuir Isotherm. Derived from rational considerations, the Langmuir adsorption isotherm is defined as:

$$\frac{x}{m} = \frac{abC_e}{1 + bC_e} \tag{11-53}$$

where x/m = mass of adsorbate adsorbed per unit mass of adsorbent, mg adsorbate/g activated carbon
a, b = empirical constants
C_e = equilibrium concentration of adsorbate in solution after adsorption, mg/L

The Langmuir adsorption isotherm was developed by assuming: (1) a fixed number of accessible sites are available on the adsorbent surface, all of which have the same energy, and (2) adsorption is reversible. Equilibrium is reached when the rate of adsorption of molecules onto the surface is the same as the rate of desorption of molecules from the surface. The rate at which adsorption proceeds is proportional to the driving force, which is the difference between the amount adsorbed at a particular concentration and the amount that can be adsorbed at that concentration. At the equilibrium concentration, this difference is zero.

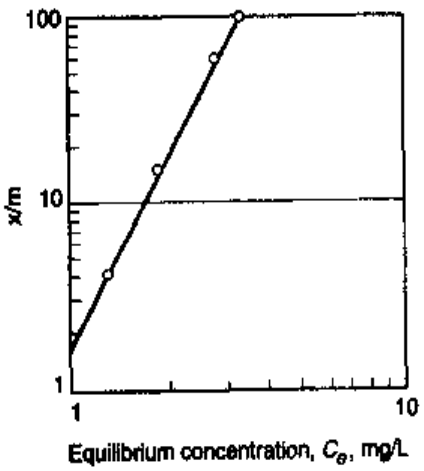
Correspondence of experimental data to the Langmuir equation does not mean that the stated assumptions are valid for the particular system being studied, because departures from the assumptions can have a canceling effect. The constants in the Langmuir isotherm can be determined by plotting $C_e/(x/m)$ versus C_e and making use of Eq. (11–53) rewritten as:

$$\frac{C_e}{(x/m)} = \frac{1}{ab} + \frac{1}{a}C_e \tag{11-54}$$

Application of the Langmuir adsorption isotherm is illustrated in Example 11–9.

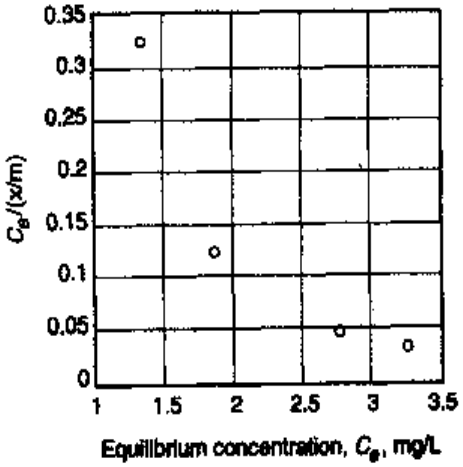
EXAMPLE 11–9 Analysis of Activated-Carbon Adsorption Data Determine the Freundlich and Langmuir isotherm coefficients for the following GAC adsorption test data. The liquid volume used in the batch adsorption tests was 1 L. The initial concentration of the adsorbate in solution was 3.37 mg/L. Equilibrium was obtained after 7 days.

Mass of GAC, m, g	Equilibrium concentration of adsorbate in solution, C_e, mg/L
0.0	3.37
0.001	3.27
0.010	2.77
0.100	1.86
0.500	1.33



Solution

1. Derive the values needed to plot the Freundlich and Langmuir adsorption isotherms using the batch adsorption test data.



Adsorbate concentration, mg/L					
C_o	C_e	$C_o - C_e$	m, g	x/m,[a] mg/g	$C_e/(x/m)$
3.37	3.37	0.00	0.000	—	—
3.37	3.27	0.10	0.001	100	0.0327
3.37	2.77	0.60	0.010	60	0.0462
3.37	1.86	1.51	0.100	15.1	0.1232
3.37	1.33	2.04	0.500	4.08	0.3260

[a] $q_e = \frac{x}{m} = \frac{(C_o - C_e)V}{m}$

2. Plot the Freundlich and Langmuir adsorption isotherms using the data developed in Step 1 (see following figures).

(a)

(b)

3. Determine the adsorption isotherm coefficients.
   a. Freundlich
   When x/m versus C_e is plotted on log-log paper, the intercept when $C_e = 1.0$ is the value of (x/m) and the slope of the line is equal to $1/n$. Thus, $x/m = 1.55$, and $K_f = 1.55$. When $x/m = 1.0$, $C_e = 0.9$, and $1/n = 0.26$. Thus,

$$\frac{x}{m} = 1.5\,C_e^{0.26}$$

   b. Langmuir
   Because the plot for the Langmuir isotherm is curvilinear, use of the Langmuir adsorption isotherm is inappropriate.

Adsorption of Mixtures. In the application of adsorption to wastewater treatment, mixtures of organic compounds are always encountered. Typically, there is a depression of the adsorptive capacity of any individual compound in a solution of many compounds, but the total adsorptive capacity of the adsorbent may be larger than the adsorptive capacity with a single compound. The amount of inhibition due to competing compounds is related to the size of the molecules being adsorbed, their adsorptive affinities, and their relative concentrations. It is important to note that adsorption isotherms can be determined for a heterogeneous mixture of compounds including total organic carbon (TOC), dissolved organic carbon (DOC), chemical oxygen demand (COD), dissolved organic halogen (DOH), UV absorbance, and fluorescence (Snoeyink and Summers, 1999). The adsorption from mixtures is considered further in Crittenden et al. (1987b, 1987c, 1985) and Sontheimer (1988).

Activated Carbon Adsorption Kinetics

As noted previously, both granular carbon (in downflow and upflow columns) and powdered activated carbon are used for wastewater treatment. The analysis procedures for both types are described briefly in the following discussion.

Mass Transfer Zone. The area of the GAC bed in which sorption is occurring is called the mass transfer zone (MTZ) (see Fig. 11–53). After the water containing the constituent to be removed passes through a region of the bed whose depth is equal to the MTZ, the concentration of the contaminant in the water will have been reduced to its minimum value. No further adsorption will occur within the bed below the MTZ. As the top layers of carbon granules become saturated with organic material, the MTZ will move down in the bed until breakthrough occurs. Typically, breakthrough is said to have occurred when the effluent concentration reaches 5 percent of the influent value. Exhaustion of the adsorption bed is assumed to have occurred when the effluent concentration is equal to 95 percent of the influent concentration. The length of the MTZ is typically a function of the hydraulic loading rate applied to the column and the characteristics of the activated carbon. In the extreme, if the loading rate is too great the

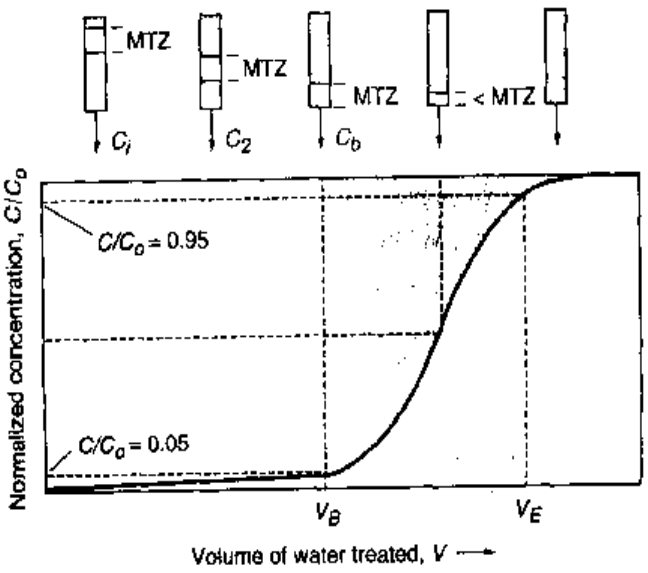


Figure 11–53
Typical breakthrough curve for activated carbon showing movement of mass transfer zone (MTZ) with throughput volume.

height of the MTZ will be larger than the GAC bed depth, and the adsorbable constituent will not be removed completely by the carbon. At complete exhaustion, the effluent concentration is equal to the influent concentration.

In addition to the applied hydraulic loading rate, the shape of the breakthrough curve will also depend on whether the applied liquid contains nonadsorbable and biodegradable constituents. The impact of the presence of nonadsorbable and biodegradable organic constituents on the shape of the breakthrough curve is illustrated on Fig. 11–54. As shown on Fig. 11–54, if the liquid contains nonadsorbable constituents, the nonadsorbable constituents will appear in the effluent as soon as the carbon column is put into operation. If adsorbable and biodegradable constituents are present in the applied liquid, the breakthrough curve will not reach a C/C_o value of 1.0, but will be depressed, and the observed C/C_o value will depend on the biodegradability of the influent constituents, because biological activity continues even though the adsorption capacity has been utilized. If the liquid contains nonadsorbable and biodegradable constituents, the observed breakthrough curve will not start at zero and will not terminate at a value of 1.0 (Snoeyink and Summers, 1999). The above effects are observed quite commonly in wastewater adsorption applications, especially with respect to the removal of COD.

The height of the MTZ (see Fig. 11–53) varies with the flowrate because dispersion, diffusion, and channeling in a granular medium are directly related to the flowrate. For a symmetrical breakthrough curve it has been shown that the height of the mass transfer zone, H_{MTZ}, is related to the column height Z and the throughput volumes V_B and V_E, as follows (Michaels, 1952; Weber, 1972).

$$H_{MTZ} = Z\left[\frac{V_E - V_B}{V_E - 0.5(V_E - V_B)}\right] \tag{11-55}$$

where H_{MTZ} = length of mass transfer zone, m
Z = height of the adsorption column, m
V_E = throughput volume to exhaustion, L, m^3
V_B = throughput volume to breakthrough L, m^3

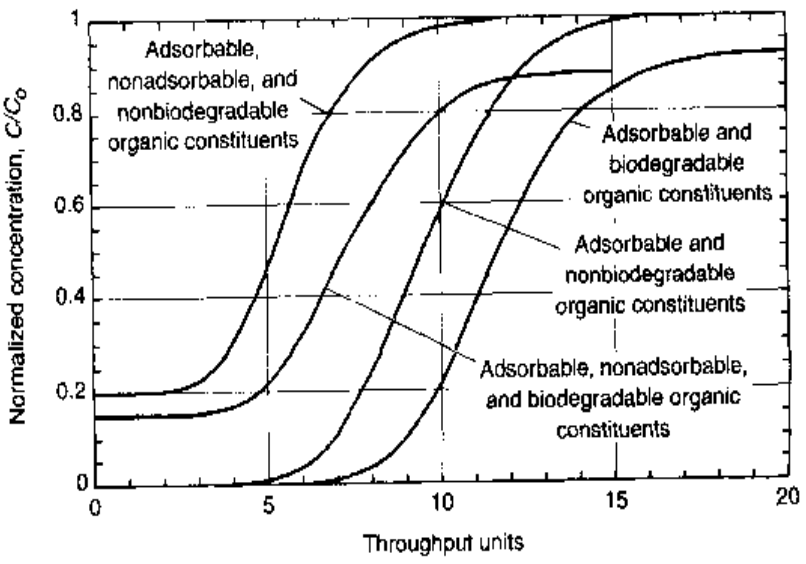

Figure 11-54
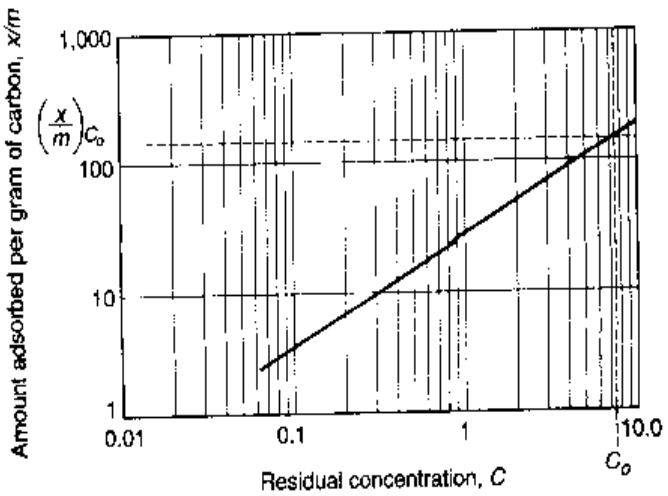
Impact of the presence of adsorbable, nonadsorbable, and biodegradable organic constituents on the shape of the activated carbon breakthrough curve. *(Adapted from Snoeyink and Summers, 1999.)*

The area above the breakthrough curve represents the mass of adsorbate adsorbed within the column and is equal to:

$$\int (C_o - C)dV$$

integrated from $V = 0$ to $V = V_b$ the throughput volume at breakthrough. At complete exhaustion, $C = C_o$.



In practice, the only way to use the capacity at the bottom of the carbon adsorption column is to have two or more columns in series and switch them as they are exhausted, or to use multiple columns in parallel so that breakthrough in one column does not affect effluent quality. The optimum flowrate and bed depth, as well as the operating capacity of the carbon, must be established to determine the dimensions and the number of columns necessary for continuous treatment. These parameters can be determined from dynamic column tests, as discussed below.

Carbon Adsorption Capacity. The adsorptive capacity of a given carbon is estimated from isotherm data as follows. If isotherm data are plotted, the resulting isotherm will be as shown on Fig. 11–55. Referring to Fig. 11–55, the adsorptive capacity of the carbon can be estimated by extending a vertical line from the point on the horizontal axis corresponding to the initial concentration C_o, and extrapolating the isotherm to intersect this line. The $q_e = (x/m)_{C_o}$ value at the point of intersection can be read from the vertical axis. The $(q_e)_{C_o}$ value represents the amount of constituent adsorbed per unit weight of carbon when the carbon is at equilibrium with the initial concentration of constituent C_o. The equilibrium condition generally exists in the upper section of a carbon bed during column treatment, and it therefore represents the ultimate capacity of the carbon for a particular waste.

Breakthrough Adsorption Capacity. In the field, the breakthrough adsorption capacity $(x/m)_b$ of the GAC in a full-scale column is some percentage of the theoretical adsorption capacity found from the isotherm. The $(x/m)_b$ of a single column can be assumed to be approximately 25 to 50 percent of the theoretical capacity, $(x/m)_o$. The value of $(x/m)_b$ can be determined using the small-scale column test described later in

Figure 11–55

Typical activated carbon adsorption isotherm.

this section. Once $(x/m)_b$ is known, the time to breakthrough can be approximated by solving the following equation for t_b.

$$\left(\frac{x}{m}\right)_b = \frac{x_b}{m_{GAC}} = Q\left(C_o - \frac{C_b}{2}\right)\frac{t_b}{m_{GAC}} \tag{11-56}$$

Where $(x/m)_b$ = field breakthrough adsorption capacity, g/g
x_b = mass of organic material adsorbed in the GAC column at breakthrough, g
m_{GAC} = mass of carbon in the column, g
Q = flowrate, m^3/d
C_o = influent organic concentration, g/m^3
C_b = breakthrough organic concentration, g/m^3
t_b = time to breakthrough, d

Equation (11–56) was developed assuming that C_o is constant and that the effluent concentration increases linearly with time from 0 to C_b (see Fig. 11–53). The term $(C_o - C_b/2)$ represents the average concentration of the organic matter adsorbed up to the breakthrough point. Rearranging Eq. (11–56), the time to breakthrough can be calculated using the following relationship:

$$t_b = \frac{(x/m)_b m_{GAC}}{Q(C_o - C_b/2)} \tag{11-57}$$

Over the years, a number of equations have been developed to describe the breakthrough curve, including those by Bohart and Adams (1920) and Crittenden et al. (1987*a*).

However, as noted previously, because of the breakthrough phenomenon (see Fig. 11–55), the usual practice is either to use *two or more columns in series and rotate them as they become exhausted, or to use multiple columns in parallel so that breakthrough in a single column will not significantly affect the effluent quality.* With proper sampling from points within the column, constituent (e.g., TOC) breakthrough can be anticipated.

Activated Carbon Treatment Process Applications

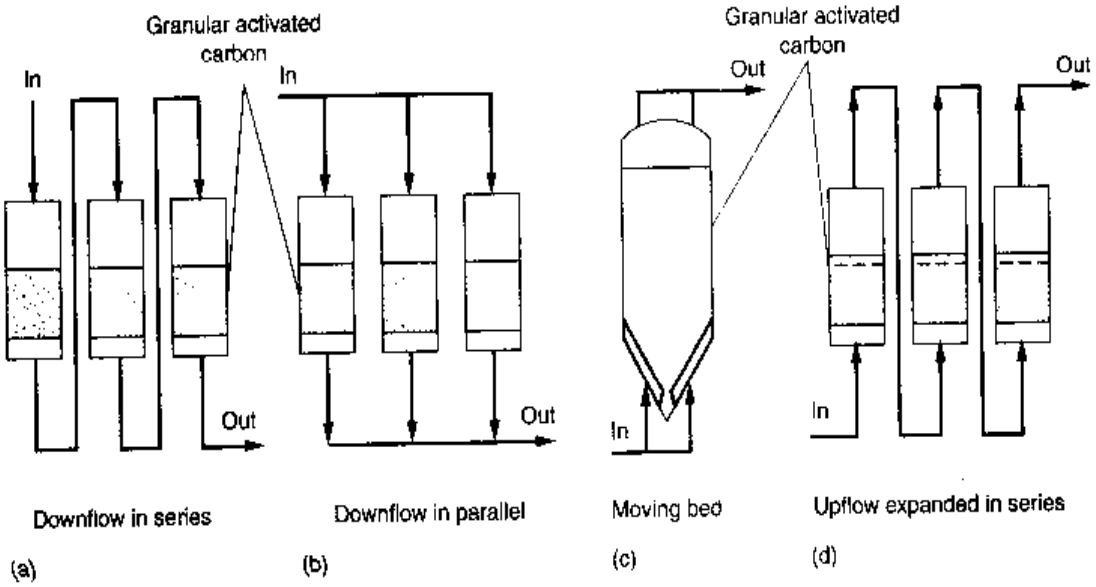
Carbon adsorption is used principally for the removal of refractory organic compounds, as well as residual amounts of inorganic compounds such as nitrogen, sulfides, and heavy metals. The removal of taste and odor compounds from wastewater is another important application, especially in reuse applications. Both powdered and granular activated carbon are used and appear to have a low adsorption affinity for low molecular weight polar organic species. If biological activity is low in the carbon contactor or in other biological unit processes, these species are difficult to remove with activated carbon. Typical compounds that can be removed by carbon adsorption are reported in Table 11–31. Under normal conditions, after treatment with carbon, the effluent BOD ranges from 2 to 7 mg/L, and the effluent COD ranges from 10 to 20 mg/L. Under optimum conditions, it appears that the effluent COD can be reduced to less than 10 mg/L.

Treatment with Granular Activated Carbon (GAC). Treatment with GAC involves passing a liquid to be treated through a bed of activated carbon held in a reactor (sometimes called a contactor). Several types of activated carbon contactors are used

for advanced wastewater treatment. Typical systems may be either pressure or gravity type, and may be downflow or upflow fixed-bed units having two or three columns in series, or expanded bed upflow-countercurrent type. Typical schematic diagrams of carbon contactors are shown on Fig. 11–56.

Fixed-Bed A fixed-bed column is used most commonly for contacting wastewater with GAC. Fixed-bed columns can be operated singly, in series, or in parallel. A typical granular activated carbon contactor is shown on Fig. 11–57*a*. Granular-medium filters are commonly used upstream of the activated carbon contactors to remove the organics associated with the suspended solids present in secondary effluent. The water to be treated is applied to the top of the column and withdrawn at the bottom. The carbon is held in place with an underdrain system at the bottom of the column. Provision for backwashing and surface washing is often provided in wastewater applications to limit the headloss buildup due to the removal of particulate suspended solids within the carbon column. Unfortunately, backwashing has the effect of destroying the adsorption front as discussed later.

The advantage of a downflow design is that adsorption of organics and filtration of suspended solids are accomplished in a single step. Although upflow fixed-bed reactors have been used, downflow beds are used more commonly to lessen the chance of accumulating particulate material in the bottom of the bed, where the particulate material would be difficult to remove by backwashing. If soluble organic removal is not maintained at a high level, more frequent regeneration of the carbon may be required. Lack of consistency in pH, temperature, and flowrate may also affect performance of carbon contactors. A typical column installation used for the treatment of wastewater is shown on Fig. 11–57*b*.



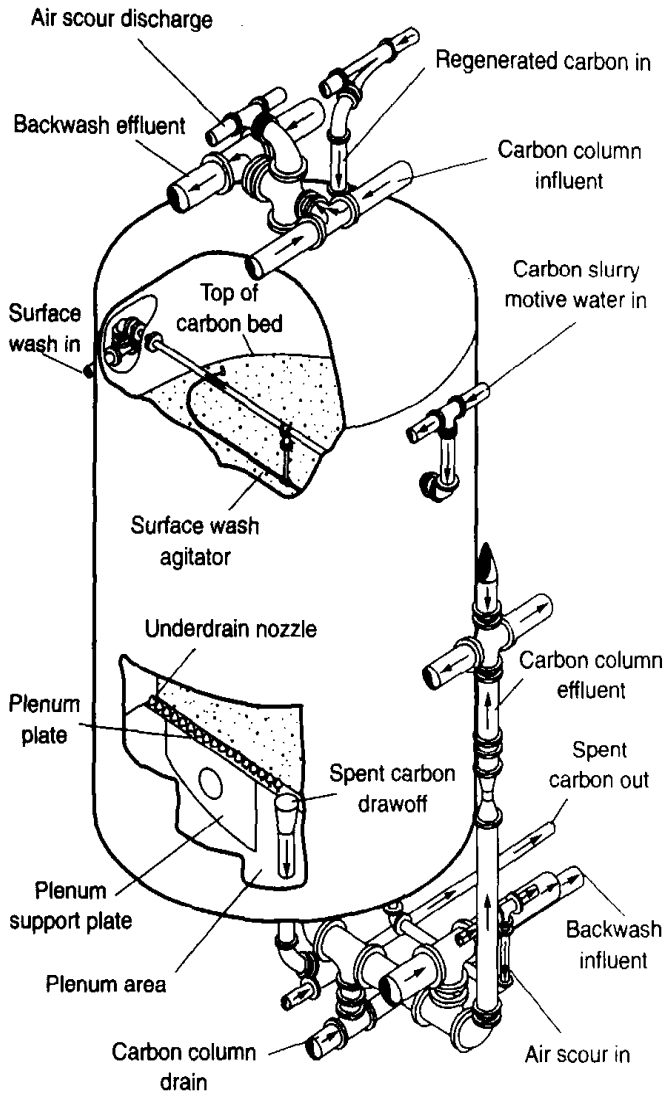


Figure 11–56

Types of activated carbon contactors: (*a*) downflow in series, (*b*) downflow in parallel, (*c*) moving bed, and (*d*) upflow expanded in series. *(Adapted from Calgon Carbon Corp.)*

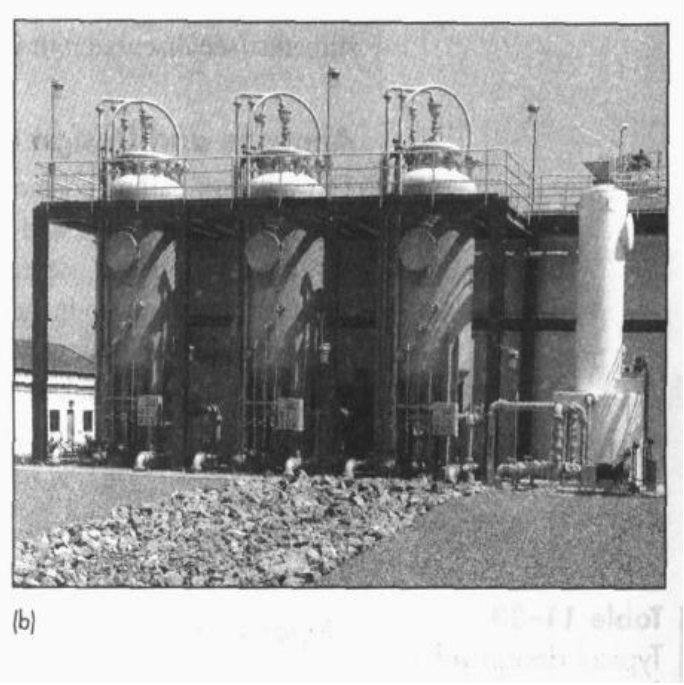

Figure 11-57

Activated carbon adsorbers: (a) Typical activated-carbon contactor in a pressure vessel and (b) view of granular activated carbon contactors operated in parallel, used for the treatment of filtered secondary effluent.

Expanded-Bed Expanded-bed, moving-bed, and pulsed-bed carbon contactors have also been developed to overcome the problems associated with headloss buildup. In the expanded-bed system, the influent is introduced at the bottom of the column and the activated carbon is allowed to expand, much as a filter bed expands during backwash. When the adsorptive capacity of the carbon at the bottom of the column is exhausted, the bottom portion of carbon is removed, and an equivalent amount of regenerated or virgin carbon is added to the top of the column. In such a system, headloss does not build up with time after the operating point has been reached. In general, expanded-bed upflow contactors may have more carbon fines in the effluent than downflow contactors because bed expansion leads to the creation of fines as the carbon particles collide and abrade, and allows the fines to escape through passageways created by the expanded bed. At present, few, if any, expanded bed contactors are used for the treatment of wastewater.

Treatment with Powdered Activated Carbon (PAC). An alternative means of achieving adsoption is through the application of powdered activated carbon (PAC). Powdered activated carbon can be applied to the effluent from biological treatment processes, directly to the various biological treatment processes, and in physical-chemical treatment process flow diagrams. In the case of biological treatment plant effluent, PAC is added to the effluent in a contacting basin. After a certain amount of time for contact, the carbon is allowed to settle to the bottom of the tank, and the treated water is then removed from the tank. Because carbon is very fine, a coagulant, such as a polyelectrolyte, may be needed to aid the removal of the carbon particles, or filtration through rapid sand filters may be required. The addition of PAC directly to the aeration basin of an activated-sludge treatment process has proved to be effective in the removal of a number of soluble refractory organics. In physical-chemical treatment processes, PAC is used in conjunction with chemicals used for the precipitation of specific constituents (see discussion in Chap. 6).

Analysis and Design of Granular Activated Carbon Contactor

The sizing of carbon contactors is based on four factors: contact time, hydraulic loading rate, carbon depth, and number of contactors. Typical design information for the first three factors is presented in Table 11–33. Typical specifications for granular activated carbon are given in Table 11–34. A minimum of two parallel carbon contactors is recommended for design. Multiple units permit one or more units to remain in operation while one unit is taken out of service for removal and regeneration of spent carbon, or for maintenance.

Table 11–33
Typical design values for GAC contactors[a]

Parameter	Symbol	Unit	Value
Volumetric flowrate	V	m^3/h	50–400
Bed volume	V_b	m^3	10–50
Cross-sectional area	A_b	m^2	5–30
Length	D	m	1.8–4
Void fraction	α	m^3/m^3	0.38–0.42
GAC density	ρ	kg/m^3	350–550
Approach velocity	V_f	m/h	5–15
Effective contact time	t	min	2–10
Empty bed contact time	EBCT	min	5–30
Operation time	t	d	100–600
Throughput volume	V_L	m^3	10–100
Specific throughput	V_{sp}	m^3/kg	50–200
Bed volumes	BV	m^3/m^3	2,000–20,000

[a] Adapted from Sontheimer et al. (1998).

For the case where the mass transfer rate is fast and the mass transfer zone is a sharp wave front, a steady-state mass balance around a carbon contactor (see Fig. 11–58) reactor yields:

Accumulation = inflow − outflow − amount absorbed

$$0 = QC_o t - QC_e t - m_{GAC} q_e \tag{11-58}$$

where Q = volumetric flowrate, L/h
C_o = initial concentration of adsorbate, mg/L
t = time, h
C_e = final equilibrium concentration of adsorbate, mg/L
m_{GAC} = mass of adsorbent, g
q_e = adsorbent phase concentration after equilibrium, mg adsorbate/g adsorbent

Table 11–34
Typical specifications for GAC

Parameter	Unit	Value
Total surface area	m^2/g	700–1300[a]
Bulk density	kg/m^3	400–440[a]
Particle density, wetted in water	kg/L	1.3–1.5[a]
Effective size	mm	0.8–0.9[a]
Uniformity coefficient	UC	≤1.9
Mean particle diameter	mm	1.5–1.7
Iodine number		850 min
Abrasion number		70 min
Ash	%	8 max
Moisture	%	4–6 max

[a] Depends on the source material for the carbon.

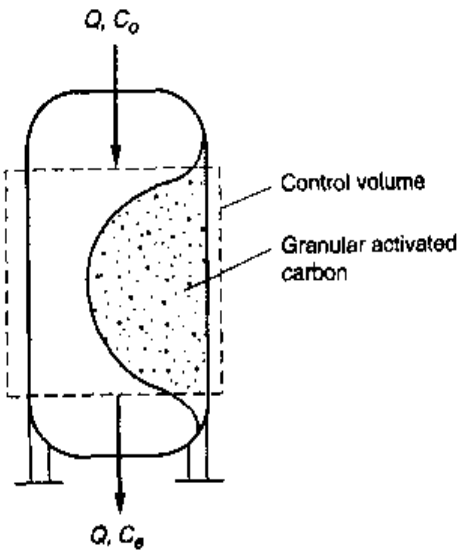

Figure 11–58
Definition sketch for the analysis of activated-carbon adsorption.

From Eq. (11–58), the adsorbent usage rate is defined as

$$\frac{m_{GAC}}{Qt} = \frac{C_o - C_e}{q_e} \tag{11–59}$$

If it is assumed that the mass of the adsorbate in the pore space is small compared to the amount adsorbed, then the term $QC_e t$ in Eq. (11–58) can be neglected without serious error and the absorbent usage rate is given by:

$$\frac{m_{GAC}}{Qt} \approx \frac{C_o}{q_e} \tag{11–60}$$

To quantify the operational performance of GAC contactors, the following terms have been developed and are used commonly.

1. Empty-bed contact time (EBCT):

$$\text{EBCT} = \frac{V_b}{Q} = \frac{A_b D}{v_f A_b} = \frac{D}{v_f} \tag{11–61}$$

where EBCT = empty bed contact time, h
V_b = volume of GAC in contactor, m^3
Q = volumetric flowrate, m^3/h
A_b = cross-sectional area of GAC filter bed, m^2
D = length of GAC in contactor, m
v_f = linear approach velocity, m/h

2. Activated carbon density:
The density of the activated carbon is defined as

$$\rho_{GAC} = \frac{m_{GAC}}{V_b} \tag{11–62}$$

where ρ_{GAC} = density of granular activated carbon, g/L
m_{GAC} = mass of granular activated carbon, g
V_b = volume of GAC filter bed, L

3. Specific throughput, expressed as m^3 of water treated per gram of carbon:

$$\text{Specific throughput, } m^3/g = \frac{Qt}{m_{GAC}} = \frac{V_b t}{\text{EBCT} \times m_{GAC}} \tag{11–63}$$

Using Eq. (11–62), Eq. (11–63) can be written as

$$\text{Specific throughput} = \frac{V_b t}{\text{EBCT}(\rho_{GAC} \times V_b)} = \frac{t}{\text{EBCT}\rho_{GAC}} \tag{11–64}$$

4. Carbon usage rate (CUR) expressed as gram of carbon per m^3 of water treated:

$$\text{CUR, } g/m^3 = \frac{m_{GAC}}{Qt} = \frac{1}{\text{Specific throughput}} \tag{11–65}$$

5. Volume of water treated for a given EBCT, expressed in liters, L:

$$\text{Volume of water treated, L} = \frac{\text{Mass of GAC for given EBCT}}{\text{GAC usage rate}} \tag{11-66}$$

6. Bed life, expressed in days, d:

$$\text{Bed life, d} = \frac{\text{Volume of water treated for given EBCT}}{Q} \tag{11-67}$$

The application of these terms is illustrated in Example 11–10.

EXAMPLE 11–10 Estimation of Activated Carbon Adsorption Breakthrough Time A fixed-bed activated carbon adsorber has a fast mass transfer rate, and the mass transfer zone is essentially a sharp wavefront. Assuming the following data apply, determine the carbon requirements to treat a flow of 1000 L/min, and the bed life.

1. Compound = trichloroethylene (TCE)
2. Initial concentration, C_o = 1.0 mg/L
3. Final concentration C_e = 0.005 mg/L
4. GAC density = 450 g/L
5. Freundlich capacity factor K_f = 28 (mg/g)(L/mg)$^{1/n}$ (see Table 11–32)
6. Freundlich intensity parameter, $1/n$ = 0.62 (see Table 11–32)
7. EBCT = 10 min

Solution

1. Estimate the GAC usage rate for toluene. The GAC usage rate is estimated using Eq. (11–59).

$$\frac{m_{GAC}}{Qt} = \frac{C_o - C_e}{q_e} = \frac{C_o - C_e}{K_f C_o^{1/n}}$$

$$= \frac{(1.0 \text{ mg/L})}{28 \text{ (mg/g)} (\text{L/mg})^{0.62} (1.0 \text{ mg/L})^{0.62}}$$

$$= 0.036 \text{ g GAC/L}$$

2. Determine the mass of carbon required for a 10 min EBCT.

The mass of GAC in the bed = $V_b \rho_{GAC}$ = EBCT × Q × ρ_{GAC}

Carbon required = 10 min (1000 L/min) (450 g/L) = 4.5×10^6 g

3. Determine the volume of water treated using a 10 min EBCT.

$$\text{Volume of water treated} = \frac{\text{mass of GAC for given EBCT}}{\text{GAC usage rate}}$$

$$\text{Volume of water treated} = \frac{4.5 \times 10^6 \text{ g}}{(0.036 \text{ g GAC/L})} = 1.26 \times 10^8 \text{ L}$$

4. Determine the bed life.

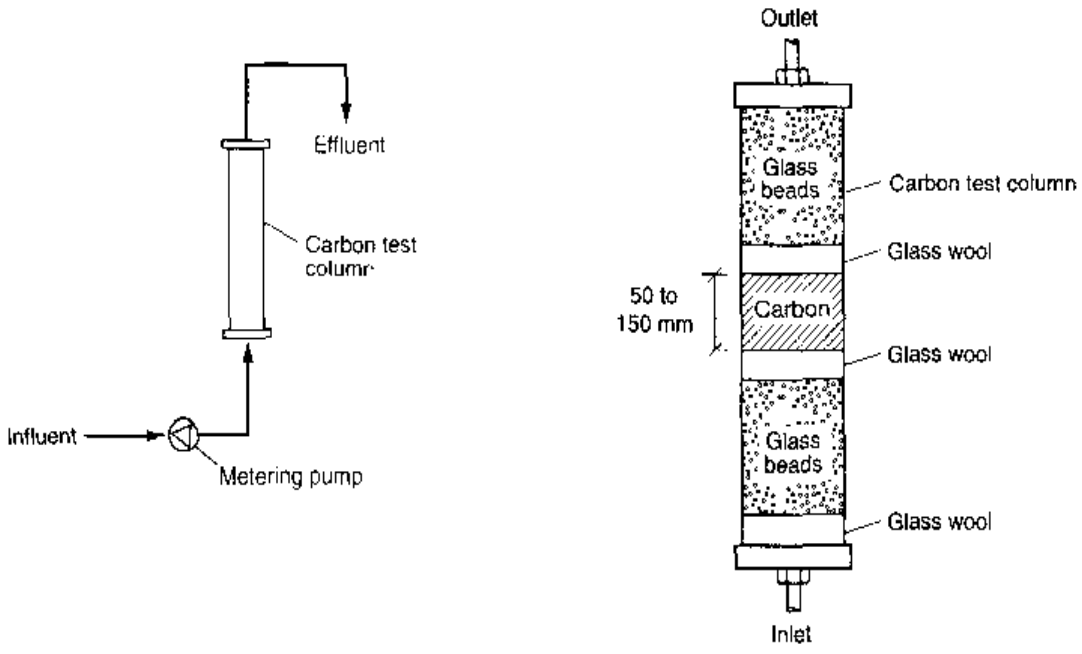
$$\text{Bed life} = \frac{\text{volume of water treated for given EBCT}}{Q}$$

$$\text{Bed life} = \frac{1.26 \times 10^8 \text{ L}}{(1000 \text{ L/min})(1440 \text{ min/d})} = 87.5 \text{ d}$$

Comment In this example, the full capacity of the carbon in the contactor was utilized based on the assumption that two columns in series will be used. If a single column is to be used, a breakthough curve must be used to arrive at the bed life. Biological activity within the column was not considered.

Small-Scale Column Tests

Over the years, a number of small-scale column tests have been developed to simulate the results obtained with full-scale reactors. One of the early column tests was the *high-pressure minicolumn* (HPMC) technique developed by Rosene et al. (1983), and later modified by Bilello and Beaudet (1983). In the HPMC test procedure, a high-pressure liquid chromatography column loaded with activated carbon is used. Typically the HPMC test procedure is used to determine the capacity of activated carbon for the adsorption of volatile organic compounds. The principal advantage of the HPMC test procedure is that it allows for the rapid determination of the GAC adsorptive capacity under conditions similar to those encountered in the field.



An alternative procedure known as the *rapid small-scale column test* (RSSCT) has been developed by Crittenden et al. (1991). The test procedure allows for the scaling of data obtained from small columns (see Fig. 11-59) to predict the performance of pilot or full-scale carbon columns. In developing the procedure, mathematical models were used to define the relationships between the breakthrough curve for small and large columns. In adsorption columns, the mass transfer mechanisms that are responsible for the spreading of the mass transfer zone are (1) dispersion, (2) film diffusion, and (3) interparticle diffusion. Two different design relationships were developed, one for constant diffusivity and one for proportional diffusivity. In the constant diffusivity model, it is assumed that dispersion is negligible because the hydraulic loading rate is high in the RSSCT, and that mass transfer occurs as a result of film diffusion. Further, it is assumed that the interparticle diffusivity is the same for both the small and large columns. In the proportional diffusivity model, it is assumed that dispersion is negligible because the hydraulic loading rate is high in the RSSCT, and that mass transfer occurs as a result of interparticle diffusion. The relationships for the two cases can be generalized as follows:

$$\frac{\text{EBCT}_{SC}}{\text{EBCT}_{LC}} = \left[\frac{d_{SC}}{d_{LC}}\right]^{2-x} = \frac{t_{SC}}{t_{LC}} \tag{11-68}$$

$$\frac{V_{SC}}{V_{LC}} = \frac{d_{LC}}{d_{SC}} \tag{11-69}$$

Figure 11-59

Small-scale column used to develop data for pilot- or full-scale carbon columns. *(Adapted from Crittenden et al., 1991.)*

where d_{SC} = diameter of particle in short column, mm
d_{LC} = diameter of particle in long column, mm
t_{SC} = time in short column, min
t_{LC} = time in long column, min
V_{SC} = superficial velocity in short column, m/h
V_{LC} = superficial velocity in long column, m/h

For constant and proportional diffusivity, the value of x in the exponent in Eq. (11–68) is 0 and 1, respectively. The application of the above equations is illustrated in Example 11–11.

EXAMPLE 11–11 Comparison of Rapid Small-Scale Column Test Parameters to Pilot-Scale Parameters Determine the corresponding parameters for an RSSCT based on the following data proposed for a pilot-scale column. Assume that film diffusion is the controlling mechanism.

Parameter	Unit	Pilot column (LC)	RSSCT (SC)
Particle diameter	mm	0.5	0.1
Carbon density	g/L	450	450
EBCT	min	10	
Loading rate	m/h	5.0	
Flowrate	mL/min	200	

(continued)

(*Continued*)

Parameter	Unit	Pilot column (LC)	RSSCT (SC)
Column diameter	mm	75	10[a]
Column length	mm	1000	
Mass adsorbent	g		
Time of operation	d	100	
Water volume	L	28,800	

[a]Assumed value for small column.

Solution

1. Estimate the EBCT for the RSSCT.

$$\text{EBCT}_{SC} = \text{EBCT}_{LC}\left[\frac{d_{SC}}{d_{LC}}\right]^2$$

$$\text{EBCT}_{SC} = 10\text{ min}\left[\frac{0.1}{0.5}\right]^2 = 0.4\text{ min}$$

2. Estimate the loading rate for the RSSCT.

$$V_{SC} = V_{LC}\frac{d_{LC}}{d_{SC}}$$

$$V_{SC} = 5\text{ m/h}\,\frac{0.5}{0.1} = 25\text{ m/h}$$

3. Estimate flowrate for the RSSCT.

$$A = \frac{\pi}{4}d_{SC}^2 = \frac{\pi}{4}(10\text{ mm})^2 = 78.5\text{ mm}^2$$

$$Q_{SC} = (V_{SC})(\text{A})$$

$$Q_{SC} = \frac{(25\text{ m/h})(10^3\text{ mm/m})(78.5\text{ mm}^2)}{(60\text{ min/h})(10^3\text{ mm}^3\text{/mL})} = 32.7\text{ mL/min}$$

4. Estimate column length for the RSSCT.

$$L_{SC} = \frac{Q_{SC}\times\text{EBCT}_{SC}}{A} = \frac{(32.7\text{ mL/min})(0.4\text{ min})}{(1\text{ mL}/10^3\text{ mm}^3)(78.5\text{ mm}^2)} = 166.7\text{ mm}$$

5. Estimate mass of adsorbent required for the RSSCT.

$$M_{SC} = \text{EBCT}_{LC}\left[\frac{d_{SC}}{d_{LC}}\right]^2(Q_{SC})(\rho_{SC})$$

$$M_{SC} = 10\text{ min}\left[\frac{0.1\text{ mm}}{0.5\text{ mm}}\right]^2\left[\frac{(32.7\text{ mL/min})(450\text{ g/L})}{10^3\text{ mL/L}}\right] = 5.9\text{ g}$$

6. Estimate time of operation for the RSSCT.

$$t_{SC} = t_{LC}\frac{\text{EBCT}_{SC}}{\text{EBCT}_{LC}}$$

$$t_{SC} = 100\text{ d}\,\frac{0.4\text{ min}}{10\text{ min}} = 4\text{ d}$$

7. Estimate volume of water required for the RSSCT.

$$V_W = Q_{SC} \times t_{SC}$$

$$V_W = \frac{(32.7\text{ mL/min})(4\text{ d})(1440\text{ min/d})}{(10^3\text{ mL/L})} = 188.4\text{ L}$$

8. Summarize the findings for the RSSCT.

Parameter	Unit	Pilot column	RSSCT
Particle radius	mm	0.5	0.1
Carbon density	g/L	450	450
EBCT	min	10	0.4
Loading rate	m/h	5.0	25.0
Flowrate	mL/min	200	32.7
Column diameter	mm	75	10[a]
Column length	mm	1000	166.7
Mass adsorbent	g		5.9
Time of operation	d	100	4
Water volume	L	28,800	188.4

[a] Assumed value for small column.

Comment The time savings in conducting the RSSCT versus the pilot column is apparent. Furthermore, many more tests can be conducted to test alternative configurations and carbon types.

Analysis and Design of Powdered Activated Carbon Contactor

For a powdered activated carbon (PAC) application, the isotherm adsorption data can be used in conjunction with a materials mass balance analysis to obtain an approximate estimate of the amount of carbon that must be added as illustrated below. Here again, because of the many unknown factors involved, column and bench scale tests are recommended to develop the necessary design data.

If a mass balance is written around the contactor (i.e., batch reactor) after equilibrium has been reached, the resulting expression is (Note: the following derivation was presented previously in Chap. 4, but is repeated here for continuity):

$$\begin{matrix}\text{Amount} \\ \text{adsorbed}\end{matrix} = \begin{matrix}\text{initial amount} \\ \text{of absorbate} \\ \text{present}\end{matrix} - \begin{matrix}\text{final amount} \\ \text{of absorbate} \\ \text{present}\end{matrix} \tag{11-70}$$

$$q_e m = VC_o - VC_e \tag{11-71}$$

where q_e = adsorbent phase concentration after equilibrium, mg adsorbate/g adsorbent
m = mass of adsorbent, g
V = volume of liquid in the reactor, L
C_o = initial concentration of adsorbate, mg/L
C_e = final equilibrium concentration of adsorbate after absorption has occurred, mg/L

It should be noted that q_e is in equilibrium with C. If Eq. (11–71) is solved for q_e, the following expression is obtained.

$$q_e = \frac{V(C_o - C_e)}{m} \tag{11-72}$$

If Eq. (11–72) is rewritten as follows:

$$\frac{V}{m} = \frac{q_e}{C_o - C_e} \tag{11-73}$$

The term V/m is defined as the *specific volume* and represents the volume of liquid that can be treated with a given amount of carbon. The graphical representation of the specific volume was presented previously on Fig. 4–33 in Chap. 4. The reciprocal value of the specific volume corresponds to the dose of adsorbent that must be used.

EXAMPLE 11-12 Estimation of Powdered Activated Carbon (PAC) Adsorption Dose and Cost

A treated wastewater with a flowrate of 1000 L/min is to be treated with PAC to reduce the concentration of residual organics measured as TOC from 5 to 1 mg/L. The Freundlich adsorption isotherm parameters were developed as discussed previously. Assuming the following data apply, determine the PAC requirements to treat the wastewater flow. If PAC costs \$0.50/kg, estimate the annual cost for treatment, assuming the PAC will not be regenerated.

1. Compound = mixed organics
2. Initial concentration, C_o = 5.0 mg/L
3. Final concentration, C_e = 1.0 mg/L
4. GAC density = 450 g/L
5. Freundlich capacity factor, K_f = 150 (mg/g)(L/mg)$^{1/n}$
6. Freundlich intensity parameter, $1/n$ = 0.5

Solution

1. Estimate the PAC dose based on the isotherm data. The PAC dose can be estimated by writing Eq. (11–71) as follows:

$$\frac{m}{V} = \frac{(C_o - C_e)}{q_e}$$

Substituting Eq. (11–15) for q_e and using the given values in the above expression yields

$$\frac{m}{V} = \frac{[(5 - 1)\ \text{mg/L}]}{(150\ \text{mg/g})(\text{L/mg})^{0.5}(1.0\ \text{mg/L})^{0.5}} = 0.0267\ \text{g/L}$$

2. Estimate the annual cost for the PAC treatment.

Annual cost

$$= \frac{(0.0267\ \text{g/L})(1000\ \text{L/min})(1440\ \text{min/d})(365\ \text{d/yr})(\$0.50/\text{kg})}{(10^3\ \text{g/kg})}$$

Annual cost = $7008/year

Comment For small wastewater flows, it is not usually cost effective to plan for carbon regeneration.

Activated Sludge with Powdered Activated Carbon Treatment

A proprietary process, "PACT," combines the use of powdered activated carbon with the activated-sludge process (see Fig. 11–60). In this process, when the activated carbon is added directly to the aeration tank, biological oxidation and physical adsorption occur simultaneously. A feature of this process is that it can be integrated into existing activated sludge systems at nominal capital cost. The addition of powdered activated carbon has several process advantages, including (1) system stability during shock loads, (2) reduction of refractory priority pollutants, (3) color and ammonia removal, and (4) improved sludge settleability. In some industrial waste applications, where nitrification is inhibited by toxic organics, the application of powdered activated carbon may reduce or limit this inhibition.

The dosage of powdered activated carbon and the mixed liquor–powdered activated carbon suspended solids concentration are related to the SRT as follows:

$$X_p = \frac{X_i \text{SRT}}{\tau} \tag{11–74}$$

where X_p = equilibrium powdered activated carbon-MLSS content, mg/L
X_i = powdered activated carbon dosage, mg/L
SRT = solids retention time, d
τ = hydraulic retention time, d

Carbon dosages typically range from 20 to 200 mg/L. With higher SRT values, the organic removal per unit of carbon is enhanced, thereby improving the process efficiency.

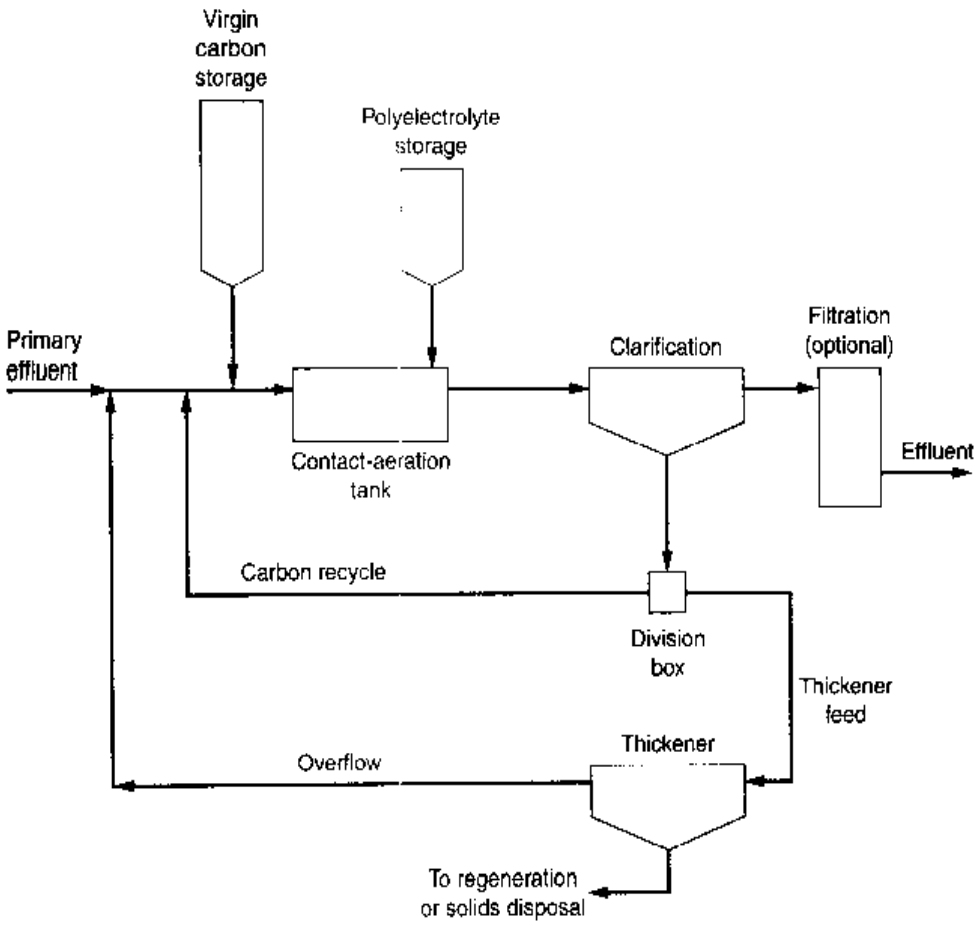


Figure 11–60
Definition sketch for the application of powdered activated carbon.

Reasons cited for this phenomenon include (1) additional biodegradation due to decreased toxicity, (2) degradation of normally nondegradable substances due to increased exposure time to the biomass through adsorption on the carbon, and (3) replacement of low-molecular-weight compounds with high-molecular-weight compounds, resulting in improved adsorption efficiency and lower toxicity.

11–8 GAS STRIPPING

Gas stripping involves the mass transfer of a gas from the liquid phase to the gas phase. The transfer is accomplished by contacting the liquid containing the gas that is to be stripped with a gas (usually air) that does not contain the gas initially. The removal of dissolved gases from wastewaters by gas (usually air) stripping has received considerable attention, especially for the removal of ammonia and odorous gases and volatile organic compounds (VOCs). Early work on the air stripping of ammonia from wastewater was conducted at Lake Tahoe, California (Culp and Slechta, 1966; Slechta and Culp, 1967). The removal of VOCs by aeration was considered earlier in Sec. 5–13.

The purpose of this section is to introduce the fundamental principles involved in gas stripping and to illustrate the general application of these principles. A design procedure is also presented. The material presented in this section is applicable to the removal of ammonia (NH_3), carbon dioxide (CO_2), oxygen (O_2), hydrogen sulfide (H_2S), and a variety of VOCs. The focus of the discussion in this section is on the analysis of facilities designed specifically for the removal of gaseous constituents as opposed

to the removal of odorous gases (see Sec. 15–3, Chap. 15) and VOCs in aeration systems designed for the biological treatment of wastewater (see Sec. 5–13, Chap. 5).

Analysis of Gas Stripping

Important factors that must be considered in the analysis of gas stripping include (1) the characteristics of the compound(s) to be stripped, (2) the type of contactor to be used and the required number of stages, (3) the materials mass balance analysis of the stripping tower, and (4) the required physical features and dimensions of the required stripping tower.

Characteristics of the Compound(s) to Be Stripped. As noted above, the removal of volatile dissolved compounds by stripping involves contacting the liquid with a gas that does not contain the compound initially. The compound that is to be stripped will come out of solution and enter the gas phase to satisfy the Henry's law equilibrium as discussed in Chap. 2. Compounds such as benzene, toluene, and vinyl chloride that have Henry's law constants greater than 500 atm (mol H_2O/mol air) are readily strippable, compounds such as ammonia 0.75 atm (mol H_2O/mol air) and sulfur dioxide 38 atm (mol H_2O/mol air) are marginally strippable, and compounds such as acetone and methyl ethyl ketone with Henry's law constants less than 0.1 atm (mol H_2O/mol air) are essentially not strippable.

The air stripping of ammonia from wastewater requires that the ammonia be present as a gas. Ammonium ions in wastewater exist in equilibrium with gaseous ammonia, as shown in Eq. (2–38):

$$NH_4^+ \leftrightarrow NH_3 + H^+ \tag{2-38}$$

As the pH of the wastewater is increased above 7, the equilibrium is shifted to the left and the ammonium ion is converted to ammonia, which may be removed by gas stripping. The amount of lime required to raise the pH of wastewater as a function of the alkalinity is given on Fig. 6–11 in Chap. 6.

Methods Used to Contact Phases. In practice, two methods are used to achieve contact between phases so that mass transfer can occur: (1) continuous contact and (2) staged contact. As shown on Fig. 11–61, three flow patterns are used in practice: (1) countercurrent, (2) cocurrent, and (3) cross-flow. In addition, the contact medium may be fixed or mobile (Crittenden, 1999). The most common flow pattern in mass transfer operations is the countercurrent mode. A schematic and photograph of a typical gas stripping tower is shown on Fig. 11–62.

Mass-Balance Analysis for a Continuous Stripping Tower. A steady-state materials balance for the lower portion of a countercurrent continuous stripping tower used for the removal of a dissolved gas from wastewater (see Fig. 11–63) is given by

1. General word statement:

$$\begin{array}{l}\text{Moles of solute}\\ \text{entering in}\\ \text{liquid stream}\end{array} + \begin{array}{l}\text{Moles of solute}\\ \text{entering in}\\ \text{gas stream}\end{array} = \begin{array}{l}\text{Moles of solute}\\ \text{leaving in}\\ \text{liquid stream}\end{array} + \begin{array}{l}\text{Moles of solute}\\ \text{leaving in}\\ \text{gas stream}\end{array} \tag{11-75}$$

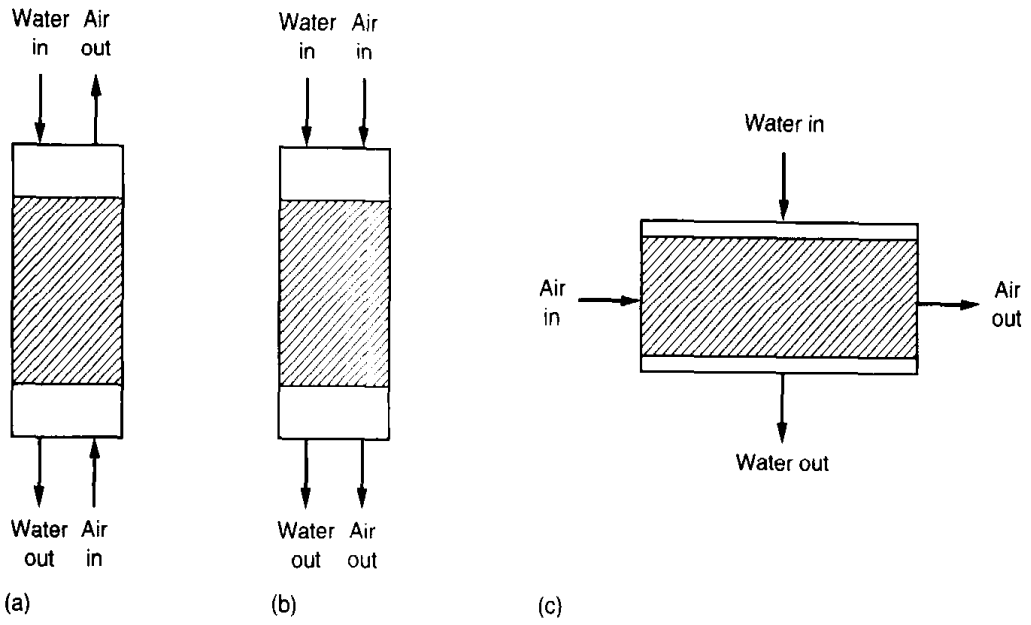

Figure 11-61

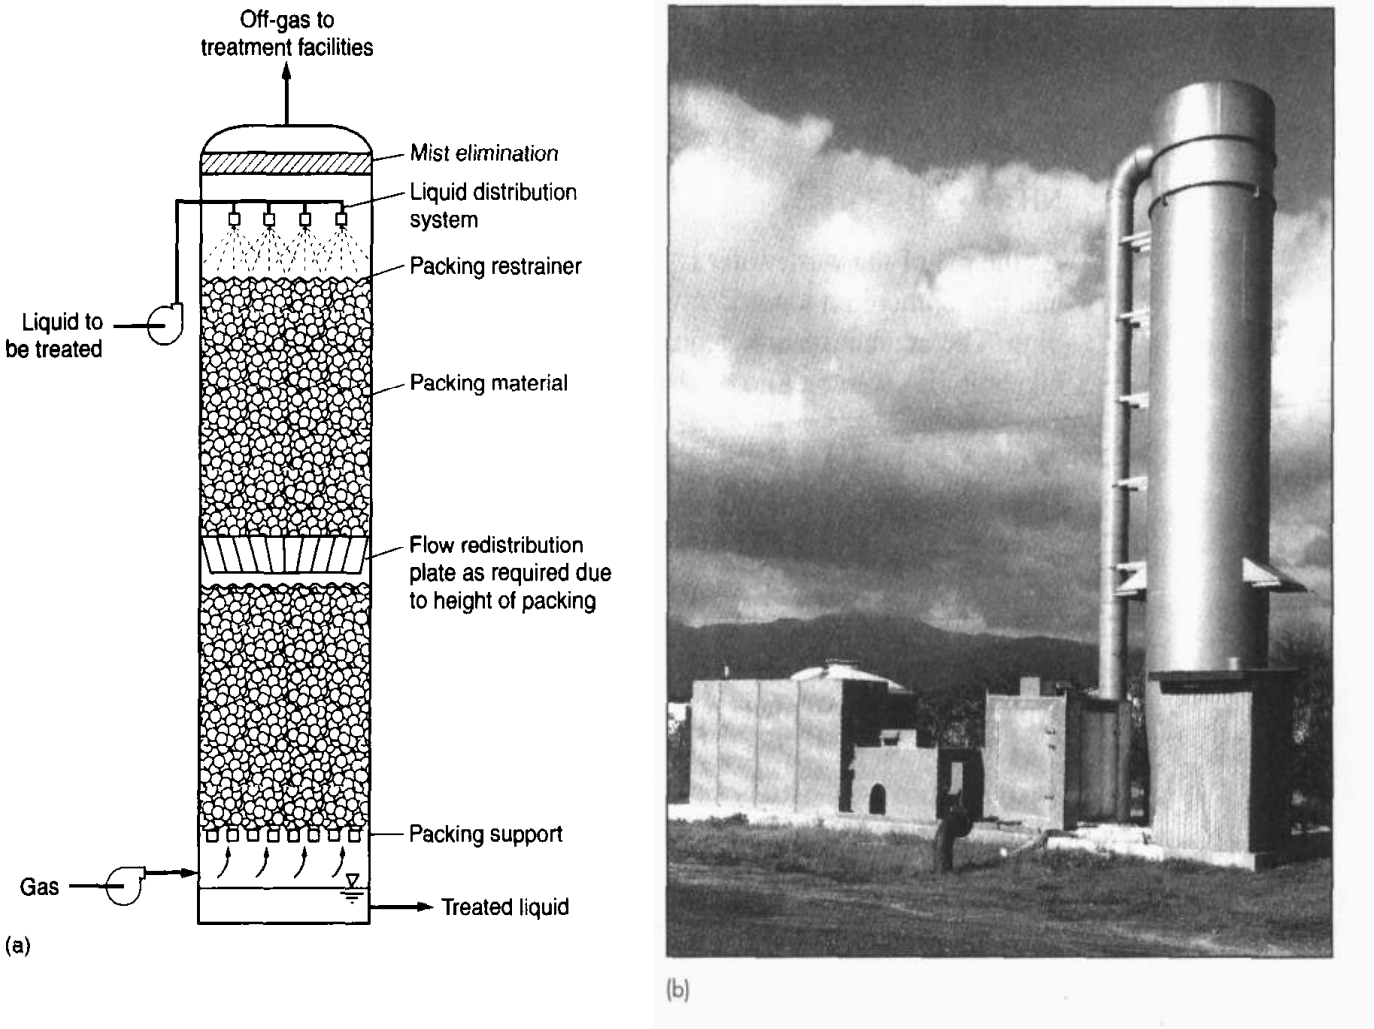
Typical water and airflow patterns for gas stripping towers: (*a*) countercurrent flow, (*b*) cocurrent flow, and (*c*) cross flow.



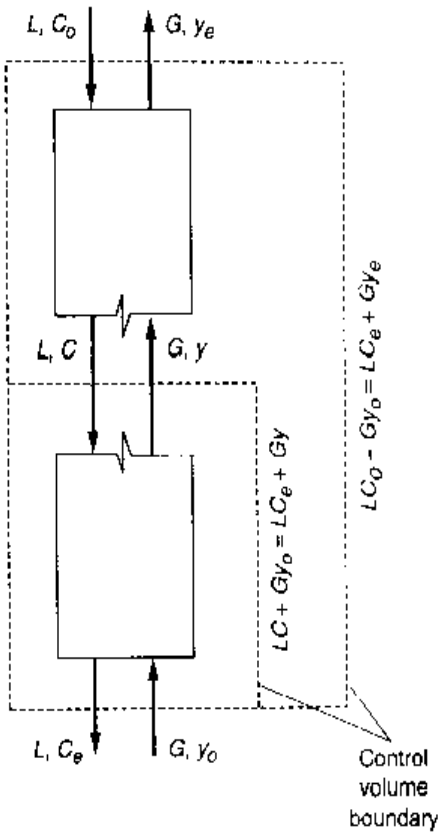


Figure 11-62

Typical stripping towers for the removal of volatile gases from water: (*a*) schematic and (*b*) typical operating facility.

Figure 11-63

Definition sketch for the analysis of a continuous countercurrent flow gas stripping tower.

2. Simplified word statement:

   Inflow = outflow (11–76)

3. Symbolic representation (refer to Fig. 11–63):

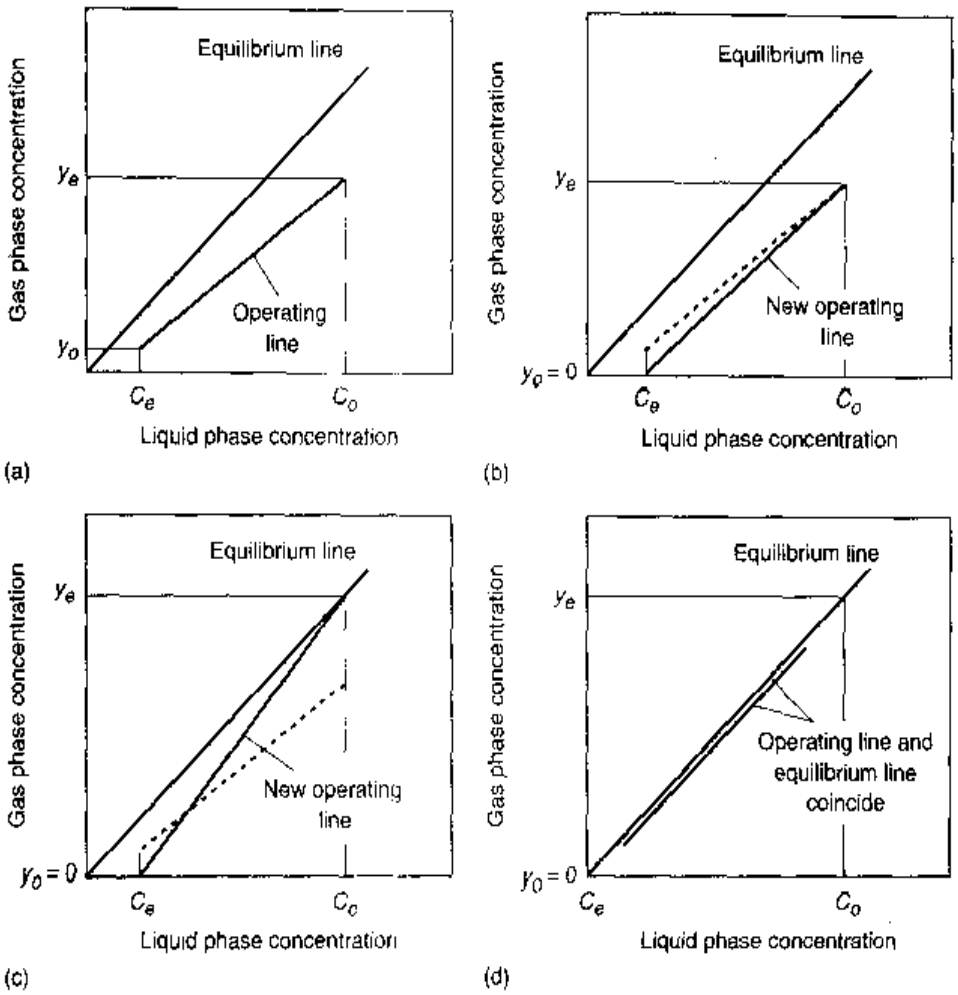
$$LC + Gy_o = LC_e + Gy \tag{11-77}$$

where L = moles of incoming liquid (i.e., wastewater) per unit time
C = concentration of solute in liquid at point within the tower, moles of solute per mole of liquid
G = moles of incoming gas per unit time
y_o = concentration of solute in gas entering the bottom of the tower, moles of solute per mole of solute-free gas
C_e = concentration of solute in liquid leaving the bottom of the tower, moles of solute per mole of liquid
y = concentration of solute at a point within the tower, moles of solute per mole of solute-free gas

Combining terms, Eq. (11–77) can be written as

$$(y_o - y) = L/G(C_e - C) \tag{11-78}$$

If the overall tower is considered, Eq. (11–77) can be written as



$$LC_o + Gy_o = LC_e + Gy_e \tag{11-79}$$

Combining terms, Eq. (11–79) can be written as

$$(y_o - y_e) = L/G(C_e - C_o) \tag{11-80}$$

Figure 11–64

Operating lines for various gas stripping conditions: (*a*) general case, (*b*) condition when $y_o = 0$, (*c*) condition when $y_o = 0$ and y_e is in equilibrium with C_o, the constituent concentration in the incoming water, and (*d*) condition when $y_o = 0$, $C_e = 0$, and y_e is in equilibrium with C_o.

where C_o = concentration of solute in liquid entering at the top of the tower, moles of solute per mole of liquid

y_e = concentration of solute in gas leaving the top of the tower, moles of solute per mole of air

Because Eq. (11–80) is derived solely from a consideration of the equality of input and output, it holds regardless of the internal equilibria that may control the mass transfer. Equation (11–80) represents the equation of a straight line with slope L/G, which passes through the point (C_o, y_e) and point (C_e, y_o). The line passed through these two points (see Fig. 11–64*a*) is known as the *operating line* and represents the conditions at any point within the column. The equilibrium line is based on Henry's law. For example, equilibrium lines defined by Henry's law for ammonia as a function of temperature are presented on Fig. 11–65. It should be noted that when a gas is being stripped from solution, the operating line will lie below the equilibrium line. If a gas is being absorbed into solution the operating line will lie above the equilibrium line.

If it is assumed that the air entering the bottom of the tower contains no solute (i.e, $y_o = 0$), then Eq. (11–80) can be written as

$$y_e = L/G(C_o - C_e) \tag{11–81}$$

The operating line for the condition defined by Eq. (11–81) is shown on Fig. 11–64*b*.

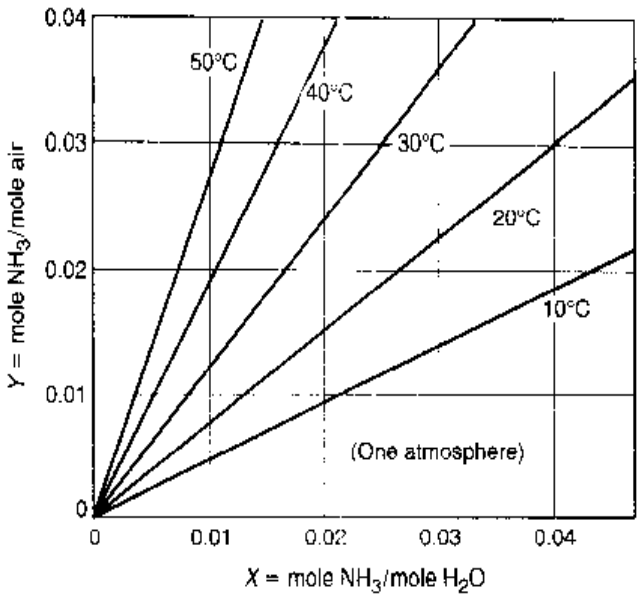


Figure 11–65

Equilibrium curves for ammonia in water as a function of temperature based on Henry's law (see also Table 2–8 in Chap. 2).

Using Henry's law [see Eq. (2–46)], y_e is defined as follows:

$$y_e = \frac{H}{P_T} C_o' \tag{11–82}$$

where y_e = concentration of solute in gas leaving the top of the tower, moles of solute per mole of air

H = Henry's law constant, $\dfrac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}$

P_T = total pressure, usually 1.0 atm

C_o' = concentration of solute in liquid that is in equilibrium with the gas leaving the tower, moles of solute per mole of liquid

Using Eq. (11–82), Eq. (11–81) can be written as follows:

$$C_o' = \frac{L}{G} \times \frac{P_T}{H} (C_o - C_e) \tag{11–83}$$

If it is assumed that the concentration of solute in the liquid entering the tower is in equilibrium with the gas leaving the tower, Eq. (11–83) can be written as

$$\frac{G}{L} = \frac{P_T}{H} \times \frac{C_o - C_e}{C_o} \tag{11–84}$$

The operating line for the condition defined by Eq. (11–84) is shown on Fig. 11–64*c*. The value of *G/L* (air to liquid ratio) defined by Eq. (11–84) represents the minimum amount of air that can be used for stripping for the given conditions (i.e, $y_o = 0$ and $y_e = HC_o/P_T$). In practice, from one and a half to three times the theoretical minimum air-to-liquid ratio is used to achieve effective stripping of most constituents. The application of this relationship is illustrated in Example 11–13.

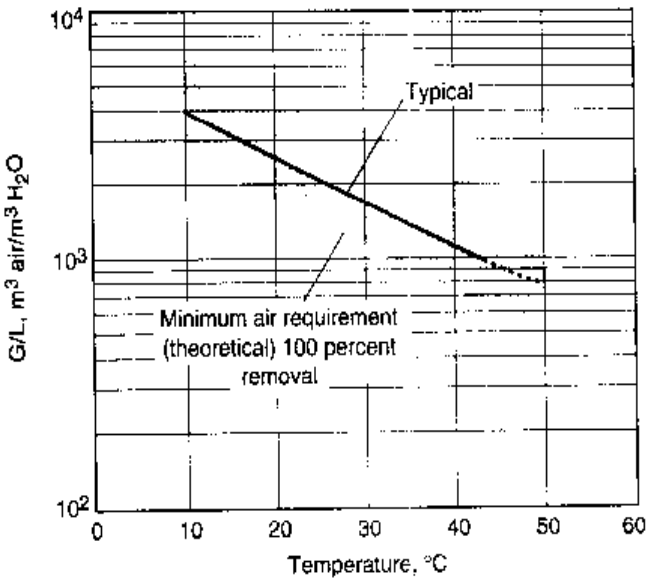

Figure 11–66
Air requirements for ammonia stripping as a function of temperature.

If it is assumed further that the liquid leaving and the air entering the bottom of the tower contains no solute, then Eq. (11–84) can be written as

$$\frac{G}{L} = \frac{P_T \times C_o}{H \times C_o} = \frac{P_T}{H} \tag{11–85}$$

The value of G/L for this condition corresponds to the equilibrium line defined by Henry's law (see Fig. 11–64*d*), and represents the theoretical minimum amount of air that can be used for stripping for the given conditions (i.e., $y_o = 0$, $C_e = 0$, and $y_e = HC_o/P_T$). The theoretical air-to-liquid ratio for stripping ammonia from wastewater for various temperatures is plotted on Fig. 11–66. The theoretical ratio is derived by assuming the process to be 100 percent efficient with a stripping tower of infinite height—obviously unachievable in practice.

EXAMPLE 11–13 Air Requirements for Ammonia Stripping Determine the theoretical amount of air required at 20°C to reduce the ammonia concentration from 40 to 1 mg/L in a treated wastewater with a flowrate of 4000 m³/d. Assume the pH of the wastewater has been increased to a value of 11 (see Fig. 2–13 in Chap. 2), the Henry's constant for ammonia at 20°C is 0.75 atm, and the air entering the bottom of the tower does not contain any ammonia.

Solution

1. Determine the influent and effluent mole fractions of ammonia in the liquid using Eq. (2–3).

$$x_B = \frac{n_B}{n_A + n_B}$$

where x_B = mole fraction of solute B
n_B = number of moles of solute B
n_A = number of moles of solute A

$$C_o = \frac{[(40 \times 10^{-3})/17]}{[55.5 + (40 \times 10^{-3})/17]} = 4.24 \times 10^{-5} \text{ mole } NH_3/\text{mole } H_2O$$

$$C_e = \frac{[(1 \times 10^{-3})/17]}{[55.5 + (1 \times 10^{-3})/17]} = 1.06 \times 10^{-6} \text{ mole } NH_3/\text{mole } H_2O$$

2. Determine the effluent mole fraction of ammonia in the air leaving the tower using Eq. (11–82).

$$y_e = \frac{H}{P_T} C_o$$

$$H = \frac{(0.75 \text{ atm})(\text{mole } NH_3/\text{mole air})}{(\text{mole } NH_3/\text{mole } H_2O)} = (0.75 \text{ atm})\left(\frac{\text{mole } H_2O}{\text{mole air}}\right)$$

$$y_e = \frac{H}{P_T} \times C_o = \frac{0.75 \text{ atm}}{1.0 \text{ atm}}\left(\frac{\text{mole } H_2O}{\text{mole air}}\right) \times (4.24 \times 10^{-5} \text{ mole } NH_3/\text{mole } H_2O)$$

$$= 3.18 \times 10^{-5} \frac{\text{mole } NH_3}{\text{mole air}}$$

3. Determine the gas-to-liquid ratio using Eq. (11–84) rearranged as follows:

$$\frac{G}{L} = \frac{P_T}{H} \times \frac{(C_o - C_e)}{C_o} = \frac{(C_o - C_e)}{y_e}$$

$$\frac{G}{L} = \frac{[(4.24 \times 10^{-5} - 0.106 \times 10^{-5}) \text{ mole } NH_3/\text{mole } H_2O]}{(3.18 \times 10^{-5} \text{ mole } NH_3/\text{mole air})} = 1.3 \frac{\text{mole air}}{\text{mole } H_2O}$$

4. Convert the moles of air and water to liters of air and water.

For air at 20°C:

1.3 mole × 24.1 L/mole = 31.33 L

For water:

$$\frac{(1.0 \text{ mole } H_2O)(18 \text{ g/mole } H_2O)}{(10^3 \text{ g/L})} = 0.018 \text{ L}$$

$$\frac{G}{L} = \frac{31.33 \text{ L}}{0.018 \text{ L}} = 1741 \text{ L/L} = 1741 \text{ m}^3/\text{m}^3$$

5. Determine the total quantity of air required based on ideal conditions.

$$\text{Air required} = \frac{(1741 \text{ m}^3/\text{m}^3)(4000 \text{ m}^3/\text{d})}{(1440 \text{ min/d})} = 4835 \text{ m}^3/\text{min}$$

Comment The approximate amount of lime required to raise the pH of wastewater to a value of 11 is given on Fig. 6–11 in Chap. 6. The procedure followed to determine the height of the stripping tower is illustrated in Example 11–14, presented later in this section.

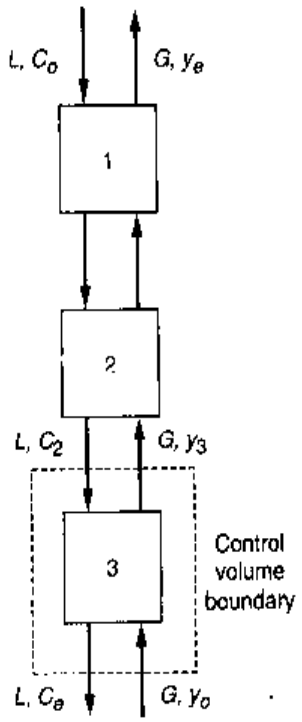

Figure 11–67
Definition sketch for the analysis of a three-stage countercurrent flow gas stripping tower.

Mass-Balance Analysis of a Multistage Stripping Tower. In the analysis of stripping towers, reference is often made to the number of ideal stages required for stripping. The analysis for the number of stages is analogous to the simulation of plug flow with a series of complete-mix reactors as detailed in Chap. 4. Separate stages are used to improve performance of stripping towers. Equilibrium conditions are assumed in each stage of the tower. A steady-state materials balance for the lower portion of a countercurrent staged stripping tower (see Fig. 11–67) is given by

$$\text{Inflow} = \text{outflow}$$

$$LC_2 + Gy_o = LC_e + Gy_3 \tag{11–86}$$

or

$$(y_3 - y_o) = L/G(C_2 - C_e) \tag{11–87}$$

If an overall mass balance is performed around the tower, the resulting equation is the same as that derived above for the continuous stripping tower [see Eq. (11–79)].

In the 1920s, McCabe and Thiele (1925) developed a graphical procedure for determining the required number of ideal stages. The method is illustrated on Fig. 11–68 for a stripping tower comprised of three stages. The operating line for the three stages is also shown on Fig. 11–68. The number of ideal stages required for stripping of a constituent is obtained as follows. The point C_o, y_e represents the airstream leaving and the water stream entering the top of the stripping column. The composition of the liquid in equilibrium with the constituent concentration in the airstream is found by extending a horizontal line from the point C_e, y_e to the point C_1, y_e. From the point C_1, y_e the value of y_2, the air entering stage 1 from stage 2, is obtained from the equation of the operating line. If a materials mass balance is performed between stages 1 and 2, the resulting expression for y_2 is

$$y_2 = \frac{L}{G} C_1 + \frac{Gy_e - LC_o}{G} \tag{11–88}$$

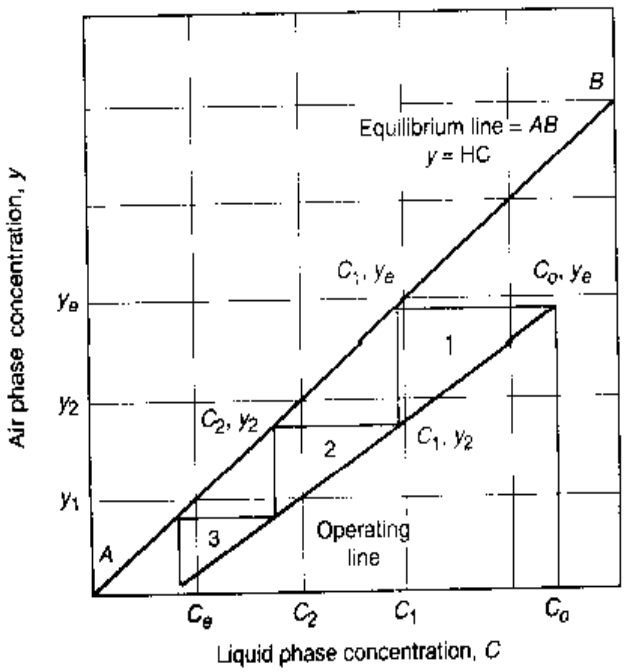

Figure 11–68
Operating line for three-stage countercurrent flow gas stripping tower.

The value of y_2 is obtained by drawing a vertical line from point C_1, y_e to the operating line at point C_1, y_2 as shown on Fig. 11–68. In a similar manner the value of C_2 is obtained by drawing a horizontal line from the point C_1, y_2 to the equilibrium line. This procedure is repeated until the point C_n, y_{n-1} is reached. The number of ideal stages is typically a fractional number (e.g., 4.2, 5.6). In practice, the number of stages is rounded to the next whole number.

Determination of Height of Stripping Tower. The purpose of the following analysis is to illustrate how the height of the packing in the stripping tower is determined, based on an analysis of the mass transfer occurring within the tower. A mass balance performed on the liquid phase within the stripping tower shown on Fig. 11–69 is as follows.

Simplified word statement:

Accumulation = inflow − outflow + volatilization

$$\frac{\partial C}{\partial t}\Delta V = LC|_{z-\Delta z} - LC|_z + r_v \Delta V \tag{11–89}$$

where $\partial C/\partial t$ = change in concentration with time, g/m^3·s
ΔV = differential volume, m^3
Δz = differential height, m
L = liquid volumetric flowrate, m^3/s
C = concentration of constituent C, g/m^3
r_v = rate of mass transfer per unit volume per unit time C, g/m^3·s

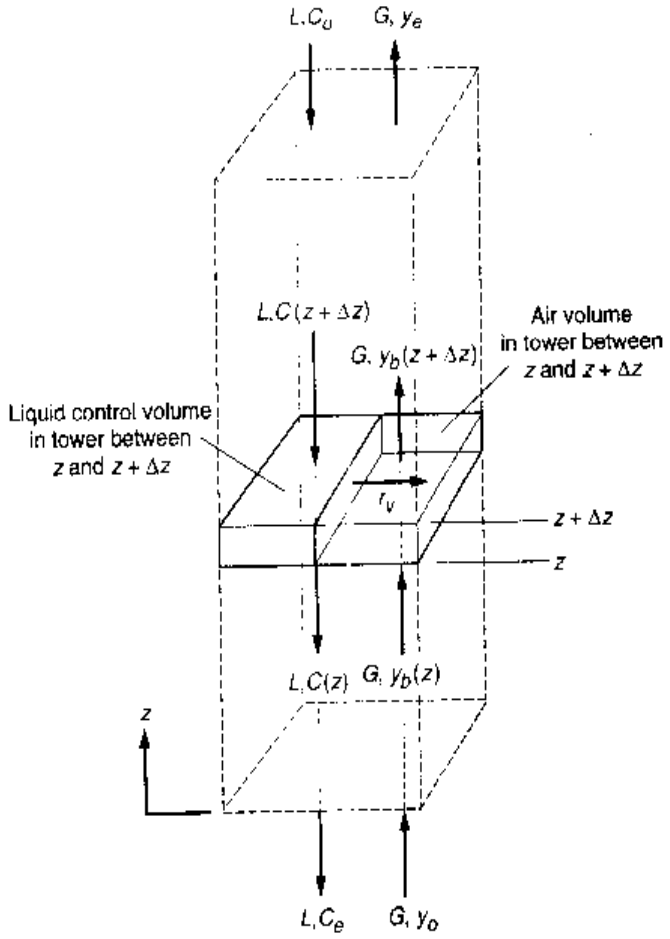

Figure 11–69
Definition sketch for the analysis of mass transfer from the liquid phase to the gas phase within a stripping tower. *Note:* the packing material is not shown. *(Adapted from Hand et al., 1999.)*

Substituting the area times the differential height ($A\Delta z$) for the differential volume (ΔV) and writing the differential form for the term $LC|_{z+\Delta z}$ in Eq. (11–89) results in the following expression:

$$\frac{\partial C}{\partial t} A\Delta z = L\left(C + \frac{\Delta C}{\Delta z}\Delta z \right) - LC + r_v A\Delta z \tag{11–90}$$

Simplifying Eq. (11–90) and taking the limit as Δz approaches zero yields

$$\frac{\partial C}{\partial t} = \frac{L}{A}\frac{\partial C}{\partial z} + r_v \tag{11–91}$$

The rate of mass transfer due to volatilization as described in Chap. 4 [see Eq. (4–127)] is given by:

$$r_v = -K_L a(C_b - C_s) \tag{11–92}$$

where r_v = rate of mass transfer per unit volume per unit time, g/m^3·s
$K_L a$ = volumetric mass transfer coefficient which depends on water-quality characteristics and temperature, 1/s
C_b = concentration in liquid bulk phase at time t, g/m^3
C_s = concentration in liquid in equilibrium with gas as given by Henry's law, g/m^3

Assuming steady-state conditions within the tower ($\partial C/\partial t = 0$) and substituting Eq. (11–92) for r_v, Eq. (11–91) can now be written as

$$\frac{dC_b}{dz} = \frac{K_L aA}{L}(C_b - C_s) \tag{11–93}$$

The height of the tower packing can be obtained by integrating the above expression:

$$\int_0^Z dz = \frac{L}{K_L aA}\int_{C_o}^{C_e} \frac{dC_b}{(C_b - C_s)} \tag{11–94}$$

To integrate the right-hand side of the above equation, a relationship must be found between C_b and C_s because C_s is changing continuously throughout the height of the tower. From Henry's law, the value of C_s is given by:

$$C_s = \frac{P_T}{H} y \tag{11–95}$$

Substituting a modified form of Eq. (11–81) for y in Eq. (11–95) yields:

$$C_s = \frac{L}{G} \times \frac{P_T}{H}(C_b - C_e) \tag{11–96}$$

If Eq. (11–96) is substituted into Eq. (11–94) and the resulting expression is integrated, the following expression is obtained (Hand et al., 1999):

$$Z = \frac{L}{K_L aA}\left[\frac{C_o - C_e}{C_o - C_e - C_o'}\right] \ln\left[\frac{C_o - C_o'}{C_e}\right] \tag{11–97}$$

where

$$C_o' = \frac{L}{G} \times \frac{P_T}{H}(C_o - C_e) \tag{11–98}$$

It should be noted that if $C_o' = C_o$, Eq. (11–98) is the same as Eq. (11–84).

Design Equations for Stripping Towers. Utilizing the above equations, a number of process models and design equations have been developed. Equations that can be used to determine the height of a stripping tower are as follows:

$$Z = \text{HTU} \times \text{NTU} \tag{11–99}$$

where Z = height of stripping tower packing, m
HTU = height of a transfer unit, m
NTU = number of transfer units

The height of a transfer unit is defined as

$$\text{HTU} = \frac{L}{K_L a A} \tag{11–100}$$

where L = liquid volumetric flowrate, m^3/s
$K_L a$ = volumetric mass transfer coefficient, 1/s
A = cross-sectional area of tower, m^2

The HTU is a measure of the mass transfer characteristics of the packing medium.

The number of transfer units is defined as

$$\text{NTU} = \left[\frac{C_o - C_e}{C_o - C_e - C_o'}\right] \ln\left[\frac{C_o - C_o'}{C_e}\right] \tag{11–101}$$

Substituting Eq. (11–98) in Eq. (11–101) yields

$$\text{NTU} = \left[\frac{S}{S-1}\right] \ln\left[\frac{(C_o/C_e)(S-1)+1}{S}\right] \tag{11–102}$$

where S is known as the stripping factor and is defined as

$$S = \frac{G}{L} \times \frac{H}{P_T} \tag{11–103}$$

A value of $S = 1$ corresponds to the minimum amount of air required for stripping. When $S > 1$ the amount of air is in excess and complete stripping is possible given a tower of infinite height. When $S < 1$, there is insufficient air for stripping. In practice, stripping factors vary from 1.5 to 5.0.

Values for $K_L a$ for specific compounds are best obtained from pilot-plant studies or by using empirical correlations such as given in Eq. (5–62) in Chap. 5, and repeated here for convenience as Eq. (11–104). It should be noted that many other relationships have been proposed in the literature (Sherwood and Hollaway, 1940, and Onda et al., 1968).

$$K_L a_{\text{VOC}} = K_L a_{O_2}\left(\frac{D_{\text{VOC}}}{D_{O_2}}\right)^n \tag{11–104}$$

where $K_L a_{VOC}$ = system mass transfer coefficient, 1/h
$K_L a_{O_2}$ = system oxygen mass transfer coefficient, 1/h
D_{VOC} = diffusion coefficient of VOC in water, cm^2/s
D_{O_2} = diffusion coefficient of oxygen in water, cm^2/s
n = coefficient (0.5 for stripping towers)

Air and water temperature are significant factors in the design of stripping towers because of their effect on air and water viscosities, Henry's law constants, and volumetric mass transfer coefficients. The effect of temperature on the Henry's law constant is illustrated on Fig. 11–65. The value of $K_L a$ can be adjusted for temperature effects using Eq. (2–25) with a theta value of 1.024.

Design of Stripping Towers

In its simplest form a stripping tower consists of a tower (usually circular), a support plate for the packing material, a distribution system for the liquid to be stripped, located above the packing material, and an air supply located at the bottom of the stripping tower (see Fig. 11–62). The process design variables include (1) the type of packing material, (2) the stripping factor, (3) the cross-sectional area of the tower, and (4) the height of the stripping tower. The cross-sectional area will depend on the pressure drop through the packing. Representative design values for stripping of VOCs and ammonia are presented in Table 11–35. The significant difference in the amount of air required for stripping is a clear illustration of the importance of the Henry's constant.

The headloss through the packing is determined using a generalized gas pressure-drop relationship such as that plotted on Fig. 11–70 (Eckert, 1975). The pressure drop is expressed in newtons per square meter per meter of depth $(N/m^2)/m$. The upper line on Fig. 11–70 labeled *approximate flooding* represents the condition that occurs when the amount of water and air applied is so great that the pore spaces fill to the point where water starts to flood within the tower. The units for the x and y axes are as follows:

x axis:

$$x = \frac{L'}{G'}\left(\frac{\rho_G}{\rho_L - \rho_G}\right)^{1/2} \approx \frac{L'}{G'}\left(\frac{\rho_G}{\rho_L}\right)^{1/2} \tag{11-105}$$

y axis:

$$y = \frac{(G')^2(C_f)(\mu_L)^{0.1}}{(\rho_G)(\rho_L - \rho_G)} \tag{11-106}$$

which can be rewritten as follows:

$$G' = \left[\frac{(\text{value from } y \text{ axis})(\rho_G)(\rho_L - \rho_G)}{(C_f)(\mu_L)^{0.1}}\right]^{1/2} \tag{11-107}$$

where L' = liquid loading rate, $kg/m^2 \cdot s$
G' = gas loading rate, $kg/m^2 \cdot s$
ρ_G = density of gas, kg/m^3
ρ_L = density of liquid, kg/m^3
C_f = packing factor for packing material, unitless
μ_L = viscosity of liquid, $N/m^2 \cdot s$

Table 11–35
Typical design parameters for stripping towers for the removal of VOC and ammonia[a]

Item	Symbol	Unit	VOC removal[b]	Ammonia removal[c]
Liquid loading rate		$L/m^2 \cdot min$	600–1800	40–80
Air-to-liquid ratio[d]	G/L	m^3/m^3	20–60:1	2000–6000:1
Stripping factor	S	unitless	1.5–5.0	1.5–5.0
Allowable air pressure drop	ΔP	$(N/m^2)/m$	100–400	100–400
Height-to-diameter ratio	Z/D	m/m	≤10:1	≤10:1
Packing depth[e]	Z	m	1–6	2–6
Factor of safety	SF	%D, %Z	20–50	20–50
Wastewater pH	pH	Unitless	5.5–8.5	10.8–11.5
Approximate packing factors				
Pall rings, Intalox saddles	C_f	12.5 mm[f]	180–240	180–240
	C_f	25 mm[f]	30–60	30–60
	C_f	50 mm[f]	20–25	20–25
Berl saddles, Raschig rings	C_f	12.5 mm[f]	300–600	300–600
	C_f	25 mm[f]	120–160	120–160
	C_f	50 mm[f]	45–60	45–60

[a] Adapted in part from Eckert (1970, 1975), Kavanaugh and Trussell (1980), and Hand et al. (1999).

[b] Typical data for VOCs with Henry's constants greater than 500 atm (mole H_2O/mole air).

[c] Ammonia with a Henry's constant of 0.75 atm (mole H_2O/mole air) is considered only marginally strippable, which accounts for the low loading rate and high air-to-liquid ratio.

[d] Ratio is highly temperature-dependent.

[e] For packing depths greater than 5 to 6 m, redistribution of the liquid flow is recommended (see Fig. 11–62*a*).

[f] Size of packing material.

The packing factor C_f depends on the type and size of the packing. Typical ranges for packing factors that can be used for preliminary assessments are reported in Table 11–35. For more detailed design calculations, current values should be obtained from manufacturers.

To use Fig. 11–70, select a value for L'/G' and compute the corresponding x value. Enter the plot at the computed value of x and move vertically upward to a preselected pressure-drop line. Move horizontally from the point of intersection to the y axis and note the value on the y axis. Using the y-axis value, determine the gas loading rate G' using Eq. (11–107) and the corresponding liquid loading rate L'. To determine the required cross-sectional area the liquid flowrate is divided by the liquid loading rate.

A generalized analysis procedure is as follows:

1. Select a packing material and its corresponding packing factor for use in Eq. (11–105).
2. Select several stripping factors for successive trials (e.g., 2.5, 3.0, 4.0)

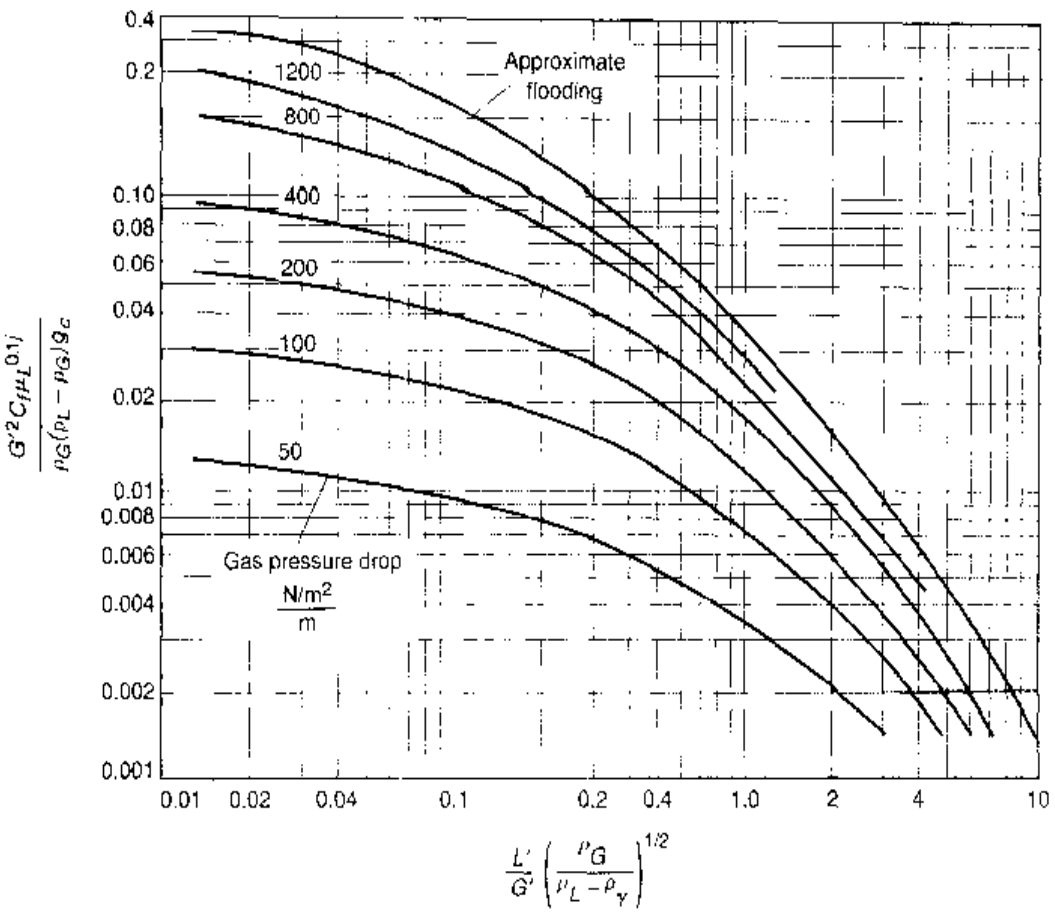

Figure 11–70
Generalized pressure-drop curves for packed-bed stripping towers. (From Eckert, 1975.)

3. Select acceptable pressure drop ΔP (typically a function of the packing material selected).
4. Determine the cross-sectional area of the tower, based on the allowable pressure drop using the data presented on Fig. 11–70 or other appropriate relationships.
5. Determine the height of the transfer units using Eq. (11–100). To apply Eq. (11–100), the value of $K_L a$ must be known or estimated using Eq. (11–104).
6. Determine the number of transfer units using Eq. (11–102).
7. Determine the height of the stripping tower using Eq. (11–99).

The design procedure outlined above is illustrated in Example 11–14. Representative design values for stripping towers are given in Table 11–35. To evaluate the stripping process more thoroughly, any of the commercially available software packages can be used.

EXAMPLE 11–14 Determination of Height of Stripping Tower for the Removal of Ammonia

Determine the diameter and height of the stripping tower required to treat the wastewater in Example 11–13 using the data given in Table 11–35. Assume 25 mm Pall rings will be used as the packing material in the stripping tower. The ammonia concentration in a treated wastewater from a flow of 4000 m^3/d is to be reduced from 40 to 1 mg/L. Assume that the Henry's constant for ammonia at 20°C is 0.75 atm, and the air entering the bottom of the tower does not contain any ammonia. Assume the $K_L a$ value for ammonia is 0.0125 s^{-1}.

Solution

1. Select a packing material and corresponding packing factor. For 25 mm Pall rings (specified), assume a packing factor of 50 (see Table 11–35).
2. Select a stripping factor. Assume a stripping factor of 3 (see Table 11–35).
3. Select an acceptable pressure drop. Assume a pressure drop of 200 $(N/m^2)/m$ (see Table 11–35).
4. Determine the cross-sectional area of the tower stripping using the pressure drop plot given on Fig. 11–71.
   a. Determine the value of the ordinate for a stripping factor of 3.

$$S = \frac{G}{L} \times \frac{H}{P_T} = \frac{\text{G mole air}}{\text{L mole water}} \times \frac{0.75 \text{ atm}}{1.0 \text{ atm}} = \frac{\text{G mole air}}{\text{L mole water}} \times 0.75$$

$$S = 0.75 \times \left(\frac{\text{G mole air}}{\text{L mole water}}\right)\left(\frac{28.8 \text{ g}}{\text{mole air}}\right)\left(\frac{\text{mole water}}{18 \text{ g}}\right)$$

$$= 1.2 \frac{G \text{ g}}{L \text{ g}} = 1.2 \frac{G' \text{ kg}}{L' \text{ kg}}$$

$$\frac{L'}{G'} = \frac{3}{1.2 \text{ kg/kg}} = 2.5$$

$$\frac{L'}{G'}\left(\frac{\rho_G}{\rho_L - \rho_G}\right)^{1/2} \approx \frac{L'}{G'}\left(\frac{\rho_G}{\rho_L}\right)^{1/2} = (2.5 \text{ kg/kg})\left[\frac{(1.204 \text{ kg/m}^3)}{(998.2 \text{ kg/m}^3)}\right]^{1/2} = 0.087$$

   b. Determine the corresponding value on the abscissa. For an ordinate value of 0.087 and a pressure drop of 200 $(N/m^2)/m$, the ordinate value is 0.04.
   c. Using an ordinate value 0.04, determine the loading rate using Eq. (11–107).

$$G' = \left[\frac{(\text{value from } y \text{ axis})(\rho_G)(\rho_L - \rho_G)}{(C_f)(\mu_L)^{0.1}}\right]^{1/2}$$

$$G' = \left[\frac{(0.04)(1.204)(998.2 - 1.204)}{(50)(0.001)^{0.1}}\right]^{1/2} = 1.38 \text{ kg/m}^2\text{·s}$$

$$L' = 2.5\, G' = 2.5 \times 1.38 \text{ kg/m}^2\text{·s} = 3.45 \text{ kg/m}^2\text{·s}$$

   d. Substitute known values and solve for the diameter of the tower.

$$D = \left[\frac{(4/\pi)(4000 \text{ m}^3/\text{d})(998.2 \text{ kg/m}^3)(1 \text{ d}/86{,}400 \text{ s})}{(4.8 \text{ kg/m}^2\text{·s})}\right]^{1/2} = 4.13 \text{ m}$$

5. Determine the height of the transfer unit using Eq. (11–100).

$$\text{HTU} = \frac{L}{K_L a A}$$

$$\text{HTU} = \frac{L}{K_L a A} = \frac{(4000 \text{ m}^3/\text{d})(1 \text{ d}/86{,}400 \text{ s})}{(0.0125/\text{s})[(3.14/4)(4.13 \text{ m})^2]} = 0.28 \text{ m}$$

6. Determine the number of transfer units using Eq. (11–102).

$$\text{NTU} = \left[\frac{S}{S-1}\right] \ln\left[\frac{(C_o/C_e)(S-1)+1}{S}\right]$$

$$\text{NTU} = \left[\frac{3}{3-1}\right] \ln\left[\frac{(40/1)(3-1)+1}{3}\right] = 4.94$$

7. Determine the height of the stripping tower packing using Eq. (11–99).

$$Z = \text{HTU} \times \text{NTU} = 0.28 \times 4.94 = 1.38 \text{ m}$$

Comment In this example, the value of K_La for ammonia was known. Quite often the required K_La value must be determined in the field, using pilot-scale facilities. Alternatively Eq. (11–104) can be used to estimate a value for K_La. In some cases, data from the literature or from manufacturers may be used to obtain preliminary sizing. To optimize the design, various stripping ratios must be evaluated. Optimization is best accomplished using one of the commercially available software packages.

Application

As noted previously, air stripping is used to remove ammonia (NH_3), carbon dioxide (CO_2), oxygen (O_2), hydrogen sulfide (H_2S), and a variety of VOCs. The application of air stripping for the removal of ammonia is considered in the following discussion. The removal and treatment of VOCs in aeration systems is considered in Sec. 5–13 in Chap. 5. The VOC management alternatives considered in Chap. 5 are also applicable for the treatment of VOCs removed with a stripping tower. The removal and treatment of odorous compounds are considered in Sec. 15–3 in Chap. 15.

Removal of Ammonia from Wastewater. In general, removal efficiency depends on the temperature, size, and proportions of the facility, and the efficiency of the air-water contact. If the removal of ammonia is unsatisfactory, the tower has not been designed correctly or is overloaded. In this case, additional air volume may improve operation. As the temperature decreases, the amount of air required increases significantly for the same degree of removal (see Fig. 11–66). A typical flow diagram for the removal of ammonia from wastewater by air stripping is shown on Fig. 11–71. The ammonia stripped from the wastewater is converted to the ammonium ion using an acid scrubber.

In most cases where ammonia stripping has been applied, a number of operating problems have developed, the most serious being (1) maintaining the required pH for effective stripping, (2) calcium carbonate scaling within the tower and feed lines, and (3) poor performance during cold weather operation. Maintaining the required pH is a control problem that can be managed with multiple sensors. The amount and nature

(soft to extremely hard) of the calcium carbonate scale formed varies with the characteristics of the wastewater and local environmental conditions, and cannot be predicted a priori. Under conditions of icing, the liquid-air contact geometry in the tower is altered, which further reduces the overall efficiency. The best solution for cold weather conditions is to enclose the stripper.

Removal of Ammonia from Digester Supernatant by Steam Stripping. Steam stripping of ammonia is similar to air stripping, with the exception that the process requires temperatures in excess of 95°C (200°F). Although costly, steam stripping has been proposed for the removal of ammonia from digester supernatant in large treatment plants, where separate facilities are used for the treatment of return flows (see discussion in Chap. 14). The flow diagram for the removal of ammonia from dewatering centrate is shown on Fig. 11–72. The ammonia stripped from the supernatant is converted to the ammonium ion by passing the off-gas through an acid bath. Acid scrubbers are also used.

In a large-scale test, two processes were evaluated for the removal of ammonia from centrate: steam stripping and hot air stripping. Steam stripping proved to be the most cost-effective. Based on the results of recent full-scale testing, it has been found that pretreatment of the centrate is essential for effective steam stripping of ammonia. Pretreatment consisting of settling followed by straining proved to be effective. Using a gas-to-liquid ratio of 300 to 1, it was possible to achieve ammonia removals of about 88 percent, at pH values of 7 to 7.5. The influent ammonia concentrations values were on the order of 500 to 600 mg/L (Gopalakrishnan et al., 2000).

Operating problems that have been encountered with steam stripping include (1) extensive fouling (iron deposits, for example) within the heat exchanger and in the stripper due to the presence of waste constituents at elevated temperatures, (2) maintaining the required pH for effective stripping, (3) controlling the steam flow, and

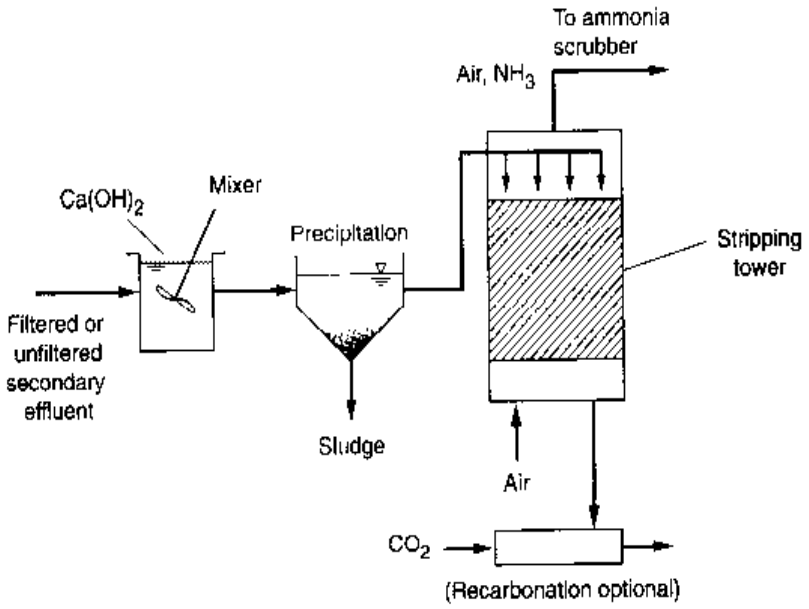

Figure 11-71

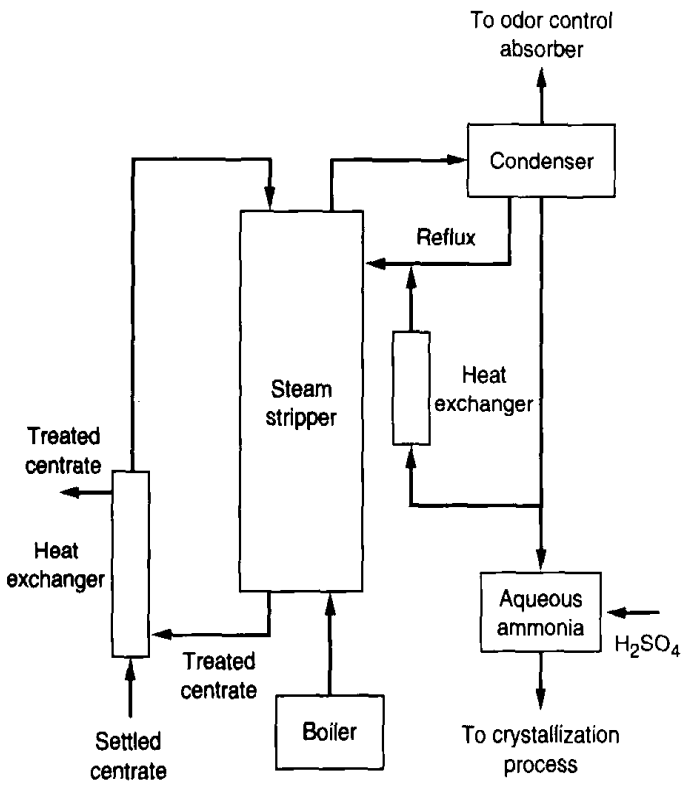

Figure 11-72

Stream stripping of ammonia from centrate from dewatering operations: (a) typical flow diagram, and (b) view of pilot-plant facility. (Courtesy of The New York City Department of Environmental Protection.)

(4) maintaining the stripping tower temperature. Because of the importance of temperature, steam stripping should be carried out in enclosed facilities. Spiral-wound heat exchangers have proved to be effective. In Europe, an acid wash is used to clean the piping, the heat exchanger, and the stripping column.

11-9 ION EXCHANGE

Ion exchange is a unit process in which ions of a given species are displaced from an insoluble exchange material by ions of a different species in solution. The most widespread use of this process is in domestic water softening, where sodium ions from a cationic-exchange resin replace the calcium and magnesium ions in the treated water,

thus reducing the hardness. Ion exchange has been used in wastewater applications for the removal of nitrogen, heavy metals, and total dissolved solids.

Ion-exchange processes can be operated in a batch or continuous mode. In a batch process, the resin is stirred with the water to be treated in a reactor until the reaction is complete. The spent resin is removed by settling and subsequently is regenerated and reused. In a continuous process, the exchange material is placed in a bed or a packed column, and the water to be treated is passed through it. Continuous ion exchangers are usually of the downflow, packed-bed column type. Wastewater enters the top of the column under pressure, passes downward through the resin bed, and is removed at the bottom. When the resin capacity is exhausted, the column is backwashed to remove trapped solids and is then regenerated. Two examples of commercial ion-exchange reactors are shown on Fig. 11–73.

Ion-Exchange Materials

Naturally occurring ion-exchange materials, known as zeolites, are used for water softening and ammonium ion removal. Zeolites used for water softening are complex aluminosilicates with sodium as the mobile ion. Ammonium exchange is accomplished using a naturally occurring zeolite clinoptilolite. Synthetic aluminosilicates are manufactured, but most synthetic ion-exchange materials are resins or phenolic polymers.

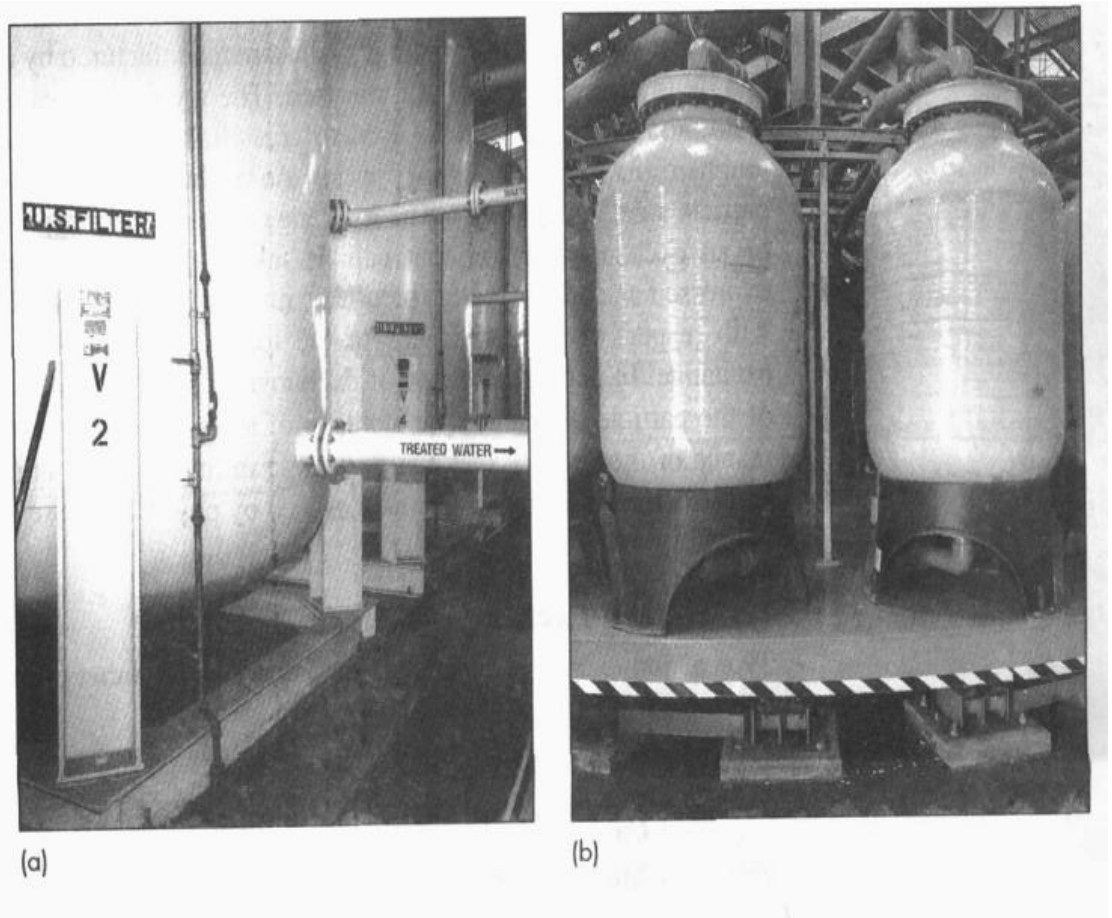

Figure 11–73

Two examples of full-scale ion-exchange installations: (*a*) large downflow packed-bed columns, and (*b*) ion-exchange canisters on a rotating platform. The canisters are rotated so that one canister can be regenerated while the others are in operation.

Table 11-36 Classification of ion-exchange resins[a]

Type of resin	Characteristics
Strong-acid cation resins	Strong-acid resins behave in a manner similar to a strong acid, and are highly ionized in both the acid ($R—SO_3H$) and salt ($R—SO_3Na$) form, over the entire pH range
Weak-acid cation resins	Weak-acid cation exchangers have a weak-acid functional group (—COOH), typically a carboxylic group. These resins behave like weak organic acids that are weakly dissociated
Strong-base anion resins	Strong-base resins are highly ionized, having strong-base functional groups such as (OH), and can be used over the entire pH range. These resins are used in the hydroxide (OH) form for water deionization
Weak-base anion resins	Weak-base resins have weak-base functional groups in which the degree of ionization is dependent on pH
Heavy-metal selective chelating resins	Chelating resins behave like weak-acid cation resins but exhibit a high degree of selectivity for heavy-metal cations. The functional group in most of these resins is EDTA, and the resin structure in the sodium form is R—EDTA—Na

[a] Adapted in part from Eckenfelder (2000).

Five types of synthetic ion-exchange resins are in use: (1) strong-acid cation, (2) weak-acid cation, (3) strong-base anion, (4) weak-base anion, and (5) heavy-metal selective chelating resins. The properties of these resins are summarized in Table 11-36.

Most synthetic ion-exchange resins are manufactured by a process in which styrene and divinylbenzene are copolymerized. The styrene serves as the basic matrix of the resin, and divinylbenzene is used to cross-link the polymers to produce an insoluble tough resin. Important properties of ion-exchange resins include exchange capacity, particle size, and stability. The exchange capacity of a resin is defined as the quantity of an exchangeable ion that can be taken up. The exchange capacity of resins is expressed as eq/L or eq/kg (meq/L or meq/g). The particle size of a resin is important with respect to the hydraulics of the ion-exchange column and the kinetics of ion exchange. In general, the rate of exchange is proportional to the inverse of the square of the particle diameter. The stability of a resin is important to the long-term performance of the resin. Excessive osmotic swelling and shrinking, chemical degradation, and structural changes in the resin caused by physical stresses are important factors that may limit the useful life of a resin.

Typical Ion-Exchange Reactions

Typical ion-exchange reactions for natural and synthetic ion-exchange materials are given below.

For natural zeolites (Z):

$$ZNa_2 + \begin{bmatrix} Ca^{2+} \\ Mg^{2+} \\ Fe^{2+} \end{bmatrix} \leftrightarrow Z \begin{bmatrix} Ca^{2-} \\ Mg^{2-} \\ Fe^{2-} \end{bmatrix} + 2Na^{+} \qquad (11\text{-}108)$$

For synthetic resins (R):

Strong-acid cation exchange:

$$R\text{SO}_3\text{H} + \text{Na}^+ \leftrightarrow R\text{SO}_3\text{Na} + \text{H}^+ \quad (11\text{-}109)$$

$$2R\text{SO}_3\text{Na} + \text{Ca}^{2+} \leftrightarrow (R\text{SO}_3)_2\text{Ca} + 2\text{Na}^+ \quad (11\text{-}110)$$

Weak-acid cation exchange:

$$R\text{COOH} + \text{Na}^+ \leftrightarrow R\text{COONa} + \text{H}^+ \quad (11\text{-}111)$$

$$2R\text{COONa} + \text{Ca}^{2+} \leftrightarrow (R\text{COO})_2\text{Ca} + 2\text{Na}^+ \quad (11\text{-}112)$$

Strong-base anion exchange:

$$RR'_3\text{NOH} + \text{Cl}^- \leftrightarrow RR'_3\text{NCl} + \text{OH}^- \quad (11\text{-}113)$$

Weak-base anion exchange:

$$R\text{NH}_3\text{OH} + \text{Cl}^- \leftrightarrow R\text{NH}_3\text{Cl} + \text{OH}^- \quad (11\text{-}114)$$

$$2R\text{NH}_3\text{Cl} + \text{SO}_4^{2-} \leftrightarrow (R\text{NH}_3)_2\,\text{SO}_4 + 2\text{Cl}^- \quad (11\text{-}115)$$

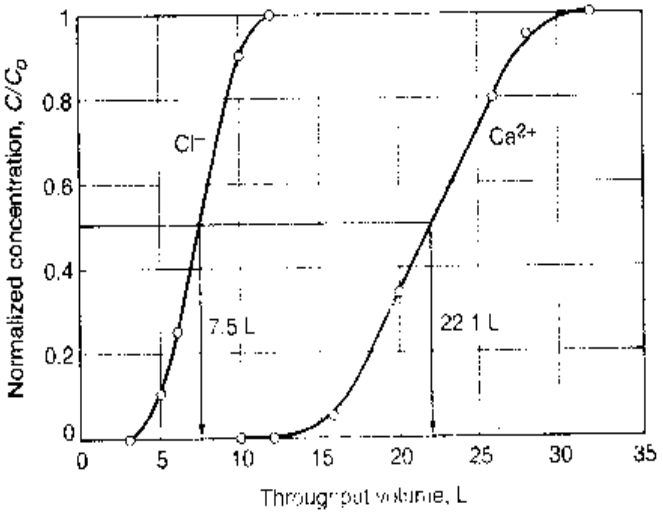
Exchange Capacity of Ion-Exchange Resins

Reported exchange capacities vary with the type and concentration of regenerant used to restore the resin. Typical synthetic resin exchange capacities are in the range of 2 to 10 eq/kg of resin; zeolite cation exchangers have exchange capacities of 0.05 to 0.1 eq/kg. Exchange capacity is measured by placing the resin in a known form. A cationic resin would be washed with a strong acid to place all of the exchange sites on the resin in the H^+ form or washed with a strong NaCl brine to place all of the exchange sites in the Na^+ form. A solution of known concentration of an exchangeable ion (e.g., Ca^{2+}) can then be added until exchange is complete and the amount of exchange capacity can be measured, or in the acid case, the resin is titrated with a strong base. Determination of the capacity of an ion resin based on titration is illustrated in Example 11–15.

Exchange capacities for resins often are expressed in terms of grams $CaCO_3$ per cubic meter of resin (g/m^3) or gram equivalents per cubic meter (g eq/m^3). Conversion between these two units is accomplished using the following expression:

$$\frac{1\text{ eq}}{\text{m}^3} = \frac{(1\text{ eq})\left(50\text{ g CaCO}_3/\text{eq}\right)}{\text{m}^3} = 50\text{ g CaCO}_3/\text{m}^3 \quad (11\text{-}116)$$

Calculation of the required resin volume for an ion-exchange process is also illustrated in Example 11–15.



EXAMPLE 11–15 Determination of Ion-Exchange Capacity for a New Resin A column study was conducted to determine the capacity of a cation-exchange resin. In conducting the study, 0.1 kg of resin was washed with NaCl until the resin was in the R-Na form. The column was then washed with distilled water to remove the chloride ion (Cl^-) from the interstices of the resin. The resin was then titrated with a solution of calcium chloride ($CaCl_2$), and

the concentrations of chloride and calcium were measured at various throughput volumes. The measured concentrations of Cl^- and Ca^{2-} and the corresponding throughput volumes are as given below. Using the data given below, determine the exchange capacity of the resin and the mass and volume of a resin required to treat 4000 m^3 of water containing 18 mg/L of ammonium ion NH_4^+. Assume the density of the resin is 700 kg/m^3.

Throughput volume, L	Constituent, mg/L	
	Cl^-	Ca^{2+}
2	0	0
3	Trace	0
5	7	0
6	18	0
10	65	0
12	71	Trace
20	71	13
26	71	32
28	71	38
32	C_o = 71	C_o = 40

Solution

1. Prepare a plot of the normalized concentrations of Cl^- and Ca^{2+} as a function of the throughput volume. The required plot is given below.

2. Determine the exchange capacity. The exchange capacity (EC) of the resin in meq/kg is

$$EC = \frac{VC_o}{R}$$

where V = throughput volume between the Cl^- and Ca^{2+} breakthrough curves at $C/C_0 = 0.5$
C_{Ca} = calcium concentration in meq/L
R = amount of resin in kg

$$EC = \frac{(22.1\text{ L} + 7.5\text{ L})\left[\dfrac{(40\text{ mg/L})}{(20\text{ mg/meq})}\right]}{0.1\text{ kg of resin}} = 292\text{ meq/kg of resin}$$

3. Determine the mass and volume of resin required to treat 4000 m^3 of water containing 18 mg/L of ammonium ion NH_4^+.
   a. Determine the meq of NH_4^+.

$$NH_4^+, \text{meq/L} = \frac{(18\text{ mg/L as } NH_4^+)}{(18\text{ mg/meq})} = 1\text{ meq/L}$$

   b. The required exchange capacity is equal to

$$(1.0\text{ meq/L})(4000\text{ m}^3)(10^3\text{ L/m}^3) = 4 \times 10^6\text{ meq}$$

   c. The required mass of resin is

$$R_{mass}, \text{kg} = \frac{4 \times 10^6\text{ meq}}{(292\text{ meq/kg of resin})} = 13{,}700\text{ kg of resin}$$

   d. The required volume of resin is

$$R_{vol}, \text{m}^3 = \frac{13{,}700\text{ kg of resin}}{(700\text{ kg/m}^3)} = 19.6\text{ m}^3\text{ of resin}$$

Comment In practice, because of leakage and other operational and design limitations, the required volume of resin will usually be about 1.1 to 1.4 times that computed on the basis of exchange capacity. Also, the above computation is based on the assumption that the entire capacity of the resin is utilized.

Ion-Exchange Chemistry

The chemistry of the ion-exchange process may be represented by the following equilibrium expression for the reaction of constituent A on a cation-exchange resin and constituent B in solution.

$$nR^-A^+ + B^{+n} \leftrightarrow R_n^-B^{+n} + nA^+ \tag{11-117}$$

where R^- is the anionic group attached to an ion-exchange resin and A and B are cations in solution. The generalized form of the equilibrium expression for the above reaction is

$$\frac{[A^+]_S^n[R_n^-B^{+n}]_R}{[R^-A^+]_R^n[B^{+n}]_S} = K_{A^+ \rightarrow B^{+n}} \tag{11-118}$$

where $K_{A^+ \rightarrow B^{n+}}$ = selectivity coefficient
$[A^+]_S$ = concentration of A in solution
$[R^-A^+]_R$ = concentration A on the exchange resin

The reactions for the removal of sodium (Na^+) and calcium (Ca^{2+}) ions from water using a strong-acid synthetic cationic-exchange resin *R*, and the regeneration of the exhausted resins with hydrochloric acid (HCl) and sodium chloride (NaCl) are as follows:

Reaction:

$$R^-H^+ + Na^+ \rightarrow R^-Na^+ + H^+ \quad (11\text{–}119)$$

$$2R^-Na^+ + Ca^{2+} \rightarrow R_2^-Ca^{2+} + 2Na^+ \quad (11\text{–}120)$$

Regeneration:

$$R^-Na^+ + HCl \rightarrow R^-H^+ + NaCl \quad (11\text{–}121)$$

$$R_2^-Ca^{2+} + 2NaCl \rightarrow 2R^-Na^+ + CaCl_2 \quad (11\text{–}122)$$

The corresponding equilibrium expressions for sodium and calcium are as follows:

For sodium:

$$\frac{[H^+][R^-Na^-]}{[R^-H^+][Na^+]} = K_{H \rightarrow Na} \quad (11\text{–}123)$$

For calcium:

$$\frac{[Na^-]^2[R^-Ca^{2+}]}{[R^-Na^+]^2[Ca^{2+}]} = K_{Na \rightarrow Ca} \quad (11\text{–}124)$$

The selectivity coefficient depends primarily on the nature and valence of the ion, the type of resin and its saturation, and the ion concentration in wastewater and typically is valid over a narrow pH range. In fact, for a given series of similar ions, exchange resins have been found to exhibit an order of selectivity or affinity for the ions. Approximate selectivity coefficients for cationic and anionic resins are given in Tables 11–37 and 11–38, respectively. The use of the selectivity coefficients given in these tables is illustrated in Example 11–16.

For synthetic cationic and anionic exchange resins, typical series are

$$Li^- < H^+ < Na^+ < NH_4^- < K^- < Rb^- < Ag^+ \quad (11\text{–}125)$$

$$Mg^{2+} < Zn^{2+} < Co^{2+} < Cu^{2+} < Ca^{2+} < Sr^{2+} < Ba^{2+} \quad (11\text{–}126)$$

$$OH^- < F^- < HCO^- < CL^- < Br^- < NO_3^- < ClO_4^- \quad (11\text{–}127)$$

In practice, the selectivity coefficients are determined by measurement in the laboratory and are valid only for the conditions under which they were measured. At low concentrations, the value of the selectivity coefficient for the exchange of monovalent ions by divalent ions is, in general, larger than the exchange of monovalent ions by monovalent ions. This fact has, in many cases, limited the use of synthetic resins for the removal of certain substances in wastewater, such as ammonia in the form of the ammonium ion. There are, however, certain natural zeolites that favor NH_4^+ or Cu^{2+}.

Table 11–37
Approximate selectivity scale for cations on 8 percent cross-linked strong-acid ion-exchange resins[a]

Cation	Selectivity	Cation	Selectivity
Li^+	1.0	Co^{2+}	3.7
H^+	1.3	Cu^{2+}	3.8
Na^+	2.0	Cd^{2+}	3.9
NH_4^+	2.6	Be^{2+}	4.0
K^+	2.9	Mn^{2+}	4.1
Rb^+	3.2	Ni^{2+}	3.9
Cs^+	3.3	Ca^{2+}	5.2
Ag^+	8.5	Sr^{2+}	6.5
Mg^{2+}	3.3	Pb^{2+}	9.9
Zn^{2+}	3.5	Ba^{2+}	11.5

[a]Adapted from Bonner and Smith (1957); see also Slater (1991).

Table 11–38
Approximate selectivity scale for anions on strong-base ion-exchange resins[a]

Cation	Selectivity	Cation	Selectivity
HPO_4^{2-}	0.01	BrO_3^-	1.0
CO_3^{2-}	0.03	Cl^-	1.0
OH^- (Type I)	0.06	CN^-	1.3
F^-	0.1	NO_2^-	1.3
SO_4^{2-}	0.15	HSO_4^-	1.6
CH_3COO^-	0.2	Br^-	3.0
HCO_3^-	0.4	NO_3^-	3.0–4.0
OH (Type II)	0.5–0.65	I^-	18.0

[a]Adapted from Peterson (1953) and Bard (1966).

Anderson (1975) in a classic paper developed a method that can be used to evaluate the effectiveness of a proposed ion-exchange process using strong ionic resins. In the development proposed by Anderson, it is assumed that at 100 percent leakage, the effluent concentration of a constituent is equal to the influent concentration (i.e., equilibrium has been reached). The equilibrium condition can be assumed to be either the limiting operating exchange capacity of the resin or the capacity corresponding to the maximum regeneration level that can be attained. Using this assumption, Eq. (11–118) is converted from concentration units to units of equivalent fractions by making the following substitutions:

$$X_{A^+} = \frac{[A^+]_S}{C} \quad \text{and} \quad X_{B^+} = \frac{[B^+]_S}{C} \tag{11–128}$$

$$X_{A^+} + X_{B^+} = 1 \tag{11–129}$$

where $X_{A'}$ and $X_{B'}$ are the equivalent fractions of A and B in solution and C is the total cationic or anionic concentration in solution.

$$\bar{X}_{A'} = \frac{[\overline{R\ A^-}]_R}{\bar{C}} \quad \text{and} \quad X_{B'} = \frac{[\overline{R\ B^-}]_R}{\bar{C}} \tag{11-130}$$

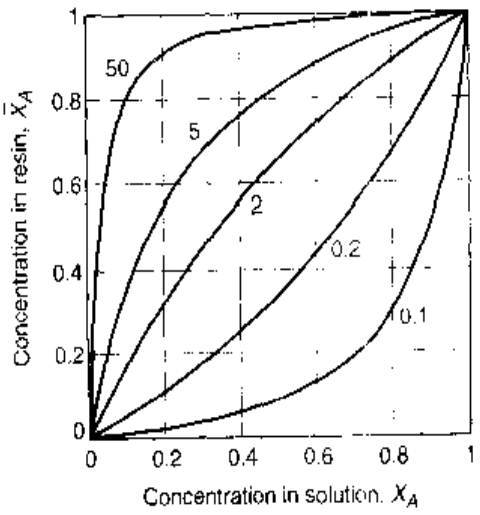
$$\bar{X}_{A'} + \bar{X}_{B'} = 1 \tag{11-131}$$

where $\bar{X}_A$ and $\bar{X}_B$ are the equivalent fractions of A and B in the resin (i.e., the total resin capacity in eq/L). Substituting the above terms into Eq. (11-118) and simplifying results in the following expression:

$$\frac{\bar{X}_{B'} X_{A'}}{\bar{X}_{A'} X_{B'}} = K_{A'\rightarrow B'} \tag{11-132}$$

Substituting for X_A and $\bar{X}_A$ in Eq. (11-132) results in

$$\frac{\bar{X}_{B'}}{1 - \bar{X}_{B'}} = [K_{A'\rightarrow B'}]\left[\frac{X_B}{1 - X_{B'}}\right] \tag{11-133}$$



It should be noted that Eq. (11-133) is only valid for exchanges between monovalent ions on fully ionized exchange resins. The distribution of a single monovalent ion A between the solution and the resin for different values of the selectivity coefficient is presented on Fig. 11–74. The distribution curves can be used to assess the effectiveness of a resin for the removal of a given ion, based on the selectivity coefficient.

The following three attributes of Eq. (11-133) were identified by Anderson (1975).

1. The term $\bar{X}_B/(1 - \bar{X}_B)$ corresponds to the state of the resin in an exchange column when the influent and effluent concentrations are the same.
2. The term $\bar{X}_B$ corresponds to the extent to which the resin can be converted to the B' form when the resin is in equilibrium with a solution of composition X_B.
3. The term $\bar{X}_B$ also corresponds to the maximum extent of regeneration that can be achieved with a regenerant composition of X_B.

Figure 11–74

Distribution curves for a single monovalent ion A between the solution and the resin for different values of the selectivity coefficient.

The corresponding equation for exchanges between monovalent and divalent ions on a fully ionized exchange resin is

$$\frac{\bar{X}_{B^{2+}}}{(1-\bar{X}_{B^{2+}})^2} = [K_{A^+ \rightarrow B^{2+}}]\left[\frac{\bar{C}}{C}\right]\frac{X_{B^{2+}}}{(1-X_{B^{2+}})^2} \tag{11–134}$$

The application of these equations is illustrated in Example 11–16.

Application of Ion Exchange

As noted previously, ion exchange has been used in wastewater applications for the removal of nitrogen, heavy metals, and total dissolved solids.

For Nitrogen Control. For nitrogen control, the ions typically removed from the waste stream are ammonium, NH_4^+, and nitrate, NO_3^-. The ion that the ammonium displaces varies with the nature of the solution used to regenerate the bed. Although both natural and synthetic ion-exchange resins are available, synthetic resins are used more widely because of their durability. Some natural resins (zeolites) have found application in the removal of ammonia from wastewater. Clinoptilolite, a naturally occurring zeolite, has proved to be one of the best natural exchange resins. In addition to having a greater affinity for ammonium ions than other ion-exchange materials, it is relatively inexpensive when compared to synthetic media. One of the novel features of this zeolite is the regeneration system employed. Upon exhaustion, the zeolite is regenerated with lime $Ca(OH)_2$, and the ammonium ion removed from the zeolite is converted to ammonia because of the high pH. A flow diagram for this process is shown on Fig. 11–75. The stripped liquid is collected in a storage tank for subsequent reuse. A problem that must be solved is the formation of calcium carbonate precipitates within the zeolite exchange bed and in the stripping tower and piping appurtenances. As indicated on Fig. 11–76, the zeolite bed is equipped with backwash facilities to remove the carbonate deposits that form within the filter.

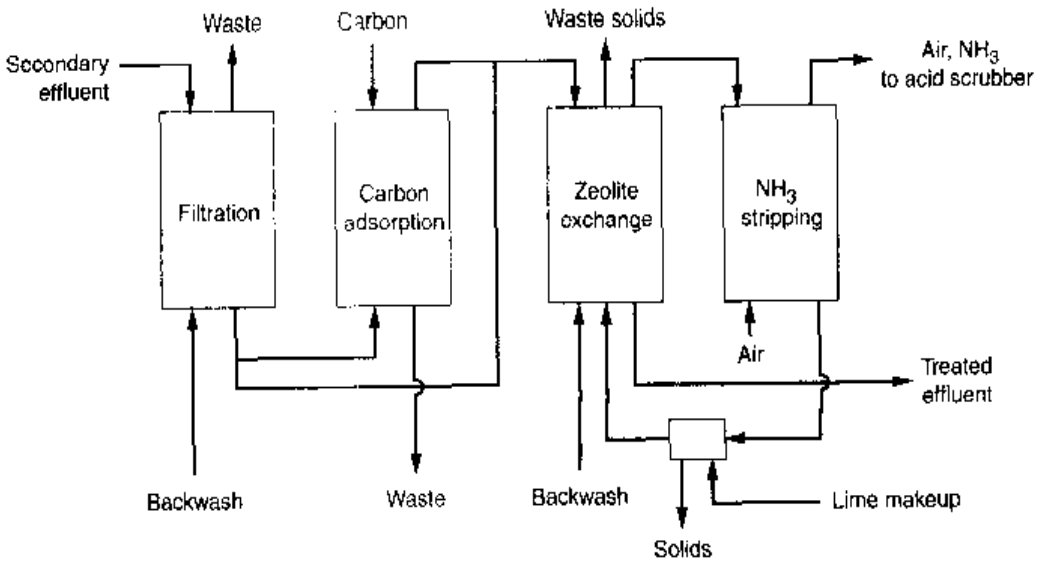


Figure 11–75
Typical flow diagram for the removal of ammonia by zeolite exchange. *Note:* The ammonia removed is removed in ammonia scrubber.

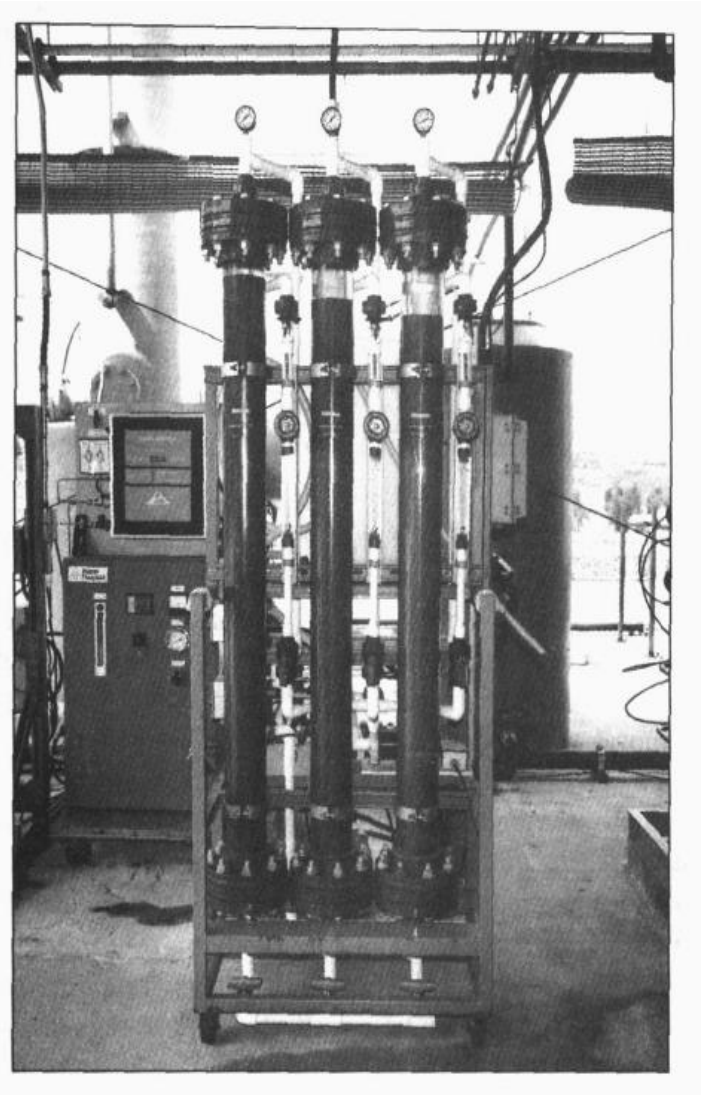

Figure 11-76

Typical ion-exchange test columns used to study the removal of nitrate from water that has been processed with reverse osmosis.

When using conventional synthetic ion-exchange resins for the removal of nitrate, two problems are encountered. First, while most resins have a greater affinity for nitrate over chloride or bicarbonate, they have a significantly lower affinity for nitrate as compared to sulfate, which limits the useful capacity of the resin for the removal of nitrate. The impact of the presence of sulfate on the nitrate removal capacity of conventional resins is illustrated in Example 11–16. Second, because of the lower affinity for nitrate over sulfate, a phenomenon known as *nitrate dumping* can occur. Nitrate dumping occurs when an ion-exchange column is operated past the nitrate breakthrough, at which point the sulfate in the feedwater will displace the nitrate on the resin, causing a release of nitrate. To overcome the problems associated with low affinity and nitrate breakthrough, new types of resins have been developed in which the affinities for nitrate and sulfate have been exchanged. When significant amounts of sulfate are present (i.e., typically greater than 25 percent of the total of the sum of the sulfate and nitrate expressed in meq/L), the use of nitrate-selective resins is advantageous. Because the performance of nitrate-selective resins will vary with the composition of the treated wastewater, pilot testing will usually be required (McGarvey et al., 1989; Dimotsis and McGarvey, 1995). Typical ion-exchange test columns used to study the removal of nitrate from water which has been processed with reverse osmosis are shown on Fig. 11–76.

EXAMPLE 11-16 Ion Exchange for the Removal of Nitrate without and with Sulfate Present in the Water Nitrate is to be removed from two different treated wastewaters with the compositions given below. For the purpose of illustration, assume a conventional ion-exchange resin will be used.

Wastewater A

Cation	Conc., mg/L	mg/meq	meq/L	Anion	Conc., mg/L	mg/meq	meq/L
Ca^{2+}	82.2	20.04	4.10	HCO_3^-	305.1	61.02	5.00
Mg^{2+}	17.9	12.15	1.47	SO_4^{2-}	0.00	48.03	0.00
Na^+	46.4	23.00	2.02	Cl^-	78.0	35.45	2.20
K^+	15.5	39.10	0.40	NO_3^-	50.0	62.01	0.91
		Σ cations	7.99			Σ anions	8.11

Wastewater B

Cation	Conc., mg/L	mg/meq	meq/L	Anion	Conc., mg/L	mg/meq	meq/L
Ca^{2+}	82.2	20.04	4.10	HCO_3^-	220	61.02	3.61
Mg^{2+}	17.9	12.15	1.47	SO_4^{2-}	79.2	48.03	1.65
Na^+	46.4	23.00	2.02	Cl^-	78.0	35.45	2.20
K^+	15.5	39.10	0.40	NO_3^-	50.0	62.01	0.81
		Σ cations	7.99			Σ anions	8.27

Determine the maximum amount of water that can be processed per liter of a strong-base anion-exchange resin with an exchange capacity of 2.0 eq/L.

Solution:
Wastewater A

1. Estimate the selectivity coefficient (see Table 11–38). To apply Eq. (11–133) the system must be reduced to two components. For this purpose, HCO_3^- and Cl^- are combined into a single component. Using a selectivity value of 4 for nitrate, the selectivity coefficient is estimated as follows:

$$K_{HCO_3^- \rightarrow NO_3^-} = \frac{4.0}{0.4} = 10.0$$

$$K_{Cl^- \rightarrow NO_3^-} = \frac{4.0}{1.0} = 4.0$$

$$K_{\{(HCO_3^-)(Cl^-)\} \rightarrow NO_3^-} = 7.0 \text{ (estimated)}$$

2. For the equilibrium condition ($C_e/C_o = 1.0$), estimate the nitrate equivalent fraction in solution.

$$X_{NO_3^-} = \frac{0.91}{8.11} = 0.112$$

3. Compute the equilibrium resin composition using Eq. (11–133).

$$\frac{\bar{X}_{B^+}}{1 - \bar{X}_{B^+}} = [K_{A^+ \rightarrow B^+}]\left[\frac{X_{B^+}}{1 - X_{B^+}}\right]$$

$$\frac{\bar{X}_{NO_3^-}}{1 - \bar{X}_{NO_3^-}} = 7.0\left[\frac{0.112}{1 - 0.112}\right]$$

$$\bar{X}_{NO_3^-} = 0.47$$

Thus, 47 percent of the exchange sites on the resin can be used for the removal of nitrate.

4. Determine the limiting operating capacity of the resin for the removal of nitrate.

Limiting operating capacity = (2 eq/L of resin)(0.47) = 0.94 eq/L of resin

5. Determine the volume of water that can be treated during a service cycle.

$$\text{Vol} = \frac{(\text{nitrate removal capacity of resin, eq/L of resin})}{(\text{nitrate in solution, eq/L of water})}$$

$$= \frac{(0.94 \text{ eq/L of resin})}{(0.91 \times 10^{-3} \text{ eq/L of water})} = 1033 \frac{\text{L of water}}{\text{L of resin}}$$

Solution: Wastewater B

1. Estimate the selectivity coefficient (see Table 11–38). To apply Eq. (11–134) the system must be reduced to two components. For this purpose, HCO_3^-, Cl^-, and NO_3^- are combined into a single monovalent component. The selectivity coefficient is estimated as follows:

$$K_{HCO_3^- \rightarrow SO_4^{2-}} = \frac{0.15}{0.4} = 0.4$$

$$K_{Cl^- \rightarrow SO_4^{2-}} = \frac{0.15}{1.0} = 0.15$$

$$K_{NO_3^- \rightarrow SO_4^{2-}} = \frac{0.15}{4.0} = 0.04$$

$$K_{[(NO_3^-)(HCO_3^-)(Cl^-)] \rightarrow SO_4^{2-}} = 0.2 \text{ (estimated)}$$

2. For the equilibrium condition ($C_e/C_o = 1.0$), estimate the sulfate equivalent fraction in solution.

$$X_{SO_4^{2-}} = \frac{1.65}{8.27} = 0.2$$

3. Compute the equilibrium resin composition using Eq. (11–134).

$$\frac{\bar{X}_{B^{2-}}}{(1 - \bar{X}_{B^{2-}})^2} = [K_{A^- \rightarrow B^{2-}}] \frac{\bar{C}}{C} \left[\frac{X_{B^{2-}}}{(1 - X_{B^{2-}})^2} \right]$$

$$\frac{\bar{X}_{SO_4^{2-}}}{(1 - \bar{X}_{SO_4^{2-}})^2} = 0.2 \frac{2}{0.00827} \left[\frac{0.2}{(1 - 0.2)^2} \right]$$

$$\bar{X}_{SO_4^{2-}} = 0.68$$

Thus, 68 percent of the exchange sites on the resin will be in the divalent form at equilibrium. The relative amount of NO_3^- can be estimated by assuming that the remaining 32 percent of the resin sites are in equilibrium with a solution of NO_3^-, HCO_3^-, and Cl^- with the same relative concentration as the feed.

The equivalent fraction of nitrate in the solution will then be

$$X_{NO_3^-} = \frac{0.81}{6.62} = 0.12$$

The selectivity coefficient for the monovalent system is estimated:

$$K_{HCO_3^- \rightarrow NO_3^-} = \frac{4.0}{0.4} = 10.0$$

$$K_{Cl^- \rightarrow NO_3^-} = \frac{4.0}{1.0} = 4.0$$

$$K_{[(HCO_3^-)(Cl^-)] \rightarrow NO_3^-} = 7.0 \text{ (estimated)}$$

Compute the equilibrium resin composition using Eq. (11–133).

$$\frac{\bar{X}'_{B^+}}{1 - \bar{X}'_{B^+}} = [K_{A^+ \rightarrow B^+}] \left[\frac{X'_{B^+}}{1 - X'_{B^+}} \right]$$

$$\frac{\bar{X}'_{NO_3^-}}{1 - \bar{X}'_{NO_3^-}} = 7.0 \left[\frac{0.12}{1 - 0.12} \right]$$

$$\bar{X}'_{NO_3^-} = 0.5$$

The fraction of the total resin capacity in the nitrate form is then computed.

$$\bar{X}_{NO_3^-} = (1 - \bar{X}_{SO_4^{2-}})(\bar{X}'_{NO_3^-}) = (0.32)(0.5) = 0.16$$

4. Determine the limiting operating capacity of the resin for the removal of nitrate.

   Limiting operating capacity = (2 eq/L of resin)(0.16) = 0.32 eq/L of resin

5. Determine the volume of water that can be treated during a service cycle.

$$\text{Vol} = \frac{(\text{nitrate removal capacity of resin, eq/L of resin})}{(\text{nitrate in solution, eq/L of water})}$$

$$= \frac{(0.32 \text{ eq/L of resin})}{(0.81 \times 10^{-3} \text{ eq/L of water})} = 395 \frac{\text{L of water}}{\text{L of resin}}$$

Comment As illustrated in this example, the ionic composition of the wastewater can have a significant effect on the amount of water that can be treated per unit volume of resin, especially where nitrate is to be removed. Because the sulfate is more than 25 percent of the sum of the sulfate and nitrate, the use of a nitrate-selective resin would be advantageous in this application. The approximate nature of these calculations also demonstrates the importance of conducting pilot-plant tests to establish actual throughput volumes.

Removal of Heavy Metals. Metal removal may be required as a pretreatment before discharge to a municipal sewer system. Because of the potential accumulation and toxicity of these metals, it is desirable to remove them from wastewater effluents before release to the environment. Ion exchange is one of the most common forms of treatment used for the removal of metals. Facilities and activities that may discharge wastewater containing high concentrations of metals include metal processing, electronics industries (semiconductors, printed circuit boards), metal plating and finishing, pharmaceuticals and laboratories, and vehicle service shops. High metal concentrations can also be found in leachate from landfills, and stormwater runoff.

Where industries produce effluents with widely fluctuating metal concentrations, flow equalization may be required to make ion exchange feasible, making process design difficult. The economic feasibility of using ion-exchange processes for metal removal greatly improves when the process is used for the removal and recovery of valuable metals. Because it is now possible to manufacture resins for specific applications, the use of resins that have a high selectivity for the desired metal(s) also improves the economics of ion exchange.

Materials used for the exchange of metals include zeolites, weak and strong anion and cation resins, chelating resins, and microbial and plant biomass. Biomass materials are generally more abundant and therefore less expensive when compared to other commercially available resins. Natural zeolites, clinoptilolite (selective for Cs) and chabazite (mixed metals background Cr, Ni, Cu, Zn, Cd, Pb) (Ouki and Kavannagh 1999), have been used to treat wastewater with mixed metal backgrounds. Chelating resins, such as aminophosphonic and iminodiacetic resins, have been manufactured to have a high selectivity for specific metals, such as Cu, Ni, Cd, and Zn.

Ion-exchange processes are highly pH-dependent. Solution pH has a significant impact on the metal species present and the interaction between exchanging ions and

the resin. Most metals bind better at higher pH, due to less competition from protons for adsorption sites. Operating and wastewater conditions determine selectivity of resin, pH, temperature, other ionic species, and chemical background. The presence of oxidants, particles, solvents, and polymers may affect the performance of ion-exchange resins. The quantity and quality of regenerate produced and subsequently requiring management must also be considered.

Removal of Total Dissolved Solids. For the reduction of the total dissolved solids, both anionic- and cationic-exchange resins must be used (see Fig. 11–77). The wastewater is first passed through a cation exchanger where the positively charged ions are replaced by hydrogen ions. The cation-exchanger effluent is then passed over an anionic-exchange resin where the anions are replaced by hydroxide ions. Thus, the dissolved solids are replaced by hydrogen and hydroxide ions that react to form water molecules.

Total dissolved solids removal can take place in separate exchange columns arranged in series, or both resins can be mixed in a single reactor. Wastewater application rates range from 0.20 to 0.40 $m^3/m^2 \cdot min$ (5 to 10 $gal/ft^2 \cdot min$). Typical bed depths are 0.75 to 2.0 m (2.5 to 6.5 ft). In reuse applications, treatment of a portion of the wastewater by ion exchange, followed by blending with wastewater not treated by ion exchange, would possibly reduce the dissolved solids to acceptable levels. In some situations, it appears that ion exchange may be as competitive, if not more so, with reverse osmosis.

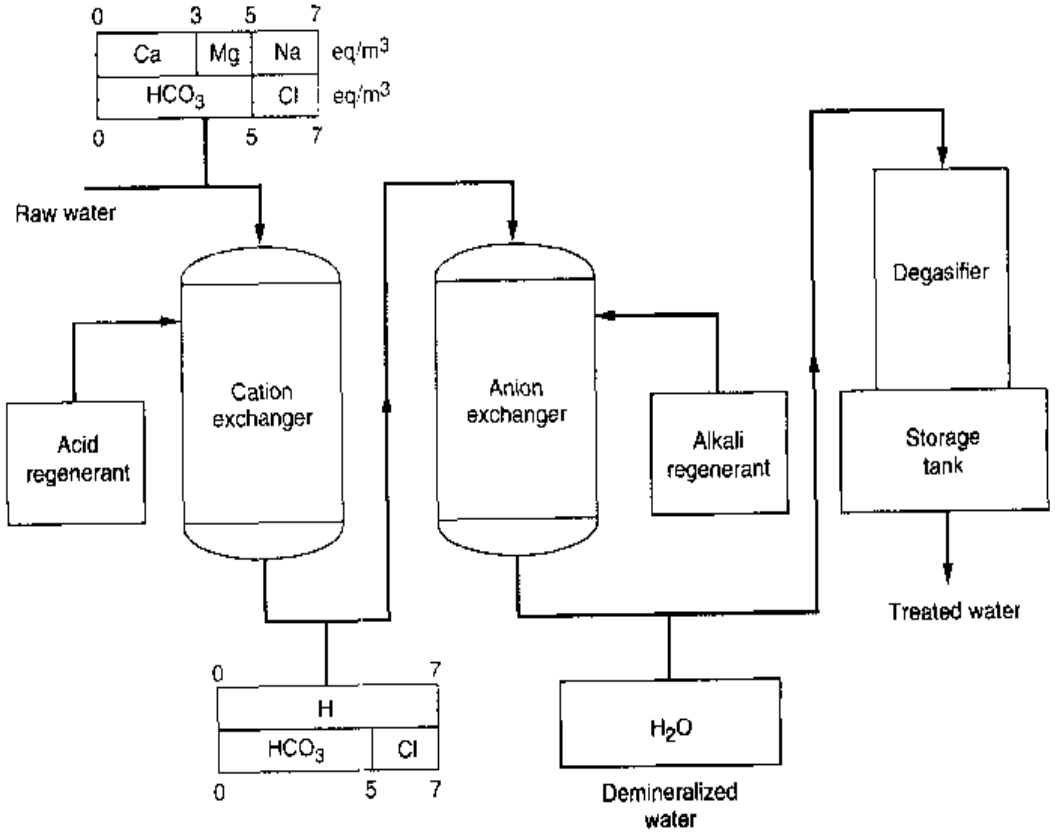

Figure 11–77

Typical flow diagram for the removal of hardness and for the complete demineralization of water using ion-exchange resins.

Operational Considerations

To make ion exchange economical for advanced wastewater treatment, it would be desirable to use regenerants and restorants that would remove both the inorganic anions and the organic material from the spent resin. Chemical and physical restorants found to be successful in the removal of organic material from resins include sodium hydroxide, hydrochloric acid, methanol, and bentonite. To date, ion exchange has had limited application because of the extensive pretreatment required, concerns about the life of the ion-exchange resins, and the complex regeneration system required.

High concentrations of influent TSS can plug the ion-exchange beds, causing high headlosses and inefficient operation. Resin binding can be caused by residual organics found in biological treatment effluents. Some form of chemical treatment and clarification is required before ion-exchange demineralization. This problem has been solved partially by prefiltering the wastewater or by using scavenger exchange resins before application to the exchange column.

11-10 ADVANCED OXIDATION PROCESSES

Advanced oxidation processes (AOPs) are used to oxidize complex organic constituents found in wastewater that are difficult to degrade biologically into simpler end products. When chemical oxidation is used, it may not be necessary to oxidize completely a given compound or group of compounds. In many cases, partial oxidation is sufficient to render specific compounds more amenable to subsequent biological treatment or to reduce their toxicity. The oxidation of specific compounds may be characterized by the extent of degradation of the final oxidation products as follows (Rice, 1996):

1. *Primary degradation.* A structural change in the parent compound.
2. *Acceptable degradation (defusing).* A structural change in the parent compound to the extent that toxicity is reduced.
3. *Ultimate degradation (mineralization).* Conversion of organic carbon to inorganic CO_2.
4. *Unacceptable degradation (fusing).* A structural change in the parent compound resulting in increased toxicity.

Theory of Advanced Oxidation

Advanced oxidation processes typically involve the generation and use of the hydroxyl free radical ($HO^{\bullet}$) as a strong oxidant to destroy compounds that cannot be oxidized by conventional oxidants such as oxygen, ozone, and chlorine. The relative oxidizing power of the hydroxyl radical, along with other common oxidants, is summarized in Table 11–39. As shown, with the exception of fluorine, the hydroxyl radical is one of the most active oxidants known. The hydroxyl radical reacts with the dissolved constituents, initiating a series of oxidation reactions until the constituents are completely mineralized. Nonselective in their mode of attack and able to operate at normal temperature and pressures, hydroxyl radicals are capable of oxidizing almost all reduced materials present without restriction to specific classes or groups of compounds, as compared to other oxidants.

Advanced oxidation processes differ from the other treatment processes discussed (such as ion exchange or stripping) because wastewater compounds are degraded rather

Table 11–39
Comparison of oxidizing potential of various oxidizing agents[a]

Oxidizing agent	Electrochemical oxidation potential (EOP), V	EOP relative to chlorine
Fluorine	3.06	2.25
Hydroxyl radical	2.80	2.05
Oxygen (atomic)	2.42	1.78
Ozone	2.08	1.52
Hydrogen peroxide	1.78	1.30

than concentrated or transferred into a different phase. Because secondary waste materials are not generated, there is no need to dispose of or regenerate materials. Additional details on AOPs may be found in Singer and Reckhow (1999).

Technologies Used to Produce Hydroxyl Radicals (HO•)

At the present time, a variety of technologies are available to produce HO• in the aqueous phase. The various technologies are summarized in Table 11–40, according to

whether ozone is used in the reaction. Of the technologies reported in Table 11–40, only ozone/UV, ozone/hydrogen peroxide, ozone/UV/hydrogen peroxide, and hydrogen peroxide/UV are being used on a commercial scale (Rice, 1996).

Ozone/UV. Production of the free radical HO$^{\bullet}$ with UV light can be illustrated by the following reactions for the photolysis of ozone (Glaze et al., 1987; Glaze and Kang, 1990):

$$O_3 + \text{UV (or } h\nu, \lambda < 310 \text{ nm}) \rightarrow O_2 + O(^1D) \quad (11\text{–}135)$$

$$O(^1D) + H_2O \rightarrow HO^{\bullet} + HO^{\bullet} \text{ (in wet air)} \quad (11\text{–}136)$$

$$O(^1D) + H_2O \rightarrow HO^{\bullet} + HO^{\bullet} \rightarrow H_2O_2 \text{ (in water)} \quad (11\text{–}137)$$

where O_3 = ozone
UV = ultraviolet radiation (or $h\nu$ = energy)
O_2 = oxygen
$O(^1D)$ = excited oxygen atom. The symbol (^1D) is a spectroscopic notation used to specify the atomic and molecular configuration (also known as a singlet oxygen)
HO$^{\bullet}$ = hydroxyl radical. The dot ($^{\bullet}$) that appears next to the hydroxyl and other radicals is used to denote the fact that these species have an unpaired electron.

As shown in Eq. (11–127), the photolysis of ozone in wet air results in the formation of hydroxyl radicals. In water, the photolysis of ozone leads to the formation of hydrogen peroxide [see Eq. (11–128)]. Because the photolysis of ozone in water leads to the formation of hydrogen peroxide, which is subsequently photolyzed to form hydroxyl radicals, the use of ozone in this application is generally not cost-effective. In air, the ozone/UV process can degrade compounds through direct ozonation, photolysis, or reaction with the hydroxyl radical. The ozone/UV process is more effective when the compounds of interest can be degraded through the absorption of the UV irradiation as well as through the reaction with the hydroxyl radicals. A schematic flow diagram of the processes is illustrated on Fig. 11–78.

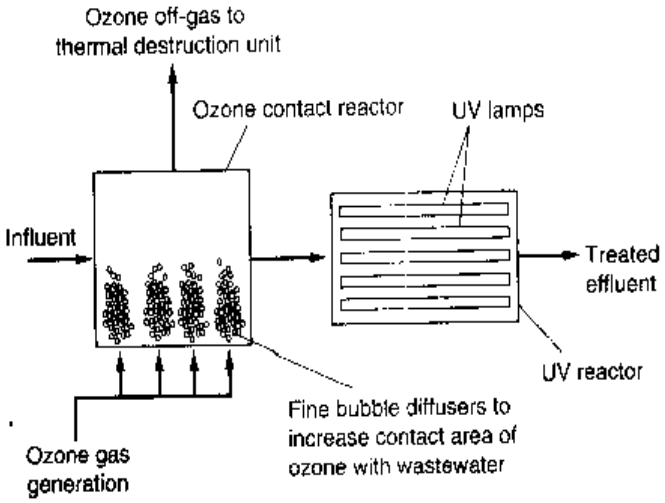

Figure 11–78
Schematic representation of advanced oxidation process involving the use of ozone and UV radiation.

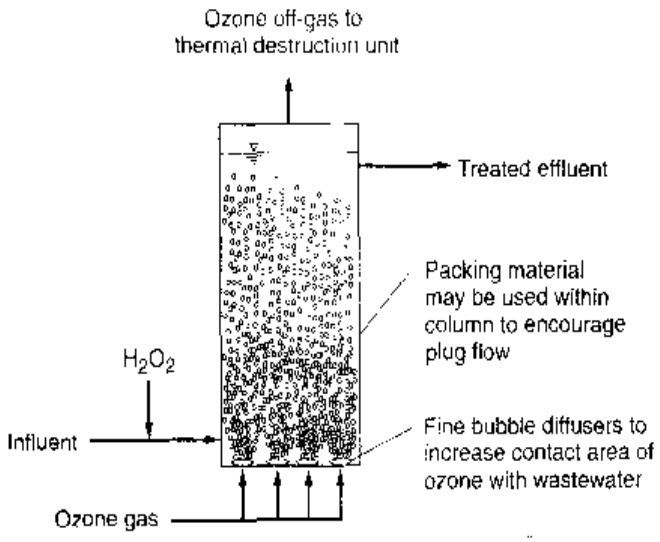

Figure 11–79
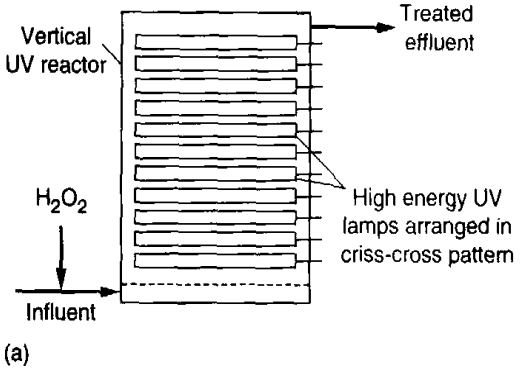
Schematic representation of advanced oxidation process involving the use of ozone and hydrogen peroxide.

Ozone/Hydrogen Peroxide. For compounds that do not adsorb UV, AOPs involving ozone/H_2O_2 may be more effective. A schematic flow diagram of the processes is illustrated on Fig. 11–79. Compounds in water such as trichloroethylene (TCE) and perchloroethylene (PCE) have been reduced significantly with AOPs using hydrogen peroxide and ozone to generate HO$^\bullet$ (Karimi et al., 1997). The overall reaction for the production of hydroxyl radicals using hydrogen peroxide and ozone is as follows:

$$H_2O_2 + 2O_3 \rightarrow HO^\bullet + HO^\bullet + 3O_2 \qquad (11\text{–}138)$$

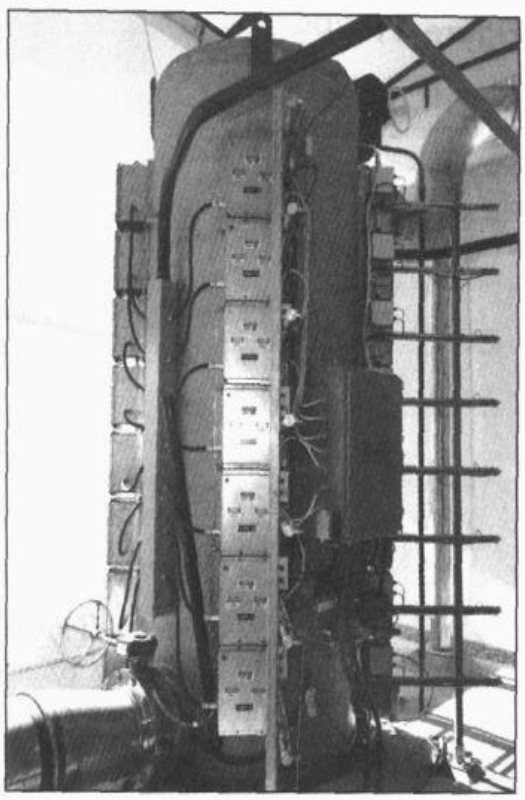
Hydrogen Peroxide/UV. Hydroxyl radicals are also formed when water containing H_2O_2 is exposed to UV light (200 to 280 nm). The following reaction can be used to describe the photolysis of H_2O_2:

$$H_2O_2 + \text{UV (or } h\nu,\ \lambda \approx 200\text{–}280 \text{ nm}) \rightarrow HO^\bullet + HO^\bullet \qquad (11\text{–}139)$$



In some cases the use of the hydrogen peroxide/UV process has not been feasible because H_2O_2 has a small molar extinction coefficient, requiring high concentrations of H_2O_2 and not using the UV energy efficiently. A schematic flow diagram and a typical installation of the hydrogen peroxide/UV process is shown on Fig. 11–80.

Most recently, the hydrogen peroxide/UV process has been applied to the oxidation of trace constituents found in treated water. The process has been studied for the removal of N-Nitrosodimethylamine (NDMA) and other compounds of concern in treated wastewater including (1) sex and steroidal hormones, (2) human prescription and nonprescription drugs, (3) veterinary and human antibiotics, and (4) industrial and household wastewater products (see Table 2–20 in Chap. 2). At the relatively low concentration range of these compounds encountered in treated water (typically in the μg/L range), their oxidation appears to follow first-order kinetics. The electrical energy required for their oxidation is expressed in EE/O units, defined as the electrical energy input per unit volume per log order of reduction (Bolton et al., 1999). In equation form, the EE/O is given by



$$EE/O = \frac{EE_f}{V[\log(C_i/C_f)]} \qquad (11\text{–}140)$$

Figure 11-80

Hydrogen peroxide and UV radiation advanced oxidation process: (a) schematic flow diagram. The hydrogen peroxide feed system and storage container are placed in a contained area and (b) photograph of typical vertical-flow UV reactor used to treat a flowrate of about 4000 m^3/d. Fifteen high-energy UV lamps (20 kW each) are employed in the reactor.

(a)

(b)

where EE/O = electrical energy input per log reduction, kWh/m^3·log order of reduction
EE_i = electrical energy input, kWh
V = volume of liquid treated, m^3
C_i = initial concentration, ng
C_f = final concentration, ng

Based on currently available technology (2001), the required EEO value for a one-log order of reduction (i.e., 100 to 10) of NDMA is on the order of 21 to 265 kWh/10^3 m^3·log order (0.08 to 1.0 kWh/10^3 gal·log order) with a 5 to 6 mg/L dose of H_2O_2, although in some cases it did not appear that the peroxide was necessary (Soroushian et al., 2001). The required EE/O value will vary significantly with the characteristics of the treated wastewater.

Other Processes. Other reactions that yield HO• include the reactions of H_2O_2 and UV with Fenton's reagent and the adsorption of UV by semiconductor metal oxides such as TiO_2 suspended in water, which acts as a catalyst. Still others are currently under development.

Applications

Based on numerous studies, it has been found that combined AOPs are more effective than any of the individual agents (e.g., ozone, UV, hydrogen peroxide). AOPs are usually applied to low COD wastewaters because of the cost of ozone and/or H_2O_2 required

to generate the hydroxyl radicals. Material that was previously resistant to degradation may be transformed into compounds that will require further biological treatment. The application of AOPs for the disinfection of treated wastewater and for the treatment of refractory organic compounds is considered below. Some operational problems are also identified.

Disinfection. Because it was recognized that free radicals generated from ozone were more powerful oxidants than ozone alone, it was reasoned that the hydroxyl free radicals could be used effectively to oxidize microorganisms and refractory organic materials in water and wastewater. Unfortunately, because the half-life of the hydroxyl free radicals is short, on the order of microseconds, it is not possible to develop high concentrations. With extremely low concentrations, the required detention times for microorganism disinfection, based on the CT concept (see Chap 12), are prohibitive.

Oxidation of Refractory Organic Compounds. For the reasons cited above hydroxyl radicals are not used for conventional disinfection; instead they are used more commonly for the oxidation of trace amounts of refractory organic compounds found in highly treated effluents. The hydroxyl radicals, once generated, can attack organic molecules by radical addition, hydrogen abstraction, electron transfer, and radical combination (SES, 1994).

1. *By radical addition.* The addition of the hydroxyl radical to an unsaturated aliphatic or aromatic organic compound (e.g., C_6H_6) results in the production of a radical organic compound that can be oxidized further by compounds such as oxygen or ferrous iron to produce stable oxidized end products. In the following reactions the abbreviation R is used to denote the reacting organic compound.

$$R + HO^{\bullet} \rightarrow ROH \qquad (11\text{-}141)$$

2. *By hydrogen abstraction.* The hydroxyl radical can be used to remove a hydrogen atom from organic compounds. The removal of a hydrogen atom results in the formation of a radical organic compound, initiating a chain reaction where the radical organic compound reacts with oxygen, producing a peroxyl radical, which can react with another organic compound, and so on.

$$R + HO^{\bullet} \rightarrow R^{\bullet} + H_2O \qquad (11\text{-}142)$$

3. *By electron transfer.* Electron transfer results in the formation of ions of a higher valence. Oxidation of a monovalent negative ion will result in the formation of an atom or a free radical.

$$R^n + HO^{\bullet} \rightarrow R^{n-1} + OH \qquad (11\text{-}143)$$

4. *By radical combination.* Two radicals can combine to form a stable product.

$$HO^{\bullet} + HO^{\bullet} \rightarrow H_2O_2 \qquad (11\text{-}144)$$

In general, the reaction of hydroxyl radicals with organic compounds, at completion, will produce water, carbon dioxide, and salts; this process is also known as minera.

Operational Problems

High concentrations of carbonate and bicarbonate in some wastewater can react with HO• and reduce the efficiency of advanced oxidation treatment processes. Other factors can also affect the treatment process, such as suspended material, pH, type and nature of the residual TOC, and other wastewater constituents. *Because the chemistry of the wastewater matrix is different for each wastewater, pilot testing is almost always required to test the technical feasibility, to obtain usable design data and information, and to obtain operating experience with a specific AOP.*

11–11 DISTILLATION

Distillation is a unit operation in which the components of a liquid solution are separated by vaporization and condensation. Along with reverse osmosis, distillation can be used to control the buildup of salts in critical reuse applications. Because distillation is expensive, its application is generally limited to applications such as (1) a high degree of treatment is required, (2) contaminants cannot be removed by other methods, and (3) inexpensive heat is available. The purpose of this section is to introduce the basic concepts involved in distillation. As the use of distillation for wastewater reclamation is a recent development, the current literature must be consulted for the results of ongoing studies and more recent applications.

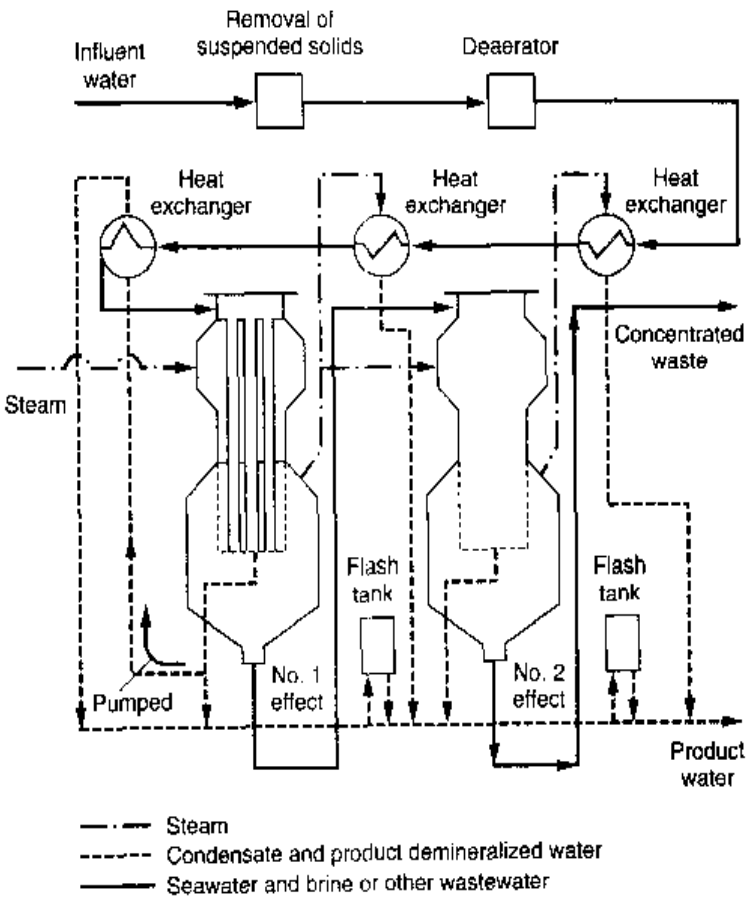
Distillation Processes

Over the past 20 years, a variety of distillation processes, employing a variety of evaporator types and methods of using and transferring heat energy, have been evaluated or used. The principal distillation processes are (1) boiling with submerged-tube heating surface, (2) boiling with long-tube vertical evaporator, (3) flash evaporation, (4) forced circulation with vapor compression, (5) solar evaporation, (6) rotating-surface evaporation, (7) wiped-surface evaporation, (8) vapor reheating process, (9) direct heat transfer using an immiscible liquid, and (10) condensing-vapor-heat transfer by vapor other than steam. Of these types of distillation processes, multistage flash evaporation, multiple-effect evaporation, and the vapor-compression distillation appear most feasible for the reclamation of municipal wastewater.

Multiple-Effect Evaporation. In multiple-effect evaporation several evaporators (boilers) are arranged in series, each operating at a lower pressure than the preceding one. In a three-stage, vertical-tube evaporator (see Fig. 11–81), after the influent water is pretreated, it enters the heat exchanger in the last stage (No. 2) and progressively warms as it goes through the heat exchangers in the other effects (i.e., stages). As the water moves through the heat exchangers, it condenses the water vapor emanating from the various effects. When the progressively warmed influent water reaches the first stage, it flows down the internal periphery of vertical tubes in a thin film, which is heated by steam. The wastewater feed to the second effect comes from the bottom of the first effect. If entrainment is kept low, almost all of the nonvolatile contaminants can be removed in a single evaporation step. Volatile contaminants, such as ammonia gas and low-molecular-weight organic acids, may be removed in a preliminary evaporation step, but if their concentration is so small that their presence in the final product is not objectionable, this step with its added cost can be eliminated.

Figure 11–81

Schematic of multiple-effect evaporation distillation process. *(Adapted from Liu and Liptak, 2000.)*



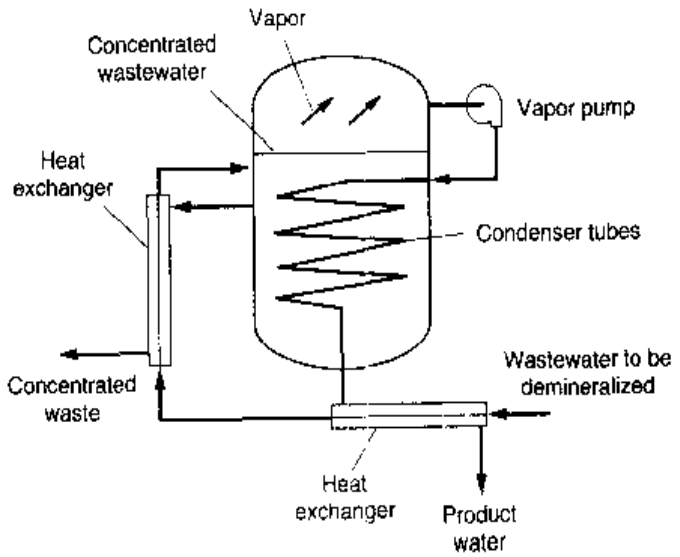


Figure 11–82

Schematic of multistage flash evaporation distillation process.

Multistage Flash Evaporation. Multistage flash evaporation systems have been used commercially in desalination for many years. In the multistage flash process (see Fig. 11–82), the influent wastewater is first treated to remove TSS and deaerated before being pumped through heat transfer units in the several stages of the distillation system, each of which is maintained at a lower pressure. Vapor generation or boiling caused by reduction in pressure is known as *flashing*. As the water enters each stage through a pressure-reducing nozzle, a portion of the water is flashed to form a vapor. In

turn, the flashed water vapor condenses on the outside of the condenser tubes and is collected in trays (see Fig. 11–82). As the vapor condenses, its latent heat is used to preheat the wastewater that is being returned to the main heater, where it will receive additional heat before being introduced to the first flashing stage. When the concentrated wastewater reaches the lowest-pressure stage, it is pumped out. Thermodynamically, multistage flash evaporation is less efficient than ordinary evaporation. However, by combining a number of stages in a single reactor, external piping is eliminated and construction costs are reduced.

Vapor-Compression Distillation. In the vapor-compression process an increase in pressure of the vapor is used to establish the temperature difference for the transfer of heat. The basic schematic of a vapor-compression distillation unit is shown on Fig. 11–83. After initial heating of the wastewater, the vapor pump is operated so that the vapor under higher pressure can condense in the condenser tubes, at the same time causing the release of an equivalent amount of vapor from the concentrated solution. Heat exchangers can conserve heat from both the condensate and the waste brine. The only energy input required during operation is the mechanical energy for the vapor pump. Hot concentrated wastewater must be discharged at intervals to prevent the buildup of excessive concentrations of salt in the boiler.

Performance Expectations in Reclamation Applications

The theoretical thermodynamic minimum energy required to raise the temperature of wastewater and to provide the latent heat of vaporization is about 2280 kJ/kg. Unfortunately, because of the many irreversibilities in an actual distillation process, the thermodynamic minimum energy requirements are of little practical relevance in the practical evaluation of distillation processes. Typically, about 1.25 to 1.35 times the latent heat of vaporization will be required.

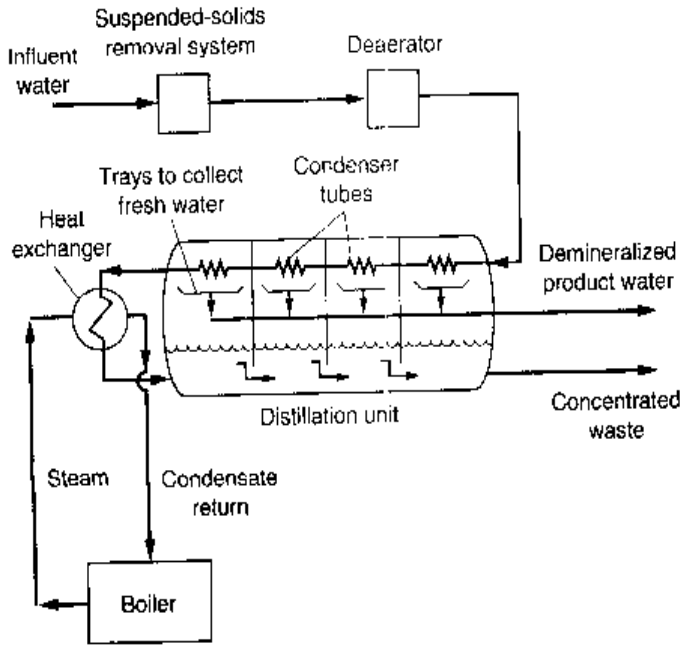

Figure 11–83
Schematic of vapor-compression distillation process. *(Adapted from Liu and Liptak, 2000.)*

The principal issues with the application of the distillation processes for wastewater reclamation are the carry-over of volatile constituents found in treated wastewater and the degree of subsequent cooling and treatment that may be required to renovate the distilled water. Typical water-quality performance data for a multiple-effect distillation process have been reported for a pilot-scale unit by Rose et al. (1999).

Operating Problems

The most common operating problems encountered include scaling and corrosion. Due to temperature increases, inorganic salts come out of solution and precipitate on the inside walls of pipes and equipment. The control of scaling due to calcium carbonate, calcium sulfate, and magnesium hydroxide is one of the most important design and operational considerations in distillation desalination processes. Controlling the pH minimizes carbonate and hydroxide scales. Most inorganic solutions are corrosive. Cupronickel alloys are used most commonly in seawater desalination. Other metals that are used include aluminum, titanium, and monel.

Disposal of Concentrated Waste

All distillation processes reject part of the influent wastewater. Hence, all of these processes have concentrated wastewater disposal problems. The permissible maximum concentration in the wastewater depends on the solubility, corrosion, and vapor pressure characteristics of the wastewater. Therefore, the waste concentration is an important consideration in process optimization. Disposal of concentrated wastewater brines is essentially the same problem encountered with the membrane process discussed in Section 11–6.

PROBLEMS AND DISCUSSION TOPICS

11–1 The following sieve analysis results were obtained for four different stock sands.

U.S. sieve size designation[a]	Size of opening, mm	Cumulative weight passing, %			
		A	B	C	D
140	0.105	0.4	1.5	0.1	5.0
100	0.149	1.5	4.1	0.8	11.1
70	0.210	4.0	10.0	2.5	20.0
50	0.297	9.5	21.0	8.2	32.0
40	0.420	18.5	40.6	18.5	49.5
30	0.590	31.0	61.0	32.0	62.3
20	0.840	49.0	78.3	58.1	78.3
16	1.190	63.2	90.0	76.3	88.5
12	1.680	82.8	96.0	90.0	94.4
8	2.380	89.0	99.0	96.7	97.8
6	3.360	98.0	99.9	99.0	99.0
4	4.760	100.0	100.0	100.0	100.0

[a]Note: sieve size number 18 has an opening size of 1.0 mm.

a. For sand sample A, B, C, or D (to be selected by instructor) determine the geometric mean size, the geometric standard deviation, the effective size, and the uniformity coefficient for the stock sand.
b. It is desired to produce from the stock sand a filter sand with an effective size of 0.45 mm and a uniformity coefficient of 1.6. Estimate the amount of stock sand needed to obtain one ton of filter sand.
c. What U.S. standard sieve size should be used to eliminate the excess coarse material?
d. If the sand remaining after sieving in part (c) above is placed in a filter, what backwash rise rate would be needed to eliminate the excess fine material?
e. What depth of sieved material would have to be placed in the filter to produce 600 mm of usable filter sand?
f. On log-probability paper, plot the size distribution of the modified sand. Check against the required distribution and sizes.
g. Determine the headloss through 600 mm of the filter sand specified in part (b) for a filtration rate of 160 L/m^2·min. Assume the sand is stratified and that the maximum and minimum sand sizes are 1.68 (sieve size 12) and 0.297 mm (sieve size 12), respectively. Assume also that T = 20°C, α for all layers = 0.4, and $\phi = 0.75$.

An excellent discussion of the procedures involved in developing a usable filter sand from a stock filter sand may be found in Fair et al. (1968).

11-2 Using the equations developed by Fair and Hatch, Kozeny, and Rose, compare the headloss through a 600-mm sand bed. Assume that the sand bed is composed of spherical unisized sand with a diameter of 0.55 mm, the porosity of the sand is 0.40, and the filtration velocity is 240 L/m^2·min (5 gal/ft^2·min). The temperature is 18°C.

11-3 Using the equation developed by Rose, determine the headloss through a 750-mm sand bed for a filtration rate of 240 L/m^2·mm. Assume that the sand bed is composed of spherical unisized sand with a diameter of 0.40, 0.45, 0.5, and 0.6 mm (size to be selected by instructor) and a porosity of 0.40. The kinematic viscosity is equal to 1.306×10^{-6} m^2/s.

11-4 Solve Problem 11-3 assuming the bed is stratified. Assume that the given sand sizes correspond to the effective size (d_{10}) and that the uniformity coefficient for all of the sand sizes is equal to 1.5.

11-5 If a 0.3-m layer of uniform anthracite is placed on top of the sand bed in Prob. 11-3, determine the ratio of the headloss through the anthracite to that of the sand. Assume that the grain-size diameter of the anthracite is 2.0 mm and porosity is 0.50. Will intermixing occur?

11-6 Given the particle size distribution A, B, C, or D (to be selected by instructor), determine the effective size (d_{10}) and uniformity coefficient UC, and clean water headloss through a stratified bed 600 mm deep. If a layer of anthracite is to be added over 600 mm of sand, determine the effective size required to minimize intermixing.

	Percent of sand retained			
Sieve number	**A**	**B**	**C**	**D**
6–8	2	0	1	0.1
8–10	8	0.1	2	0.7
10–14	10	0.5	4	1.2

(continued)

(*Continued*)

Sieve number	Percent of sand retained			
	A	B	C	D
14–20	30	7.4	13	10
20–30	26	32	20	24
30–40	14	30	20	29
40–60	8	25	23	25
Pan	2	5	17	10

11-7 For a given filtration operation it has been found that straining is the operative particulate-matter-removal mechanism and that the change in concentration with distance can be approximated with a first-order equation ($dC/dx = -rC$). If the initial concentration of particulate matter is 10 mg/L, the removal-rate constant is equal to 2.0 cm ^{1}, and the filtration velocity is equal to 100 L/m^2·min, determine the amount of material arrested within the filter in the layer between 3 and 6 cm over a 1.0-h period. Express your answer in mg/cm·m^2. Estimate the headloss in the layer at the end of 1.0 h.

11-8 The data in the following table were obtained from a pilot-plant study on the filtration of settled secondary effluent from an activated-sludge treatment process. Using these data, estimate the length of run that is possible with and without the addition of polymer if the maximum allowable headloss is 3 m, the filtration rate is 150 L/m^2·min, and the influent suspended-solids concentration is 15 mg/L. Uniform sand with a diameter of 0.55 mm and a depth of 600 mm was used in the pilot filters.

Depth, cm	Concentration ratio C/C_o	
	With polymer addition	Without polymer addition
0	1.00	1.00
4	0.65	0.70
8	0.26	0.52
12	0.20	0.46
16	0.16	0.42
20	0.15	0.40
24	0.13	0.39
28	0.12	0.38
32	0.12	0.38
36	0.12	0.38
40	0.12	0.38
44	0.12	0.38
48	0.12	0.38
52	0.12	0.38
56	0.12	0.38
60	0.12	0.38

11-9 Gravity filters are to be used to treat 24,000 m^3/d of settled effluent at a filtration rate of 200 $L/m^2 \cdot min$ (5 $gal/ft^2 \cdot min$). The filtration rate with one filter taken out of service for backwashing is not to exceed 240 $L/m^2 \cdot min$ (6 $gal/ft^2 \cdot min$). Determine the number of units and the area of each unit to satisfy these conditions. If each filter is backwashed for 30 min every 24 h at a wash rate of 960 $L/m^2 \cdot min$ (24 $gal/ft^2 \cdot min$), determine the percentage of filter output used for washing if the filter is out of operation for a total of 30 min/d. What would be the total percentage of filter output used for backwashing if a surface washing system that requires 40 $L/m^2 \cdot min$ (1 $gal/ft^2 \cdot min$) of filtered effluent is to be installed?

11-10 Four different waters are to be desalinized by reverse osmosis using a thin-film composite membrane. For water A, B, C, or D (water to be selected by instructor), determine the required membrane area, the rejection rate, and the concentration of the concentrate stream.

		Water			
Item	**Unit**	**A**	**B**	**C**	**D**
Flowrate	m^3/d	4000	5500	20,000	10,000
Influent TDS	g/m^3	2850	3200	2000	2700
Effluent TDS	g/m^3	200	500	400	225
Flux rate coefficient k_w	m/s	1.5×10^{-6}	1.5×10^{-6}	1.5×10^{-6}	1.5×10^{-6}
Mass transfer rate coefficient, k_i	m/s	1.8×10^{-6}	1.8×10^{-6}	1.8×10^{-6}	1.8×10^{-6}
Net operating pressure	kPa	2750	2500	2800	3000
Recovery	%	88	90	89	86

11-11 Using the data given below, determine the recovery and rejection rates for one of the following reverse osmosis units (unit to be selected by instructor).

		Reverse osmosis unit			
Item	**Unit**	**A**	**B**	**C**	**D**
Flowrate	m^3/d	25,000	50,000	20,000	10,000
Concentrate flowrate	m^3/d	2500	4800	2200	850
Effluent TDS	g/m^3	65	88	125	175
Concentrate	g/m^3	1500	2500	1850	2850

11-12 Using the data given below, determine the flux rate coefficient and the mass transfer rate coefficient.

		Reverse osmosis unit			
Item	**Unit**	**A**	**B**	**C**	**D**
Flowrate	m^3/d	4000	5500	20,000	10,000
Influent TDS	g/m^3	250	3300	5300	2700
Effluent TDS	g/m^3	200	500	400	225
Net operating pressure	kPa	2750	2500	2800	3000
Recovery	%	88	90	89	86

11-13 Estimate the SDI for the following filtered wastewater samples. If the water is to be treated with reverse osmosis will additional treatment be required?

Test run time, min	Volume filtered, mL			
	A	B	C	D
2		600	400	500
5		300	350	500
10	100	150	0	
20	0	100	0	

11-14 Determine the cost (based on the current price of electricity) to treat a flow of 2500 m^3/d with a TDS concentration of 1300 g/m^3 and a cation-to-anion ratio of 0.13 g-eq/L using an electrodialysis unit. Assume typical values of operation for the electrodialysis unit.

11-15 A wastewater is to be treated with activated carbon to remove residual COD. The following data were obtained from a laboratory adsorption study in which 1 g of activated carbon was added to a beaker containing 1 L of wastewater at selected COD values. Using these data, determine the more suitable isotherm (Langmuir or Fruendlich) to describe the data (sample to be selected by instructor).

Initial COD, mg/L	Equilibrium COD, mg/L			
	A	B	C	D
140	5	10	0.4	5
250	12	30	0.9	18
300	17	50	2	28
340	23	70	4	36
370	29	90	6	42
400	36	110	10	50
450	50	150	35	63

11-16 Using the results from Prob. 11–15, determine the amount of activated carbon that would be required to treat a flow of 5000 m^3/d to a final COD concentration of 20 mg/L if the COD concentration after secondary treatment is equal to 120 mg/L.

11-17 Using the following carbon adsorption data (data set to be selected by instructor), determine the Freundlich capacity factor (mg absorbate/g activated carbon) and Freundlich intensity parameter, 1/n.

Carbon dose, mg/L	Residual concentration, mg/L					
	A	B	C	D	E	F
0	25.9	9.20	9.89	27.5	20.4	9.88
5	17.4	7.36		24.8	19.3	7.95
10	13.2	6.86	8.96	24.2	18.6	7.02

(continued)

(Continued)

Carbon dose, mg/L	Residual concentration, mg/L					
	A	B	C	D	E	F
25	10.2	3.86	7.83	18.9	16.1	3.66
50	3.6	1.13	5.81	11.8	12.2	0.98
100	2.5	0.22	4.45	2.3	6.7	0.25
150	2.1	0.18	2.98	1.1	3.1	0.09
200	1.4	0.11	2.01	0.9	1.1	0.04

11–18 Determine the theoretical air flowrate required to remove the following compounds in a stripping tower at the indicated concentrations (compound and water to be selected by instructor). Also estimate the height of the stripping tower for a water flowrate of 3000 m^3/d. Values of the Henry's constant may be found in Table 5–36 in Chap. 5.

Compound	Concentration μg			
	Water A		Water B	
	Influent	Effluent	Influent	Effluent
Chlorobenzene	100	5	120	7
Chloroethene	100	5	150	5
TCE	100	5	180	10
Toluene	100	5	200	15

11–19 A quantity of sodium-form ion-exchange resin (5 g) is added to a water containing 2 meq of potassium chloride and 0.5 meq of sodium chloride. Calculate the residual concentration of potassium if the exchange capacity of the resin is 4.0 meq/g of dry weight and the selectivity coefficient is equal to 1.46.

11–20 Determine the exchange capacity for one of the following resins (resin to be selected by instructor). How much resin would be required to treat a flowrate of 4000 m^3/d to reduce the concentration of calcium Ca^{2+} from 125 to 45 mg/L?

Throughput volume, L	Resin A		Resin B	
	Cl^-	Ca^{2+}	Cl^-	Ca^{2+}
0	0	0	0	0
5	2	0	2	0
10	8	0	13	0
15	44	0	29	0
20	65	0	45	0
25	70	0	60	1
30	71	0	69	8
35	71	6	71	17

(continued)

(*Continued*)

Throughput volume, L	Resin A		Resin B	
	Cl^-	Ca^{2+}	Cl^-	Ca^{2+}
40	71	20	71	27
45		34	71	354
50		39		39
55		40		40
60		40		40

11–21 Determine the exchange capacity for one of the resins given in Problem 11–20 (resin to be selected by instructor). How much resin would be required to treat a flowrate of 5500 m^3/d to reduce the concentration of calcium Mg^{2+} from 115 to 15 mg/L?

11–22 Four different wastewaters have been reported to have the following ionic composition data. Estimate the selectivity coefficient and determine the amount of wastewater (A, B, C, D, to be selected by instructor) that can be treated by a strong-base ion-exchange resin, per service cycle, for the removal of nitrate. Assume the resin has an ion-exchange capacity of 1.8 eq/L.

Cation	Conc., mg/L	Anion	Concentration, mg/L			
			A	B	C	D
Ca^{2+}	82.2	HCO_3^-	304.8	152	254	348
Mg^{2+}	17.9	SO_4^{2-}	0	0	0	0
Na^+	46.4	Cl^-	58.1	146.3	124	60
K^+	15.5	NO_3^-	82.5	90	21.5	42

11–23 Four different wastewaters have been reported to have the following ionic composition data. Estimate the selectivity coefficient and determine the amount of wastewater (A, B, C, D, to be selected by instructor) that can be treated by a strong-base ion-exchange resin, per service cycle, for the removal of nitrate. Assume the resin has an ion-exchange capacity of 2.5 eq/L.

Cation	Conc., mg/L	Anion	Concentration, mg/L			
			A	B	C	D
Ca^{2+}	82.2	HCO_3^-	321	180	198.5	69
Mg^{2-}	17.9	SO_4^{2-}	65	36.5	124	136
Na^+	46.4	Cl^-	22	95	56	87
K^+	15.5	NO_3^-	46	93	34.5	97

11–24 For the following list of compounds, determine the most suitable method of treatment to reduce the concentration from 100 to 10 μg/L using the advanced wastewater-treatment processes discussed in this chapter.

Benzene
Chloroform
Dieldrin
Heptachlor
N-Nitrosodimethylamine
Trichloroethylene (TCE)
Vinyl chloride

The principal authors were responsible for scope of the textbook, writing, editing, and coordination with the reviewers and the publisher. Two of our principal authors have enjoyed a long association with the textbook. The third principal author, Dr. Stensel, has joined the team for the fourth edition. Dr. Tchobanoglous was the principal author for the first three editions of this text and for the first two editions of the companion volume, *Wastewater Engineering: Collection and Pumping of Wastewater.* Mr. Burton was technical reviewer for the second edition of this text and the companion text and a principal author for the third edition.

The staff of Metcalf & Eddy played a significant role in the preparation of this edition. We acknowledge the contributions of the following members of the staff for their valuable efforts in review of manuscripts:

Kevin L. Anderson	Jonathan W. Doane
David P. Bova	Robert Gay
John G. Chalas	Charles E. Pound

We would also like to offer our sincere gratitude to Dr. Roger T. Haug for his review of the chapters that cover biological wastewater treatment processes. Dr. Haug's comments were very helpful with respect to achieving one of our goals: the presentation of wastewater engineering in a forward-looking fashion.

Special appreciation is extended to Jonathan W. Doane for his efforts in managing Metcalf & Eddy's efforts and to John G. Chalas, the former director of technology of Metcalf & Eddy, now retired, who served as special advisor.

An effort such as this fourth edition could not be successful without the professional encouragement and support of corporate management. We gratefully acknowledge the contributions of Robert H. Fisher, chairman and CEO of Metcalf & Eddy, Inc., and John Somerville, president of Metcalf & Eddy. We would also like to acknowledge the vision of our parent company, AECOM Technologies, Inc., acting through Richard Newman, chairman, and Raymond Holdsworth, president, for the commitment they made to complete this effort and to pave the way for future editions.

Metcalf & Eddy would like to make special note of the passing in 2001 of Harry L. Kinsel, a former president of Metcalf & Eddy. Harry Kinsel was known for his professionalism and commitment to education. Metcalf & Eddy established an internal competition for technical papers in 1973 in Harry Kinsel's honor and this competition will continue as an inspiration to Metcalf & Eddy staff and the industry.

Finally, I would like to personally express my appreciation to the entire team of authors, editors, and reviewers for their tireless effort, and the senior management of Metcalf & Eddy, Inc., and AECOM Technologies, Inc., for the opportunity to direct this effort for Metcalf & Eddy.

James Anderson
Senior Vice President
Chief Engineer

PROBLEMS AND DISCUSSION TOPICS 1332

REFERENCES 1340

Disinfection refers to the partial destruction of disease-causing organisms. All the organisms are not destroyed during the process. The fact that all of the organisms are not destroyed differentiates disinfection from sterilization, which is the destruction of all organisms. In the field of wastewater treatment, the four categories of human enteric organisms of the greatest consequence in producing disease are bacteria, protozoan oocysts and cysts, helminths, and viruses. Diseases caused by these waterborne microorganisms have been discussed previously in Chap. 2 and are reported in Table

2–24. The purpose of this chapter is to introduce the reader to the general concepts involved in the disinfection of wastewater and the design of disinfection systems. Topics to be considered include (1) the regulatory requirements for wastewater disinfection, (2) a general introduction to disinfection theory, (3) disinfection with chlorine and related compounds, (4) disinfection with chlorine dioxide, (5) dechlorination, (6) the design of chlorination and dechlorination facilities, (7) disinfection with ozone, (8) other chemical disinfection methods, (9) disinfection with UV radiation, and (10) a comparison of the disinfection methods. Because of the concern over the use of chlorine, the use of UV radiation as an alternative disinfectant is emphasized in this chapter.

12–1 REGULATORY REQUIREMENTS FOR WASTEWATER DISINFECTION

From the early 1900s to the early 1970s, treatment objectives were concerned primarily with (1) the removal of colloidal, suspended, and floatable material, (2) the treatment of biodegradable organics, and (3) the elimination of pathogenic organisms, but generally with unspecified treatment goals. Passage of the Federal Water Pollution Control Act Amendments of 1972 (Public Law 92-500), as amended in 1977 and 1978 (Clean Water Act, Public Laws 95-217 and 97-117, respectively), stimulated substantial changes in wastewater treatment to achieve the principal objective of these acts, which was "to restore and maintain the chemical, physical, and biological integrity of the Nations Waters." In effect, the goal of the Clean Water Act was to make the nation's waters "fishable and swimmable."

To implement the Clean Water Act, the U.S. EPA in 1973 adopted regulations for secondary treatment. These regulations were contained in Part 133, Title 40, of the Code of Federal Regulations (40 CFR 133). Secondary treatment was defined in terms of biochemical oxygen demand (BOD), total suspended solids (TSS), pH, and fecal coliform (FC) bacteria (see Table 1-3 in Chap. 1). The fecal coliform bacteria requirement was deleted in 1976 and replaced with a provision that allowed individual states to develop site-specific water-quality standards including disinfection standards for wastewater-treatment plants (WWTP). As a consequence, today (2001) some states have fecal coliform standards varying from ≤2.2 to 5000 MPN/100 mL and total coliform standards varying from ≤2.2 to 10,000 MPN/100 mL. Further, a number of states have seasonal standards. More than 40 states have variable standards, depending on the quality of the receiving water and, if the treated wastewater is to be reused, on the reuse application. The most common standard for receiving waters is 200 MPN FC/100 mL. Because the regulations for disinfection are site-specific and are under continual review, the governing regulatory authority must be consulted to determine current requirements.

12–2 DISINFECTION THEORY

The purpose of this section is to introduce the basic concepts involved in disinfection. The background material presented in this section is intended to serve as a basis for the discussion of disinfectants used for wastewater. Topics to be discussed include a review of the requirements for an ideal disinfectant, current disinfection methods and means, mechanisms of disinfectants, and a general discussion of the factors influencing the action of disinfectants.

Characteristics of an Ideal Disinfectant

The characteristics for an ideal disinfectant are reported in Table 12–1. As shown, an ideal disinfectant would have to possess a wide range of characteristics. Although such a compound may not exist, the characteristics set forth in Table 12–1 should be considered in evaluating proposed or recommended disinfectants. It is also important that the disinfectant be safe to handle and apply, and that its strength or concentration in treated waters be measurable. The latter consideration is an issue with the use of ozone and UV disinfection where no residual is measured.

Disinfection Methods and Means

Disinfection is most commonly accomplished by the use of (1) chemical agents, (2) physical agents, (3) mechanical means, and (4) radiation. Each of these techniques is considered briefly in the following discussion.

Chemical Agents. Chemical agents that have been used as disinfectants include (1) chlorine and its compounds, (2) bromine, (3) iodine, (4) ozone, (5) phenol and phenolic compounds, (6) alcohols, (7) heavy metals and related compounds, (8) dyes, (9) soaps and synthetic detergents, (10) quaternary ammonium compounds, (11) hydrogen peroxide, (12) peracetic acid, (13) various alkalies, and (14) various acids. Of these, the most common disinfectants are the oxidizing chemicals, and chlorine is the one used most universally. Although not discussed in this chapter, bromine and iodine have also been used for wastewater disinfection. Ozone is a highly effective disinfectant, and its use is increasing even though it leaves no residual (see Sec. 12–7). Highly acid or alkaline water can also be used to destroy pathogenic bacteria, because water with a pH greater than 11 or less than 3 is relatively toxic to most bacteria.

Table 12–1
Characteristics of an ideal disinfectant

Characteristic	Properties/response
Availability	Should be available in large quantities and reasonably priced
Deodorizing ability	Should deodorize while disinfecting
Homogeneity	Solution must be uniform in composition
Interaction with extraneous material	Should not be absorbed by organic matter other than bacterial cells
Noncorrosive and nonstaining	Should not disfigure metals or stain clothing
Nontoxic to higher forms of life	Should be toxic to microorganisms and nontoxic to humans and other animals
Penetration	Should have the capacity to penetrate through surfaces
Safety	Should be safe to transport, store, handle, and use
Solubility	Must be soluble in water or cell tissue
Stability	Should have low loss of germicidal action with time on standing
Toxicity to microorganisms	Should be effective at high dilutions
Toxicity at ambient temperatures	Should be effective in ambient temperature range

Physical Agents. Physical disinfectants that can be used are heat, light, and sound waves. Heating water to the boiling point, for example, will destroy the major disease-producing non-spore-forming bacteria. Heat is commonly used in the beverage and dairy industry, but it is not a feasible means of disinfecting large quantities of wastewater because of the high cost. However, pasteurization of sludge is used extensively in Europe.

Sunlight is also a good disinfectant, due primarily to the ultraviolet (UV) radiation portion of the electromagnetic spectrum. The decay of microorganisms observed in oxidation ponds is due, in part, to their exposure to the UV component of sunlight. Special lamps developed to emit ultraviolet rays have been used successfully to disinfect water and wastewater. The efficiency of the process depends on the penetration of the rays into water. The contact geometry between the ultraviolet radiation source and the water is extremely important because suspended matter, dissolved organic molecules, and water itself will absorb the radiation, in addition to the microorganisms.

Mechanical Means. Bacteria and other organisms are also removed by mechanical means during wastewater treatment. Typical removal efficiencies for various treatment operations and processes are reported in Table 12–2. The first four operations listed may be considered to be physical. The removals accomplished are byproducts of the primary function of the process.

Radiation. The major types of radiation are electromagnetic, acoustic, and particle. Gamma rays are emitted from radioisotopes, such as cobalt-60. Because of their penetration power, gamma rays have been used to disinfect (sterilize) both water and wastewater. Although the use of a high-energy electron-beam device for the irradiation of wastewater or sludge has been studied extensively, there are no commercial devices or full-scale installations in operation.

Comparison of Wastewater Disinfectants. Using the criteria defined in Table 12–1, disinfectants that have been used in wastewater are compared in Table 12–3.

Table 12-2 Removal or destruction of bacteria by different treatment processes

Process	Percent removal
Coarse screens	0–5
Fine screens	10–20
Grit chambers	10–25
Plain sedimentation	25–75
Chemical precipitation	40–80
Trickling filters	90–95
Activated sludge	90–98
Chlorination of treated wastewater	98–99.999

Table 12–3
Comparison of ideal and actual characteristics of commonly used disinfectants[a,b]

Characteristic[a]	Chlorine	Sodium hypochlorite	Calcium hypochlorite	Chlorine dioxide	Ozone	UV radiation
Availability/cost	Low cost	Moderately low cost	Moderately low cost	Moderately low cost	Moderately high cost	Moderately high cost
Deodorizing ability	High	Moderate	Moderate	High	High	na
Homogeneity	Homogeneous	Homogeneous	Homogeneous	Homogeneous	Homogeneous	na
Interaction with extraneous material	Oxidizes organic matter	Active oxidizer	Active oxidizer	High	Oxidizes organic matter	Absorbance of UV radiation
Noncorrosive and nonstaining	Highly corrosive	Corrosive	Corrosive	Highly corrosive	Highly corrosive	na
Nontoxic to higher forms of life	Highly toxic to higher life forms	Toxic	Toxic	Toxic	Toxic	Toxic
Penetration	High	High	High	High	High	Moderate
Safety concern	High	Moderate	Moderate	High	Moderate	Low
Solubility	Moderately	High	High	High	High	na
Stability	Stable	Slightly unstable	Relatively stable	Unstable, must be generated as used	Unstable, must be generated as used	na
Toxicity to microorganisms	High	High	High	High	High	High
Toxicity at ambient temperatures	High	High	High	High	High	High

[a] See Table 12–1 for a description of each characteristic.
[b] na = not applicable.

Mechanisms of Disinfectants

The five principal mechanisms that have been proposed to explain the action of disinfectants are (1) damage to the cell wall, (2) alteration of cell permeability, (3) alteration of the colloidal nature of the protoplasm, (4) alteration of the organism DNA or RNA, and (5) inhibition of enzyme activity.

Damage or destruction of the cell wall will result in cell lysis and death. Some agents, such as penicillin, inhibit the synthesis of the bacterial cell wall.

Agents such as phenolic compounds and detergents alter the permeability of the cytoplasmic membrane. These substances destroy the selective permeability of the membrane and allow vital nutrients, such as nitrogen and phosphorus, to escape.

Heat, radiation, and highly acid or alkaline agents alter the colloidal nature of the protoplasm. Heat will coagulate the cell protein and acids or bases will denature proteins, producing a lethal effect.

UV radiation can cause the formation of double bonds in microorganisms as well as rupturing some DNA strands. When UV photons are absorbed by the DNA in bacteria and protozoa and the DNA and RNA in viruses, covalent dimers can be formed from adjacent thymines in DNA or uracils in RNA. The formation of double bonds disrupts the replication process so that the organism can no longer reproduce and is thus inactivated.

Another mode of disinfection is the inhibition of enzyme activity. Oxidizing agents, such as chlorine, can alter the chemical arrangement of enzymes and inactivate the enzymes.

A comparison of the mechanism of disinfection using chlorine, ozone, and UV radiation, commonly used disinfectants for wastewater, is presented in Table 12–4. To a large extent, observed performance differences for the various disinfectants can be explained on the basis of the operative removal mechanisms.

Factors Influencing the Action of Disinfectants

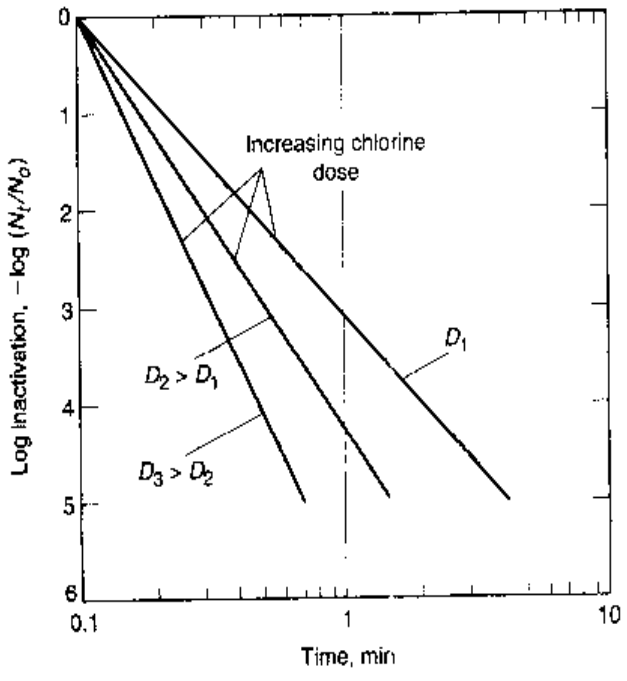
In applying the disinfection agents or means that have been described, the following factors must be considered: (1) contact time, (2) concentration of the disinfectant,

Table 12–4
Mechanisms of disinfection using chlorine, UV, and ozone

Chlorine	Ozone	UV radiation
1. Oxidation	1. Direct oxidation/destruction of cell wall with leakage of cellular constituents outside of cell	1. Photochemical damage to RNA and DNA (e.g., formation of double bonds) within the cells of an organism
2. Reactions with available chlorine	2. Reactions with radical byproducts of ozone decomposition	2. The nucleic acids in microorganisms are the most important absorbers of the energy of light in the wavelength range of 240–280 nm
3. Protein precipitation	3. Damage to the constituents of the nucleic acids (purines and pyrimidines)	3. Because DNA and RNA carry genetic information for reproduction, damage of these substances can effectively inactivate the cell
4. Modification of cell wall permeability	4. Breakage of carbon-nitrogen bonds leading to depolymerization	
5. Hydrolysis and mechanical disruption		

(3) intensity and nature of physical agent or means, (4) temperature, (5) types of organisms, and (6) nature of suspending liquid. The subjects introduced in this section are considered further in the subsequent sections. It is important to note that in the discussion that follows, the various formulations used to explain the action of disinfectants are based on an analysis of data derived using discrete organisms in solution. The presence of suspended material, which may provide shielding of microorganisms, is considered in the subsequent section dealing with chlorine and in the section dealing with UV disinfection.

Contact Time. Perhaps one of the most important variables in the disinfection process is contact time. Working in England in the early 1900s, Harriet Chick observed that for a given concentration of disinfectant, the longer the contact time, the greater the kill (see Fig. 12–1). This observation was first reported in the literature in 1908 (Chick, 1908). In differential form, Chick's law is



$$\frac{dN_t}{dt} = -kN_t \tag{12-1}$$

where dN_t/dt = rate of change in the concentration of organisms with time
k = inactivation rate constant, T^{-1}
N_t = number of organisms at time t
t = time

If N_o is the number of organisms when t equals 0, Eq. (12–1) can be integrated to

$$\frac{N_t}{N_o} = e^{-kt} \tag{12-2}$$

Figure 12–1
Effect of time and concentration on survival of dispersed *E. coli* in a batch reactor using chlorine as disinfectant at 20°C.

or

$$\ln \frac{N_t}{N_o} = -kt \tag{12-3}$$

The value of the inactivation rate constant k in Eq. (12–3) can be obtained by plotting $-\ln (N_t/N_o)$ versus the contact time t.

Concentration of Disinfectant. Also working in England in the early 1900s, Herbert Watson reported that the inactivation rate constant was related to the concentration as follows (Watson, 1908):

$$k = k'C^n \tag{12-4}$$

where k = inactivation rate constant
k' = die-off constant
C = concentration of disinfectant
n = coefficient of dilution

Combining the expressions proposed by Chick and Watson in differential form yields (Hass and Kara, 1984)

$$\frac{dN_t}{dt} = -k'C^nN_t \tag{12-5}$$

The integrated form of Eq. (12–5) is

$$\frac{N_t}{N_o} = e^{-k'C^nt} \tag{12-6}$$

or

$$\ln \frac{N_t}{N_o} = -k'C^nt \tag{12-7}$$

The linearized form of Eq (12–7) is:

$$\ln C = -\frac{1}{n} \ln t + \frac{1}{n} \ln \left[\frac{1}{k'} \left(-\ln \frac{N_t}{N_o} \right) \right]$$

The value of n can be obtained by plotting C versus t on log-log paper for a given level of inactivation (see Example 12–1). The following explanation has been offered for various values of n:

$n = 1$ both the concentration and time are equally important

$n > 1$ concentration is more important than time

$n < 1$ time is more important than concentration

Departures from this rate law are common, as shown on Fig. 12–2. As shown on Fig. 12–2*a*, there can be a lag or shoulder effect in which constituents in the suspending liquid react initially with the disinfectant, rendering the disinfectant ineffective. The tailing effect in which large particles shield the organisms to be disinfected is shown on

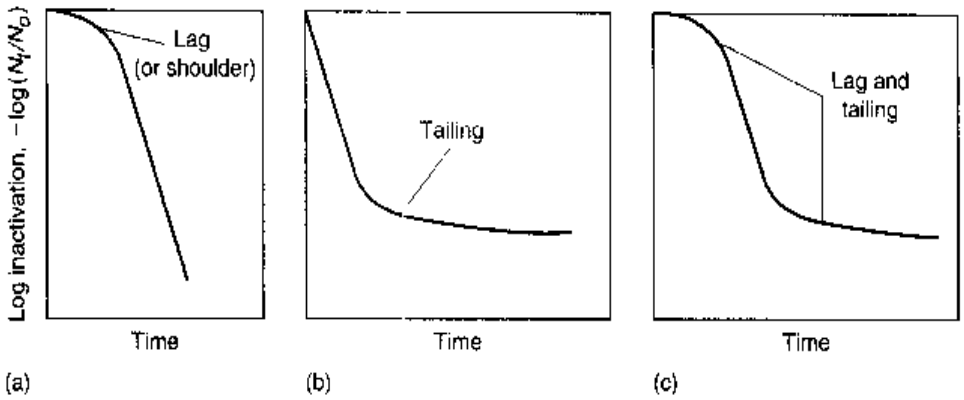


Figure 12–2

Departures observed from Chick's law: (*a*) lag or shoulder effect in which constituents in the suspending liquid react initially with the disinfectant, (*b*) tailing effect in which large particles shield the organisms to be disinfected, and (*c*) combined lag and tailing effects.

Fig. 12–2*b*. The combined effects of lag and tailing are illustrated on Fig. 12–2*c*. These observed phenomena are discussed in greater detail in the following section dealing with the disinfection of wastewater. Further, Eq. (12–6) as applied to wastewater fails to account for the variable, heterogeneous characteristics of wastewater.

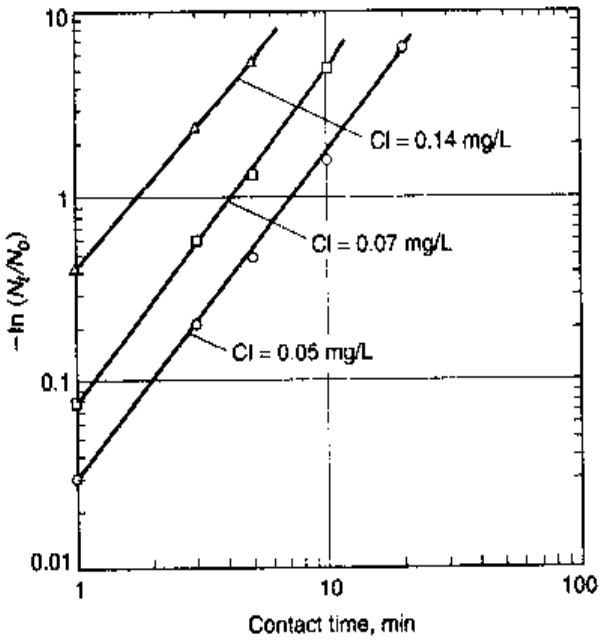
Using an n value of 1 and assuming the C value corresponds to the chlorine residual C_R, the relationship given by Eq. (12–6) is used by a number of regulatory agencies to control the wastewater disinfection process. This subject is considered in greater detail in the discussion dealing with chlorine disinfection (Sec. 12–3).

EXAMPLE 12–1 Application of the Modified Chick/Watson Equation Given the following chlorination test survival data for *E. coli*, expressed as a percentage, determine the values of the constants in the Chick and Watson equation [Eq. (12–6)] for 99 percent reduction. The results were obtained using a batch reactor.

	Percent survival				
	Contact time, min[a]				
Free Cl,[b] mg/L	1	3	5	10	20
0.05	97	82	63	21	0.3
0.07	93	60	28	0.5	—
0.14	67	11	0.7	—	—

[a] Test conditions pH = 8.5; temp = 5°C.

[b] HOCl (hypochlorous acid) and OCl^- (hypochlorite ion). See also discussion in Sec. 12–3.

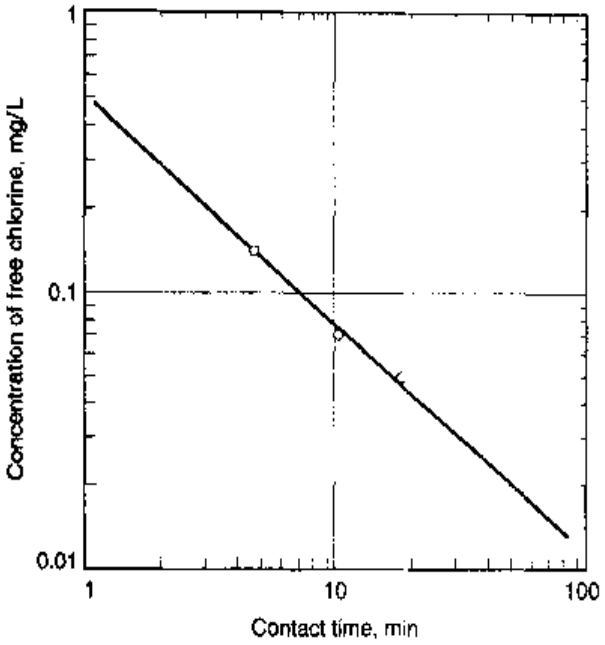


Solution

1. To determine the constants in the Chick and Watson equation form of Chick's law, convert the survival data to log removal values and then plot on arithmetic and log-log paper to determine the time required for a given degree of kill.

a. Convert the given percentage removal data to log removal values.

	$-\ln (N_t/N_o)$				
	Contact time, min				
Free Cl, mg/L	1	3	5	10	20
0.05	0.030	0.198	0.462	1.561	5.809
0.07	0.073	0.511	1.273	5.298	
0.14	0.400	2.207	4.962		



b. Plot the converted values on both arithmetic and log-log paper to determine the best fit of the data. After plotting the data, it was found that the data could be represented best by a straight line as shown on the following log-log plot.

c. Determine the required contact time for a log inactivation value of 99 percent $[-\ln (N_t/N_o) = 4.61]$ for the various concentrations. The required values are:

Concentration, mg/L	Time, min
0.05	18.0
0.07	10.0
0.14	4.7

2. Determine the constants in the Chick and Watson equation using the data from Step 1.
   a. Plot the concentration versus time values determined in Step 1c.

b. Use the linear form of Eq. (12–7) to determine the constants

$$\ln C = -\frac{1}{n} \ln t + \frac{1}{n} \ln \left[\frac{1}{k'}\left(-\ln \frac{N_t}{N_o}\right)\right]$$

$$\ln C = -\frac{1}{n} \ln t + \frac{1}{n} \text{(constant)}$$

From the above plot, the value of n equals

$$\text{Slope} = -\frac{1}{n} = -\frac{\log 0.5 - \log 0.011}{\log 100 - \log 1} = -\frac{[-0.30 - (-1.96)]}{2 - 0}$$

$$= -\frac{1.66}{2} = -0.83$$

$$n = 1.20$$

When $t = 1$, the Y-intercept $= \ln 0.5 = \frac{1}{n} \ln \left[\frac{1}{k'}\left(-\ln \frac{N_t}{N_o}\right)\right]$

$$n(\ln 0.5) = \ln \left[\frac{1}{k'}\left(-\ln \frac{N_t}{N_o}\right)\right]$$

$$1.20(-0.69) = \ln \left[\frac{1}{k'}(-\ln 0.01)\right]$$

$$0.44 = -\left[\frac{1}{k'}(4.61)\right]$$

$$k' = -\frac{1}{0.44}(4.61) = -10.48$$

$$\ln \frac{N_t}{N_o} = -10.48C^{1.20}t$$

Comment The equation developed in this example can also be used to determine the degree of inactivation at different temperatures (see Example 12–2).

Intensity and Nature of Physical Agent. As noted earlier, heat and light are physical agents that have been used from time to time in the disinfection of wastewater. It has been found that their effectiveness is a function of intensity. For example, if the decay of organisms can be described with a first-order reaction [see Eq. (12–1)], then the effect of the intensity of the physical disinfectant is reflected in the constant k through some functional relationship.

Temperature. The effect of temperature on rate of kill with chemical disinfectants can be represented by a form of the van't Hoff–Arrhenius relationship. Increasing the temperature results in a more rapid kill. In terms of the time t required to effect a given percentage kill, the relationship is

$$\ln \frac{t_1}{t_2} = \frac{E(T_2 - T_1)}{RT_1T_2} \tag{12-8}$$

where t_1, t_2 = time for given percentage kill at temperatures T_1 and T_2, K, respectively
E = activation energy, J/mole (cal/mole)
R = gas constant, 8.3144 J/mole·K = (1.99 cal/mole·K)

Some typical values for the activation energy for various chlorine compounds at different pH values are reported in Table 12–5. The effect of temperature is considered in Example 12–2.

Table 12-5 Activation energies for aqueous chlorine and chloramines at normal temperatures (~20°C)[a]

Compound	pH	E, Cal/mole	E, J/mole
Aqueous chlorine	7.0	8,200	34,340
	8.5	6,400	26,800
	9.8	12,000	50,250
	10.7	15,000	62,810
Chloramines	7.0	12,000	50,250
	8.5	14,000	58,630
	9.5	20,000	83,750

[a]From Fair et al. (1948).

EXAMPLE 12–2 Effect of Temperature on Disinfection Times Estimate the time required for a 99.9 percent kill for a chlorine dosage of 0.05 mg/L at a temperature of 20°C and pH of 8.5, using the data and relationship developed in Example 12–1. The test data given in Example 12–1 were obtained at a temperature of 5°C using a batch reactor.

Solution

1. Estimate the time required for a 99.9 percent kill using the equation developed in Example 12–1.

$$\ln \frac{N_t}{N_o} = -10.48C^{1.20}t$$

$$\ln \frac{0.10}{100} = -(10.48)(0.05)^{1.20}t$$

$$t = \frac{-6.91}{(-10.48)(0.027)} = 24.4 \text{ min at } 5°C$$

2. Estimate the time required at 20°C using the modified form of the van't Hoff–Arrhenius equation [Eq. (12–8)] and the data given in Table 12–5.

$$\ln \frac{t_1}{t_2} = \frac{E(T_2 - T_1)}{RT_1T_2}$$

$$\ln \frac{t_1}{20.4 \text{ min}} = \frac{(26{,}800 \text{ J/mole})[(278.15 - 293.15)\text{K}]}{(8.3144 \text{ J/mole·K})[(293.15 \text{ K})(278.15 \text{ K})]}$$

$$\ln \frac{t_1}{24.4 \text{ min}} = -0.60$$

$$\frac{t_1}{24.4 \text{ min}} = e^{-0.60} = 0.549$$

$$t = 13.4 \text{ min at } 20°C$$

Types of Organisms. The effectiveness of various disinfectants will be influenced by the type, nature, and condition of the microorganisms. For example, viable, growing bacteria cells are often killed more easily than older cells that developed a slime coating. In contrast, bacterial spores are extremely resistant, and many of the chemical disinfectants normally used will have little or no effect. Similarly, many of the viruses and protozoa of concern respond differently to each of the chemical disinfectants. In some cases, other disinfecting agents, such as heat or UV radiation, may have to be used. The inactivation of different microorganism groups is considered further in the following sections.

Nature of Suspending Liquid. In reviewing the development of the various relationships proposed for the inactivation of microorganisms, it is important to note

that most of the tests were conducted in batch reactors using distilled or buffered water, under laboratory conditions. In practice, the nature of the suspending liquid must be evaluated carefully. For example, extraneous organic material will react with most oxidizing disinfectants and reduce their effectiveness. The presence of suspended matter will reduce the effectiveness of disinfectants by absorption of the disinfectant and by shielding the entrapped bacteria. The characteristics of the suspending liquid are examined in more detail in the following sections and in the discussion of UV disinfection (Sec. 12–9).

12–3 DISINFECTION WITH CHLORINE

As noted earlier, of all the chemical disinfectants, chlorine is the one used most commonly throughout the world. The reason is that chlorine satisfies most of the requirements specified in Table 12–1. The first use of chlorine for the disinfection of wastewater in the United States was in 1914 at Altoona, PA and Milwaukee, WI (Enslow, 1938). Specific topics considered in this section include a brief description of the characteristics of the various chlorine compounds, a review of chlorine chemistry and breakpoint chlorination, an analysis of the performance of chlorine as a disinfectant and the factors that may influence the effectiveness of the chlorination process, a discussion of the formation of disinfection byproducts (DBPs), and a consideration of the potential impacts of the discharge of DBPs to the environment. Disinfection with chlorine dioxide, chlorination and dechlorination, and the design of chlorination and dechlorination facilities are considered in the following three sections, respectively.

Characteristics of Chlorine Compounds

The principal chlorine compounds used at wastewater-treatment plants are chlorine (Cl_2), sodium hypochlorite (NaOCl), calcium hypochlorite [$Ca(OCl)_2$], and chlorine dioxide (ClO_2). Many large cities have switched from chlorine gas to sodium hypochlorite because of the safety concerns related to handling and storage of liquid chlorine. The characteristics of Cl_2, NaOCl, and $Ca(OCl)_2$ are considered in the following discussion. The characteristics of chlorine dioxide and its use as a disinfectant are discussed in the following section.

Chlorine. Chlorine (Cl_2) can be present as a gas or a liquid. Chlorine gas is greenish yellow in color and about 2.48 times as heavy as air. Liquid chlorine is amber colored and about 1.44 times as heavy as water. Unconfined liquid chlorine vaporizes rapidly to a gas at standard temperature and pressure with 1 liter of liquid yielding about 450 liters of gas. Chlorine is moderately soluble in water, with a maximum solubility of about 1 percent at 10°C (50°F). Chlorine is supplied as a liquefied gas under high pressure in containers varying in size from 45 kg (100 lb) and 68 kg (150 lb) cylinders, 908 kg (1 ton) containers, multiunit railcars containing fifteen 908 kg (1 ton) containers, and railcars with capacities of 14.5, 27.2, and 49.9 Mg (16, 30, and 55 tons) (see Fig. 12–3). Selection of the size of chlorine pressure vessel depends on an analysis of the rate of chlorine usage, cost of chlorine, facilities requirements, and dependability of supply. The properties of chlorine are summarized in Table 12–6.

Figure 12-3
Typical supply and storage containers for chlorine: (*a*) 908 kg (1.0 ton) containers and (*b*) railcars of varying capacity.

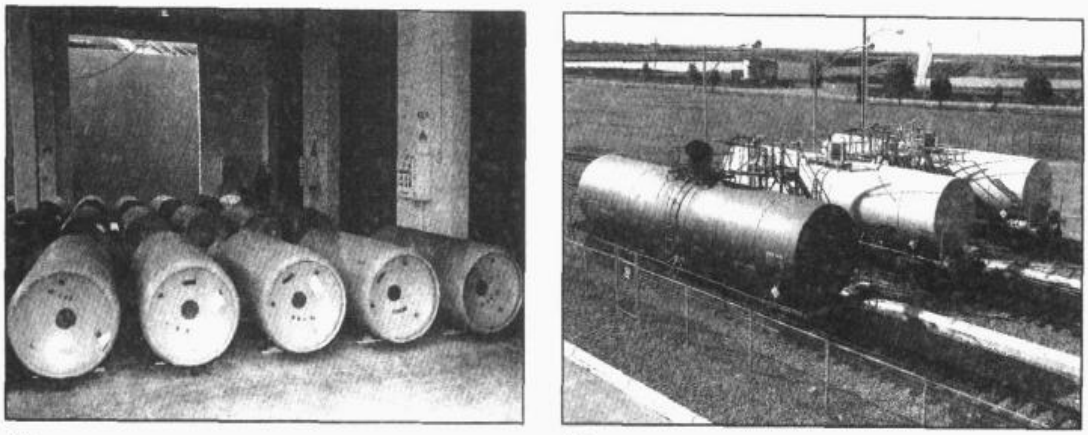


Table 12-6
Properties of chlorine, chlorine dioxide, and sulfur dioxide[a]

Property	Unit	Chlorine (Cl_2)	Chlorine dioxide (ClO_2)	Sulfur dioxide (SO_2)

[b] At 20°C.

Although the use of chlorine for the disinfection of both potable water supplies and treated wastewater has been of great significance from a public health perspective, serious concerns have been raised of its continued use. Important concerns include:

1. Chlorine is a highly toxic substance that is transported by rail and truck, both of which are prone to accidents.
2. Chlorine is a highly toxic substance that potentially poses health risks to treatment-plant operators and the general public if released by accident.

3. Because chlorine is a highly toxic substance, stringent requirements for containment and neutralization must be implemented as specified in the Uniform Fire Code (UFC).
4. Chlorine reacts with the organic constituents in wastewater to produce odorous compounds.
5. Chlorine reacts with the organic constituents in wastewater to produce byproducts, many of which are known to be carcinogenic and/or mutagenic.
6. Residual chlorine in treated wastewater effluent is toxic to aquatic life.
7. Concern exists over the discharge of chloro-organic compounds to the environment whose long-term effects are not known.

Sodium Hypochlorite. Many of the safety concerns related to the transport, storage, and feeding of liquid-gaseous chlorine are eliminated by the use of either sodium or calcium hypochlorite. Sodium hypochlorite (NaOCl) (i.e., liquid bleach), is only available as liquid and usually contains 12.5 to 17 percent available chlorine at the time it is manufactured. Sodium hypochlorite can be purchased in bulk lots of 12 to 15 percent of available chlorine or manufactured onsite. The solution decomposes more readily at high concentrations and is affected by exposure to light and heat. A 16.7 percent solution stored at 26.7°C (80°F) will lose 10 percent of its strength in 10 days, 20 percent in 25 days, and 30 percent in 43 days. It must therefore be stored in a cool location in a corrosion-resistant tank (see Fig. 12–4). Another disadvantage of sodium hypochlorite is the chemical cost. The purchase price may range from 150 to 200 percent of the cost of liquid chlorine. The handling of sodium hypochlorite requires special design considerations because of its corrosiveness and the presence of chlorine fumes.

Several proprietary systems are available for the generation of sodium hypochlorite from sodium chloride (NaCl) or seawater. These systems are electric power intensive and, in the case of generation from seawater, result in a very dilute solution, a maximum of 0.8 percent hypochlorite. The onsite generation systems have been used only on a limited basis due to their complexity and high power cost.

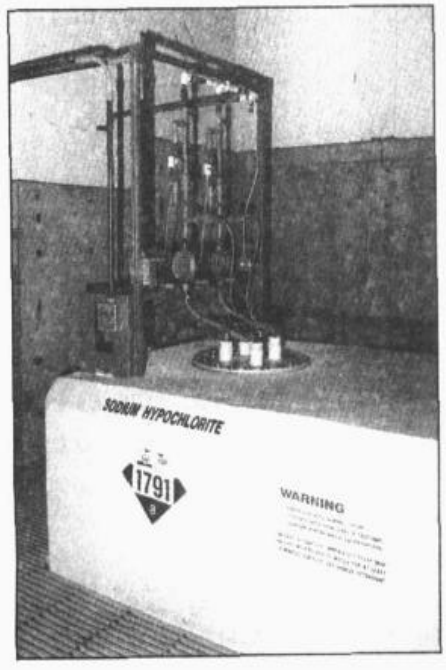

Figure 12–4

Typical onsite storage and feeding equipment for sodium hypochlorite. The facility shown is typical of those used at smaller treatment plants; in larger facilities multiple storage tanks are used.

Calcium Hypochlorite. Calcium hypochlorite [$Ca(OCl)_2$] is available commercially in either a dry or a wet form. High-test calcium hypochlorite contains at least 70 percent available chlorine. In dry form it is available as an off-white powder or as granules, compressed tablets, or pellets. A wide variety of container sizes are available depending on the source. Calcium hypochlorite granules or pellets are readily soluble in water, varying from about 21.5 g/100 mL at 0°C (32°F) to 23.4 g/100 mL at 40°C (104°F). Because of its oxidizing potential, calcium hypochlorite should be stored in a cool, dry location away from other chemicals in corrosion-resistant containers. With proper storage conditions, the granules are relatively stable. Hypochlorite is more expensive than liquid chlorine, loses its available strength on storage, and may be difficult to handle. Because it tends to crystallize, calcium hypochlorite may clog metering pumps, piping, and valves. Calcium hypochlorite is used most commonly at small installations.

Chemistry of Chlorine Compounds

The following discussion deals with the reactions of chlorine in water and the reaction of chlorine with ammonia.

Chlorine Reactions in Water. When chlorine in the form of Cl_2 gas is added to water, two reactions take place: hydrolysis and ionization.

Hydrolysis may be defined as the reaction in which chlorine gas combines with water to form hypochlorous acid (HOCl).

$$Cl_2 + H_2O \leftrightarrow HOCl + H^+ + Cl \tag{12–9}$$

The equilibrium constant K_H for this reaction is

$$K_H = \frac{[HOCl][H^+][Cl^-]}{[Cl_2]} = 4.5 \times 10^{-4} \text{ (mole/L)}^2 \text{ at } 25°C \tag{12–10}$$

Because of the magnitude of the equilibrium constant, large quantities of chlorine can be dissolved in water.

Ionization of hypochlorous acid to hypochlorite ion (OCl^-) may be defined as

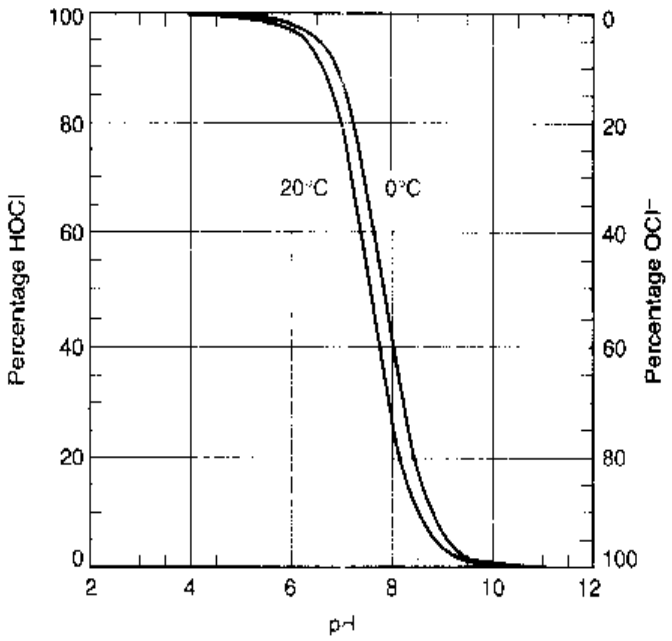
$$HOCl \leftrightarrow H^+ + OCl^- \tag{12–11}$$

The ionization constant K_i for this reaction is

$$K_i = \frac{[H^+][OCl^-]}{[HOCl]} = 3 \times 10^{-8} \text{ mole/L at } 25°C \tag{12–12}$$

The variation in the value of K_i with temperature is reported in Table 12–7.

The total quantity of HOCl and OCl^- present in water is called the "free available chlorine." The relative distribution of these two species (see Fig. 12–5) is very important because the killing efficiency of HOCl is about 40 to 80 times that of OCl^-. The percentage distribution of HOCl at various temperatures can be computed using Eq. (12–13) and the data in Table 12–7.



$$\frac{[HOCl]}{[HOCl] + [OCl^-]} = \frac{1}{1 + [OCl^-]/[HOCl]} = \frac{1}{1 + K_i[H^+]} = \frac{1}{1 + K_i 10^{pH}} \tag{12–13}$$

Table 12–7
Values of the ionization constant of hypochlorous acid at different temperatures[a]

Temperature, °C	$K_i \times 10^8$, mole/L
0	1.5
5	1.7
10	2.0
15	2.3
20	2.6
25	2.9

[a]Computed using equation from Morris (1966).

Figure 12–5
Percentage distribution of hypochlorous acid and hypochlorite in water as a function of pH at 0 and 20°C.

Hypochlorite Reactions in Water. Free available chlorine can also be added to water in the form of hypochlorite salts. Both calcium and sodium hypochlorite hydrolyze to form hypochlorous acid (HOCl) as follows:

$$Ca(OCl)_2 + 2H_2O \rightarrow 2HOCl + Ca(OH)_2 \qquad (12\text{–}14)$$

$$NaOCl + H_2O \rightarrow HOCl + NaOH \qquad (12\text{–}15)$$

The ionization of hypochlorous acid was discussed previously [see Eq. (12–11)].

Chlorine Reactions with Ammonia. As noted in Chaps. 2 and 3, untreated wastewater contains nitrogen in the form of ammonia and various combined organic forms. The effluent from most treatment plants also contains significant amounts of nitrogen, usually in the form of ammonia, or nitrate if the plant is designed to achieve nitrification (see Chaps. 8 and 9). Because hypochlorous acid is a very active oxidizing

agent, it will react readily with ammonia in the wastewater to form three types of chloramines in successive reactions:

$$NH_3 + HOCl \rightarrow NH_2Cl \text{ (monochloramine)} + H_2O \quad (12\text{–}16)$$

$$NH_2Cl + HOCl \rightarrow NHCl_2 \text{ (dichloramine)} + H_2O \quad (12\text{–}17)$$

$$NHCl_2 + HOCl \rightarrow NCl_3 \text{ (nitrogen trichloride)} + H_2O \quad (12\text{–}18)$$

These reactions are dependent on the pH, temperature, and contact time, and on the ratio of chlorine to ammonia (White, 1999). The two species that predominate, in most cases, are monochloramine (NH_2Cl) and dichloramine ($NHCl_2$). The ratio of dichloramine to monochloramine as a function of the ratio of chlorine to ammonia at various pH values is presented in Table 12–8. The amount of nitrogen trichloride present is negligible up to chlorine-to-nitrogen ratios of 2.0. The chlorine in these compounds is called "combined available chlorine." As will be discussed subsequently, chloramines also serve as disinfectants, although they are slow-reacting. When chloramines are the only disinfectants, the measured residual chlorine is defined as "combined chlorine residual" as opposed to free chlorine in the form of hypochlorous acid and hypochlorite ion.

Actual and Available Chlorine. The percent actual and available chlorine can be used to compare the effectiveness of compounds containing chlorine. The percent actual chlorine is determined as follows:

$$(Cl_2)_{actual},\ \% = \frac{(\text{weight of chlorine in compound})}{(\text{molecular weight of compound})} \times 100 \quad (12\text{–}19)$$

Available chlorine is the term used to compare the "oxidizing power" of chlorine compounds. The oxidizing power of chlorine is based on the value of the valence of the

Table 12–8 Ratio of dichloramine to monochloramine under equilibrium conditions as a function of pH and applied molar dose ratio of chlorine to ammonia[a]

Molar ratio Cl_2:NH_4	pH			
	6	7	8	9
0.1	0.13	0.014	1E-03	0.000
0.3	0.389	0.053	5E-03	0.000
0.5	0.668	0.114	0.013	1E-03
0.7	0.992	0.213	0.029	3E-03
0.9	1.392	0.386	0.082	0.011
1.1	1.924	0.694	0.323	0.236
1.3	2.700	1.254	0.911	0.862
1.5	4.006	2.343	2.039	2.004
1.7	6.875	4.972	4.698	4.669
1.9	20.485	18.287	18.028	18.002

[a] From U.S. EPA (1986).

chloride in the compound that is reduced to a valence value of −1. For example, the half reaction for hypochlorous acid is as given below (see Table 6–11, Chap. 6)

$$HOCl + H^+ + 2e^- \rightarrow Cl^- + H_2O \qquad (12\text{–}20)$$

As shown in Eq. (12–20), the electron change was 2. The percent available chlorine is given by the following relationship:

$$(Cl_2)_{available} = (\text{Cl equivalent})\,[(Cl_2)_{actual}, \%)] \qquad (12\text{–}21)$$

Thus, for HOCl the actual percentage of chlorine is 67.7 percent [(35.5/52.5) × 100] and the available chlorine is 135.4 percent (2 × 67.7). Values for the actual and available percent chlorine are given in Table 12–9 for chlorine and various compounds containing chlorine that have been used as disinfectants.

Breakpoint Reaction with Chlorine

The maintenance of a residual (combined or free) for the purpose of wastewater disinfection is complicated because free chlorine not only reacts with ammonia, as noted previously, but also is a strong oxidizing agent. The term "breakpoint chlorination" is the term applied to the process whereby enough chlorine is added to react with all oxidizable substances such that if additional chlorine is added it will remain as free chlorine. The main reason for adding enough chlorine to obtain a free chlorine residual is that effective disinfection can usually then be assured. Breakpoint chlorination chemistry, acid generation, and the buildup of dissolved solids are considered in the following discussion.

Breakpoint Chlorination Chemistry. The stepwise phenomena that result when chlorine is added to wastewater containing oxidizable substances and ammonia can be explained by referring to Fig. 12–6. As chlorine is added, readily oxidizable substances, such as Fe^{2+}, Mn^{2+}, H_2S, and organic matter, react with the chlorine and

Table 12–9
Actual and available chlorine in compounds containing chlorine[a]

Compound	Molecular weight	Chlorine equivalent[a]	Actual chlorine, %	Available chlorine, %
Cl_2	71	1	100	100

[a] Valence change to obtain reduced form of chloride (Cl^{-1}).

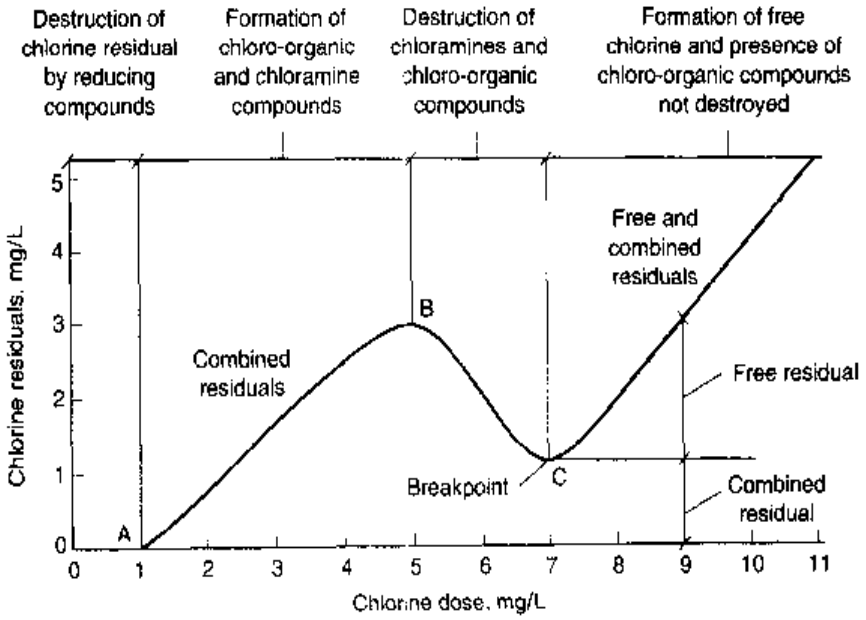

Figure 12–6
Generalized curve obtained during breakpoint chlorination of wastewater.

reduce most of it to the chloride ion (point *A* on Fig. 12–6). After meeting this immediate demand, the added chlorine continues to react with the ammonia to form chloramines between points *A* and *B*, as discussed above. For mole ratios of chlorine to ammonia less than 1, monochloramine and dichloramine will be formed. The distribution of these two forms is governed by their rates of formation, which are dependent on the pH and temperature. Between point *B* and the breakpoint, point C, some chloramines will be converted to nitrogen trichloride [see Eq. (12–18)], the remaining chloramines will be oxidized to nitrous oxide (N_2O) and nitrogen (N_2), and the chlorine will be reduced to the chloride ion. With continued addition of chlorine, most of the chloramines will be oxidized at the breakpoint. Continued addition of chlorine past the breakpoint, as shown on Fig. 12–6, will result in a directly proportional increase in the free available chlorine (unreacted hypochlorite). Theoretically, the weight ratio of chlorine to ammonia nitrogen at the breakpoint is 7.6 to 1 (see Example 12–3). The weight ratio to reach point *B* is about 5.0 to 1.

Possible reactions to account for the appearance of N_2 and N_2O and the disappearance of chloramines during breakpoint chlorination are as follows (Saunier, 1976; Saunier and Selleck, 1976):

$$NH_4^+ + HOCl \rightarrow NH_2Cl + H_2O + H^- \quad (12\text{–}22)$$

$$NH_2Cl + HOCl \rightarrow NHCl_2 + H_2O \quad (12\text{–}23)$$

$$0.5NHCl_2 + 0.5H_2O \rightarrow 0.5NOH + H^+ + Cl^- \quad (12\text{–}24)$$

$$0.5NHCl_2 + 0.5NOH \rightarrow 0.5N_2 + 0.5HOCl + 0.5H^+ + 0.5Cl^- \quad (12\text{–}25)$$

The overall reaction, obtained by summing Eq. (12–22) through Eq. (12–25), is given as

$$NH_4^+ + 1.5HOCl \rightarrow 0.5N_2 - 1.5H_2O + 2.5H^+ + 1.5Cl^- \quad (12\text{–}26)$$

Occasionally, serious odor problems have developed during breakpoint-chlorination operations because of the formation of nitrogen trichloride and related compounds. The presence of additional compounds that will react with chlorine, such as organic nitrogen, may greatly alter the shape of the breakpoint curve, as shown on Fig. 12–7. The

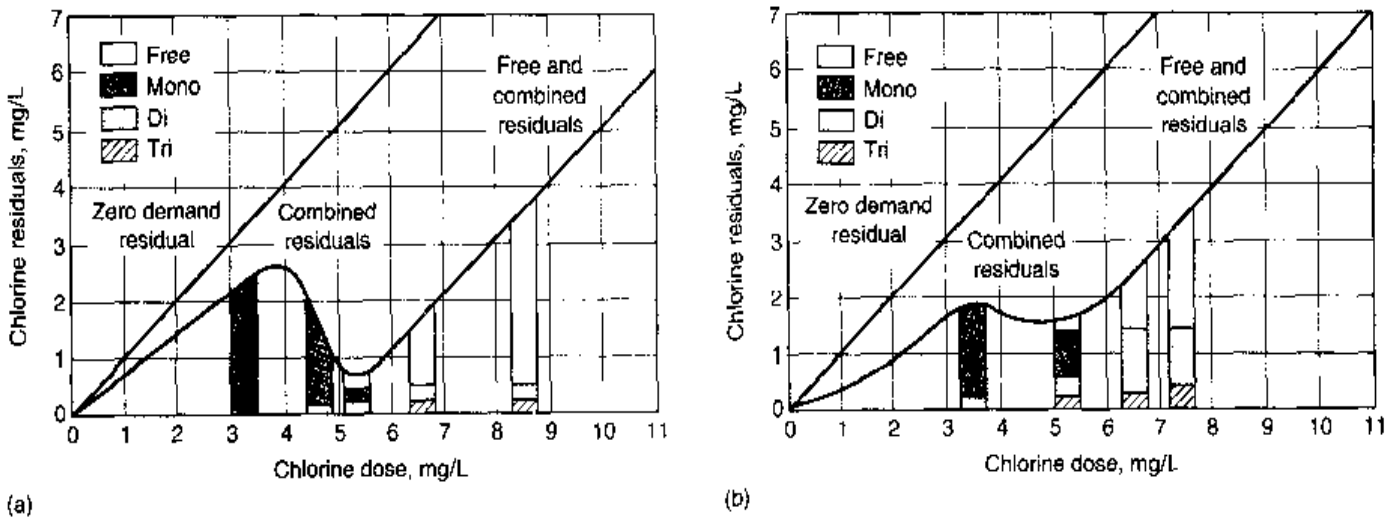

Figure 12–7

Curves of chlorine residual versus chlorine dosage for wastewater: (*a*) for wastewater containing ammonia nitrogen and (*b*) for wastewater containing nitrogen in the form of ammonia and organic nitrogen. *(Adapted from White, 1999).*
Note: 1.8(°C) + 32 = °F.

corresponding drop in pH is usually slight. The formation of disinfection byproducts is considered later in this section. The amount of chlorine that must be added to reach a desired level of residual is called the "chlorine demand."

Acid Generation. In practice, the hydrochloric acid formed during chlorination [see Eq. (12–9)] will react with the alkalinity of the wastewater, and under most circumstances, the pH drop will be slight. Stoichiometrically, 14.3 mg/L of alkalinity, expressed as $CaCO_3$, will be required for each 1.0 mg/L of ammonia nitrogen that is oxidized in the breakpoint-chlorination process as illustrated in Example 12–3.

EXAMPLE 12–3 Analysis of Chlorine Breakpoint Stoichiometry Determine the stoichiometric weight ratio of chlorine to ammonia nitrogen at the breakpoint and the amount of alkalinity required for each mg/L of ammonia nitrogen oxidized at the breakpoint.

Solution

1. Determine the molecular weight ratio of hypochlorous acid (HOCl), expressed as Cl_2, to ammonia (NH_4^+), expressed as N, using the overall reaction for the breakpoint phenomenon given by Eq. (12–26).

$$NH_4^+ + 1.5HOCl \rightarrow 0.5N_2 + 1.5H_2O + 2.5H^+ + 1.5Cl^-$$

(17) 1.5(52.45)

(14) 1.5(2 × 35.45)

$$\text{Molecular ratio} = \frac{Cl_2}{N} = \frac{1.5(2 \times 35.45)}{14} = 7.60$$

2. Determine the alkalinity required per 1.0 mg/L of ammonia nitrogen oxidized at the breakpoint. Assuming the pH of the solution is alkaline, the following expression can be written to describe the oxidation of ammonia:

$$NH_4^+ + Cl_2 \rightarrow 0.5N_2 + 4H^+ + 2Cl^-$$

Assuming lime will be used to neutralize the acidity, the required alkalinity ratio is

$$2CaO + 2H_2O \rightarrow 2Ca^{2+} + 4OH^-$$

$$\text{Alkalinity required} = \frac{2(100 \text{ mg/millimole of } CaCO_3)}{(14 \text{ mg/millimole of } NH_4^+ \text{ as N})} = 14.3$$

Thus, stoichiometrically, 14.3 mg/L of alkalinity are required per mg/L of ammonia.

Comment The ratio computed in Step 1 will vary somewhat, depending on the actual reactions involved. In practice, the actual ratio typically has been found to vary from 8:1 to 10:1. Similarly, in Step 2, the stoichiometric coefficients will also depend on the actual reactions involved. In practice, it has been found that about 15 mg/L of alkalinity are required because of the hydrolysis of chlorine.

Buildup of Total Dissolved Solids. In addition to the formation of hydrochloric acid, the chemicals added to achieve the breakpoint reaction will also contribute an incremental increase to the total dissolved solids of the wastewater. In situations where the level of total dissolved solids may be critical with respect to reuse applications, this incremental buildup from breakpoint chlorination should always be checked. The total dissolved solids contribution for each of several chemicals that may be used in the breakpoint reaction is summarized in Table 12–10. The magnitude of the possible buildup of total dissolved solids is illustrated in Example 12–4 in which the use of breakpoint chlorination is considered for the seasonal control of nitrogen.

Table 12–10 Effects of chemical addition on total dissolved solids in breakpoint chlorination

Chemical addition	Increase in total dissolved solids per unit of NH_4^+ consumed
Breakpoint with chlorine gas	6.2:1
Breakpoint with sodium hypochlorite	7.1:1
Breakpoint with chlorine gas—neutralization of all acidity with lime (CaO)	12.2:1
Breakpoint with chlorine gas—neutralization of all acidity with sodium hydroxide (NaOH)	14.8:1

EXAMPLE 12-4 Analysis of Breakpoint-Chlorination Process Used for Seasonal Control of Nitrogen Estimate the daily required chlorine dosage and the resulting buildup of total dissolved solids when breakpoint chlorination is used for the seasonal control of nitrogen. Assume that the following data apply to this problem:

1. Plant flowrate = 3800 m^3/d (1.0 Mgal/d)
2. Effluent characteristics
   a. BOD_5 = 20 mg/L
   b. Total suspended solids = 25 mg/L
   c. NH_3 N = 23 mg/L
3. Required effluent NH_3–N concentration = 1.0 mg/L

Solution

1. Estimate the required Cl_2 dosage. Assume that the required mass ratio of chlorine to ammonia is 9:1.

   kg Cl_2/d = (3800 m^3/d)[(23 − 1) g/m^3](9.0)(10^3 g/kg) = 752.4 kg/d

2. Determine the increment of total dissolved solids added to the wastewater. Using the data reported in Table 12–10, the total dissolved solids increase per mg/L of ammonia consumed is equal to 6.2.

   Total dissolved solids increment = 6.2(23 − 1) mg/L = 136.4 mg/L

Comment In this example, it was assumed that the acid produced from the breakpoint reaction would not require the addition of a neutralizing agent such as NaOH (sodium hydroxide). If the addition of NaOH were required, the total dissolved solids would have increased significantly. It is noted that although breakpoint chlorination can be used to control nitrogen, it may be counterproductive if in the process the treated effluent is rendered unusable for other applications because of the buildup of total dissolved solids and the formation of disinfection byproducts.

Measurement and Reporting of Disinfection Process Variables

To provide a framework in which to consider the effectiveness of disinfection and the factors that affect the disinfection of wastewater, it will be appropriate to consider how the effectiveness of the chlorination process is now assessed and how the results are analyzed. When using chlorine for the disinfection of wastewater, the principal parameters that can be measured, apart from environmental variables such as pH and temperature, are the number of organisms and the chlorine residual remaining after a specified period of time.

Number of Organisms Remaining. The coliform group of organisms can be determined using the most probable number (MPN) procedure as discussed in Chap. 2. The organisms remaining can also be determined by the plate-count procedure using an

agar mixture as the plating medium. Either the standard "pour-plate" method or the "spread-plate" method can be used. The plates should be incubated at 37°C (98.6°F), because this temperature results in the optimum growth of *E. coli*, and the colonies should be counted after a 24-h incubation period.

Measurement of Chlorine Residual. The chlorine residual (free and combined) should be measured using the amperometric method, which has proved to be the most consistently reliable method now available. Also, because almost all the commercial analyzers of residual chlorine use it, the adoption of this method will allow the results of independent studies to be compared directly.

Reporting of Results. Disinfection process laboratory results are reported in terms of the number of organisms and the chlorine residual remaining after a specified period of time. When the results are plotted, it is common practice to plot the logs of removal versus the corresponding $C_R t$ value. A typical plot for the inactivation of *Giardia* cysts with free chlorine is illustrated on Fig. 12–8.

Germicidal Efficiency of Chlorine and Various Chlorine Compounds

Numerous tests have shown that when all the physical parameters controlling the chlorination process are held constant, the germicidal efficiency of disinfection, as measured by the survival of "discrete bacteria," depends primarily on the residual bactericidal chlorine present C_R and the contact time t. A comparison of the relative germicidal efficiency of hypochlorous acid (HOCl), hypochlorite ion (OCl^-), and monochloramine (NH_2Cl) is presented on Fig. 12–9. For a given contact time or chlorine residual, the germicidal efficiency of hypochlorous acid, in terms of either time or residual, is significantly greater than that of either the hypochlorite ion or monochloramine. It should

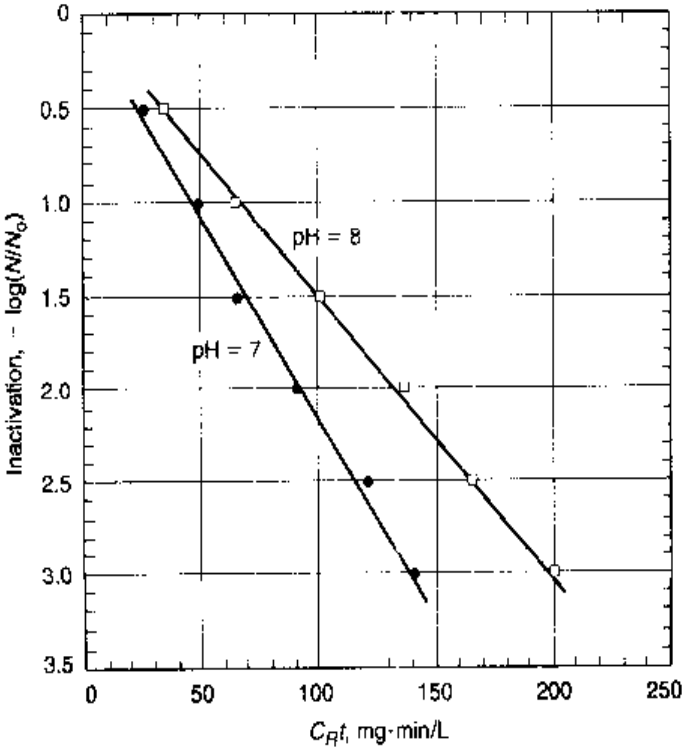

Figure 12–8

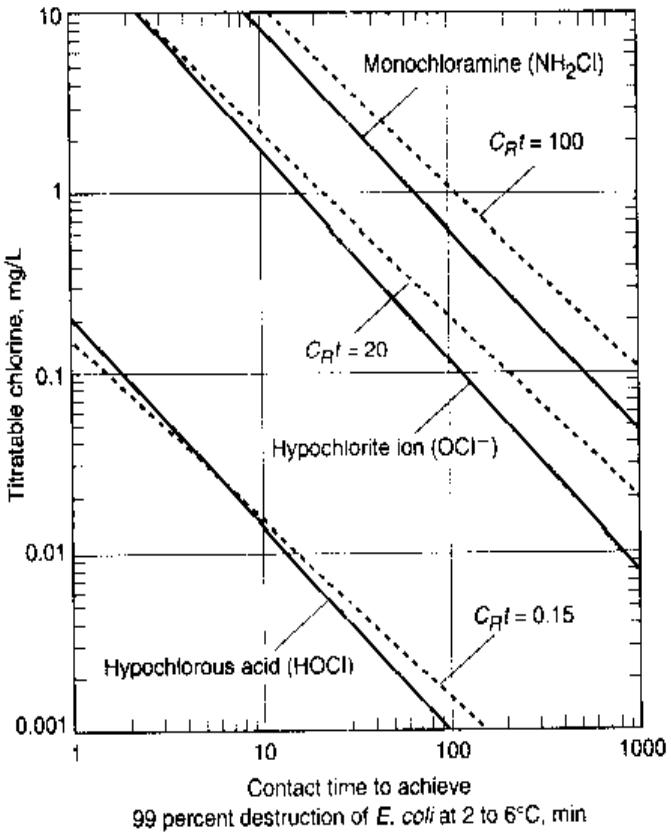

Figure 12–9

Comparison of the germicidal efficiency of hypochlorous acid, hypochlorite ion, and monochloramine for 99 percent destruction of *E. coli* at 2 to 6°C with C_Rt values added for the purpose of comparison. *(From Butterfield et al., 1943.)*

be noted, however, that given an adequate contact time, monochloramine is nearly as effective as free chlorine in achieving disinfection. In addition to the data for the chlorine compounds, C_Rt values have been added for the purpose of comparison. As shown, the disinfection data presented on Fig. 12–9 can be represented quite well with the C_Rt relationship.

Referring to Fig. 12–9, it is clear that hypochlorous acid offers the most positive way of achieving disinfection. For this reason, with proper mixing, the formation of hypochlorous acid following the breakpoint is most effective in achieving wastewater chlorination. However, when free chlorine is present, the formation of disinfection byproducts is enhanced, as discussed later in this section. If sufficient chlorine cannot be added to achieve the breakpoint reaction, great care must be taken to ensure that the proper contact time is maintained to ensure effective disinfection. Because of the equilibrium between hypochlorous acid and the hypochloric ion, maintenance of the proper pH is also important if effective disinfection is to be achieved.

In view of the renewed interest in public health, environmental water quality, and wastewater reclamation, the effectiveness of the chlorination process is of great concern. Generalized data on the relative germicidal effectiveness of chlorine and other disinfectants for the disinfection of different microorganisms are presented in Table 12–11. It is very important to note that the data presented in Table 12–11 were derived primarily using batch reactors operated under controlled conditions and, as such, are of limited use other than for the purpose of illustrating the relative differences in the effectiveness of the different disinfectants for different organism groups. As shown, there are significant differences in the effectiveness of the various disinfectants for each organism group.

Table 12-11
Estimated range of $C_R t$ values for various levels of inactivation of dispersed bacteria, viruses, and protozoan oocysts and cysts in filtered secondary effluent (pH ~ 7 and T ~ 20°C)[a]

Disinfectant	Unit	Inactivation			
		1-log	2-log	3-log	4-log
Bacteria					
Chlorine (free)	mg·min/L	0.1–0.2	0.4–0.8	1.5–3	10–12
Chloramine	mg·min/L	4–6	12–20	30–75	200–250
Chlorine dioxide	mg·min/L	2–4	8–10	20–30	50–70
Ozone	mg·min/L		3–4		
UV radiation[b]	mJ/cm^2		30–60	60–80	80–100
Virus					
Chlorine (free)	mg·min/L		2.5–3.5	4–5	6–7
Chloramine	mg·min/L		300–400	500–800	200–1200
Chlorine dioxide	mg·min/L		2–4	6–12	12–20
Ozone	mg·min/L		0.3–0.5	0.5–0.9	0.6–1.0
UV radiation[b]	mJ/cm^2		20–30	50–60	70–90
Protozoan cysts					
Chlorine (free)	mg·min/L	20–30	35–45	70–80	
Chloramine	mg·min/L	400–650	700–1000	1100–2000	
Chlorine dioxide	mg·min/L	7–9	14–16	20–25	
Ozone	mg·min/L	0.2–0.4	0.5–0.9	0.7–1.4

[b] UV dose = UV intensity × time [see Eq. (12-68)].
[c] Based on the results of infectivity studies.

Factors That Affect Disinfection Efficiency of Chlorine

The purpose of the following discussion is to explore the important factors that affect the disinfection efficiency of chlorine compounds in wastewater applications. These include (1) the importance of initial mixing, (2) the chemical characteristics of the wastewater, (3) the impact of particles found in wastewater, (4) particles with coliform organisms, and (5) the characteristics of the microorganisms.

Initial Mixing. The importance of initial mixing on the disinfection process cannot be overstressed. It has been shown that the application of chlorine in a highly turbulent regime ($N_R \geq 10^4$) will result in kills two orders of magnitude greater than when chlorine is added separately to a conventional rapid-mix reactor under similar conditions. Although the importance of initial mixing is well delineated, the optimum level

of turbulence is not known. Based on recent findings, questions have now been raised about the form in which the chlorine compounds are added.

In some plants where chlorine injectors are used, there is concern over the practice of using chlorinated wastewater for the chlorine injection water. The concern is that if nitrogenous compounds are present in the wastewater, a portion of the chlorine that is added will react with these compounds, and by the time chlorine solution is injected, it will be in the form of monochloramine or dichloramine. The formation of chloramines can be a problem if adequate retention time is not available in the chlorine contact basin. Again, it should be remembered that hypochlorous acid (HOCl) and monochloramine (NH_2Cl) are equally effective as disinfecting compounds; only the contact time required is different (see Fig. 12–9).

The formation of disinfection byproducts (DBPs) is another major concern with the use of chlorine inductors, in which molecular chlorine is added directly to the wastewater (see Sec. 12–6). When wastewater is exposed to free chlorine, competing reactions such as the formation of chloramines (free chlorine and ammonia), the formation of DBPs, and the formation of *N*-nitrosodimethylamine (free chlorine, nitrite, and amines) can occur. The predominant reaction will depend on the applicable kinetic rates for the various reactions. The formation and control of DBPs is discussed later in this section.

Chemical Characteristics of the Wastewater. It has often been observed that, for treatment plants of similar design with exactly the same effluent characteristics measured in terms of BOD, COD, and nitrogen, the effectiveness of the chlorination process varies significantly from plant to plant. To investigate the reasons for this observed phenomenon, and to assess the effects of the compounds present in the chlorination process, Sung (1974) studied the characteristics of the compounds in untreated and treated wastewater. Among the more important conclusions derived from Sung's study are the following:

1. In the presence of interfering organic compounds, the total chlorine residual cannot be used as a reliable measure for assessing the bactericidal efficiency of chlorine.
2. The degree of interference of the compounds studied depended on their functional groups and their chemical structure.
3. Saturated compounds and carbohydrates exert little or no chlorine demand and do not appear to interfere with the chlorination process.
4. Organic compounds with unsaturated bonds may exert an immediate chlorine demand, depending on their functional groups. In some cases, the resulting compounds may titrate as chlorine residual and yet may possess little or no disinfection potential.
5. Compounds with polycyclic rings containing hydroxyl groups and compounds containing sulfur groups react readily with chlorine to form compounds which have little or no bactericidal potential, but which still titrate as chlorine residual.
6. To achieve low bacterial counts in the presence of interfering organic compounds, additional chlorine and longer contact times will be required.

From the results of this work, it is easy to see why the efficiency of chlorination at plants with the same general effluent characteristics can be quite different. Clearly, it is

not the value of the BOD or COD that is significant, but the nature of the compounds that make up the measured values. Thus, the nature of the treatment process used in any plant will also have an effect on the chlorination process. The impact of wastewater characteristics on chlorine disinfection is presented in Table 12–12. The presence of oxidizable compounds such as humics and iron will cause the inactivation curve to have a lag or shoulder effect as shown on Fig. 12–10. In effect, the added chlorine is being utilized in the oxidization of these substances and is not available for the inactivation of microorganisms.

Because more wastewater-treatment plants are now removing nitrogen, operational problems with chlorine disinfection are now reported more frequently. In treatment plants where the effluent is nitrified completely, the chlorine added to the wastewater will be present as free chlorine, after satisfying any immediate chlorine demand. In general, the presence of free chlorine will reduce significantly the required chlorine dosage. However, the presence of free chlorine may lead to the formation of *N*-nitrosodimethylamine (NDMA), an undesirable disinfection byproduct (see subsequent discussion under the heading Formation and Control of Disinfection By-products). In treatment plants that do not nitrify completely, or partially nitrify, control of the chlorination process is especially difficult because of the variation in the effectiveness of the chlorine compounds. Some of the chlorine is used to satisfy the demand of the residual nitrite and/or ammo-

Table 12–12 Impact of wastewater constituents on the use of chlorine for wastewater disinfection

Constituent	Effect
BOD, COD, TOC, etc.	Organic compounds that comprise the BOD and COD can exert a chlorine demand. The degree of interference depends on their functional groups and their chemical structure
Humic materials	Reduce effectiveness of chlorine by forming chlorinated organic compounds that are measured as chlorine residual but are not effective for disinfection
Oil and grease	Can exert a chlorine demand
TSS	Shield embedded bacteria
Alkalinity	No or minor effect
Hardness	No or minor effect
Ammonia	Combines with chlorine to form chloramines
Nitrite	Oxidized by chlorine, formation of *N*-nitrosodimethylamine (NDMA)
Nitrate	Chlorine dose is reduced because chloramines are not formed. Complete nitrification may lead to the formation of NDMA due the presence of free chlorine. Partial nitrification may lead to difficulties in establishing the proper chlorine dose
Iron	Oxidized by chlorine
Manganese	Oxidized by chlorine
pH	Affects distribution between hypochlorous acid and hypochlorite ion
Industrial discharges	Depending on the constituents, may lead to diurnal and seasonal variations in the chlorine demand

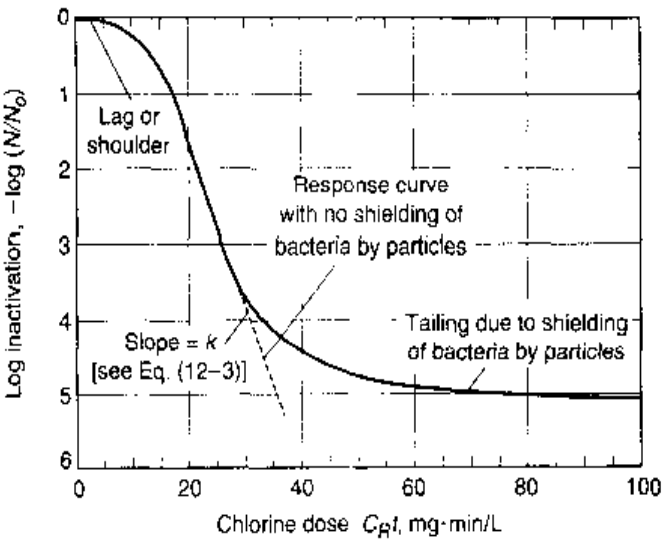

Figure 12–10
Typical disinfection curve obtained with wastewater containing oxidizable constituents and suspended solids.

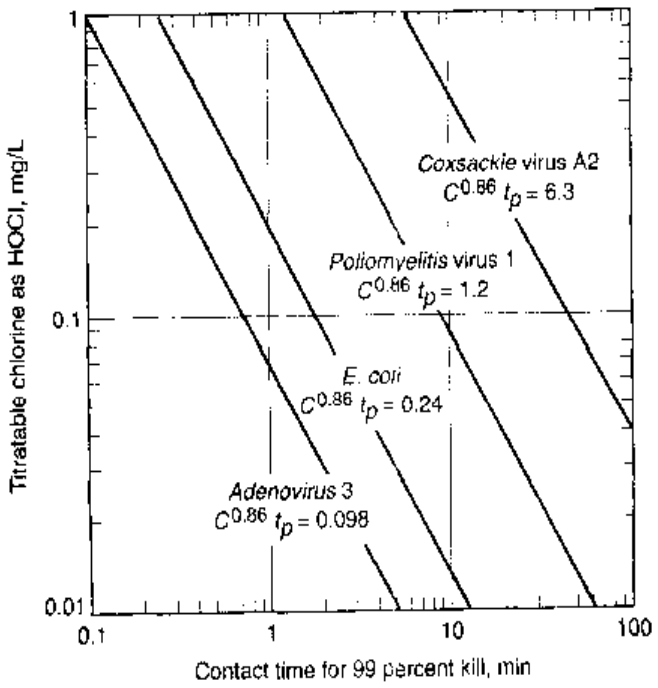
nia. Because of the uncertainties involved in knowing to what degree the plant is nitrifying at any point in time, the chlorine dosage that is added is based on the dosage required if the disinfection of the wastewater is to be accomplished by combined chlorine compounds resulting in excessive chlorine use.

Impact of Particles Found in Wastewater. Another factor that must be considered is the presence of suspended solids in the wastewater to be disinfected. As shown on Fig. 12–10, when suspended solids are present, the disinfection process is controlled by two different mechanisms. The large bacterial inactivation that is observed initially, after the shoulder effect, is of individual free-swimming bacteria and bacteria in small clumps. The straight-line portion of the bacterial inactivation can be described using Eq. (12-3). In the second portion of the curve the bacterial kill is controlled by the presence of suspended solids. Further the slope of the second portion of the curve is a function of the particle size distribution.

Particles with Coliform Organisms. In addition to the particle size distribution, the number of particles with associated coliform organisms is another factor that will impact the performance of both chlorine and UV disinfection for unfiltered effluents. Based on recent studies dealing with UV disinfection, as discussed in Sec. 12–9, it has been found that for activated-sludge plants, the number of particles with associated coliform organisms is a function of the solids retention time (Darby et al., 1999). If particles contain significant numbers of organisms, the organisms can provide protection to other organisms embedded within the particle by limiting the penetration of chlorine through diffusion. Thus, when suspended solids are present, a single equation based on a single mechanism cannot be used to describe the observed results (see Fig. 12–10). Unfortunately, the observed variability caused by the presence of particles usually is masked by the addition of excess chlorine to overcome both chemical and particle effects.

Characteristics of the Microorganisms. Other important variables in the chlorination process are the type, characteristics, and age of the microorganisms. For a young bacterial culture (1 day old or less) with a chlorine dosage of 2 mg/L, only 1 min

was needed to reach a low bacterial number. When the bacterial culture was 10 days old or more, approximately 30 min was required to achieve a comparable reduction for the same applied chlorine dosage. It is likely that the resistance offered by the polysaccharide sheath, which the microorganisms develop as they age, accounts for this observation. In the activated-sludge treatment process, the operating mean cell residence time, which to some extent is related to the age of the bacterial cells in the system, will, as discussed previously, affect the performance of the chlorination process. The relative effectiveness of chlorine and other disinfectants was reported previously in Table 12–11. Because the data were not derived using wastewater, they are only provided to illustrate broad differences between organism groups.



Some representative data on the effectiveness of chlorine in killing *E. coli* and three enteric viruses are reported on Fig. 12-11. Again, because newer analytical techniques have been developed, the data presented on Fig. 12–11 are meant only to illustrate the differences in the resistances of different organisms. From the available evidence on the viricidal effectiveness of the chlorination process, it appears that chlorination beyond the breakpoint to obtain free chlorine will be required to kill many of the viruses of concern. Where breakpoint chlorination is used, it will be necessary to dechlorinate the treated wastewater before reuse to reduce any residual toxicity that may remain after chlorination. Recently, based on the use of integrated cell culture PCR techniques, it has been reported that the inactivation of poliovirus may require five times more chlorine than thought previously (Blacknier et al., 2000).

Modeling the Chlorine Disinfection Process

As discussed in Sec. 12–1, a number of models have been developed to describe the disinfection process. The use of these conventional models for predicting microorganism inactivation has, for the most part, proved to be of limited value. Two types of effluent are considered in the following discussion: (1) secondary and filtered secondary effluent and (2) microfiltration and reverse osmosis effluent.

Figure 12–11

Concentration of chlorine as HOCl required for 99 percent kill of *E. coli* and three enteric viruses at 0 to 6°C.

Secondary and Filtered Secondary Effluent. When considering the disinfection of both secondary and filtered secondary effluent, both the lag or shoulder effect and the effect of the residual particles (see Fig. 12–10) must be considered. As noted previously, depending on the constituents in the treated wastewater, a shoulder region may be observed in which there is no reduction in the number of organisms as the result of the addition of disinfectant. As additional chlorine is added beyond some limiting value, a log-linear reduction in the number of organisms will be observed with increased chlorine dosages. If particles (typically greater than 20 μm) are present, the disinfection curve will start to diverge from the log-linear form and a tailing region will be observed due to particle shielding of the microorganisms. The tailing region is of importance as more restrictive standards are to be achieved (e.g., 23 MPN/100 mL). It is interesting to note that the first attempt to determine the effect of suspended solids on disinfection dates back to 1918 to work conducted by H. P. Eddy at Cleveland, OH (Pearse et al., 1934). The tailing region was also identified in an early paper dealing with the disinfection of wastewater effluents (Tiedeman, 1927).

Because the lag and tailing regions, identified on Fig. 12–10, are not considered, most classic disinfection models are not applicable. Nevertheless, it is appropriate to review some of the models that have been developed more recently. In 1957, Gard noted that the rate of inactivation was not constant, but decreased with time, resulting in a tailing effect (Gard, 1957). Gard proposed the following relationship to define the decreasing rate constant:

$$\frac{dN}{dt} = -\frac{kN}{1 + a(Ct)} \tag{12–27}$$

The integrated form of Eq. (12–27) is

$$\frac{N}{N_o} = \frac{1}{[1 + a(Ct)]^{k/a}} \tag{12–28}$$

where N = number of organisms remaining after disinfection at time t
N_o = number of organisms present before disinfection
k = first-order inactivation rate at time $t = 0$
a = rate coefficient
C = concentration of chemical agent held constant over time, mg/L
t = contact time, min

It is interesting to note that the form of Eq. (12–28) corresponds to the retarded rate expression given by Eq. (4–102) in Chap. 4.

In the early 1970s, Collins conducted extensive experiments on the disinfection of various wastewaters (Collins, 1970; Collins and Selleck, 1972). Using the batch reactor whose contents were well stirred, Collins and Selleck found that the reduction of coliform organisms in a chlorinated primary treated effluent followed a linear relationship when plotted on log-log paper. The original equation developed to describe the observed results is

$$\frac{N}{N_o} = \frac{1}{(1 + 0.23C_R t)^3} \tag{12–29}$$

It will be noted that the original form of the equation developed by Collins did not account for the lag effect, but did account for the tailing effect (see Fig. 12–12).

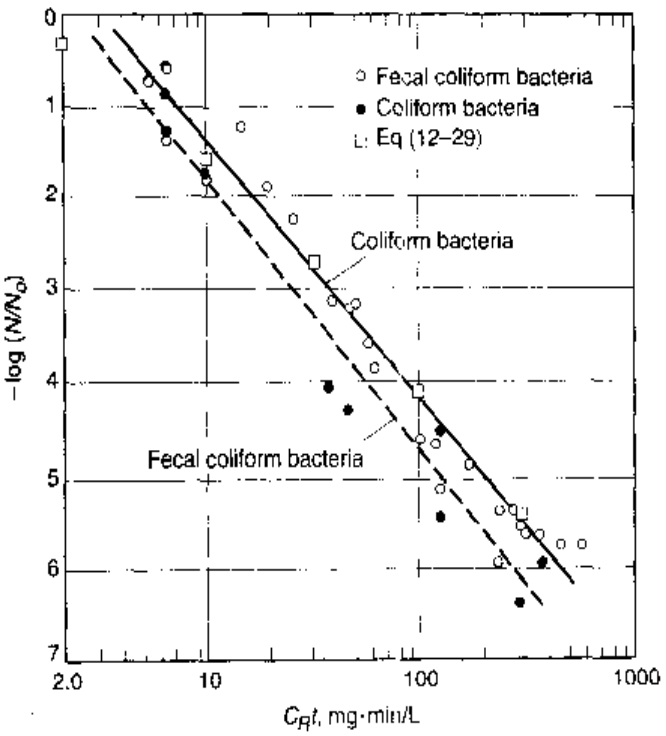


Figure 12–12

Coliform survival in a batch reactor as a function of amperometric chlorine residual and contact time (temperature range 11.5 to 18°C). It should be noted that if the $C_R t$ values had been plotted on an arithmetic scale, a tailing effect would be observed in the plotted values. *(From Collins, 1970; Collins and Selleck, 1972; Sellect et al., 1978.)*

A refinement of the original Collins model for the disinfection of secondary effluent in which both lag and tailing effects are observed (see Fig. 12–12), as proposed by Selleck et al. (1978) and later modified by White (1999), is

$$\frac{N}{N_o} = 1 \qquad \text{for } C_R t < b \tag{12–30}$$

$$\frac{N}{N_o} = [(C_R t)/b]^{-n} \qquad \text{for } C_R t > b \tag{12–31}$$

where C_R = chlorine residual remaining at the end of time t
t = contact time
n = slope of inactivation curve
b = value of x-intercept when $N/N_o = 1$ or $\log N/N_o = 0$ (see Fig. 12–13)

Typical values for the coefficients n and b for secondary effluent for coliform and fecal coliform organisms are 2.8 and 4.0 and 2.8 and 3.0, respectively (Roberts et al., 1980; White, 1999). However, because of the variability of the chemical composition of the secondary effluent and the variable particle size distribution, it is recommended that the constants be determined for each wastewater. When the $C_R t$ values become large (>100 mg·min/L), Eq. (12–29) is essentially the same as Eq. (12–31). It should be noted that numerous other models have been proposed for wastewater disinfection including an empirical model proposed by Hom (1972), which was subsequently rationalized by Haas and Joffe (1994).

An alternative approach that can be used to model the disinfection process in secondary and filtered secondary effluent is to model the inactivation of the free-swimming microorganisms and the inactivation of the microorganisms associated with particles

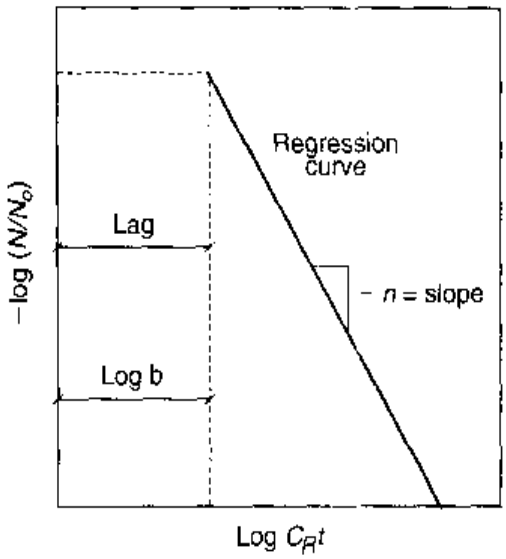

Figure 12–13
Definition sketch for the application of Eq. (12–31).

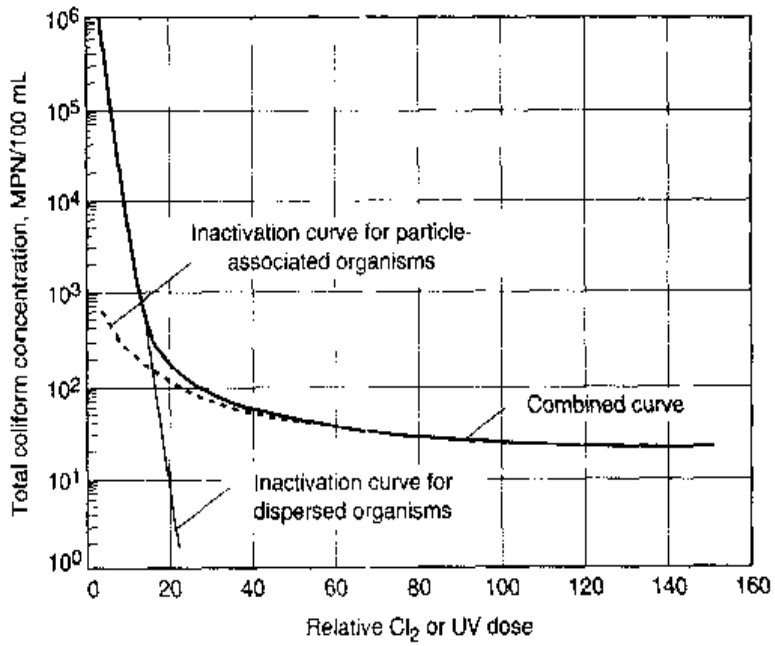

Figure 12–14
Disinfection curves for chlorine and UV radiation for dispersed coliform organisms, particle-associated coliform organisms, and the combined curve for both the free-swimming and associated coliform organisms.

separately as has been proposed for UV disinfection (see Fig. 12–14). The resulting formulation takes the following form:

$$N(t) = N_D(0)e^{-k(C_R t)} + \frac{N_P(0)}{k(C_R t)}(1 - e^{-k(C_R t)}) \tag{12–32}$$

where $N(t)$ = total number of surviving coliform bacteria at time t
$N_D(0)$ = total number of disperse coliform bacteria prior to application of disinfectant at time $t = 0$
$N_P(0)$ = total number of particles containing at least one coliform bacterium at time $t = 0$
k = inactivation rate coefficient
C_R = residual chlorine at time t
t = time

It will be recognized that the first term in Eq. (12–32) corresponds to the Chick and Watson formulation as given by Eq. (12-6). The inactivation rate coefficient in Eq. (12–32) could also be modified to account for a lag effect and the fact that the inactivation may not be constant but decreases with time.

Microfiltration and Reverse Osmosis Effluent. The most important characteristic of these effluents is that they do not contain particles that can shield microorganisms. For these effluents, the Chick-Watson model, as given by Eq. (12–7), can be used to model the disinfection process with chlorine. A lag term can also be added, if needed. Typically, the lag effect is reduced considerably, especially with reverse osmosis effluent.

Review of the $C_R t$ Concept

Use of the $C_R t$ concept to control the disinfection process is now becoming more common in the wastewater field. In some states, the $C_R t$ value and the chlorine contact time are specified in regulatory requirements. For example, the state of California requires a $C_R t$ value of 450 mg·min/L and a modal contact time of 90 min at peak flow for certain reclamation applications. It is assumed, based on past testing, that a $C_R t$ value of 450 mg·min/L will produce a four-log inactivation of poliovirus. As the use of the $C_R t$ concept becomes more common in the wastewater field, there are a number of limitations that must be considered in the application of this concept for regulatory purposes. Most of the $C_R t$ values reported in the literature are obtained: (1) using complete mixed batch reactors (i.e., ideal flow conditions) in a laboratory setting under controlled conditions, (2) using discrete organisms grown in the laboratory in pure culture, and (3) using a buffered fluid for the suspension of the discrete organisms.

Further, many of the $C_R t$ values reported in the literature were based on older analytical techniques. As a consequence, $C_R t$ values used for regulatory purposes often do match what is observed in the field. Referring to Fig. 12–10, it can be seen that in the tailing region, the residual concentration of microorganisms is essentially independent of the $C_R t$ value. As shown on Fig. 12-15, it is clear that a $C_R t$ value of 450 mg·min/L, as used by the state of California, will not result in a four-log reduction of virus, when the measured residual chlorine is combined chlorine (i.e., mono- and dichloramine). Clearly, site-specific testing is required to establish the appropriate chlorine dose.

Required Chlorine Dosage for Disinfection

The required chemical dosage for disinfection can be estimated by considering (1) the initial chlorine demand of the wastewater, (2) the allowance needed for decay during the chlorine contact time, and (3) the required chlorine residual concentration determined using Eq. (12–31) for the organism under consideration (e.g., bacteria, virus, or protozoan oocysts and cysts). The chlorine dosage required to meet the initial demand will depend on the wastewater constituents. It is important to remember that the chlorine added to meet the initial demand due to inorganic compounds will be reduced to the chloride ion and will not be measured as chlorine residual. On the other hand, chlorine that combines with humic materials will not be effective as a disinfectant but will nevertheless be measured as a chlorine residual contributing to the lag term b in Eq. (12–31). Typical decay values for chlorine residual are on the order of 2 to 4 mg/L for contact time of about 1 h. Typical chlorine dosage values for various wastewaters

Figure 12–15

Inactivation of MS2 coliphage and poliovirus with combined chlorine. *(From BioVir Laboratories, 2001.)*

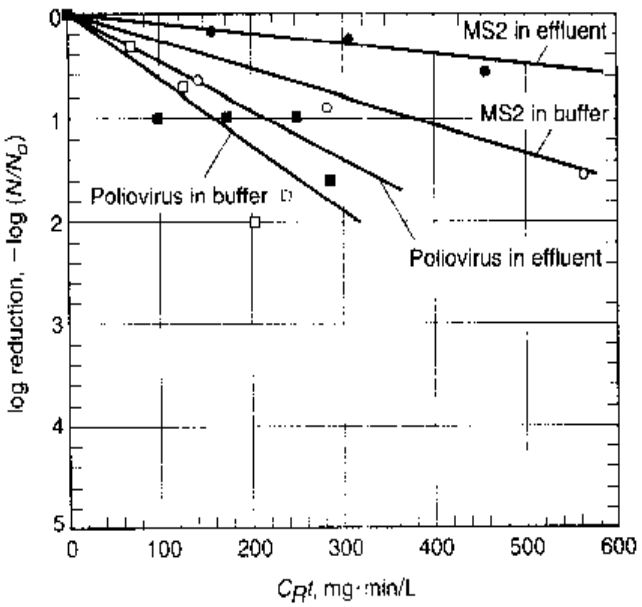

Table 12–13
Typical chlorine dosages, based on combined chlorine unless otherwise indicated, required to achieve different effluent total coliform disinfection standards for various wastewaters based on a 30-min contact time[a]

Type of wastewater	Initial coliform count, MPN/100 mL	Chlorine dose, mg/L			
		Effluent standard, MPN/100 mL			
		1000	200	23	≤2.2
Raw wastewater	10^7–10^9	15–40			
Primary effluent	10^7–10^9	10–30	20–40		
Trickling filter effluent	10^5–10^6	3–10	5–20	10–40	
Activated-sludge effluent	10^5–10^6	2–10	5–15	10–30	
Filtered activated-sludge effluent	10^4–10^6	4–8	5–15	6–20	8–30
Nitrified effluent	10^4–10^6	4–12	6–16	8–18	8–20
Filtered nitrified effluent	10^4–10^6	4–10	6–12	8–14	8–16
Microfiltration effluent	10^1–10^3	1–3	2–4	2–6	4–10
Reverse osmosis[b]	~0	0	0	0	0–2
Septic tank effluent	10^7–10^9	20–40	40–60		
Intermittent sand filter effluent	10^2–10^4	1–5	2–8	5–10	8–18

[a] Adapted in part from U.S. EPA (1986); White (1999).

[b] Based on free chlorine.

for total coliform, based on a contact time of 30 min, are reported in Table 12–13. It should be noted that the dosage values given in Table 12–13 are only meant to serve as a guide for the initial estimation of the required chlorine dose. As noted above, site-specific testing is required to establish the appropriate chlorine dose. Estimation of the required chlorine dose is illustrated in Example 12–5.

EXAMPLE 12-5 Estimate the Required Chlorine Dose for a Typical Secondary Effluent Estimate the chlorine dose needed to disinfect a filtered secondary effluent assuming a shoulder effect exists and that the following conditions apply:

1. Effluent total coliform count before disinfection = 10^7/100 mL
2. Required summer effluent total coliform count = 23/100 mL
3. Required winter effluent total coliform count = 240/100 mL
4. Initial effluent chlorine demand = 4 mg/L
5. Demand due to decay during chlorine contact = 2.5 mg/L
6. Required chlorine contact time = 60 min

Solution

1. Estimate the required chlorine residual using Eq. (12–31).

   $N/N_o = (C_R t/b)^{n}$

   Use the typical values given above for the coefficients.

   $b = 4.0$

   $n = 2.8$

   a. Summer

   $23/10^7 = (C_R t/4.0)^{-2.8}$

   $(23/10^7)^{-1/2.8} = (C_R t/4.0)$

   $(234.3)4 = C_R\,(60)$

   $C_R = 15.6$ mg/L

   b. Winter

   $240/10^7 = (C_R t/4.0)^{-2.8}$

   $C_R = 3.0$ mg/L

2. The required chlorine dosage is

   a. Summer

   Chlorine dosage = 4.0 mg/L + 2.5 mg/L + 15.6 mg/L = 22.1 mg/L

   b. Winter

   Chlorine dosage = 4.0 mg/L + 2.5 mg/L + 3.0 mg/L = 9.5 mg/L

Comment The chlorine dosage increases significantly as the effluent standards become more stringent. In the above computation, it was assumed that the wastewater to be disinfected remained in the chlorine contact tank for the full 60 min. Thus, it is clear that the proper design of a plug-flow chlorine contact basin is critical to the effective use of chlorine as disinfectant. The design of chlorine contact basins is discussed in Sec. 12–6 and in Chap. 4.

Formation and Control of Disinfection Byproducts

In the early 1970s, it was found that the use of oxidants, such as chlorine and ozone, in water-treatment plants for disinfection; for taste, odor, and color removal; and other in-plant uses resulted in the production of undesirable disinfection byproducts (DBPs) (U.S. EPA, 1999*b*). The DBPs occurring most frequently and with the highest concentration are trihalomethanes (THMs) and haloacetic acids (HAAs). In addition to trihalomethanes and haloacetic acids, a variety of other DBPs is also produced. The principal DBPs that have been identified are reported in Table 12–14. Many of the compounds identified in Table 12–14 have also been identified in treated effluent that has been disinfected using chlorine.

Formation of DBPs is of great concern because of the potential impact of these compounds on public health and the environment. Chloroform, for example, is a well-known animal carcinogen, and many of the haloforms are also thought to be animal carcinogens. In addition, many of these compounds have been classified as probable human carcinogens. Still others of these compounds are known to cause chromosomal aberrations and sperm abnormalities. Recognizing the many unknowns and the potential public health and environmental risks associated with these compounds, the U.S. EPA has moved aggressively to control their formation in drinking water.

Formation of DBPs Due to the Addition of Chlorine for Disinfection. Trihalomethanes (THMs) and other DBPs are formed as a result of a series of complex reactions between free chlorine and a group of organic acids known collectively as humic acids. The reactions lead to the formation of single carbon molecules that are often designated as HCX_3, where X is either a chlorine (Cl^-) or bromine (Br^-) atom. For example, the chemical formula for chloroform is $HCCl_3$.

The rate of formation of DBPs is dependent on a number of factors including:

- Presence of organic precursors
- Free chlorine concentration
- Bromide concentration
- pH
- Temperature

The type and concentration of the organic precursor will affect both the rate of the reaction and the extent to which the reaction is completed. The presence of free chlorine was thought to be necessary for the THM formation reaction to proceed, but it appears that THMs can form in the presence of combined chlorine, but at a very reduced rate. It is important to note that initial mixing can affect the formation of THMs because of the competing reactions between chlorine and ammonia and chlorine and humic acids. If bromide is present, it can be oxidized to bromine by free chlorine. In turn the bromine ion can combine with the organic precursors to form THMs, including bromodichloromethane, dibromochloromethane, and bromoform. The rate of formation of THMs has been observed to increase with both pH and temperature. Additional details on the formation of THMs may be found in U.S. EPA (1999*b*).

Another DBP that has recently surfaced in disinfected treated wastewater effluents is *N*-nitrosodimethylamine (NDMA), which is a member of a class of compounds known as nitrosamines. As a class of compounds nitrosamines are among the most

powerful carcinogens known (Snyder, 1995). The compounds in this class have been found to produce cancer in every species of laboratory animal tested. Formation of NDMA can be illustrated with the following two reactions:

$$\underset{\text{nitrite anion}}{NO_2^-} + \underset{\text{hydrochloric acid}}{HCl} \rightarrow \underset{\text{nitrous acid}}{HNO_2} + \underset{\text{chloride ion}}{Cl^-} \qquad (12\text{–}33)$$

$$\underset{\text{nitrous acid}}{HNO_2} + \underset{\text{dimethylamine}}{CH_3{-}NH{-}CH_3} \rightarrow \underset{\text{N-nitrosodimethylamine}}{CH_3{-}\overset{\overset{NO}{|}}{N}{-}CH_3} \qquad (12\text{–}34)$$

The concern in biological wastewater-treatment facilities is that some nitrite may leak through the process. While the concentration of nitrite may be too low to measure by conventional means, concentrations of NDMA as low as 5 ng/L (ppt) are being measured and the action level for NDMA in drinking water in California has been set temporarily (2001) at 20 ng/L. Based on a limited number of test locations, it has been observed that the concentrations of NDMA in the incoming wastewater can be quite variable, with concentrations varying from below 10 to greater than 10,000 ng/L being measured. In addition to the formation of NDMA as outlined above, it appears the addition of chlorine serves to amplify the concentration of any NDMA that may be present in the treated effluent before chlorination.

Control of DBP Formation Due to the Addition of Chlorine for Disinfection. The principal means of controlling the formation of THMs and other related DBPs in wastewater is to avoid the direct addition of free chlorine. Based on the evidence to date, it appears that the use of chloramines will not lead to the formation of THMs and other related DBPs in amounts that would be of concern relative to current standards. It is important to note that if chloramines are to be used for disinfection, the chloramine solution must be prepared with a potable water supply containing little or no ammonia; treated plant water cannot be used. If the formation of DBPs is of concern due to the presence of specific organic precursors (i.e., humic materials), the practice of breakpoint chlorination cannot be used. Further, if humic materials are present consistently, it may be appropriate to investigate alternative means of disinfection such as UV radiation.

With respect to NDMA it appears that with proper control and operation of the biological treatment process, the potential for the formation or amplification of this compound can be reduced. Removals of 50 to 70 percent have been reported for NDMA when using reverse osmosis employing thin-film composite membranes. The use of UV disinfection has also proved to be effective in the control of NDMA. At present, a variety of studies are under way to develop means for controlling the discharge of effluents with high concentrations of NDMA.

Environmental Impacts

The environmental impacts associated with the use of chlorine and chlorine compounds as a wastewater disinfectant include the regrowth of organisms and the discharge of DBPs.

Regrowth of Microorganisms. In many locations, a regrowth of microorganisms has been observed in receiving water bodies and in long transmission pipelines following dechlorination of secondary effluent disinfected with chlorine. It has been hypothesized that regrowth (also known as aftergrowth), which occurs in films on the pipe surface exposed to treated wastewater, results because the amount of organic matter in secondary effluent is sufficient to sustain the limited number of organisms remaining after disinfection, and because predators such as protozoa are absent. Regrowth is an especially important issue in transmission lines used for the transport of reclaimed water. In many reuse applications, a chlorine residual is maintained (a common practice in water distribution systems) in the pipeline to control regrowth. In very long pipelines, it may be necessary to add additional chlorine at intermediate points along the length of the pipeline. Additional details on regrowth may be found in the vast literature dealing with regrowth in water supply distribution systems, as the controlling factors are similar, with the exception that the residual organic content in treated wastewater is higher and not all treated wastewaters are disinfected completely.

Discharge of DBPs. It has been shown that many of the DBPs can cause environmental impacts at very low concentrations. The occurrence of DBPs and compounds such as NDMA raises serious questions about the continued use of free chlorine for wastewater disinfection.

12–4 DISINFECTION WITH CHLORINE DIOXIDE

Chlorine dioxide (ClO_2) is another bactericide, equal to or greater than chlorine in disinfecting power. Chlorine dioxide has proved to be an effective virocide, being more effective in achieving inactivation of viruses than chlorine. A possible explanation is that because chlorine dioxide is adsorbed by peptone (a protein), and that viruses have a protein coat, adsorption of ClO_2 onto this coating could cause inactivation of the virus. In the past, ClO_2 did not receive much consideration as a wastewater disinfectant due to its high costs.

Characteristics of Chlorine Dioxide

Chlorine dioxide (ClO_2) is, under atmospheric conditions, a yellow to red unpleasant-smelling irritating unstable gas with a high specific gravity. Physical properties of chlorine dioxide are reported in Table 12–6. Because chlorine dioxide is unstable and decomposes rapidly, it is usually generated onsite before its application. Chlorine dioxide is generated by mixing and reacting a chlorine solution in water with a solution of sodium chlorite ($NaClO_2$) according to the following reaction:

$$2NaClO_2 + Cl_2 \rightarrow 2ClO_2 + 2NaCl \qquad (12\text{–}35)$$

Based on Eq. (12–35), 1.34 mg sodium chlorite reacts with 0.5 mg chlorine to yield 1.0 mg chlorine dioxide. Because technical-grade sodium chlorite is only about 80 percent pure, about 1.68 mg of the technical-grade sodium chlorite would be required to produce 1.0 mg of chlorine dioxide. Sodium chlorite may be purchased and stored as a liquid (generally a 25 percent solution) in refrigerated storage facilities.

The chlorine and liquid sodium chlorite solutions are brought together at the base of a porcelain ring filled reaction tower (see Fig. 12–16). As this combined solution

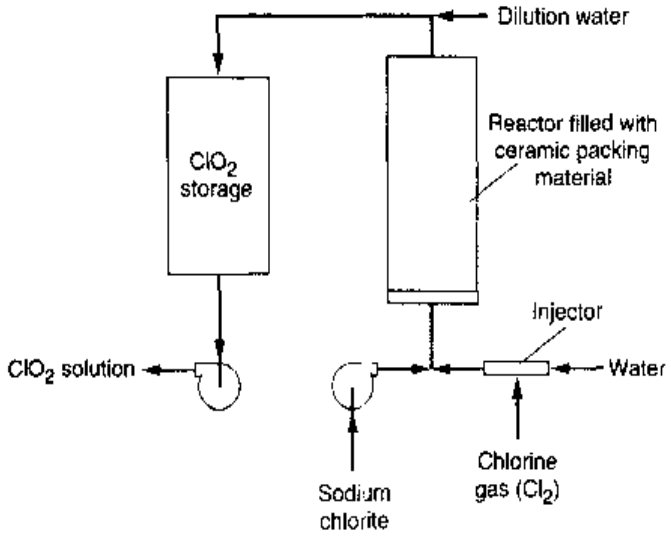

Figure 12–16
Schematic flow diagram for the generation of chlorine dioxide. *(Adapted from Wallace and & Tiernan.)*

flows upward, chlorine dioxide is generated. A contact time of about 1 min is generally adequate. To increase the reaction rate and obtain the highest yield of chlorine dioxide, a slight excess of chlorine is recommended. Because sodium chlorite is about ten times as expensive as chlorine on a weight basis, economical considerations must be taken into account. The solution discharged from the tower is only partly chlorine dioxide, with the remaining portion being chlorine in solution as hypochlorous acid.

Chlorine Dioxide Chemistry

The active disinfecting agent in a chlorine dioxide system is free dissolved chlorine dioxide (ClO_2). At the present time, the complete chemistry of chlorine dioxide in an aqueous environment is not clearly understood. Because ClO_2 does not hydrolyze in a manner similar to the chlorine compounds discussed in the previous section, the oxidizing power of ClO_2 is often referred to as "equivalent available chlorine." The definition of the term equivalent available chlorine is based on a consideration of the following oxidation half reaction for ClO_2:

$$ClO_2 + 5e^- + 4H^+ \rightarrow Cl^- + 2H_2O \qquad (12\text{–}36)$$

As shown in Eq. (12–36), the chlorine atom undergoes a 5-electron change in its conversion from chlorine dioxide to the chloride ion. Because the weight of chlorine in ClO_2 is 52.6 percent and there is a 5-electron change, the equivalent available chlorine content is equal to 263 percent as compared to chlorine. Thus, ClO_2 has 2.63 times the oxidizing power of chlorine. The concentration of ClO_2 is usually expressed in g/m^3. On a molar basis, 1 mole of ClO_2 is equal to 67.45 g, which is equivalent to 177.5 g (5×35.45) of chlorine. Thus, 1 g/m^3 of ClO_2 is equivalent to 2.63 g/m^3 of chlorine.

Effectiveness of Chlorine Dioxide as a Disinfectant

Chlorine dioxide has an extremely high oxidation potential, which probably accounts for its potent germicidal powers. Because of its extremely high oxidizing potential, possible bactericidal mechanisms may include inactivation of critical enzyme systems or disruption of protein synthesis. It should be noted, however, that when ClO_2 is added to wastewater it is often reduced to chlorite according to the following reaction:

$$ClO_2 + e^- \rightarrow ClO_2^- \qquad (12\text{–}37)$$

Equation (12–37) may help to explain the variability that is sometimes observed in the performance of ClO_2 as a disinfectant.

Modeling the Chlorine Dioxide Disinfection Process. As discussed previously in Sec. 12–3, the models that have been developed to describe the disinfection process with chlorine can also be used with appropriate caution, for chlorine dioxide. As with chlorine, the shoulder effect and the effect of the residual particles must be considered. Further, the differences between (1) secondary and filtered secondary effluent and (2) microfiltration and reverse osmosis effluent must also be considered.

Required Chlorine Dioxide Dosages for Disinfection. The required chlorine dioxide dosage will depend on the pH and the specific organism under investigation. Relative $C_R t$ values for chlorine dioxide are given in Table 12–11, presented in Sec. 12–3. In general, the effectiveness of chlorine dioxide is similar to that of combined chlorine for bacteria. The values given in Table 12–11 can be used as a starting point. However, there is a significant difference in the effectiveness of chlorine dioxide for the disinfection of virus, which is essentially the same as that for free chlorine. Chlorine dioxide appears to be more effective than free chlorine in the inactivation of protozoan cysts. Because the data on chlorine dioxide in the literature are limited, site-specific testing is recommended to establish appropriate dosage ranges.

Byproduct Formation and Control

The formation of DBPs is of great concern with the use of chlorine dioxide. The formation and control of DBPs with chlorine dioxide is considered in the following discussion.

Formation of DBPs Due to the Addition of Chlorine Dioxide for Disinfection. The principal DBPs formed when chlorine dioxide is used as a disinfectant are chlorite (ClO_2^-) and chlorate (Cl_2O_2), both of which are potentially toxic. The principal sources of the chlorite ion are from the process used to generate the chlorine dioxide and from the reduction of chlorine dioxide. As given by Eq. (12–35), all of the sodium chlorite reacts with chlorine to form chlorine dioxide. Unfortunately, on occasion some unreacted chlorite ion can escape from the reactor where the chlorine dioxide is being generated and find its way into the wastewater that is being treated. The second source of chlorite is from the reduction of chlorine dioxide as discussed above [see Eq. (12–37)]. The chlorate ion can be derived from the oxidation of chlorine dioxide, from the impurities in the sodium chlorite feedstock, and from the photolytic decomposition of chlorine dioxide.

The chlorine dioxide residuals and other end products are believed to degrade more quickly than chlorine residuals and therefore may not pose as serious a threat to aquatic life as the chlorine residuals. An advantage in using chlorine dioxide is that it does not react with ammonia to form the potentially toxic chlorinated DBPs. It has also been reported that halogenated organic compounds are not produced to any appreciable extent. This finding is specifically true with respect to the formation of chloroform, which is a suspected carcinogenic substance.

Control of DBP Formation Due to the Addition of Chlorine Dioxide for Disinfection. The formation of chlorite can be controlled by careful management of the feedstock or increasing the chlorine dose beyond the stoichiometric

amount. Treatment methods for the removal of the chlorite ion involve reducing the chlorite ion to the chloride ion using either ferrous iron or sulfite. At the present time there are no cost-effective methods for the removal of the chlorate ion. The control of the chlorate ion depends primarily on the effective management of the facilities used for the production of chlorine dioxide (White, 1999).

Environmental Impacts

The environmental impacts associated with the use of chlorine dioxide as a wastewater disinfectant are not well known. It has been reported that the impacts are less adverse than those associated with chlorination. Chlorine dioxide does not dissociate or react with water as does chlorine. However, because chlorine dioxide is normally produced from chlorine and sodium chlorite, free chlorine may remain in the resultant chlorine dioxide solution (depending on the process) and impact the receiving aquatic environment, as do chlorine residuals. A free chlorine dioxide residual will also remain, but it has been found to be less harmful to aquatic life than chlorine.

12-5 DECHLORINATION

In cases where low-level chlorine residuals may have potential toxic effects on aquatic organisms, dechlorination of treated effluent is practiced. Dechlorination may be accomplished by reacting the residual chlorine with a reducing agent such as sulfur dioxide or sodium metabisulfite or by adsorption on activated carbon. The design of dechlorination systems is considered in the following section.

Need for Dechlorination

Chlorination is one of the most commonly used methods for the destruction of pathogenic and other harmful organisms that may endanger human health. As noted in the previous sections, however, certain organic constituents in wastewater interfere with the chlorination process. Many of these organic compounds may react with the chlorine to form toxic compounds that can have long-term adverse effects on the beneficial uses of the waters to which they are discharged. To minimize the effects of these potentially toxic chlorine residuals on the environment, dechlorination of wastewater is necessary.

Dechlorination of Wastewater Treated with Chlorine and Chlorine Compounds

Where effluent toxicity requirements are applicable, or where dechlorination is used as a polishing step following the breakpoint-chlorination process for the removal of ammonia nitrogen, sulfur dioxide is used most commonly for dechlorination. Other chemicals that have been used are sodium sulfite (Na_2SO_3), sodium bisulfite ($NaHSO_3$), sodium metabisulfite ($Na_2S_2O_5$), and sodium thiosulfate ($Na_2S_2O_3$). Activated carbon has also been used for dechlorination. The use of these chemicals for dechlorination is discussed below.

Dechlorination with Sulfur Dioxide. Sulfur dioxide (SO_2) is available commercially as a liquefied gas under pressure in steel containers with capacities of 45, 68, and 908 kg (100, 150, and 2000 lb). Properties of sulfur dioxide are reported in Table 12–6. Sulfur dioxide is handled in equipment very similar to standard chlorine systems. When added to water, sulfur dioxide reacts to form sulfurous acid ($H_2SO_3^-$), a strong

reducing agent. In turn, the sulfurous acid dissociates to form HSO_3^- that will react with free and combined chlorine, resulting in formation of chloride and sulfate ions. Sulfur dioxide gas successively removes free chlorine, monochloramine, dichloramine, nitrogen trichloride, and poly-*n*-chlor compounds as illustrated in Eqs. (12–38) through (12–42).

Reactions between sulfur dioxide and free chlorine:

$$SO_2 + H_2O \rightarrow HSO_3^- + H^+ \quad (12\text{–}38)$$

$$HOCl + HSO_3^- \rightarrow Cl^- + SO_4^{2-} + 2H^+ \quad (12\text{–}39)$$

$$SO_2 + HOCl + H_2O \rightarrow Cl^- + SO_4^{2-} + 3H^+ \quad (12\text{–}40)$$

Reactions between sulfur dioxide and monochloramine, dichloramine, and nitrogen trichloride are

$$SO_2 + NH_2Cl + 2H_2O \rightarrow Cl^- + SO_4^{2-} + NH_4^+ + 2H^+ \quad (12\text{–}41)$$

$$SO_2 + NHCl_2 + 2H_2O \rightarrow 2Cl^- + SO_4^{2-} + NH_3 + 2H^+ \quad (12\text{–}42)$$

$$SO_2 + NCl_3 + 3H_2O \rightarrow 3Cl^- + SO_4^{2-} + NH_4^+ + 2H^+ \quad (12\text{–}43)$$

For the overall reaction between sulfur dioxide and chlorine [Eq. (12–40)], the stoichiometric weight ratio of sulfur dioxide to chlorine is 0.903:1 (see Table 12–15). In practice, it has been found that about 1.0 to 1.2 mg/L of sulfur dioxide will be required for the dechlorination of 1.0 mg/L of chlorine residue (expressed as Cl_2). Because the reactions of sulfur dioxide with chlorine and chloramines are nearly instantaneous, contact time is not usually a factor and contact chambers are not used, but rapid and positive mixing at the point of application is an absolute requirement.

The ratio of free chlorine to the total combined chlorine residual before dechlorination determines whether the dechlorination process is partial or proceeds to completion. If the ratio is less than 85 percent, it can be assumed that significant organic nitrogen is present and that it will interfere with the free residual chlorine process.

In most situations, sulfur dioxide dechlorination is a very reliable unit process in wastewater treatment, provided that the precision of the combined chlorine residual monitoring service is adequate. Excess sulfur dioxide dosages should be avoided, not only because of the chemical wastage but also because of the oxygen demand exerted by the excess sulfur dioxide. The relatively slow reaction between excess sulfur dioxide and dissolved oxygen is given by the following expression:

$$HSO_3^- + 0.5O_2 \rightarrow SO_4^{2-} + H^+ \quad (12\text{–}44)$$

The result of this reaction is a reduction in the dissolved oxygen contained in the wastewater, a corresponding increase in the measured BOD and COD, and a possible drop in the pH. All these effects can be eliminated by proper control of the dechlorination system.

Dechlorination with Sulfite Compounds. When sodium sulfite (Na_2SO_3) and sodium bisulfite ($NaHSO_3$) and sodium metabisulfite ($Na_2S_2O_5$) are used for dechlorination, the following reactions occur. The stoichiometric weight ratios of these compounds needed per mg/L of residual chlorine are given in Table 12–15.

Reaction between sodium sulfite and free chlorine residual and combined chlorine residual, as represented by monochloramine:

$$Na_2SO_3 + Cl_2 + H_2O \rightarrow Na_2SO_4 + 2HCl \quad (12\text{–}45)$$

Table 12–15
Typical information on the quantity of dechlorinating compound required for each mg/L of residual chlorine

Dechlorinating compound			Quantity, mg/(mg/L) residual	
Name	**Formula**	**Molecular weight**	**Stoichiometric amount**	**Range in use**
Sulfur dioxide	SO_2	64.09	0.903	1.0–1.2
Sodium sulfite	Na_2SO_3	126.04	1.775	1.8–2.0
Sodium bisulfite	$NaHSO_3$	104.06	1.465	1.5–1.7
Sodium metabisulfite	$Na_2S_2O_5$	190.10	1.338	1.4–1.6
Sodium thiosulfate	$Na_2S_2O_3$	112.12	0.556	0.6–0.9

$$Na_2SO_3 + NH_2Cl + H_2O \rightarrow Na_2SO_4 - Cl + NH_4^+ \quad (12\text{–}46)$$

Reaction between sodium bisulfite and free chlorine residual and combined chlorine residual, as represented by monochloramine:

$$NaHSO_3 + Cl_2 + H_2O \rightarrow NaHSO_4 + 2HCl \quad (12\text{–}47)$$

$$NaHSO_3 + NH_2Cl + H_2O \rightarrow NaHSO_4 + Cl^- + NH_4^+ \quad (12\text{–}48)$$

Reactions between sodium metabisulfite and free chlorine residual and combined chlorine residual, as represented by monochloramine:

$$Na_2S_2O_5 + Cl_2 + 3H_2O \rightarrow 2NaHSO_4 + 4HCl \quad (12\text{–}49)$$

$$Na_2S_2O_5 + 2NH_2Cl + 3H_2O \rightarrow Na_2SO_4 + H_2SO_4 + 2Cl^- + 2NH_4^+ \quad (12\text{–}50)$$

Dechlorination with Sodium Thiosulfate. Although sodium thiosulfate ($Na_2S_2O_3$) is often used as a dechlorinating agent in analytical laboratories, its use in full-scale wastewater-treatment plants is limited for the following reasons. It appears the reaction of sodium thiosulfate with residual chlorine is stepwise, creating a problem with uniform mixing. The ability of sodium thiosulfate to remove residual chlorine is a function of the pH (White, 1999). The reaction with residual chlorine is only stoichiometric at pH = 2, making prediction of the required dose impossible in wastewater applications. As reported in Table 12–15, the stoichiometric weight ratio of sodium thiosulfate per mg/L of residual chlorine is 0.556.

Dechlorination with Activated Carbon. Carbon adsorption for dechlorination provides complete removal of both combined and free residual chlorine. When activated carbon is used for dechlorination, the following reactions occur:

Reactions with free chlorine residual:

$$C + 2Cl_2 + 2H_2O \rightarrow 4HCl + CO_2 \quad (12\text{–}51)$$

Reactions with combined residual as represented by mono- and dichloramine:

$$C + 2NH_2Cl + 2H_2O \rightarrow CO_2 + 2NH_4^+ + 2Cl^- \quad (12\text{–}52)$$

$$C + 4NHCl_2 + 2H_2O \rightarrow CO_2 + 2N_2 + 8H^+ + 2Cl^- \quad (12\text{–}53)$$

Granular activated carbon is used in either a gravity or pressure filter bed. If carbon is to be used solely for dechlorination, it must be preceded by an activated-carbon process for the removal of other constituents susceptible to removal by activated carbon. In treatment plants where granular activated carbon is used to remove organics, either the same or separate beds can also be used for dechlorination.

Because granular carbon in column applications has proved to be very effective and reliable, activated carbon should be considered where dechlorination is required. However, this method is quite expensive. It is expected that the primary application of activated carbon for dechlorination will be in situations where high levels of organic removal are also required.

Dechlorination of Chlorine Dioxide with Sulfur Dioxide

Dechlorinating wastewater disinfected with chlorine dioxide can be achieved using sulfur dioxide. The reaction that takes place in the chlorine dioxide solution can be expressed as

$$SO_2 + H_2O \rightarrow H_2SO_3 \qquad (12\text{–}54)$$

$$5H_2SO_3 + 2ClO_2 + H_2O \rightarrow 5H_2SO_4 + 2HCl \qquad (12\text{–}55)$$

Based on Eq. (12–55), it can be seen that 2.5 mg of sulfur dioxide will be required for each mg of chlorine dioxide residual (expressed as ClO_2). In practice, 2.7 mg SO_2/mg ClO_2 would normally be used.

12–6 DESIGN OF CHLORINATION AND DECHLORINATION FACILITIES

The chemistry of chlorine in water and wastewater has been discussed in the previous sections, along with an analysis of how chlorine functions as a disinfectant. However, chlorine has been applied for a wide variety of objectives other than disinfection in the wastewater-treatment field including prechlorination for hydrogen sulfide control, activated-sludge bulking control, and odor control. Therefore, the purpose of this section is to discuss briefly the design of chlorination and dechlorination facilities for a variety of purposes.

Important practical design factors that must be considered in the design of chlorine mixing and contact facilities include (1) estimation of the chlorine dosage, (2) application flow diagrams, (3) dosage control, (4) injection and initial mixing, (5) chlorine contact basin design, (6) maintenance of solids transport velocity, (7) outlet control and chlorine residual measurement, (8) chlorine storage facilities, (9) chemical containment and neutralization facilities, and (10) dechlorination facilities. These topics are considered briefly in the following discussion. Additional details on the design of chlorination and dechlorination facilities may be found in U.S. EPA (1986), WEF (1996), and White (1999).

Sizing Chlorination Facilities

To aid in the design and selection of the required chlorination facilities and equipment, it is important to know the uses, including dosage ranges, to which chlorine and its compounds have been applied. Chlorination capacities for disinfection are generally selected to meet the specific design criteria of the state or other regulatory agencies con-

Table 12-16
Typical dosages for various chlorination applications in wastewater collection and treatment

Application	Dosage range, mg/L
Collection:	
Corrosion control (H_2S)	2–9[a]
Odor control	2–9[a]
Slime growth control	1–10
Treatment:	
BOD reduction	0.5–2[b]
Digester and Imhoff tank foaming control	2–15
Digester supernatant oxidation	20–140
Ferrous sulfate oxidation	—[c]
Filter fly control	0.1–0.5
Filter ponding control	1–10
Grease removal	2–10
Sludge bulking control	1–10

[a] Per mg/L of H_2S.
[b] Per mg/L of BOD_5 destroyed.
[c] $6FeSO_4 \cdot 7H_2O + 3Cl_2 \rightarrow 2Fe_2(SO_4)_3 + 42H_2O$.

trolling the receiving body of water. In any case, where the residual in the effluent is specified or the final number of coliform bacteria is limited, onsite testing is preferred to determine the dosage of chlorine required. Typical chlorine dosages for disinfection have been given previously in Table 12–13. Chlorine dosages can also be estimated using the equations given previously in Sec. 12–2. Typical chlorine dosages for applications other than disinfection are given in Table 12–16. A range of dosage values is given because they will vary depending on the characteristics of the wastewater. In the absence of more specific data, the maximum values given in Tables 12–13 and 12–16 can be used as a guide in sizing chlorination equipment.

EXAMPLE 12–6 Sizing of Chlorination Facilities Determine the capacity of a chlorinator for a treatment plant with an average wastewater flow of 1000 m^3/d (0.26 Mgal/d). The peak daily factor for the treatment plant is 3.0 and the maximum required chlorine dosage (set by state regulations) is to be 20 mg/L.

Solution

1. Determine the capacity of the chlorinator at peak flow.

$$Cl_2, kg/d = (20\ g/m^3)(1000\ m^3/d)(3)(1\ kg/10^3\ g)$$
$$= 60\ kg/d$$

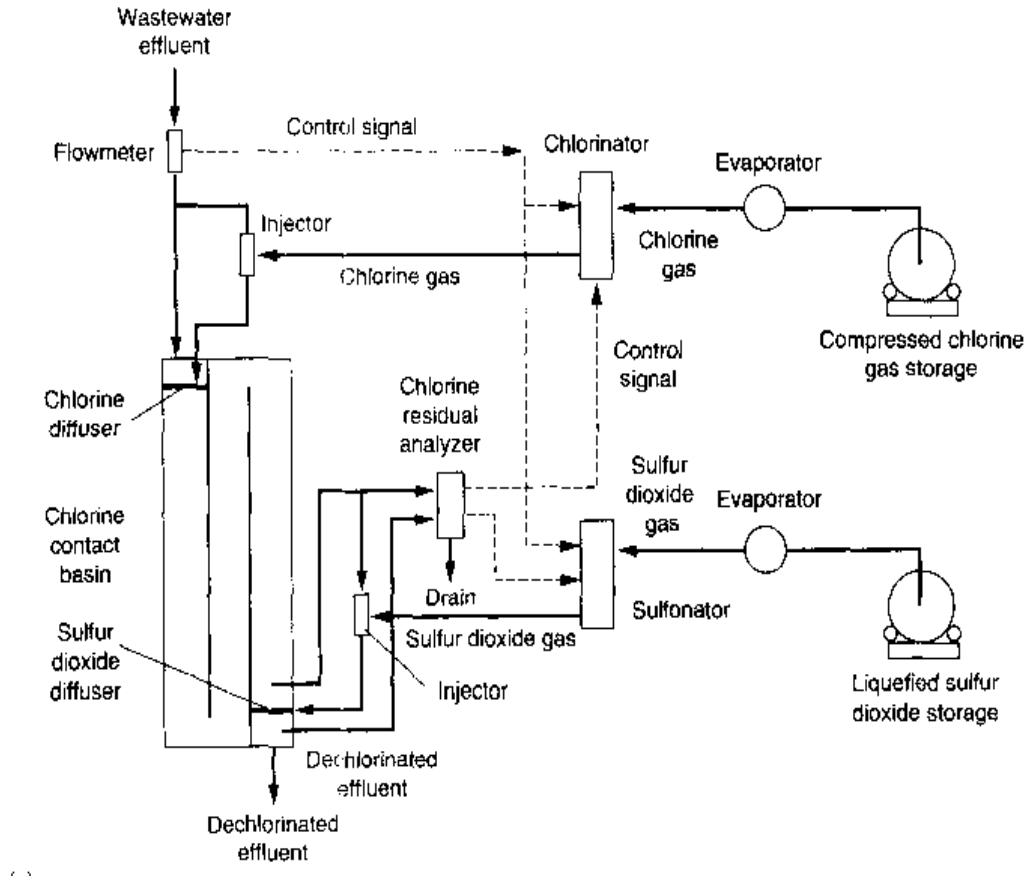
Use the next largest standard-size chlorinator: two 90 kg/d (200 lb/d) units with one unit serving as a spare. Although the peak capacity will not be required during most of the day, it must be available to meet the chlorine requirements at peak flow. Best design practice calls for the availability of a standby chlorinator.

2. Estimate the daily consumption of chlorine. Assume an average dosage of 10 mg/L.

$$Cl_2, \text{kg/d} = (10 \text{ g/m}^3)(1000 \text{ m}^3\text{/d})(1 \text{ kg}/10^3 \text{ g})$$
$$= 10 \text{ kg/d}$$

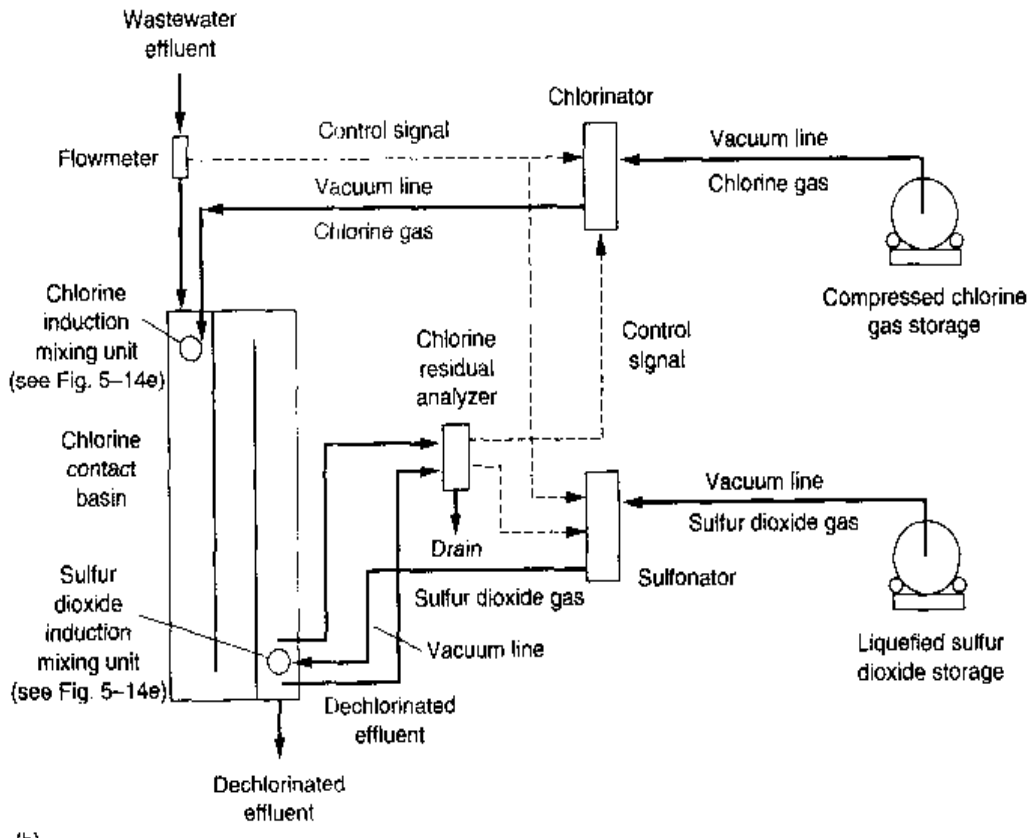
Comment In sizing and designing chlorination systems, it is also important to consider the low flow/dosage requirements. The chlorination system should have sufficient turndown capability for these conditions so that excessive chlorine is not applied. In some cases, consideration should be given to the use of two units to cover high and low flow dosage requirements, when the turndown required gets to be too high.

Application Flow Diagrams



In this section, the flow diagrams and equipment used to inject (feed) chlorine and its related compounds into the wastewater are discussed.

Flow Diagram for Chlorine. Chlorine may be applied directly as a gas or in an aqueous solution. Typical chlorine/sulfur dioxide chlorination/dechlorination process flow diagrams are shown on Fig. 12–17. Chlorine can be withdrawn from storage containers in either liquid or gas form. If withdrawn as a gas, the evaporation of the liquid in the container results in frost formation that restricts gas withdrawal rates to 18 kg/d (40 lb/d) for 68 kg (150 lb) cylinders and 205 kg/d (450 lb/d) for 908 kg (1 ton) containers at 21°C (70°F). Evaporators are used normally where the maximum rate of chlorine gas withdrawal from a 908 kg (1 ton) container must exceed approximately 180 kg/d (400 lb/d). Although multiple-ton cylinders can be connected to provide more than 180 kg/d (400 lb/d), the use of an evaporator conserves space. Evaporators are almost always used when the total dosage exceeds 680 kg/d (1500 lb/d). Chlorine evaporators are available in sizes ranging from 1816 to 4540 kg/d (4000 to 10,000 lb/d) capacities; chlorinators are available normally in sizes ranging from 227 to 4540 kg/d (500 to 10,000 lb/d).



Flow Diagram for Liquid Hypochlorite Solutions. A typical sodium hypochlorite/sodium bisulfite chlorination/dechlorination process flow diagram is shown on Fig. 12–18. For small treatment plants, the most satisfactory means of feeding sodium or calcium hypochlorite is through the use of low-capacity proportioning pumps (see Fig. 12–4). Generally, the pumps are available in capacities up to 450 L/d (120 gal/d), with adjustable stroke for any value below this. Large capacities or multiple units are available from some of the manufacturers. The pumps can be arranged to

feed at a constant rate, or they can be provided with variable speed and with analog signals for varying the feed rate. The stroke length can also be controlled.

Flow Diagram for Dry Calcium Hypochlorite Feed System. For small wastewater flowrates up to about 400 m^3/d (10^5 gal/d) chlorine in the form of dry calcium hypochlorite tablets is used for disinfection. Two of the most common types of tablet chlorinators (nonpressurized and pressurized) are shown on Fig. 12–19. The schematic flow diagrams for the two tablet chlorinators are essentially the same, a side stream of water is diverted from the main discharge line, chlorine at relatively high concentrations is added to the side stream, and the chlorinated side stream is discharged back into the main flow by means of a pump (see Fig. 12–19*a*) or by reducing the pressure in the main discharge line (see Fig. 12–19*b*). As shown on Fig. 12–19*a*, in the nonpressurized tablet chlorinator the side stream contacts the bottom surface of the chlorine tablets that rest on a screen. The chlorine tablets have been designed to erode at a more-or-less constant rate, releasing a controlled amount of chlorine. The amount of chlorine added is dependent on the flowrate through the tablet chlorinator. The tablet chlorinator shown on Fig. 12-19*b* is pressurized and hypochlorite is released as water flows over the hypochlorite tablets. Dry calcium hypochlorite tablets, typically 75 mm (3 in) in diameter, contain about 65 to 70 percent available chlorine. For small treatment plants, the use of chlorine tablets eliminates the hazards associated with handling chlo-

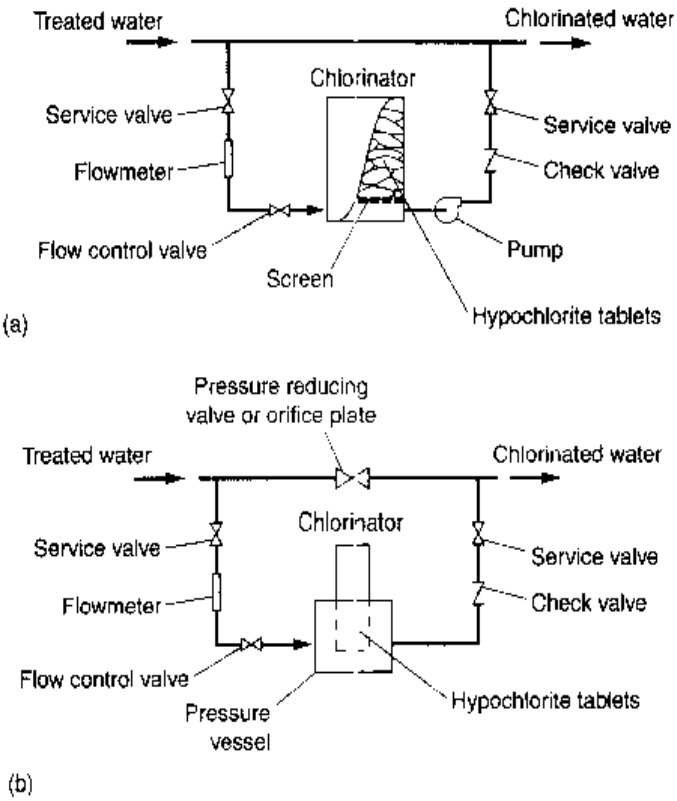

Figure 12–19

rine cylinders. Further, because there are no moving parts, tablet chlorinators are simple to operate and maintain.

Flow Diagram for Chlorine Dioxide. The chlorine dioxide, generated onsite (see Fig. 12–16), is present in an aqueous solution that is applied in the same manner as that used for typical chlorination systems. A schematic process flow diagram of a typical chlorine dioxide installation is shown on Fig. 12–20.

Dosage Control

Dosage may be controlled in several ways. The simplest method is manual control, where the operator changes the feed rate to suit conditions. The required dosage is usually determined by measuring the chlorine residual after 15 min of contact time and adjusting the dosage to obtain a residual of 0.5 mg/L. A second method is to pace the chlorine flowrate to the wastewater flowrate as measured by a primary meter such as a magnetic meter, Parshall flume, or flow tube. The flowmeter may be placed before the inlet or after the outlet of the chlorine contact basin. A third method is to control the chlorine dosage by automatic measurement of the chlorine residual. An automatic analyzer with signal transmitter and recorder is required. When using on-line analyzers a sample should be taken and analyzed within 2 min so the control system will have time to react. Finally, a compound system that incorporates both the second and third methods may be used. In a compound system, the control signals obtained from the wastewater flowmeter and from the residual recorder and fed to a programmable logic controller (PLC) provide more precise control of chlorine dosage and residual.

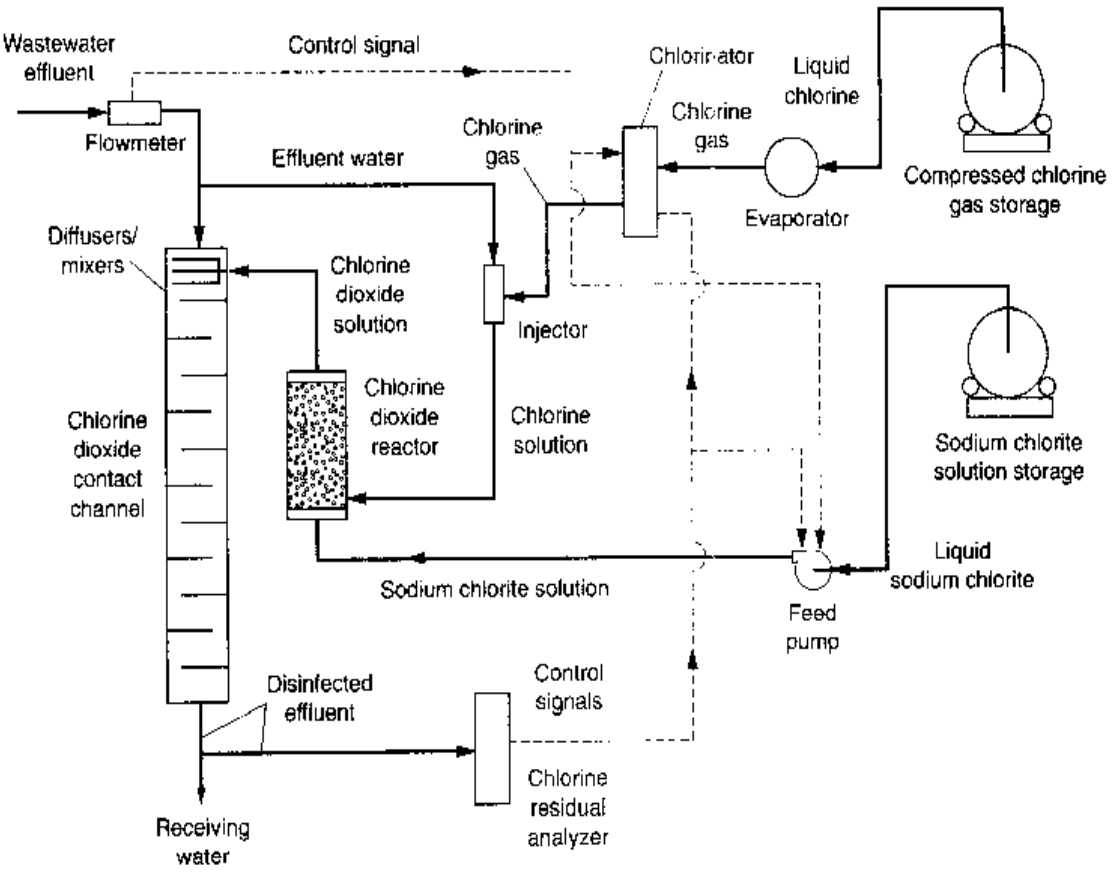

Figure 12–20

Typical flow diagram for the addition of chlorine dioxide.

Injection and Initial Mixing

As pointed out in Sec. 12–3, other things being equal, effective mixing of the chlorine solution with the wastewater, the contact time, and the chlorine residual are the principal factors involved in achieving effective bacterial kill. The addition of chlorine solution is often accomplished with a diffuser, which may be a plastic pipe with drilled holes through which the chlorine solution can be distributed into the path of wastewater flow (see Fig. 12–21). Unfortunately, the use of diffusers for adding chlorine is not very effective. To optimize the performance of disinfection systems, the chlorine should be introduced and mixed as rapidly as possible (ideally in less than a second). Techniques that can be used to mix chlorine in a fraction of a second were introduced and discussed in Chap. 5. Effective methods of mixing chlorine with the wastewater include the use of (1) in-line static mixers, (2) in-line mixers, (3) high-speed induction mixers, (4) pressurized water jets, and (5) pumps. Two typical mixing devices are shown on Fig. 12–22. Additional mixing devices are illustrated on Fig. 5–14 in Chap. 5. A complete analysis of mixing may be found in Chap. 5.

Chlorine Contact Basin Design

The principal design objective for chlorine contact basins is to ensure that some defined percentage of the flow remains in the chlorine contact basin for the design contact time to ensure effective disinfection. The contact time is usually specified by the regulatory

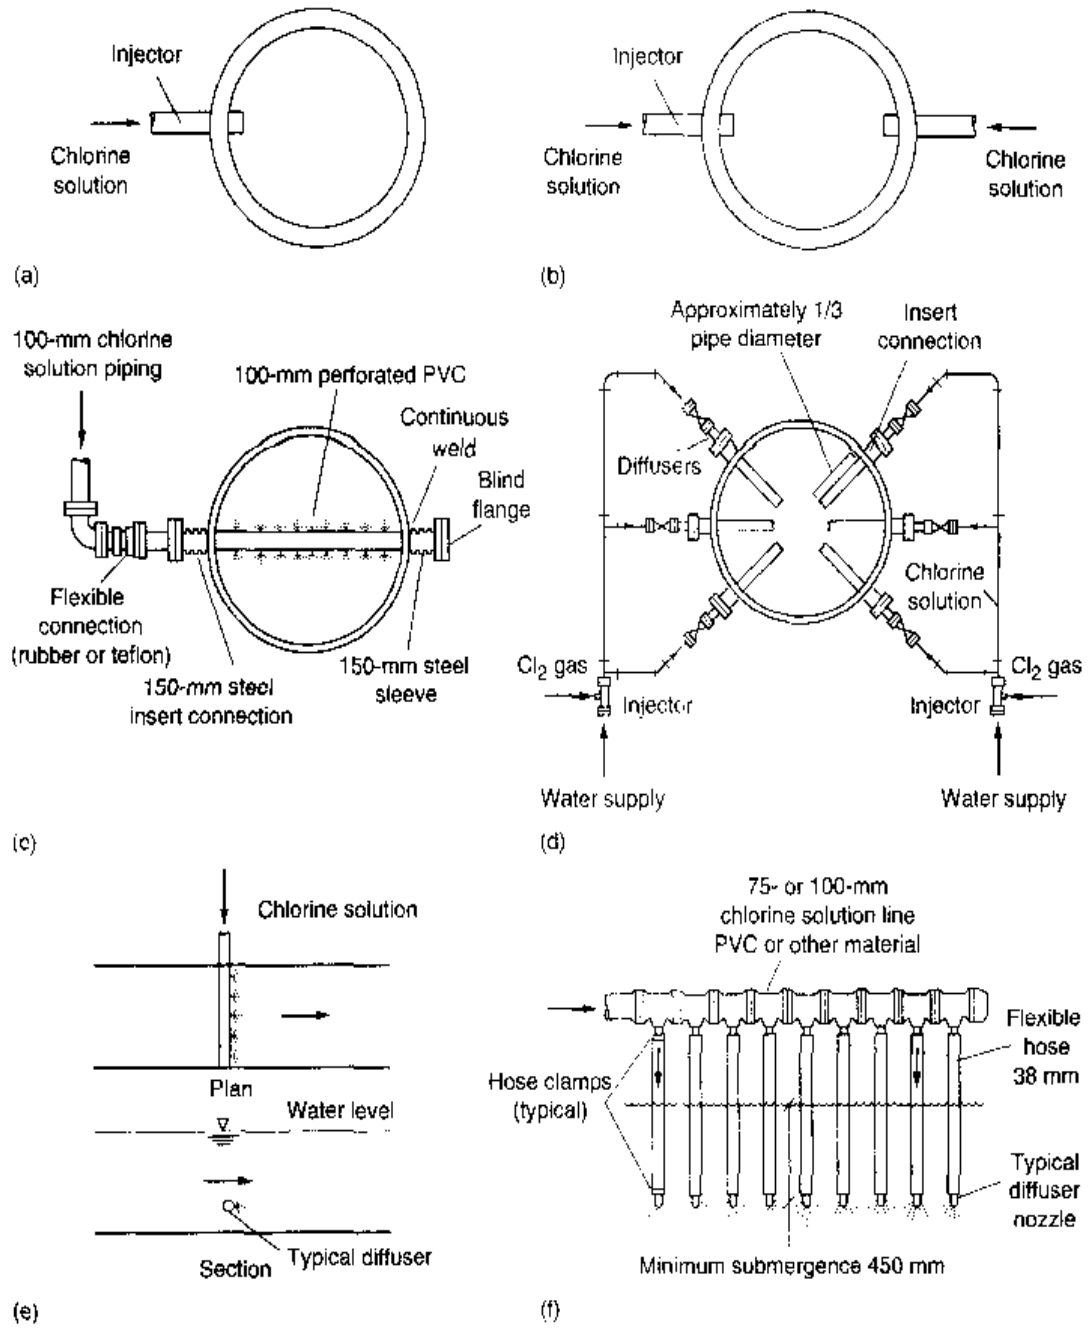

Figure 12-21

Typical diffusers used to inject chlorine solution: (*a*) single injector for small pipe, (*b*) dual injector for small pipe, (*c*) across the pipe diffuser for pipes larger than 0.9 m (3 ft) in diameter, (*d*) diffuser system for large conduits, (*e*) single across-the-channel diffuser, and (*f*) typical hanging nozzle type chlorine diffuser for open channels. *(Adapted from White, 1999.)*

agency and may range from 30 to 120 min; periods of 15 to 90 min at peak flow are common. For example, for reuse applications the Department of Health Services of the State of California requires a $C_R t$ value of 450 mg·min/L with a modal contact time of 90 min at peak flow. Issues related to the design and analysis of chlorine contact basins considered in the following discussion include (1) basin configuration, (2) the use of baffles and guide vanes, (3) number of chlorine contact basins, (4) precipitation of

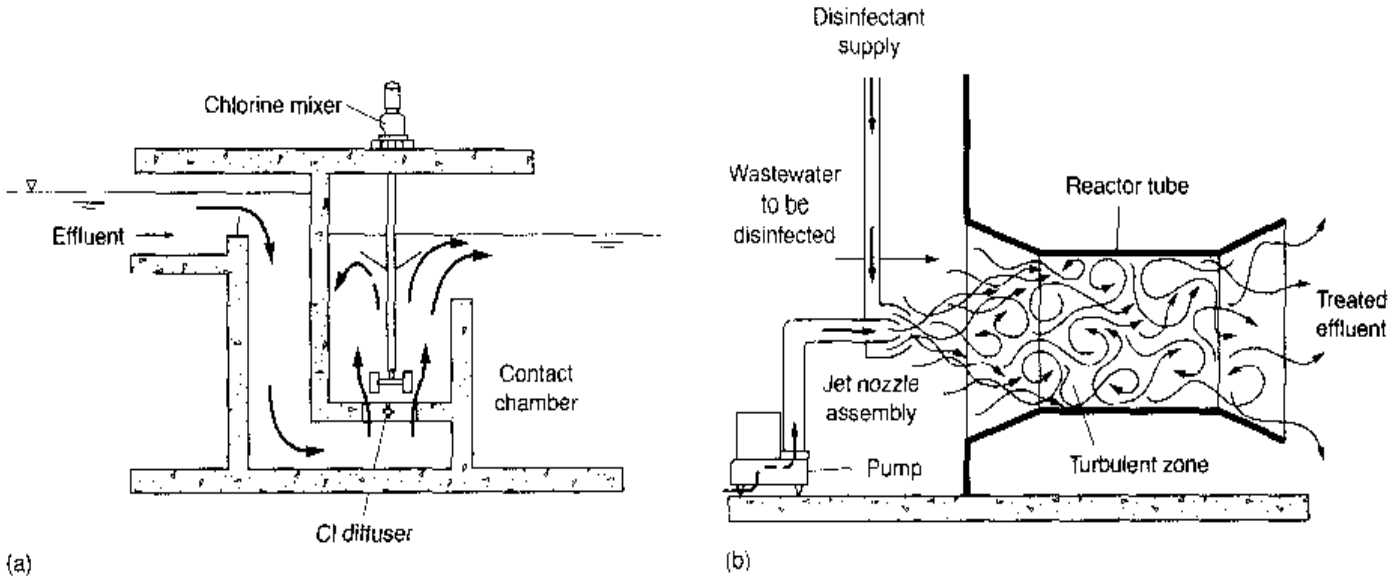

Figure 12–22

solids in chlorine contact basins, (5) solids transport velocity, and (6) a procedure for predicting disinfection performance.

Chlorine Contact Basin Configuration. To be assured that a given percentage of the flow will remain in the chlorine contact basin for a given period of time, the most common approach is to use long plug-flow, around-the-end type of contact basins (see Fig. 12–23) or a series of interconnected basins or compartments. Plug-flow chlorine contact basins that are built in a serpentine fashion (e.g., folded back and forth) to conserve space require special attention in their design to eliminate the formation of hydraulic dead zones that will reduce the hydraulic detention times. Length-to-width ratios (L/W) of at least 20 to 1 [preferably 40 to 1, Marske and Boyle (1973)] and the use of baffles and guide vanes, as described below, will help to minimize short circuiting. In some small plants, chlorine contact basins have been constructed of large-diameter sewer pipe. The importance of dispersion in the design of chlorine contact basins was considered in early papers by Marske and Boyle (1973), Trussell and Chao (1977), and Hart (1979). The design of a chlorine contact basin based on dispersion is considered in Example 12–7.

Use of Baffles and Deflection Guide Vanes. To improve the hydraulic performance of chlorine contact basins, it has become common practice to use either submerged baffles, deflection guide vanes, or combinations of the two. Submerged baffles are used to break up density currents caused by temperature gradients, to limit short circuiting, and to minimize the effect of hydraulic dead spaces. The location of the baffles is critical in improving the performance of chlorine contact basins. The recommended location for baffles, at the beginning of each pass, and the effect on the corresponding tracer response curves, is illustrated on Fig. 12–24. As shown on Fig. 12–24, the addi-

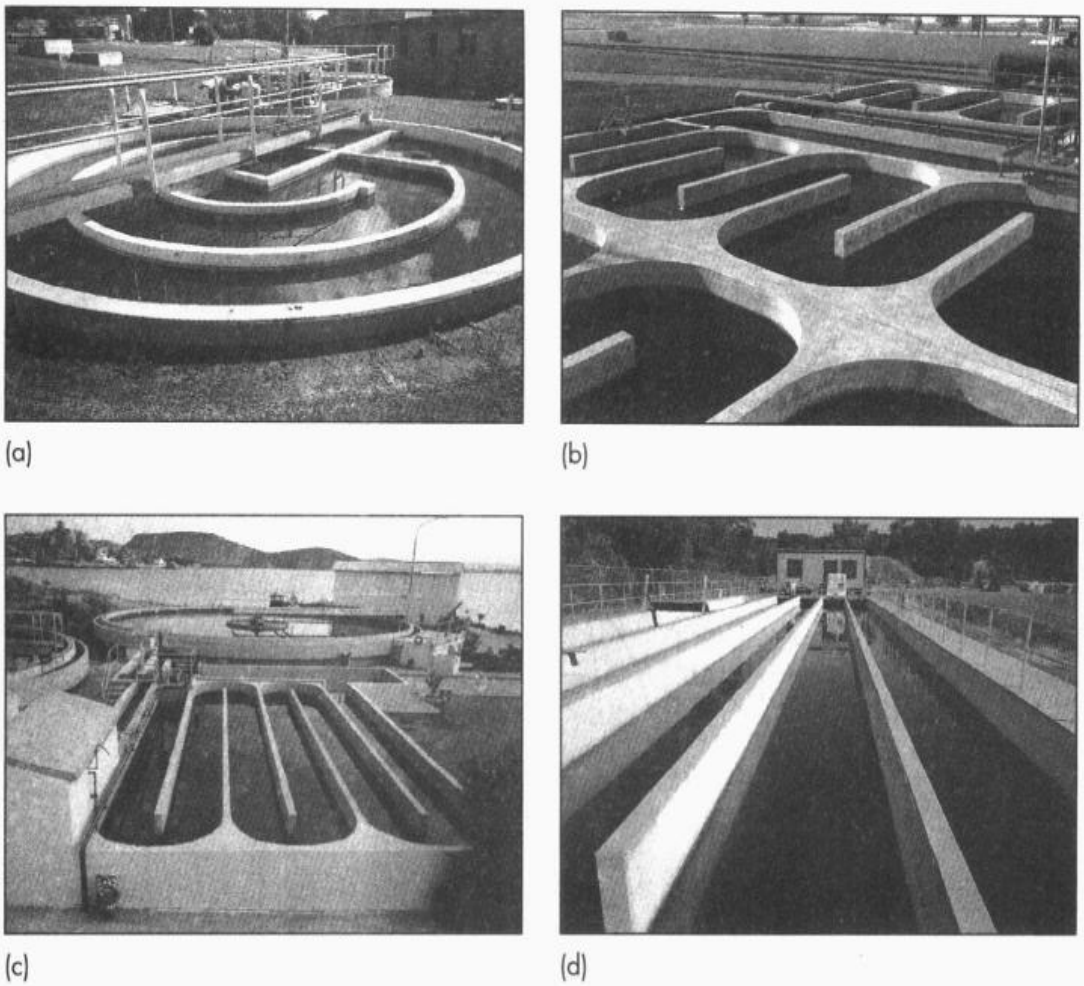

Figure 12–23
Typical examples of chlorine contact basins: (*a*) spiral wraparound design, (*b*) serpentine design with short channels, (*c*) serpentine design with long channels, and (*d*) back-and-forth straight long-channel design.

tion of baffles improves the hydraulic performance of the chlorine contact basin significantly. The open area in submerged baffles will typically vary from 6 to 10 percent of the cross-sectional area of flow. The headloss through each baffle can be estimated using the following expression.

$$h = \frac{1}{2g}\left(\frac{Q}{Cna}\right)^2 \tag{12–56}$$

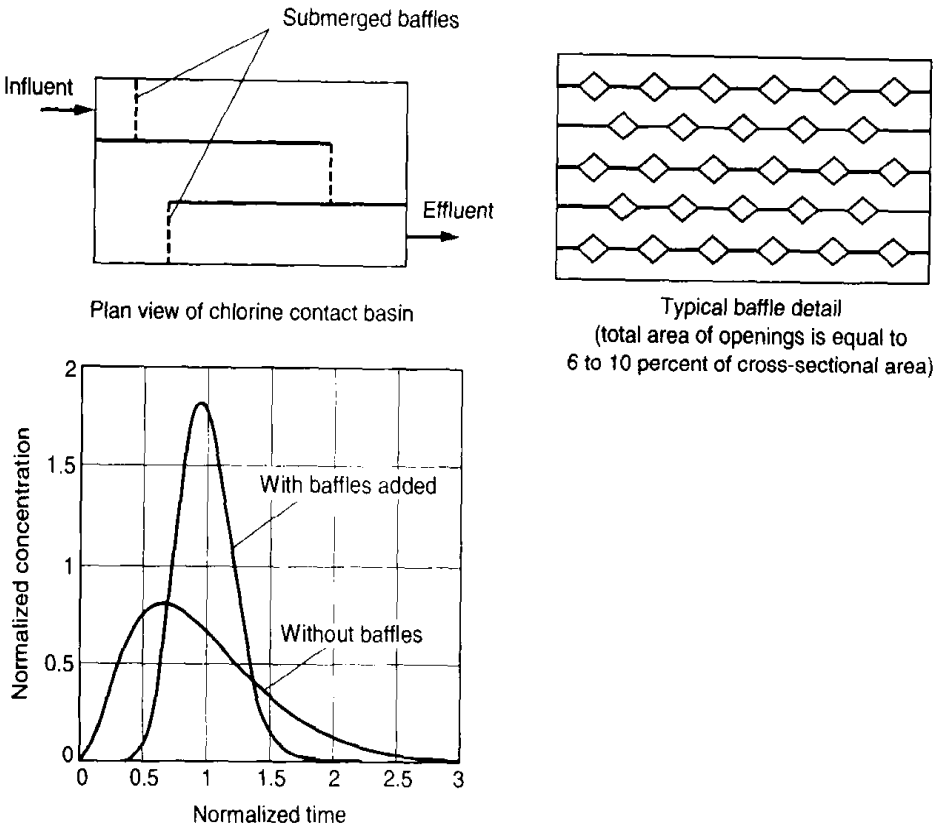
where h = headloss, m
g = acceleration due to gravity, 9.81 m/s^2
Q = discharge through chlorine contact basin channel, m^3/s
C = discharge coefficient, unitless (typically about 0.8)
n = number of openings
a = area of individual opening, m^2

A typical serpentine chlorine contact basin equipped with removable baffles is shown on Fig. 12–25. The spacing of the baffles can be adjusted to improve performance.

An alternative approach that has been used to improve the performance of chlorine contact basins is through the addition of deflection guide vanes, as shown on Fig. 12–26. The placement and number of vanes will depend on the layout of the chlorine contact basin. Two or three guide vanes are used most commonly. The beneficial effect of adding guide vanes is illustrated on Fig. 12–27.

Figure 12-24

Effect of baffle addition on hydraulic performance of chlorine contact basin. The recommended location for baffles is at the beginning of each pass. *(Adapted from Hart, 1979 and Montgomery, 1985.)*



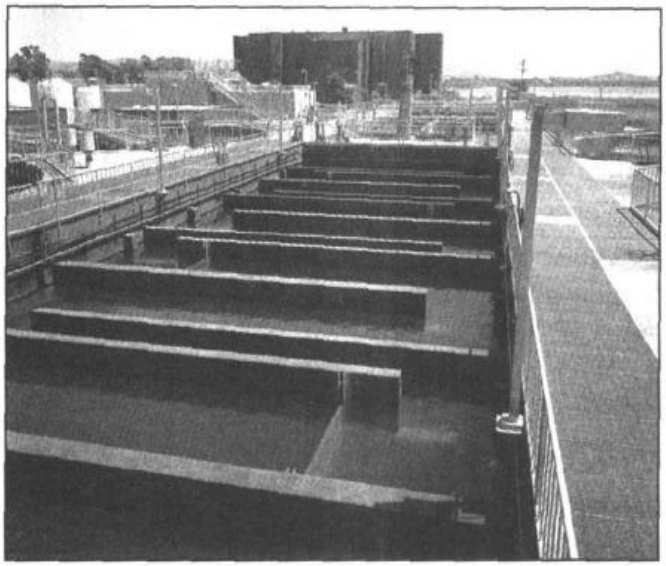


Figure 12-25

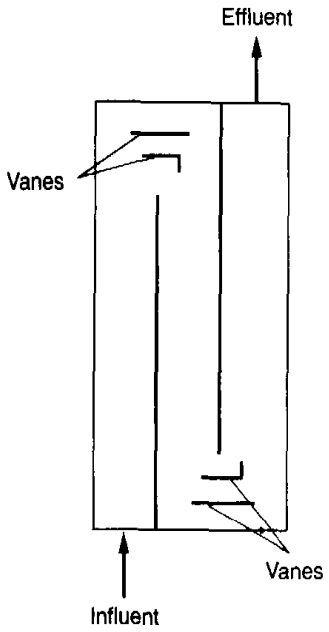
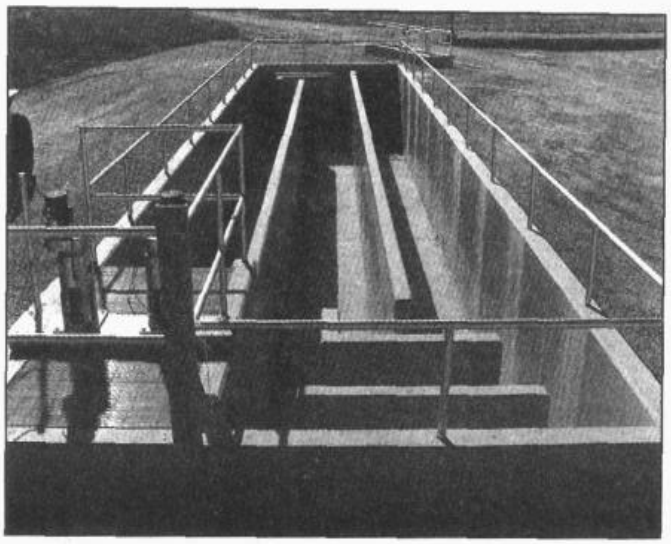


Typical chlorine contact basin with removable baffles.



Number of Chlorine Contact Basins. For most treatment plants, two or more contact basins should be used to meet reliability and redundancy requirements to facilitate maintenance and cleaning. Provisions should also be included for draining and scum removal. Vacuum-type cleaning equipment may be used as an alternative to draining the basin for removal of accumulated solids. Bypassing the contact basin for maintenance should only be practiced on rare occasions, with the approval of regulatory agencies. If the time of travel in the outfall sewer at the maximum design flow is suffi-

Minimum	21.0	17.6	15.3	15.2	25.0
Mean	29.2	26.4	23.9	20.5	31.1
Maximum	36.5	37.8	34.8	31.9	39.5

cient to equal or exceed the required contact time, it may be possible to eliminate the chlorine contact chambers, provided regulatory authorities agree.

Precipitation in Chlorine Contact Basins. A problem often encountered in the operation of chlorine contact basins is the formation and precipitation of a light flocculent material. The principal cause of the formation and precipitation of floc is the lowering of the pH that results from the addition of chlorine. The problem occurs most frequently where alum is used for phosphorus removal in separate precipitation facilities or is added before the effluent filters. For a variety of reasons including high pH and inadequate initial mixing, not all of the alum added will react completely to form a floc that can be removed by precipitation or filtration. However, when the pH is lowered in the chlorine contact basin due to the addition of chlorine, some of the unreacted alum may form a floc. Thus, in addition to meeting reliability and redundancy requirements,

a minimum of two chlorine contact basins is necessary to allow one basin to be removed from service so that the accumulated solids can be removed from the basins.

Solids Transport Velocity. The horizontal velocity at minimum flow in a chlorine contact basin should, in theory, be sufficient to scour the bottom or to limit the deposition of sludge solids that may have passed through the settling tank. To limit excessive deposition, horizontal velocities should be at least 2 to 4.5 m/min (6.5 to 15 ft/min). In general, it will be difficult to achieve such velocities and simultaneously meet stringent dispersion requirements (see Example 12-7). If floc particles form, it will generally be impossible to avoid the accumulation of a sludge layer in the chlorine contact basins, another reason at least two chlorine contact basins should be used.

EXAMPLE 12-7 Design of a Chlorine Contact Basin Based on Dispersion Design a chlorine contact basin for an average flow of 4000 m^3/d. The estimated peaking factor is 2.0. The detention time at peak flow is to be 90 min. A minimum of two parallel channels must be used for redundancy requirements. The dimensions of the chlorine contact basin should be such as to achieve a dispersion number of about 0.015 at peak flow. Also check the dispersion number at average flow. What will happen if the low flow drops to 33 percent of the average flow in the early morning hours? Based on the resulting calculations, will solids deposition occur, requiring periodic scouring or cleaning of the chlorine contact basin?

Solution

1. Assume some trial cross-sectional dimensions for the chlorine contact basin and determine the corresponding length and flow velocity.
   a. Assumed dimensions

      Width = 2 m

      Depth = 3 m

      Number of parallel channels = 2

   b. Determine required length.

$$L = \frac{(2 \times 4000\ m^3/d)}{(2)(1440\ min/d)} \times (90\ min) \times \frac{1}{(2\ m \times 3\ m)} = 41.7\ m$$

   c. Check velocity at peak flow.

$$V = \frac{(2 \times 4000\ m^3/d)}{(2)(1440\ min/d)(60\ s/min)} \times \frac{1}{(2\ m \times 3\ m)} = 0.0077\ m/s$$

2. Check the dispersion number for the chlorine contact basin using Eq. (4–48).

$$D = 1.01\nu(N_R)^{0.875}$$

where D = coefficient of dispersion, m^2/s
ν = kinematic viscosity, m^2/s (see Appendix C)
N_R = Reynolds number, unitless

a. Compute the Reynolds number.

$N_R = 4vR/\nu$

v = velocity in open channel, m/s

R = hydraulic radius = area/wetted perimeter m

$v = 0.0077$ m/s

$\nu = 1.003 \times 10^{-6}$ m^2/s

$$N_R = \frac{(4)(0.0077 \text{ m/s})[(2.0 \text{ m} \times 3.0 \text{ m})/(2 \times 3.0 \text{ m} + 2.0 \text{ m})]}{(1.003 \times 10^{-6} \text{ m}^2/\text{s})} = 23{,}031$$

b. Compute the coefficient of dispersion.

$D = 1.01\nu(N_R)^{0.875}$

$D = (1.01)(1.003 \times 10^{-6} \text{ m}^2/\text{s})(23{,}031)^{0.875} = 6.648 \times 10^{-3} \text{ m}^2/\text{s}$

c. Determine the dispersion number using Eq. (4–43).

$$d = \frac{D}{uL} = \frac{Dt}{L^2} = \frac{(0.006648 \text{ m}^2/\text{s})(90 \text{ min} \times 60 \text{ s/min})}{(41.7 \text{ m})^2} = 0.0206$$

Because the computed dispersion number (0.0206) is greater than the desired value (0.015), an alternative design must be evaluated. For the alternative design, assume three parallel channels will be used.

3. Assume new trial cross-sectional dimensions for the chlorine contact basin and determine the new length and flow velocity.

a. Assumed dimensions

Width = 1.25 m

Depth = 3 m

Number of parallel channels = 3

b. Determine required length.

$$L = \frac{(2 \times 4000 \text{ m}^3/\text{d})}{(3)(1440 \text{ min/d})} \times (90 \text{ min}) \times \frac{1}{(1.25 \text{ m} \times 3 \text{ m})} = 44.4 \text{ m}$$

c. Check velocity at peak flow.

$$V = \frac{(2 \times 4000 \text{ m}^3/\text{d})}{(3)(1440 \text{ min/d})(60 \text{ s/min})} \times \frac{1}{(1.25 \text{ m} \times 3 \text{ m})} = 0.0082 \text{ m/s}$$

4. Check the dispersion number for the chlorine contact basin.

a. Compute the Reynolds number.

$N_R = 4vR/\nu$

$v = 0.0082$ m/s

$$\nu = 1.003 \times 10^{-6}\ \text{m}^2/\text{s}$$

$$N_R = \frac{(4)(0.0082\ \text{m/s})[(1.25\ \text{m} \times 3.0\ \text{m})/(2 \times 3.0\ \text{m} + 1.25\ \text{m})]}{(1.003 \times 10^{-6}\ \text{m}^3/\text{s})} = 16{,}915$$

b. Compute the coefficient of dispersion.

$$D = 1.01\nu N_R^{0.875}$$

$$D = (1.01)(1.003 \times 10^{-6}\ \text{m}^2/\text{s})(16{,}915)^{0.875} = 5.07 \times 10^{-3}\ \text{m}^2/\text{s}$$

c. Determine the dispersion number.

$$d = \frac{D}{uL} = \frac{Dt}{L^2} = \frac{(0.00507\ \text{m}^2/\text{s})(90\ \text{min} \times 60\ \text{s/min})}{(44.4\ \text{m})^2} = 0.0139$$

Because the computed dispersion number (0.0139) is smaller than the desired value (0.015), the proposed design is acceptable.

5. Check the dispersion number for the chlorine contact basin at average flow.
   a. Compute the Reynolds number.

$$N_R = 4vR/\nu$$

$$v = 0.0082/2 = 0.0041\ \text{m/s}$$

$$\nu = 1.003 \times 10^{-6}\ \text{m}^2/\text{s}$$

$$N_R = \frac{(4)(0.0041\ \text{m/s})[(1.25\ \text{m} \times 3.0\ \text{m})/(2 \times 3.0\ \text{m} + 1.25\ \text{m})]}{(1.003 \times 10^{-6}\ \text{m}^2/\text{s})} = 8457$$

   b. Determine the coefficient of dispersion.

$$D = 1.01\nu N_R^{0.875}$$

$$D = 1.01 \times 1.003 \times 10^{-6}\ \text{m}^2/\text{s}\ (8457)^{0.875} = 2.77 \times 10^{-3}\ \text{m}^2/\text{s}$$

   c. Determine the dispersion number using Eq. (4–43).

$$d = \frac{D}{uL} = \frac{Dt}{L^2} = \frac{(0.00277\ \text{m}^2/\text{s})(90\ \text{min} \times 60\ \text{s/min})}{(44.4\ \text{m})^2} = 0.0076$$

   d. Because the velocity is reduced at average flow, the computed dispersion number is equivalent to about 66 complete-mix reactors in series.

Comment Under all flow conditions, deposition of residual suspended solids would be expected in the chlorine contact basin, especially so at low flow.

Predicting Disinfection Performance. An extremely important issue in the design of chlorine contact basins is being able to predict the performance of the proposed design. To predict performance, the actual residence time that a given molecule of the fluid spends in the reactor must be known. The residence time in the reactor can

be determined using some of the analytical techniques developed in Chap. 4. From Chap. 4, it was noted that the Peclet number divided by 2 is equal to the number of reactors in series. The relationship of the Peclet number to the dispersion number is

$$P_e = \frac{uL}{D} = \frac{1}{d} \tag{4-47}$$

For complete-mix reactors in series, the normalized residence time distribution curve for n reactors in series is given by

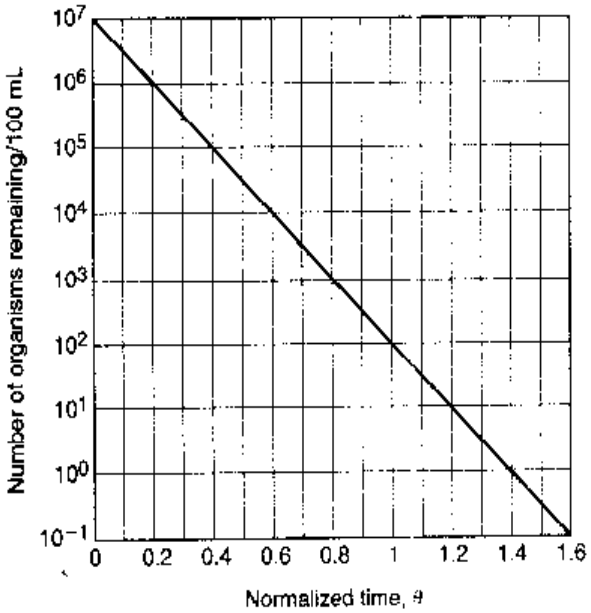
$$E(\theta) = \frac{n}{(n-1)!}(n\theta)^{n-1}e^{-n\theta} \tag{4-63}$$

Further, the fraction of tracer that has been in the reactor for less than time t is defined as follows:

$$F(\theta) = \int_0^t E(\theta)d\theta \approx \sum_0^n E(\theta)\Delta\theta \tag{4-32}$$

Thus, for a given dispersion number, the Peclet number can be used to determine the corresponding number of complete-mix reactors in series needed to achieve that dispersion number. Knowing the number of reactors in series, the value of $E(\theta)$ can be computed for various values of θ, the normalized detention time. The value of $F(\theta)$ can then be determined by summing the area under the $E(\theta)$ curve. The amount of flow that has been in the reactor for less than time θ can now be determined. Coupling normalized microorganism inactivation-dose response data, obtained using a batch reactor, with the normalized detention-time data, the actual performance for the chlorine contact basin can be estimated using what is known as a segregated flow model (SFM). In the SFM approach, it is assumed that each block of fluid that enters a chlorine contact basin does not interact with other blocks of water. Thus, each block of water corresponds to an ideal plug flow reactor, each having a different residence time as defined by the value of $E(\theta)$, as given above. The reduction in organisms that would occur in each block of water can then be estimated for the period of time the block of water has remained in the chlorine contact basin. The overall performance is obtained by summing the results for each block of water. The SFM approach can be described as follows (Fogler, 1999).

Word statement



Mean reduction in number of microorganisms spending between time t and $t + dt$ in the chlorine contact basin	=	number of organisms remaining after spending a time t in the chlorine contact basin based on batch test results	×	fraction of flow that remained in the chlorine contact basin between time t and $t + dt$	(12–57)

In equation form

$$d\bar{N} = N(\theta) \times E(\theta)dt \tag{12-58}$$

The values of $N(\theta)$ and $E(\theta)$ are obtained from batch disinfection and tracer or dispersion prediction studies. Application of the above equations for predicting the hydraulic performance and the effluent microorganism concentration using the SFM are illustrated in Example 12-8 using the data from Example 12-7.

EXAMPLE 12-8 Estimation of Performance of a Chlorine Contact Basin Using the design information from Example 12–7, determine the fraction of flow that has not remained in the chlorine contact basin for the full hydraulic detention time. Determine how much larger the chlorine contact basin must be to be assured that 90 percent of the flow remains in the chlorine contact basin for the full design hydraulic detention time. Using the following normalized-dose response data for an enteric virus, estimate the performance of the chlorine contact basin in terms of the residual number of organisms remaining in the effluent.

Solution

1. Determine the number of complete-mix reactors in series.
   a. From Example 12–7, the dispersion number at peak flow is

      $d = 0.0139$

   b. The number of complete-mix reactors in series is

      $$\text{Number of reactors in series} = \frac{P_e}{2} = \frac{1}{2d} + \frac{1}{(2)\,0.0139} = 36$$

2. Determine the percentage of the flow that has been in the chlorine contact basin for less than the hydraulic detention time.
   a. Set up a computation table and compute $E(\theta)$ using Eq. (4–63), as given above.

      $$E(\theta) = \frac{n}{(n-1)!}(n\theta)^{n-1}e^{-n\theta}$$

Normalized time, θ	$E(\theta)$	$E(\theta) \times \Delta\theta \times 100$	Cumulative percent, $F(\theta)$
0.30	0.0000	0.000	0.000
0.40	0.0000	0.000	0.000
0.50	0.0046	0.046	0.046
0.60	0.0737	0.737	0.783
0.70	0.4435	4.435	5.218
0.80	1.2976	12.976	18.193
0.90	2.1878	21.878	40.071
1.00	2.3881	23.881	63.952
1.10	1.8337	18.337	82.290
1.20	1.0531	10.531	92.821
1.30	0.4739	4.739	97.560
1.40	0.1733	1.733	99.293
1.50	0.0530	0.530	99.822
1.60	0.0139	0.139	99.961
1.70	0.0031	0.032	99.992
1.80	0.0006	0.006	99.999
1.90	0.0001	0.001	100.00
2.00	0.0000	0.000	100.00

b. Plot the cumulative percent values from the above table.

c. From the computation table and graph given above, the percentage of the flow that has been in the chlorine contact basin for less than the hydraulic residence time is 64 percent. In fact, about 18 percent of the flow has left the chlorine contact basin before 80 percent of the actual hydraulic detention time has elapsed.

3. Estimate how much larger the chlorine contact basin must be to be assured that 90 percent of the flow remains in the chlorine contact basin for the full hydraulic detention time. From the above graph, the size of the chlorine contact basin would have to be increased by a factor of 1.2.

4. Estimate the performance of the chlorine contact basin.
   a. Set up a computation table to determine the number of organisms remaining in the effluent from the chlorine contact basin. The SFM approach, described above, will be used for this analysis. In effect, flow in each time period is treated as a batch reactor for the time interval it has remained in the reactor. The corresponding concentration of microorganisms leaving in any given volume of liquid is taken from the normalized-dose response curve. The computation table for the application of the SFM is given below. The data in columns (1) and (3) are from the computation table prepared in Step 2 above, except that the data in column (3) are divided by 100. The data in column (2) are from the normalized-dose response curve obtained as part of the process analysis for the design of the chlorine contact basin.

Normalized time, θ (1)	Number of organisms remaining, $N(\theta)$ MPN/100 mL (2)	$E(\theta) \times \Delta\theta$ (3)	Number of organisms remaining in effluent, ΔN MPN/100 mL (4)

b. The number of organisms in the effluent leaving the chlorine contact basin is

Organisms in effluent $N = \Sigma[N(\theta) \times E(\theta)\Delta\theta] = 447$ MPN/100 mL

c. By comparison, if it was assumed that the basin had performed as an ideal plug-flow reactor, then the organism concentration in the effluent would have been estimated to be 100 MPN/100 mL.

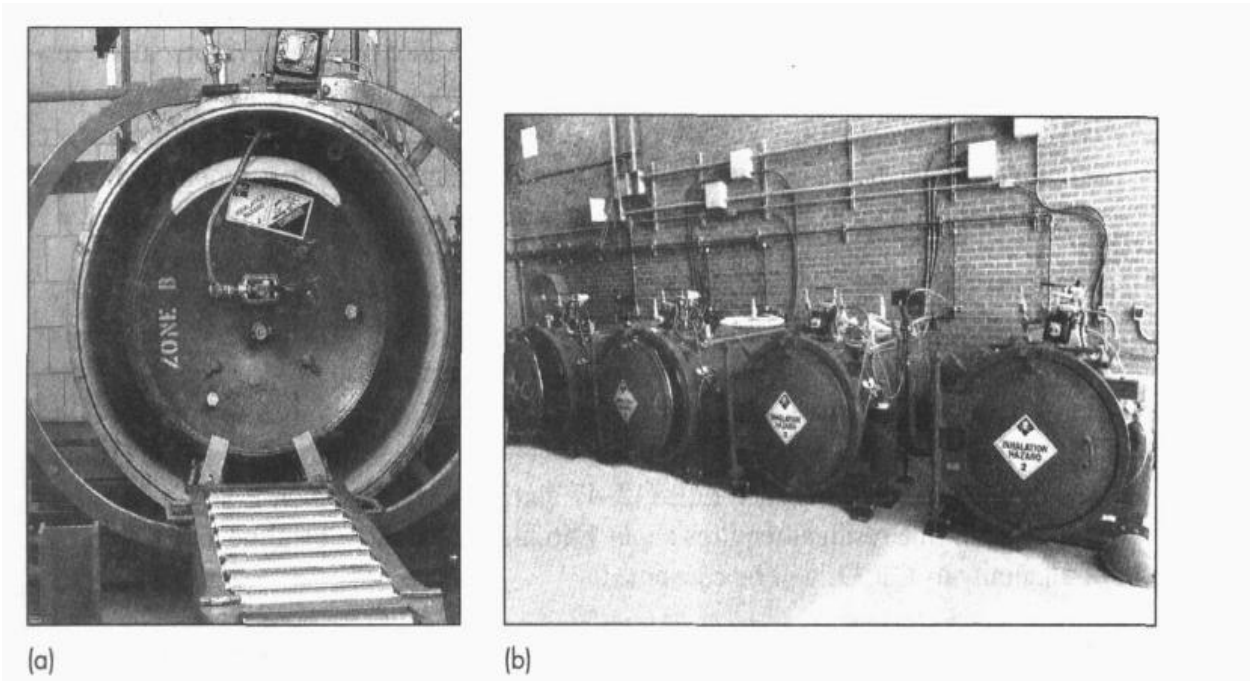
Comment The SFM method of analysis used to determine the number of organisms in the effluent is useful for estimating the performance of reactors with varying amounts of dispersion such as chlorine contact basins.

Chlorine Residual Measurement

The flow at the inlet or outlet of the chlorine contact basin may be metered, as noted previously, by means of a magnetic meter, Parshall flume, or flow tube. Control devices for chlorination in direct proportion to the flowrate may be operated from these meters or from the main plant flowmeter using an analog flow signal transmitter. Final determination of the success of a chlorine contact basin must be based on samples taken and analyzed to correlate chlorine residual and the MPN of coliform or other indicator organisms. When the chlorine residual is used for chlorinator control, chlorine residual sample pumps should be located at the front end of the first pass of the contact basin immediately after rapid mixing. More precise control of the chlorine feed can be maintained as compared to monitoring the chlorine residual at the chlorine contact basin effluent. Chlorine residual measurements should also be taken at the contact basin outlet to ensure compliance with the regulatory agency requirements. In the event that no chlorine contact basin is provided and the effluent pipeline is used for contact, the sample can be obtained at the point of chlorination, held for the theoretical detention time, and the residual determined. The sample is then dechlorinated and subsequently analyzed for bacteria using standard laboratory procedures.

Chlorine Storage Facilities

Storage and handling facilities for chlorine can be designed with the aid of information developed by the Chlorine Institute. Although all the safety devices and precautions that must be designed into the chlorine handling facilities are too numerous to mention, the following are fundamental:



1. Chlorine gas is toxic and very corrosive. Adequate exhaust ventilation at floor level should be provided because chlorine gas is heavier than air. The ventilation system should be capable of at least 60 air changes per hour.
2. Chlorine storage and chlorinator equipment rooms should be walled off from the rest of the plant and should be accessible only from the outdoors. A fixed glass viewing window should be included in an inside wall, to check for leaks before entering the equipment rooms. Fan controls should be located at the room entrance. Air masks should also be located nearby in protected but readily accessible locations.
3. Temperatures in the scale and chlorinator areas should be controlled to avoid freezing.
4. Dry chlorine liquid and gas can be handled in black steel piping, but chlorine solution is highly corrosive and should be handled in schedule 80 polyvinylchloride (PVC) piping.
5. Adequate storage of standby cylinders should be provided. The amount of storage should be based on the availability and dependability of the supply and the quantities used. Cylinders in use are set on scales and the loss of weight is used as a positive record of chlorine dosage.
6. Chlorine cylinders should be protected from direct sunlight in warm climates to prevent overheating of the full cylinders.
7. In larger systems, chlorine residual analyzers should be provided for monitoring and control purposes to prevent the under- or overdosing of chlorine.
8. The chlorine storage and feed facilities should be protected from fire hazards. In addition, chlorine leak detection equipment should be provided and connected to an alarm system.

Chlorine Containment Facilities

In 1991, the International Conference of Building Officials revised Article 80: Hazardous Material of the Uniform Fire Code (UFC). The revisions were extensive and covered a variety of issues. The provisions of the new code apply to new facilities and to old facilities, if it is determined that they constitute a distinct hazard to life or property. The new code provisions contained in the following divisions apply to the chemicals used for disinfection: I General Provisions, II Classification by Hazard, III Storage Requirements, and IV Dispensing, Use, and Handling. The classification of hazardous materials used for wastewater disinfection is summarized in Table 12–17. Storage requirements include provisions for spill control and containment, ventilation, treatment, and storage. Emergency caustic scrubbing systems are also required to neutralize leaking chlorine and sulfur dioxide gas. Many of the same topics contained in the storage requirements section also apply to the dispensing, use, and handling. Hazardous material management, provision for standby power, security, and alarms are among the

Table 12-17
Classification of hazardous materials used in wastewater disinfection

Category	Typical chemicals
Physical hazards:	
Compressed gases	Oxygen, ozone, chlorine, ammonia, sulfur dioxide
Oxidizers	Oxygen, ozone, chlorine, hydrogen peroxide, acids, chlorine
Health hazards:	
Highly toxic and toxic material	Chlorine, chlorine dioxide, ozone, acids, bases
Corrosives	Acids, bases, chlorine, sulfur dioxide, ammonia, hypochlorite, sodium bisulfite
Other health hazards—irritants, suffocating, etc.	Chlorine, sulfur dioxide, ammonia

(a) (b)

Figure 12-28

Containment system for chlorine storage containers. Chlorine cylinders are sealed totally within the containment vessel. Vessels are available for one or two 68 kg (150 lb) cylinders and 908 kg (1 ton) chlorine storage containers: (*a*) containment vessel for one 908 kg chlorine container and (*b*) view of multiple 908 kg chlorine container containment vessels. *(Courtesy TGO Technologies, Inc.)*

additional topics covered. It is extremely important to review current UFC regulations in the design of new facilities and in the refurbishing of existing facilities.

A relatively recent development (1996) for the storage of chlorine and sulfur dioxide in either 68 kg (150 lb) or 908 kg (1 ton) cylinders is the total containment vessel (see Fig. 12–28) manufactured by TGO Technologies, Inc. Known as the *ChlorTainer*™, the total enclosure vessel is a passive device with no need for pumps, fans or scrubbers, or caustic circulation systems, which meets all of the requirements of the UFC. Should a chlorine and sulfur gas cylinder fail while in the containment vessel, the gas contained

within the vessel is processed at the normal rate through the existing chlorination facilities. The containment vessels do require a specially designed truck unloading platform so that the gas cylinders can be moved to and placed in the containment vessel (see Fig. 12–28*a*). In addition to eliminating the need for specialized chemical handling and storage facilities, the total containment vessel will shut down automatically during a seismic event and does not require mechanical devices to function.

Dechlorination Facilities

Dechlorination of chlorinated effluents is accomplished most commonly using sulfur dioxide. Where granular activated carbon is used for the removal of residual organic material, the carbon can also be used for the dechlorination of chlorinated effluents.

Sulfur Dioxide. The principal elements of a sulfur dioxide dechlorination system include the sulfur dioxide containers, scales, sulfur dioxide feeders (sulfonators), solution injectors, diffuser, mixing chamber, and interconnecting piping. For facilities requiring large withdrawal rates of SO_2, evaporators are used because of the low vaporization pressure of 240 kN/m^2 at 21°C (35 lb$_f$/in^2 at 70°F). Common sulfonator sizes are 216, 864, and 3409 kg/d (475, 1900, and 7500 lb/d). The key control parameters of this process are (1) proper dosage based on precise (amperometric) monitoring of the combined chlorine residual and (2) adequate mixing at the point of application of sulfur dioxide.

Sodium Bisulfite. Sodium bisulfite is available as white powder, a granular material, or a liquid. The liquid form is used most commonly for dechlorination at wastewater-treatment facilities. Although available in solution strengths up to 44 percent, a 38 percent solution is most typical. In most applications, a diaphragm-type pump is used to meter the sodium bisulfite. The reaction between sodium bisulfite and chlorine residual was presented previously [see Eqs. (12–47 and 12–48)]. Based on Eq. (12–47), each mg/L of chlorine residual requires about 1.46 mg/L of sodium bisulfite and 1.38 mg/L of alkalinity as $CaCO_3$ will be consumed.

Granular Activated Carbon. The common method of activated-carbon treatment used for dechlorination is downflow through either an open or an enclosed vessel. The activated-carbon system, while significantly more costly than other dechlorination approaches, may be appropriate when activated carbon is being used as an advanced wastewater-treatment process. Typical hydraulic loading rates and contact times for activated-carbon columns used for dechlorination are 3000 to 4000 L/m^2·d and 15 to 25 min, respectively.

12–7 DISINFECTION WITH OZONE

Ozone was first used to disinfect water supplies in France in the early 1900s. Its use increased and spread into several western European countries and eventually to North America. There are well over 1000 ozone disinfection installations worldwide, almost entirely for treating water supplies. Approximately 200 installations are in operation in North America. A common use for ozone at these installations is for the control of taste-, odor-, and color-producing agents. Although historically used primarily for the disinfection of water, recent advances in ozone generation and solution technology have made the use of ozone economically more competitive for wastewater disinfection.

Ozone can also be used in wastewater treatment for odor control and in advanced wastewater treatment for the removal of soluble refractory organics, in lieu of the carbon-adsorption process. The characteristics of ozone, the chemistry of ozone, the generation of ozone, an analysis of the performance of ozone as a disinfectant, and the application of the ozonation process are considered in the following discussion.

Ozone Properties

Ozone is an unstable gas produced when oxygen molecules dissociate into atomic oxygen. Ozone can be produced by electrolysis, photochemical reaction, or radiochemical reaction by electrical discharge. Ozone is often produced by ultraviolet light and lightning during a thunderstorm. The electrical discharge method is used for the generation of ozone in water and wastewater disinfection applications. Ozone is a blue gas at normal room temperatures, and has a distinct odor. Ozone can be detected at concentrations of 2×10^{-5} to 1×10^{-4} g/m^3 (0.01 to 0.05 ppm$_v$). Because it has an odor, ozone can usually be detected before health concerns develop. The stability of ozone in air is greater than it is in water, but in both cases is on the order of minutes. Gaseous ozone is explosive when the concentration reaches about 240 g/m^3 (20 percent weight in air). The properties of ozone are summarized in Table 12–18. The solubility of ozone in water is governed by Henry's law. Typical values of Henry's constant for ozone are presented in Table 12–19.

Ozone Chemistry

Some of the chemical properties displayed by ozone may be described by its decomposition reactions, which are thought to proceed as follows:

$$O_3 + H_2O \rightarrow HO_3^+ + OH^- \quad (12\text{–}59)$$

$$HO_3^+ + OH^- \rightarrow 2HO_2 \quad (12\text{–}60)$$

Table 12–18
Properties of ozone[a]

Property	Unit	Value
Molecular weight	g	48.0
Boiling point	°C	−111.9 ± 0.3
Melting point	°C	−192.5 ± 0.4
Latent heat of vaporization at 111.9°C	kJ/kg	14.90

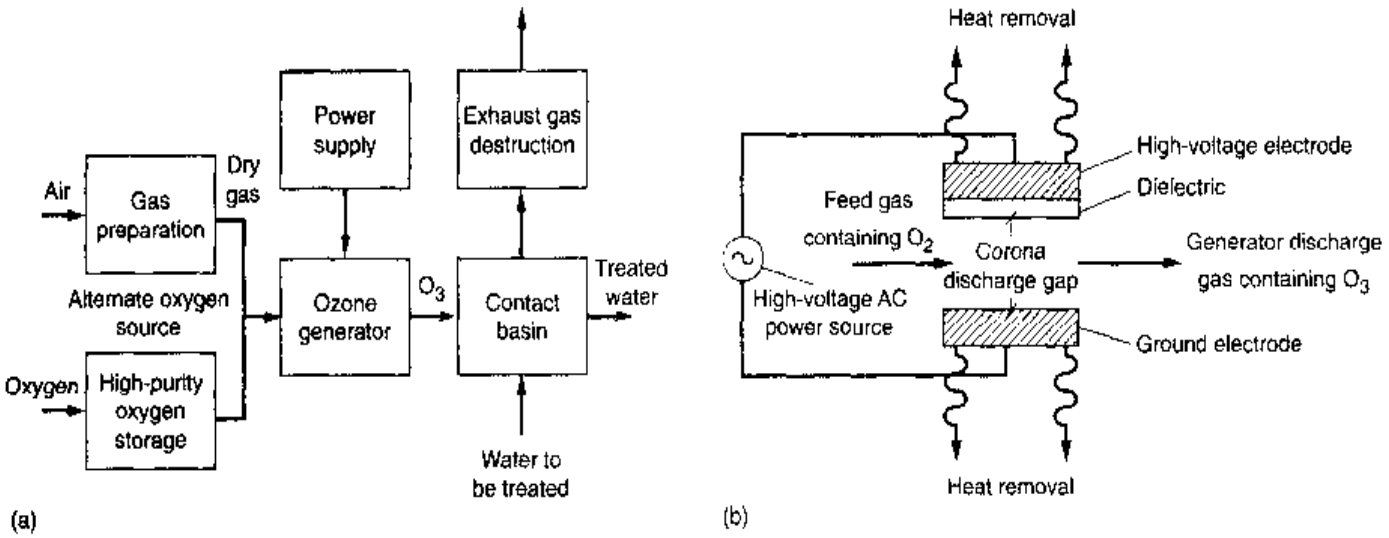

Figure 12–29
Elements of ozone disinfection system: (a) schematic flow diagram for complete ozone disinfection system and (b) schematic detail of the generation of ozone. *(Adapted from U.S. EPA, 1986.)*

$$O_3 + HO_2 \rightarrow HO + 2O_2 \qquad (12\text{–}61)$$

$$HO + HO_2 \rightarrow H_2O + O_2 \qquad (12\text{–}62)$$

The free radicals formed, HO_2 and HO, have great oxidizing powers, and are probably the active form in the disinfection process. These free radicals also possess the oxidizing power to react with other impurities in aqueous solutions.

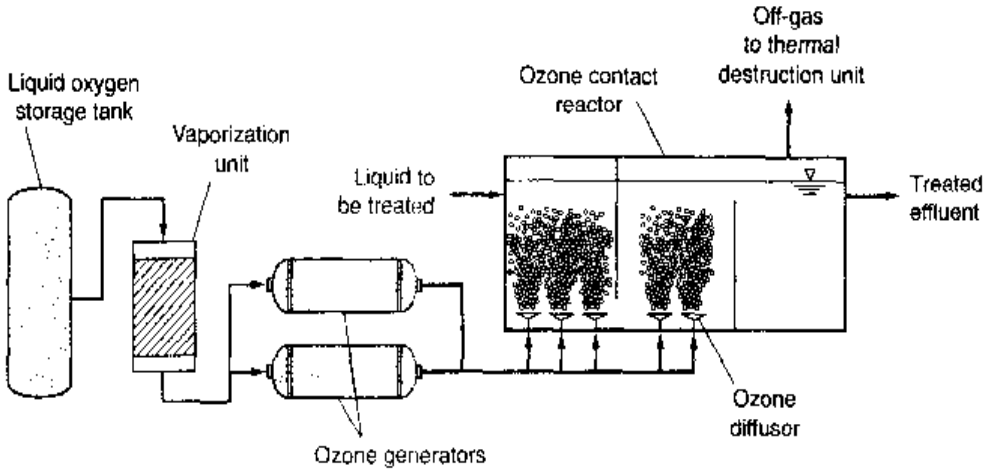
Ozone Disinfection Systems Components

A complete ozone disinfection system, as illustrated on Fig. 12–29*a*, is comprised of the following components: (1) power supply, (2) facilities for the preparation of the feed gas, (3) the ozone generation facilities, (4) facilities for contacting the ozone with the liquid to be disinfected, and (5) facilities for the destruction of the off-gas (Rice, 1996).

Table 12–20
Typical energy requirements for the application of ozone

Component	kWh/lb ozone	kWh/kg ozone
Air preparation (compressor and dryers)	2–3	4.4–6.6
Ozone generation:		
Air feed	6–9	13.2–19.8
Pure oxygen	3–6	6.6–13.2
Ozone contacting	1–3	2.2–6.6
All other uses	0.5–1	1.2–2.2

Energy Requirements. The major requirement for power is the conversion of oxygen into ozone. Additional power is required for preparation of the feed gas, contacting the ozone, destroying the residual ozone, and for the controls, instrumentation, and monitoring facilities. The energy requirements for the major components are reported in Table 12–20.



Preparation of Feed Gas. Ozone can be generated using air, oxygen-enriched air, or high-purity oxygen. If air is used for ozone generation, it must be conditioned by removing the moisture and particulate matter before being introduced into the ozone generator. The following steps are involved in conditioning the air: (1) gas compression, (2) air cooling and drying, and (3) air filtration. If high-purity oxygen is used, the conditioning steps are not required.

Ozone Generation. Because ozone is chemically unstable, it decomposes to oxygen very rapidly after generation, and thus must be generated onsite. The most efficient method of producing ozone today is by electrical discharge. Ozone is generated from either air or high-purity oxygen when a high voltage is applied across the gap of narrowly spaced electrodes (see Fig. 12–29*b*). The high-energy corona created by this arrangement dissociates one oxygen molecule, which re-forms with two other oxygen molecules to create two ozone molecules. The gas stream generated by this process from air will contain about 1 to 3 percent ozone by weight, and from pure oxygen about three times that amount, or 3 to 10 percent ozone with the latest ozone generators.

Ozone Contact Reactors. The concentration of ozone generated from either air or pure oxygen is so low that the transfer efficiency to the liquid phase is an extremely important economic consideration. For this reason, deep and covered contact chambers are normally used. A schematic process flow diagram of a typical ozone disinfection system is shown on Fig. 12–30. As shown on Fig. 12–30, the ozone is contacted in a three-chamber covered contactor. Ozone is introduced by means of porous diffusers or injectors into the bottom of the first chamber. Fast ozone reactions occur in the first chamber. The combined wastewater-ozone mixture then enters the second chamber, where slower reactions occur. Disinfection generally occurs in the second chamber. The third chamber is used to complete the slow reactions and to allow the ozone to decompose. Specially designed in-line static mixers have also been developed for the dissolution of ozone. A properly designed diffuser system should normally achieve a 90 percent transfer of ozone.

Figure 12–30

Typical flow diagram for the application of ozone for disinfection.

Destruction of Off-Gases. The off-gases from the contact chamber must be treated to destroy any remaining ozone, as it is an extremely irritating and toxic gas. The product formed by destruction of the remaining ozone is pure oxygen, which can be recycled if pure oxygen is being used to generate the ozone. In some designs ozone is introduced in both the first and second chambers.

Effectiveness of Ozone as a Disinfectant

Ozone is an extremely reactive oxidant, and it is generally believed that bacterial kill through ozonation occurs directly because of cell wall disintegration (cell lysis). The impact of the wastewater characteristics on ozone disinfection is reported in Table 12–21. The presence of oxidizable compounds will cause the ozone inactivation curve to have a shoulder effect, as discussed previously for chlorine (see Fig. 12–10).

Ozone is also a very effective viricide and is generally believed to be more effective than chlorine. Ozonation does not produce dissolved solids and is not affected by the ammonium ion or pH influent to the process. For these reasons, ozonation is considered as an alternative to either chlorination or hypochlorination, especially where dechlorination may be required and high-purity oxygen facilities are available at the treatment plant. Data on the relative germicidal effectiveness of ozone for the disinfection of different microorganisms were presented previously in Table 12–11.

Modeling the Ozone Disinfection Process

As discussed previously in Sec. 12–2, the models that have been developed to describe the disinfection process with chlorine have also been adapted for ozone. Equation (12–63) has been modified as follows (Finch and Smith, 1989, 1990; U.S. EPA, 1986):

$$N/N_o = 1 \qquad \text{for } U < q \tag{12–63}$$

$$N/N_o = [(U)/q]^{-n} \qquad \text{for } U > q \tag{12–64}$$

where N = number of organisms remaining after disinfection
N_o = number of organisms present before disinfection
U = utilized (or transferred) ozone dose, mg/L

Table 12–21 Impact of wastewater constituents on the use of ozone for wastewater disinfection

Constituent	Effect
BOD, COD, TOC, etc.	Organic compounds that comprise the BOD and COD can exert an ozone demand. The degree of interference depends on their functional groups and their chemical structure
Humic materials	Affects the rate of ozone decomposition and the ozone demand
Oil and grease	Can exert an ozone demand
TSS	Increase ozone demand and shielding of embedded bacteria
Alkalinity	No or minor effect
Hardness	No or minor effect
Ammonia	No or minor effect, can react at high pH
Nitrite	Oxidized by ozone
Nitrate	Can reduce effectiveness of ozone
Iron	Oxidized by ozone
Manganese	Oxidized by ozone
pH	Affects the rate of ozone decomposition
Industrial discharges	Depending on the constituents, may lead to diurnal and seasonal variations in the ozone demand

n = slope of dose response curve
q = value of x intercept when $N/N_o = 1$ or $\log N/N_o = 0$ (assumed to be equal to the initial ozone demand)

The required ozone dosage must be increased to account for the transfer of the applied ozone to the liquid. The required dosage can be computed with the following expression:

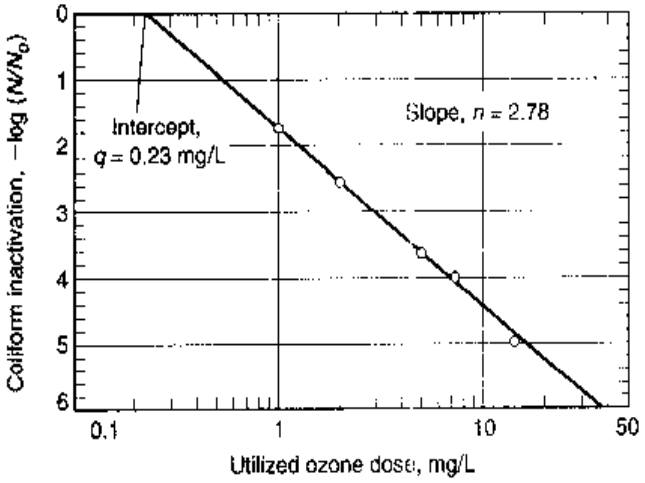
$$D = U\left(\frac{100}{TE}\right) \tag{12-65}$$

where D = total required ozone dosage, mg/L
U = utilized (or transferred) ozone dose, mg/L
TE = ozone transfer efficiency, %

Typical ozone transfer efficiencies vary from about 80 to 90 percent.

EXAMPLE 12–9 Estimate the Required Ozone Dose for a Typical Secondary Effluent Estimate the ozone dose needed to disinfect a filtered secondary effluent to an MPN value of 240/100 mL using the following disinfection data obtained from pilot-scale installation. Assume the starting coliform concentration will be 1×10^6/100 mL and that the ozone transfer efficiency is 80 percent.

Test number	Initial coliform count N_o, MPN/100 mL	Ozone transferred, mg/L	Final coliform count N, MPN/100 mL	$-\log (N/N_o)$
1	95,000	3.1	1500	1.80
2	470,000	4.0	1200	2.59
3	3,500,000	4.5	730	3.68
4	820,000	5.0	77	4.03
5	9,200,000	6.5	92	5.00



Solution

1. Determine the coefficients in Eq. (12–64) using the pilot-plant data.
   a. Linearize Eq. (12–64) and plot the log inactivation data versus the ozone dose on loglog paper to determine the constants in

   $$N/N_o = [(U)/q]^{-n}$$

   $$\log (N/N_o) = -n \log (U/q)$$

   b. The required log-log plot is given below.

   c. The required coefficients are:

   $q = 0.23$ mg/L

   $n = 2.78$

2. Determine the ozone dose required to achieve an effluent coliform concentration of 240 MPN/100 mL.
   a. Rearrange Eq. (12–64) to solve for U.

   $$U = q\,(N/N_o)^{-1/n}$$

   b. Solve for U.

   $$U = q\,(N/N_o)^{-1/n} = (0.23 \text{ mg/L})(240/10^6)^{-1/2.78} = 4.61 \text{ mg/L}$$

3. Determine the dose that must be applied using Eq. (12–65), assuming a transfer efficiency of 80 percent.

$$D = U\left(\frac{100}{TE}\right) = (4.61\ \text{mg/L})\left(\frac{100}{80}\right) = 5.76\ \text{mg/L}$$

Required Ozone Dosages for Disinfection

The required ozone dosage for disinfection can be estimated by considering (1) the initial ozone demand of the wastewater and (2) the required ozone dose using Eqs. (12–64) and (12–65). The ozone dosages required to meet the initial demand will depend on the wastewater constituents. Typical values for the ozone demand for various wastewaters based on a contact time of 15 min are reported in Table 12–22. It should be noted that the dosage values given in Table 12–22 are only meant to serve as a guide for the initial estimation of the required ozone dose. In most cases, pilot-scale studies (see Fig. 12–31) will need to be conducted to establish the required dosage ranges.

Byproduct Formation and Control

As with chlorine, the formation of unwanted byproducts is one of the problems associated with the use of ozone as a disinfectant. The formation and control of DBPs when using ozone are considered in the following discussion.

Table 12–22
Typical ozone dosages required to achieve different effluent coliform disinfection standards for various wastewaters based on a 15-min contact time[a]

Type of wastewater	Initial coliform count, MPN/100 mL	Ozone dose, mg/L			
		Effluent standard, MPN/100 mL			
		1000	200	23	<2.2
Raw wastewater	10^7–10^9	15–40			
Primary effluent	10^7–10^9	10–40			
Trickling filter effluent	10^5–10^6	4–10			
Activated-sludge effluent	10^5–10^6	4–10	4–8	16–30	30–40
Filtered activated-sludge effluent	10^4–10^6	6–10	4–8	16–25	30–40
Nitrified effluent	10^4–10^6	3–6	4–6	8–20	18–24
Filtered nitrified effluent	10^4–10^6	3–6	3–5	4–15	15–20
Microfiltration effluent	10^1–10^3	2–6	2–6	3–8	4–8
Reverse osmosis	Nil				1–2
Septic tank effluent	10^7–10^9	15–40			
Intermittent sand filter effluent	10^2–10^4	4–8	10–15	12–20	16–25

Typical pilot-scale contactor used to test the effectiveness of ozone for disinfection and oxidation of organics.

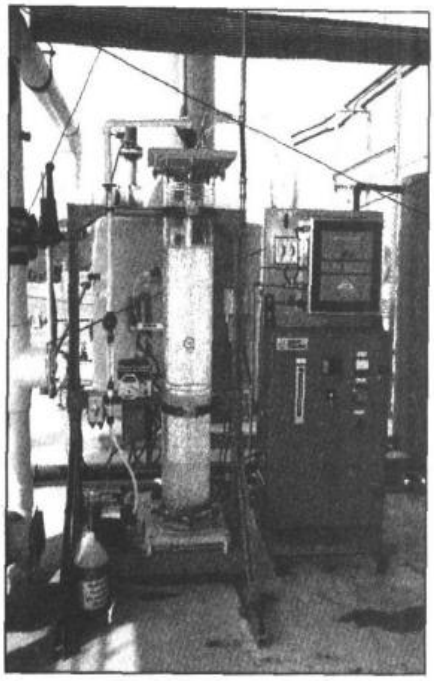

Table 12-23
Representative disinfection byproducts resulting from the ozonation of wastewater containing organic and selected inorganic constituents[a]

Aldehydes	Brominated byproducts[b]
Formaldehyde	Bromate ion
Acetaldehyde	Bromoform
Glyoxal	Brominated acetic acids
Methyl glyoxal	Bromopicrin
Acids	Brominated acetonitriles
Acetic acids	Cyanogen bromide
Formic acid	Other
Oxalic acid	Hydrogen peroxide
Succinic acid	
Aldo- and ketoacids	
Pyruvic acid	

[a] *Adapted in part from U.S. EPA (1999b).*
[b] The bromide ion must be present to form brominated byproducts.

Formation of DBPs Due to the Addition of Ozone for Disinfection. One advantage of ozone is that it does not form chlorinated DBPs such as THMs and HAAs (see Table 12–14). Ozone does, however, form other DBPs (see Table 12–23) including aldehydes, various acids, and aldo- and ketoacids when significant amounts of bromide are not present. In the presence of bromide, the following DBPs may also be produced: inorganic bromate ion, bromoform, brominated acetic acid, bromopicrin, brominated acetonitriles, and cyanogen bromide (see Table 12–14). On occasion, hydrogen peroxide can also be generated. The specific amounts and the relative distribution of

compounds will depend on the nature of the precursor compounds that are present. Because the chemical characteristics of wastewater will vary from location to location, pilot testing will be required to assess the effectiveness of ozone as a disinfectant.

Control of DBP Formation Due to the Addition of Ozone for Disinfection. Because the nonbrominated compounds appear to be readily biodegradable, they can be removed by passage through a biologically active filter or carbon column or other biologically active process. The nonbrominated compounds can also be removed by soil application. The removal of DBPs formed when bromine is present is more complex. If brominated DBPs are going to be a problem, it may be appropriate to investigate alternative means of disinfection such as UV radiation.

Environmental Impacts of Using Ozone

It has been reported that ozone residuals can be acutely toxic to aquatic life (Ward et al., 1976). However, because ozone dissipates rapidly, ozone residuals will normally not be found by the time the effluent is discharged into the receiving water. Several investigators have reported that ozonation can produce some toxic mutagenic and/or carcinogenic compounds. These compounds are usually unstable, however, and are present only for a matter of minutes in the ozonated water. White (1999) has reported that ozone destroys certain harmful refractory organic substances such as humic acid (precursor of trihalomethane formation) and malathion. Whether toxic intermediates are formed during ozonation depends on the ozone dose, the contact time, and the nature of the precursor compounds. White (1999) have reported that ozone treatment ahead of chlorination for disinfection purposes reduces the likelihood for the formation of THMs.

Other Benefits of Using Ozone

An additional benefit associated with the use of ozone for disinfection is that the dissolved oxygen concentration of the effluent will be elevated to near saturation levels as ozone rapidly decomposes to oxygen after application. The increase in oxygen concentration may eliminate the need for reaeration of the effluent to meet required dissolved oxygen water-quality standards. Further, because ozone decomposes rapidly, no chemical residual persists in the treated effluent that may require removal, as is the case with chlorine residuals.

12–8 OTHER CHEMICAL DISINFECTION METHODS

Because of the concerns over the effectiveness of disinfection processes and concern over the formation of DBPs, ongoing research is continuing into the evaluation of alternative disinfection methods. The use of peracetic acid, peroxone, and combined disinfection processes is introduced and considered briefly in this section. Because research on these and other disinfection methods is ongoing, current conference proceedings and literature must be consulted for the latest findings.

Peracetic Acid

In the late 1980s, the use of peracetic acid (PAA) was proposed as a wastewater disinfectant. Peracetic acid, made up of acetic acid and hydrogen peroxide, has been used

for many years as a disinfectant and sterilizing agent in hospitals. Peracetic acid is also used as a bactericide and fungicide, especially in food processing. Interest in the use of PAA as a wastewater disinfectant arises from considerations of safety and the possibility that its use will not result in the formation of DBPs. The use of PAA is considered briefly in this section as an example of the continuing search for alternative wastewater disinfectants to chlorine.

Peracetic Acid Chemistry and Properties. Commercially available PAA, also known as ethaneperoxide acid, peroxyacetic acid, or acetyl hydroxide, is only available as quaternary equilibrium solution containing acetic acid, hydrogen peroxide, peracetic acid, and water. The pertinent reaction is as follows:

$$\underset{\text{Acetic acid}}{CH_3CO_2H} + \underset{\text{Hydrogen peroxide}}{H_2O_2} \leftrightarrow \underset{\text{Peracetic acid}}{CH_3CO_3H} + H_2O \qquad (12\text{–}66)$$

The undissociated PAA (CH_3CO_3H) is considered to be the biocidal form in the equilibrium mixture; however, the hydrogen peroxide may also contribute to the disinfection process. Hydrogen peroxide is also more stable than PAA. The properties of PAA are summarized in Table 12–24.

Effectiveness of Peracetic Acid as a Disinfectant. The effectiveness of PAA has been studied by Lefevre et al. (1992), Lazarova et al. (1998), Liberti et al. (1999), Gehr (2000), and Colgan and Gehr (2001), among others. The findings to date are mixed concerning the bactericidal effectiveness of PAA, as well as the impact of wastewater characteristics on the effectiveness of PAA. The current literature must be consulted for more information on the application of PAA.

In a recent report by the U.S. EPA (1999*a*), PAA was included among a total of five possible disinfectants for use on combined sewer overflows (CSOs). Based on data for disinfection of secondary treatment plant effluents, it was suggested that PAA be strongly considered for CSO disinfection. Among the desirable attributes listed are absence of persistent residuals and byproducts, not affected by pH, short contact time, and high effectiveness as a bactericide and virucide.

Table 12–24
Properties of various peracetic acid (PAA) formulations[a]

Property	Unit	PAA, %		
		1.0	5	15
Weight PAA	%	0.8–1.5	4.5–5.4	14–17
Weight hydrogen peroxide	%	min 6	19–22	13.5–16

Formation of Disinfection Byproducts. Based on the limited data available, the principal end products identified were CH_3COOH (acetic acid or vinegar), O_2, CH_4, CO_2, and H_2O, none of which is considered toxic in the concentrations typically encountered.

Ozone/Hydrogen Peroxide (Peroxone)

Peroxone is an advanced oxidation process (AOP) involving the use of ozone and hydrogen peroxide (see Sec. 11–10 in Chap. 11). The peroxone process is comprised of two steps: ozone dissolution and hydrogen peroxide addition. The addition of hydrogen peroxide is used to accelerate the decomposition of ozone leading to the production of relatively high concentrations of hydroxyl radicals according to the following reaction:

$$H_2O_2 + 2O_3 \rightarrow HO^{\bullet} + HO^{\bullet} + 3O_2 \qquad (12\text{–}67)$$

The disinfection characteristics of peroxone are currently under investigation along with other AOPs. In general, the peroxone process and other AOPs have been found to be equal to or more effective than ozone for pathogen inactivation. In wastewater disinfection, the peroxone process would most likely be used primarily with highly treated effluents (e.g., effluent from microfiltration and reverse osmosis processes). It should be noted that a variety of other combination processes, many of which are classified as advanced oxidation processes, are currently under investigation for the disinfection of water and wastewater (U.S. EPA, 1999*b*).

Combined Chemical Disinfection Processes

Interest in the sequential or simultaneous use of two or more disinfectants has increased within a few years, especially in the water supply field. Reasons for the increased interest in the use of multiple disinfectants include (U.S. EPA, 1999*b*):

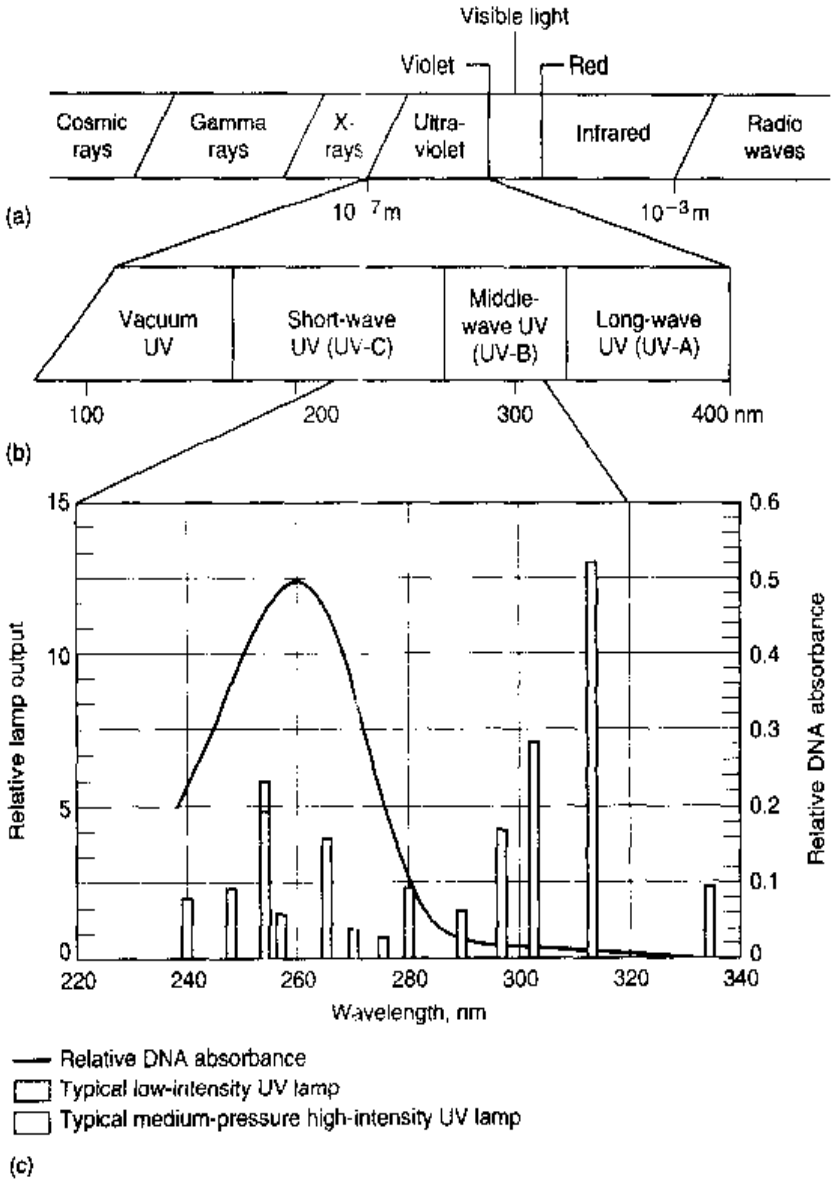
- The use of less reactive disinfectants, such as chloramines, has proved to be quite effective in reducing the formation of DBPs, and more effective for controlling biofilms in the distribution system.
- Regulatory and consumer pressure to produce water that has been disinfected to achieve high levels of inactivation for various pathogens has forced both the water and wastewater industry to search for more effective disinfectants. To meet more stringent disinfection standards, higher disinfectant doses have been used, which unfortunately has resulted in the production of increased levels of DBPs.
- Based on the results of recent research, it has been shown that the application of sequential disinfectants is more effective than the added effect of the individual disinfectants. When two (or more) disinfectants are used to produce a synergistic effect by either simultaneous or sequential application to achieve more effective pathogen inactivation, the process is referred to as *interactive disinfection* (U.S. EPA, 1999*b*).

Currently, extensive research is being conducted on these processes. The application of sequential or simultaneous use of multiple disinfectants is, at present, site-specific, depending on the treatment technologies employed. The current literature must be reviewed to assess the suitability and effectiveness of these new disinfection technologies.

12–9 ULTRAVIOLET (UV) RADIATION DISINFECTION

The germicidal properties of the radiation emitted from ultraviolet (UV) light sources have been used in a wide variety of applications since its use was pioneered in the early 1900s. First used on high-quality water supplies, ultraviolet light as a wastewater disinfectant has evolved during the 1990s with the development on new lamps, ballasts, and ancillary equipment. With the proper dosage, ultraviolet radiation has proved to be an effective bactericide and virucide for wastewater, while not contributing to the formation of toxic byproducts. To develop an understanding of the application of UV for the disinfection of wastewater, the following topics are considered in this section: (1) source of UV radiation, (2) UV system components and configurations, (3) the germicidal effectiveness of UV radiation, (4) modeling the UV disinfection process, (5) estimating the UV dose, (6) validation of UV system performance, (7) design of UV systems, (8) troubleshooting UV systems, and (9) the environmental impacts of disinfection with UV radiation.

Source of UV Radiation



The portion of the electromagnetic spectrum in which UV radiation occurs, as shown on Fig. 12–32*a*, is between 100 and 400 nm. The UV radiation range is characterized further according to wavelength as long-wave (UV-A), also known as near-ultraviolet radiation, middle-wave (UV-B), and short-wave (UV-C), also known as far UV. The germicidal portion of the UV radiation band is between about 220 and 320 nm, principally in the UV-C range. To produce UV radiation, lamps that contain mercury vapor are charged by striking an electric arc. The energy generated by the excitation of the mercury vapor contained in the lamp results in the emission of UV light. In general, UV disinfection systems fall into three categories based on the internal operating parameters of the UV lamp: *low-pressure low-intensity, low-pressure high-intensity,* and *medium-pressure high-intensity* systems. As will be discussed subsequently, UV disinfection systems may also be classified as open-channel or closed-pipe based on their hydraulic characteristics. In the brief discussion of UV lamps presented below, it is important to note that UV lamp technology is changing rapidly. It is therefore imperative that current manufacturers' literature be consulted when designing a UV disinfection facility.

Low-Pressure Low-Intensity UV Lamps. Low-pressure low-intensity UV lamps generate essentially monochromatic radiation at a wavelength of 254 nm, which is close to the 260 nm (255 to 265 nm) wavelength that is considered to be most effective for microbial inactivation (see Fig. 12–32*c*). In all cases, mercury-argon lamps are used to generate the UV-C region wavelengths. Low-pressure low-intensity UV lamps are of a slimline design with an overall length of 0.75 to 1.5 m and diameters varying from 15 to 20 mm. These lamps operate optimally at a lamp wall temperature of 40°C and an internal pressure of 0.007 mm Hg (Note: 1 mm Hg = 133.322 N/m^2). The output of low-pressure low-intensity lamps is about 25 to 27 W at 254 nm for a power input of 70 to 80 W. Approximately 85 to 88 percent of the lamp output is monochromatic at 254 nm, making it an efficient choice for disinfection processes. Comparative information on the operational characteristics of UV lamps is presented in Table 12–25.

Quartz sleeves are used to isolate the UV lamps from direct water contact and to control the lamp wall temperature by buffering the effluent temperature extremes to

Figure 12-32

Definition sketch for ultraviolet (UV) radiation disinfection: (a) identification of the ultraviolet radiation portion of the electromagnetic spectrum, (b) identification of the germicidal portion of the UV radiation spectrum, and (c) UV radiation spectra for both low-pressure low-intensity and medium-pressure high-intensity UV lamps and the relative UV adsorption for DNA superimposed over spectra of the UV lamps.

which the UV lamps are exposed, thereby maintaining a fairly uniform UV lamp output. Because there is an excess of liquid mercury in the low-pressure low-intensity UV lamp, the mercury vapor pressure is controlled by the coolest part of the lamp wall. If the lamp wall does not remain at its optimum temperature of 40°C, some of the mercury in the lamp condenses back to its liquid state, thereby decreasing the number of mercury atoms available to release photons of UV; hence UV output declines. The output of UV disinfection systems also decreases with time due to a reduction in the electron pool within the UV lamp, deterioration of the electrodes, and the aging of the quartz sleeve. The useful life of a low-pressure low-intensity UV lamp will vary from 9000 to 13,000 h depending on the number of on-off cycles per day. The useful life of the quartz sleeve is about 4 to 8 years.

Low-Pressure High-Intensity UV Lamps. Low-pressure high-intensity UV lamps are similar to the low-pressure low-intensity lamps with the exception that a mercury-indium amalgam is used in place of mercury. Low-pressure high-intensity UV lamps operate at a higher current discharge and pressures between 0.001 and

Table 12-25
Typical operational characteristics for UV lamps

Item	Unit	Type of lamp		
		Low-pressure low-intensity	Low-pressure high-intensity	Medium-pressure high-intensity
Power consumption	W	70–100	200–500	
	kW		1.2[a]	2–5
Lamp current	mA	350–550	Variable	Variable
Lamp voltage	V	220	Variable	Variable
Efficiency	%	30–40	25–35	10–12[b]

[b]Output in the germicidal range (~250–260 μm).

0.01 mm Hg. Use of the mercury amalgam allows greater UV-C output, typically from 2 to 4 times the output of conventional low-intensity lamps. However, one manufacturer offers a lamp that is said to have 20 times the output at 254 nm. The amalgam in the low-pressure high-intensity UV lamps is used to maintain a constant level of mercury atoms, and thus provides greater stability over a broad temperature range, and greater lamp life (25 percent greater than other low-pressure lamps). Current manufacturers' literature must be reviewed for lamp specifications, as new low-pressure high-intensity lamps are being developed continuously.

Medium-Pressure High-Intensity UV Lamps. Medium-pressure high-intensity UV lamps have been developed over the last decade. Medium-pressure high-intensity UV lamps, which operate at temperatures of 600 to 800°C and pressures of 10^2 to 10^4 mm Hg, generate polychromatic radiation (see Fig. 12–32*c*). About 27 to 44 percent of the total energy of a medium-pressure high-intensity lamp is in the germicidal UV-C wavelength range. Only about 7 to 15 percent of the output is near 254 nm. However, medium-pressure high-intensity UV lamps generate approximately 50 to 100 times the total UV-C output of the conventional low-pressure low-intensity UV lamp. Their use is limited primarily to higher wastewater flows, stormwater overflows, or on space-limited sites because fewer lamps are required and the footprint of the disinfection system is greatly reduced (i.e., contact time is reduced).

Because the high-intensity UV lamp operates at temperatures at which all the mercury is vaporized, the UV output can be modulated across a range of power settings (typically 60 to 100 percent) without significantly changing the spectral distribution of

the lamp. The ability to modulate the power is significant with respect to total power usage. Further, because of the high operating temperature, mechanical wiping of the quartz sleeve is essential to avoid the formation of an opaque film on the surface of the sleeve. Although there are a number of manufacturers of high-intensity UV lamps, most of the lamp manufacturers do not market complete UV disinfection systems. The particular UV lamp selected by UV system manufacturers is chosen on the basis of an integrated design approach in which the UV lamp, ballast, and reactor design are interdependent.

Emerging UV Lamp Technologies. New technologies are being developed that may have applications for wastewater disinfection. Two types of lamps that are being developed and applied to wastewater include (1) the pulsed energy broad-band xenon lamp (pulsed UV) and (2) the narrow-band excimer UV lamp. The operating principle of the pulsed UV lamp involves the conversion of alternating current (AC) to direct current (DC) which is stored in a capacitor. The energy stored in the capacitor is released through a high-speed switch and pulsed to produce an intense UV radiation field. Each time the switch closes, the lamp is fired, producing ionized gas (a plasma). The plasma expands until it reaches the wall of the lamp. The electric current carried by the plasma results in heating, which in turn raises the temperature of the plasma to about 10,000 K. At this elevated temperature an intense broad-band spectrum including UV, visible, and infrared wavelengths (see Fig. 12–32*a*) is emitted by the plasma. It is estimated that the radiation produced by the pulsed UV lamp is 20,000 times as intense as sunlight at sea level (EPRI, 1996; O'Brien et al., 1996).

Narrow-band excimer lamps produce essentially monochromatic radiation. A corona discharge is used to form excited dimers (two monomers joined together, e.g., two gas molecules joined together). Once in the excited state, the two molecules are termed *excimers*. Current flow in the discharge gap is comprised of a large number of microdischarges lasting on the order of nanoseconds. During these short discharges, electrons collide with gas molecules, causing collisions between excited gas molecules, resulting in the formation of dimers. Because the dimers are unstable, they collapse into their normal state, and in the process release energy in the form of photons. Gases that have been used for the purpose include xenon (Xe), xenon chloride (XeCl), krypton (Kr), and krypton chloride (KrCl). The specific wavelength emitted by excimer UV lamps will depend on the gas used in the lamp. Commercial excimer lamps are available that emit essentially monochromatic light in three wavelengths: 172, 222, and 308 nm. Numerous other lamps are under development (EPRI, 1996; O'Brien et al., 1996).

Because the developments in UV technology are occurring at such a rapid pace, it is essential that the current literature be consulted when designing UV disinfection systems. Note that in most cases, emerging technologies do not have a proven track record of cost-effective, reliable performance.

UV Disinfection System Components and Configurations

The principal components of a UV disinfection system consist of (1) the UV lamps, (2) the quartz sleeves in which the UV lamp is placed, (3) the supporting structure for the UV lamps and the quartz sleeves, (4) the ballasts used to supply regulated power to the UV lamps, and (5) the power supply which is used to power the ballasts. Three types of ballasts are used: (1) standard (core coil), (2) energy-efficient (core coil), and

(3) electronic (solid-state). Ballasts are used to limit the current to a lamp. Because UV lamps are arc-discharge devices, the more current in the arc, the lower the resistance becomes. Without a ballast to limit current, the lamp would destroy itself. Thus, matching the lamp and ballast is of critical importance in the design of UV disinfection systems. In addition to the type of lamp used, UV systems for the disinfection of wastewater can also be classified according to whether the flow occurs in open or closed channels. Each of these system configurations is described below.

Open-Channel Disinfection Systems. The principal components of low-pressure low- and high-intensity open-channel UV systems used for the disinfection of wastewater are illustrated on Fig. 12–33. As shown, lamp placement can be either horizontal and parallel to the flow (see Fig. 12–33*a*) or vertical and perpendicular to the flow (see Fig. 12–33*b*). Examples of typical low-pressure low-intensity UV disinfection systems for wastewater are shown on Figs. 12–34 and 12–35. The design flowrate is usually divided equally among a number of open channels. Each channel typically contains two or more banks of UV lamps in series, and each bank is comprised of a specified number of modules (or racks of UV lamps). It is important to note that a standby bank or channel should be provided for system reliability. Each module contains a specified number of UV lamps encased in quartz sleeves. The number of UV lamps per module is 2, 4, 8, 12, or 16. A spacing of 75 mm (3 in) between the centers of UV lamps is currently the most frequently used lamp configuration by UV manufacturers. A weighted flap gate, an extended sharp-crested weir, or an automatic level controller is used to control the depth of flow through each disinfection channel. To overcome the effect of fouling, which reduces the intensity of light in the liquid medium, the lamps must be removed occasionally from the flow channel and cleaned. Mechanical cleaning systems are used with low-pressure high-intensity systems to avoid fouling of the quartz sleeves.

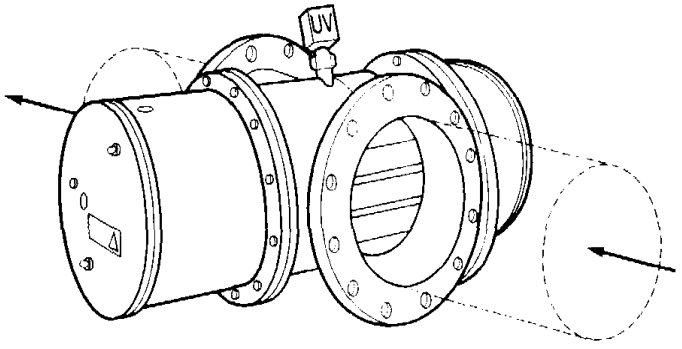
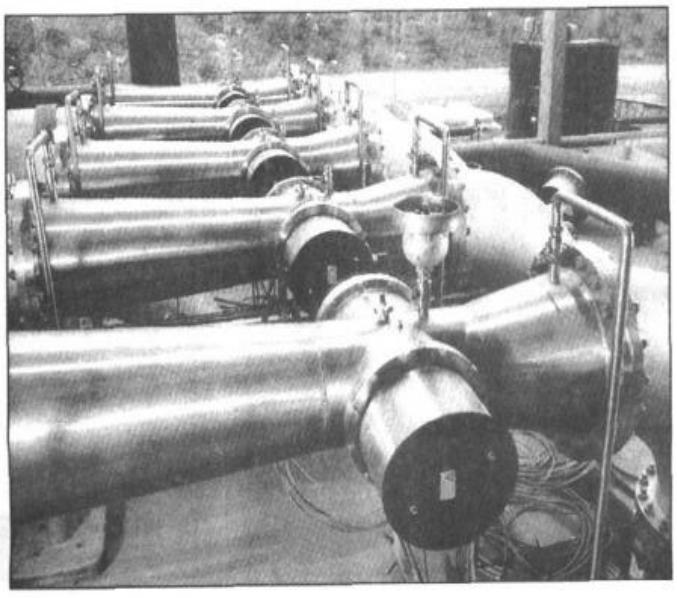
Modules to be cleaned are placed in a tank shown on the base of the left-hand crane support.



Closed-Channel Disinfection Systems. A number of low- and medium-pressure high-intensity UV disinfection systems are designed to operate in closed channels. In most design configurations, the direction of flow is perpendicular to the placement of the lamps, as shown on Fig. 12–36. There are, however, design configurations in which the direction of flow is parallel to the UV lamps (see Fig. 12–37). In the medium-pressure UV disinfection system shown on Fig. 12–38, the lamps are arranged in modules and are positioned in a reactor with a fixed geometry. Because high-intensity UV lamps (see Fig. 12–38*c*) operate at a lamp wall temperature of between 600 and 800°C, the UV output of these lamps is unaffected by the effluent temperature. Essentially all of the closed or fixed geometry systems used for the disinfection of wastewater incorporate some form of mechanical wiping of the quartz sleeves to maintain performance.

Germicidal Effectiveness of UV Radiation



Ultraviolet light is a physical rather than a chemical disinfecting agent. Radiation penetrates the cell wall of the microorganism and is absorbed by the nucleic acids (see Fig. 12–39), which either prevents replication or causes death of the cell to occur. The effectiveness of the UV disinfection process depends on a number of variables including the characteristics of the UV disinfection system, the overall system hydraulics, the presence of particles, the characteristics of the microorganisms, and the chemical charac-

(b)

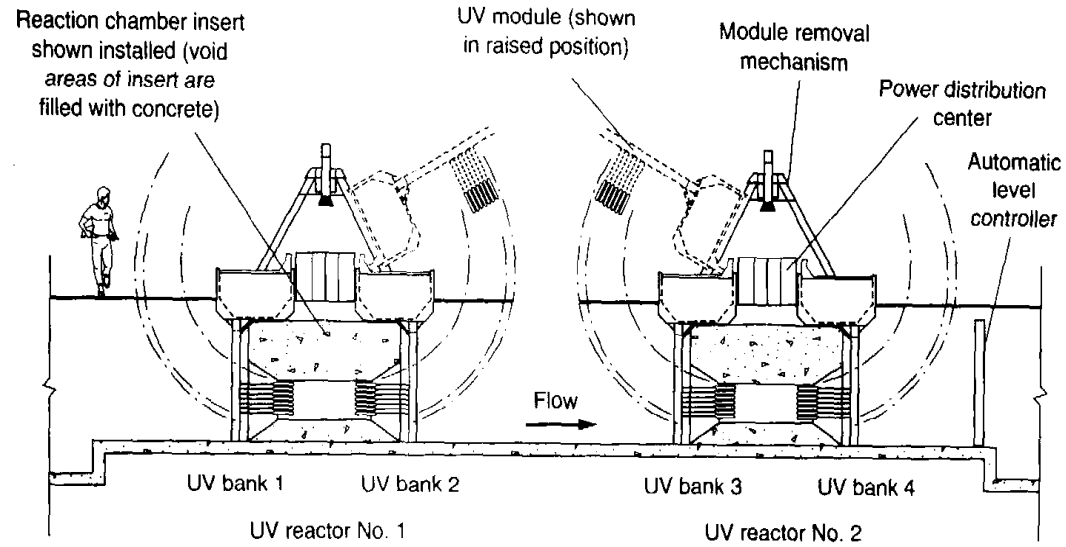
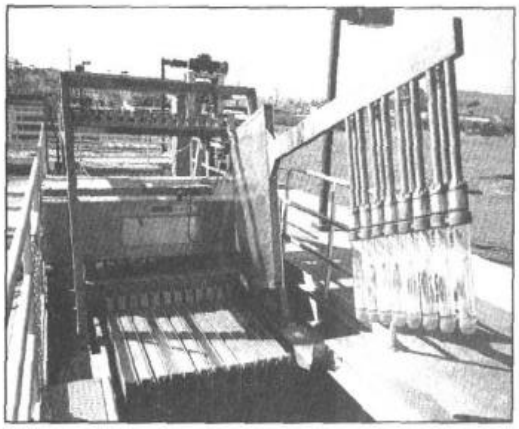
teristics of the wastewater. Before considering these subjects, it is appropriate to consider the definition of UV dose to provide a frame of reference.

Definition of UV Dose. The effectiveness of UV disinfection is based on the UV dose to which the microorganisms are exposed. The UV dose D is defined as follows:

$$D = I \times t \tag{12–68}$$



where D = UV dose, mJ/cm^2 (note mJ/cm^2 = mW·s/cm^2)
I = UV intensity, mW/cm^2
t = exposure time, s



It will be noted that the UV dose term is analogous to the dose term used for chlorine disinfection (i.e., $C_R t$). As given by Eq. (12–68), the UV dose can be varied by changing either the intensity or the exposure time. Because the UV intensity is attenuated with distance from the quartz sleeve (modeled using Beer's law), the average UV intensity within a UV disinfection system is often computed mathematically. As will be discussed later, the use of mathematical modeling has yet not proved to be satisfactory for the design of UV disinfection systems given the many variables that can affect performance.

Impact of System Characteristics. Problems with the application of Eq. (12–68) for use in the design of UV disinfection reactors are associated with (1) inaccurate knowledge of the UV intensity and (2) the exposure time associated with all of the pathogens passing through a UV disinfection system. In practice, field-scale UV

(c)

Figure 12-39

Formation of double bonds in microorganisms exposed to ultraviolet radiation.

disinfection reactors have dose distributions resulting from both the internal intensity profiles and exposure time distribution. The internal intensity profiles are a reflection of the nonhomogeneous placement of lamps within the system, lack of ideal radial mixing within the system, the scattering/absorbing effects of particulate material, and the absorbance of the liquid medium. The distribution associated with exposure time is a reflection of nonideal hydraulics leading to longitudinal mixing.

Nonideal Approach Hydraulics. One of the most serious problems encountered with UV disinfection systems in open channels is achieving a uniform velocity field in the approach and exit channel. Achieving a uniform velocity field is especially difficult when UV systems are retrofitted into existing open channels, such as converted chlorine contact basins, a practice that is not recommended if the performance of the UV disinfection system is to be optimized. Possible remedies are discussed in the section titled "Troubleshooting UV Systems" following the discussion of the design of UV systems.

Impact of Particles. Aside from the hydraulic impacts, the presence of particles within wastewater also affects the distribution of applied intensity to embedded organisms. Many organisms of interest in wastewater (e.g., coliform bacteria) occur in both a disperse state (i.e., not bound to other objects) and a particle-associated state (i.e., bound to other objects such as other bacteria or cellular debris). Coliform bacteria are of particular importance because of the central role they play in discharge permits (i.e., coliform bacteria are used as indicators for the presence of other pathogenic organisms and their inactivation is assumed to correlate with the inactivation of other pathogenic organisms). Disperse coliform bacteria are readily inactivated because they are exposed fully to UV light. Treatment process related disinfection problems most always result from the influence of particle-associated organisms (Oliver and Cosgrove, 1975; Severin, 1980; Ho and Bohm, 1981; Qualls et al., 1983; Qualls and Johnson, 1985; Scheible, 1987; Cairns, 1993; Emerick and Darby, 1993; Darby et al., 1995; Emerick et al., 1999; Emerick et al., 2000). In fact, coliform bacteria can associate with particles to such a degree that they are completely shielded from UV light resulting in a residual coliform bacteria concentration (Scheible, 1987; Parker and Darby, 1995).

It has been hypothesized (Emerick et al., 2000) that a minimum particle size (wastewater specific, but on the order of 10 μm) governs the ability to shield coliform bacteria from UV light. Due to the inherent porous nature of wastewater particles, particles smaller than that critical size are unable to reduce the applied intensity and thus embedded organisms are inactivated in a manner similar to dispersed organisms. Particles greater than the critical size can shield coliform bacteria similarly. Particle size does not appear to be a governing factor once the critical size is exceeded because coliform bacteria are located randomly within particles and are not typically located in the most shielded regions within particles.

Characteristics of the Microorganisms. The effectiveness of the UV disinfection process depends on the characteristics of the microorganisms. The relative effectiveness of UV radiation for disinfection of various discrete organisms is reported in Table 12–26. Additional data on the relative effectiveness of UV radiation for the disinfection of representative microorganisms of concern in wastewater are presented in Table 12–26. The values given in Tables 12–11 and 12–26 are only meant to serve as a guide in assessing the required UV dose. Knowledge concerning the required UV dose for specific pathogen inactivation is changing continuously as improved methods of analysis are applied. For example, before infectivity studies were conducted, it was thought that UV radiation at reasonable dosage values (i.e., less than 200 mJ/cm^2) was not effective for the inactivation of *Cryptosporidium parvum* and *Giardia lamblia*. However, based on infectivity studies, it has been found that both of these protozoan are inactivated with extremely

Table 12–26
Estimated relative effectiveness of UV radiation for the disinfection of representative microorganisms of concern in wastewater

Organism	Dosage relative to total coliform dosage[a]
Bacteria:	
Fecal coliform	0.5–0.9
Pseudomonas aeruginosa	1.5–2.0
Salmonella typhosa	0.7–0.9
Staphylococcus aureus	1.0–1.5
Total coliform	1.0
Viruses:	
Adenovirus	0.7–0.9
Coxsackie A2	1.0–1.5
F specific bacteriophage	0.4–0.8
Polio type 1	0.9–1.1
MS-2 bacteriophage	0.9–1.0
Protozoa:	
Acanthamoeba castellanii	10–12 (?)
Acanthamoeba culbertsoni	10–12 (?)
Cryptosporidium parvum oocysts[b]	0.2–0.4
Giardia lamblia cysts[b]	0.2–0.6
Other:	
Clostridum spores

[b] Based on infectivity studies.

low UV dosage values (typically in the range of 5 to 15 mJ/cm^2). The current literature should be consulted to obtain the most contemporary information regarding required UV dosages for the inactivation of specific microorganisms.

Effect of Wastewater Chemical Constituents. The effect of wastewater constituents on UV disinfection is presented in Table 12–27. Dissolved contaminants impact UV disinfection either directly via absorbance impacts (increasing absorbance serves to attenuate UV light to a larger degree) or via fouling of UV lamps such that a reduced intensity is applied to the bulk liquid medium. One of the most perplexing problems encountered in the application of UV disinfection for wastewater disinfection is the variation typically observed in the absorbance (or transmittance) of wastewater within a treatment plant. Often, the variations in transmittance are caused by industrial discharges, which can lead to diurnal as well as seasonal variations. Common industrial impacts are related to the discharge of inorganic and organic dyes, wastes containing metals, and complex organic compounds. However, stormwater inflows can also cause

Table 12–27
Impact of wastewater constituents on the use of UV radiation for wastewater disinfection

Constituent[a]	Effect
BOD, COD, TOC, etc.	No or minor effect, unless humic materials comprise a large portion of the BOD
Humic materials	Strong adsorbers of UV radiation
Oil and grease	Can accumulate on quartz sleeves of UV lamps, can absorb UV radiation
TSS	Absorption of UV radiation, can shield embedded bacteria
Alkalinity	Can impact scaling potential. Also affects solubility of metals that may absorb UV light
Hardness	Calcium, magnesium, and other salts can form mineral deposits on quartz tubes, especially at elevated temperatures
Ammonia	No or minor effect
Nitrite	No or minor effect
Nitrate	No or minor effect
Iron	Strong adsorber of UV radiation, can precipitate on quartz tubes, can adsorb on suspended solids and shield bacteria by adsorption
Manganese	Strong adsorber of UV radiation
pH	Can affect solubility of metals and carbonates
TDS	Can impact scaling potential and the formation of mineral deposits
Industrial discharges	Depending on the constituents (e.g., dyes), may lead to diurnal and seasonal variations in the transmittance
Stormwater inflow	Depending on the constituents, may lead to short-term as well as seasonal variations in the transmittance

[a]Inorganic constituents including bicarbonate, chloride ion, and nitrate can affect the direct UV photolysis of constituents such as NDMA.

wide variations, especially when humic materials are present. In either case, the solution to the problem of varying transmittance will require monitoring of industrial discharges, the implementation of source control programs, and correcting sources of infiltration. In some cases, biological treatment will mitigate the influent variations. In some extreme situations, it may be concluded that UV disinfection will simply not work.

Where the use of UV disinfection is being assessed, it is useful to install on-line transmittance monitoring equipment to document the variations that occur in the transmittance with time. The scaling potential of wastewater, as defined by the Langelier saturation index (see Sec. 6–7 in Chap. 6), should also be checked to assess whether scaling may be a problem. This recommendation is especially important where the feasibility of using high-intensity UV lamps is being assessed.

Modeling the UV Disinfection Process

Although, in general, it is believed that the concentration of suspended solids has a deleterious impact on UV disinfection performance, Emerick et al. (1999) reported that

among different treatment processes there is no correlation between the total suspended solids concentration and the number of particles containing coliform bacteria. This lack of correlation underlies the need for inactivation models based on more fundamental water-quality parameters.

The use of series-event or multihit kinetics has been suggested to describe the initial resistance that homogeneous populations of organisms tend to exhibit to UV light in addition to the subsequent loglinear inactivation behavior (Severin et al., 1983). However, the measurement of the overall response of a mixed population of bacteria (e.g., coliform bacteria) in wastewater tends to mask the initial resistances of specific bacterial species/strains. For UV doses greater than 10 mJ/cm^2 (i.e., as is typically applied for wastewater disinfection), the following equation can be used for modeling the log-linear inactivation of disperse coliform bacteria in a batch system (Jagger, 1967; Oliver and Cosgrove, 1975; Qualls and Johnson, 1985):

$$N_D(t) = N_D(0)e^{-kIt} \tag{12–69}$$

where $N_D(t)$ = total number of surviving disperse coliform bacteria at time t
$N_D(0)$ = total number of disperse coliform bacteria prior to UV light application (at time $t = 0$)
k = inactivation rate coefficient, cm^2/mW·s
I = average intensity of UV light in bulk solution, mW/cm^2
t = exposure time, s

The fundamental difference between disperse coliform bacteria and particle-associated coliform bacteria is the amount of UV intensity reaching the organism. The above equation is applicable only to disperse organisms because all members of that group receive the same intensity of UV light (assuming perfectly mixed conditions). An organism embedded within a particle will receive a reduced UV light intensity relative to that applied to the bulk solution. Knowledge of the distribution of applied intensities would allow a model, analogous to that presented above, to be developed to describe the inactivation of both disperse and particle-associated coliform bacteria. Emerick et al. (2000) demonstrated the applicability of the following modeling equation for describing the inactivation of both disperse and particle-associated coliform bacteria (see Fig. 12–14, presented previously) when knowledge of the applied intensity to the bulk liquid medium is known:

$$N(t) = N_D(0)e^{-kd} + \frac{N_P(0)}{k\,d}(1 - e^{-kd}) \tag{12–70}$$

where $N(t)$ = total number of surviving coliform bacteria at time t
$N_D(0)$ = total number of disperse coliform bacteria prior to application of disinfectant at time $t = 0$
$N_P(0)$ = total number of particles containing at least one coliform bacterium at time $t = 0$
k = inactivation rate coefficient, cm^2/mJ
d = UV dose, mJ/cm^2

Equation (12–70) is best used to describe the underlying constraints to UV disinfection performance. The numbers of particles containing coliform bacteria, the inactivation rate coefficient, and the applied UV dose (product of intensity and exposure

time) have fundamental impacts on UV disinfection performance. From experience it has been found that it is more convenient to design disinfection systems using collimated-beam inactivation data and validated UV disinfection equipment, as will be discussed subsequently.

Estimating UV Dose

Three methods have been used to estimate the UV dose. In the first method, an average UV dose is determined by assuming an average system UV intensity and exposure time. The average UV intensity is estimated using a computational procedure known as the point source summation (PSS) method (U.S. EPA, 1992). The PSS method is currently less used by designers due to its dependence on system-specific hydraulics (i.e., pilot-study results are a function of the pilot unit used during the course of study). The second method involves the use of computational fluid dynamics (CFD) to integrate both the distribution of UV intensities and velocity profiles within the reactor to obtain a distribution of UV doses within a system (Blatchley et al., 1995). Although the CFD method is promising, its use is limited at the present time (2001) because (1) the methodology is not standardized, (2) the methodology has not been validated thoroughly over a range of disinfection systems, and (3) the reporting of a distribution of UV doses, though accurate, is problematic for UV disinfection system specification. In the third, and most widely used, method the UV dose is determined by bioassays. Use of the bioassay approach in designing UV disinfection systems is discussed below.

Determination of UV Dose by Collimated-Beam Bioassay. The most common procedure for determining the required UV dose for the inactivation of microorganisms involves the use of a collimated beam and a small reactor to which a known UV dose is applied. A typical collimated-beam device is shown on Fig. 12–40. Use of a monochromatic low-pressure low-intensity lamp in the collimated-beam apparatus allows for accurate characterization of the applied UV intensity. Use of a batch reactor allows for accurate determination of exposure time. The applied UV dose, as defined by Eq. (12–68), can be controlled by varying either the UV intensity or the exposure time. Because the geometry is fixed, the depth-averaged UV intensity within the petri dish sample (i.e., the batch reactor) can be computed using the following relationship based on Beer's law.

$$I_{avg} = I_o \times \frac{(1 - 10^{-\alpha d})}{(\alpha d)} = I_o \times \frac{(1 - e^{-2.306\alpha d})}{(\alpha d)} \qquad (12\text{–}71)$$

where I_{avg} = average UV intensity, mW/cm^2
I_o = average incident UV intensity at the surface of the sample, mW/cm^2
α = absorbance, absorbance units per centimeter, a.u./cm (base 10)
d = depth of sample, cm

Typical absorbance values for various wastewaters at 254 nm are:

1. Primary effluent = 0.5 to 0.8/cm
2. Secondary effluent = 0.3 to 0.5/cm
3. Nitrified secondary effluent = 0.25 to 0.45/cm
4. Filtered secondary effluent = 0.20 to 0.40/cm

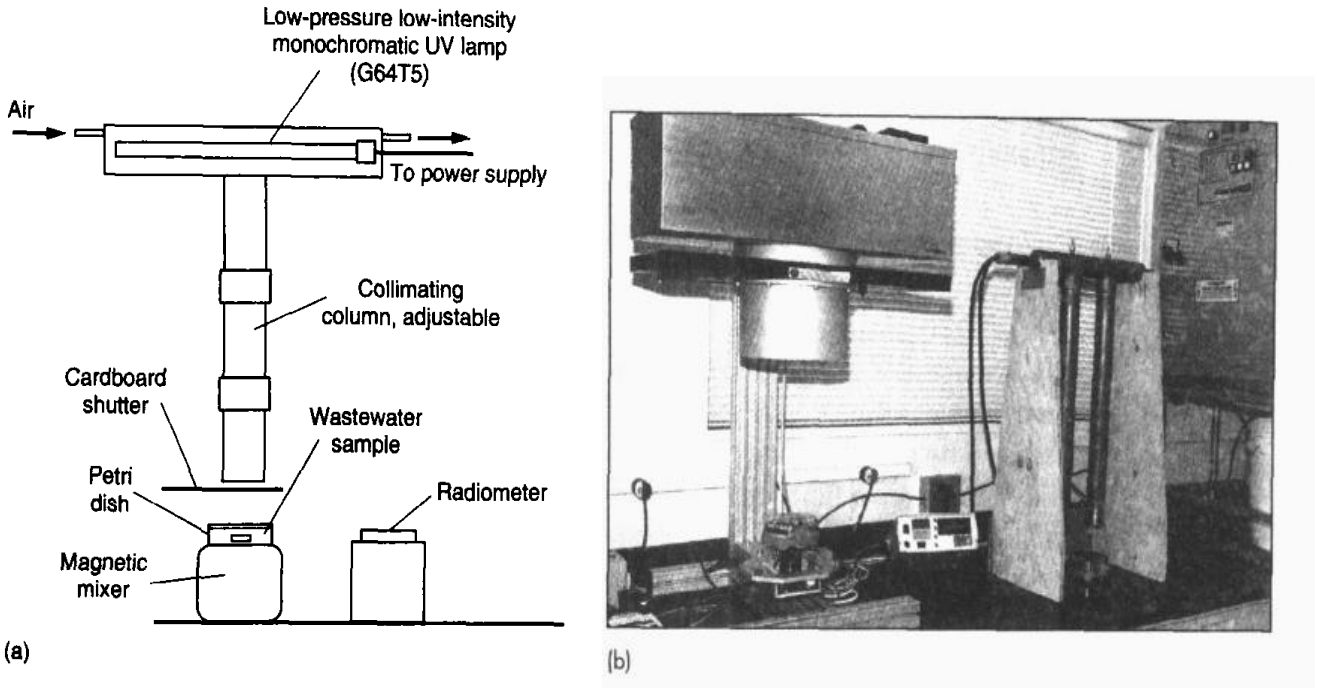

Figure 12–40

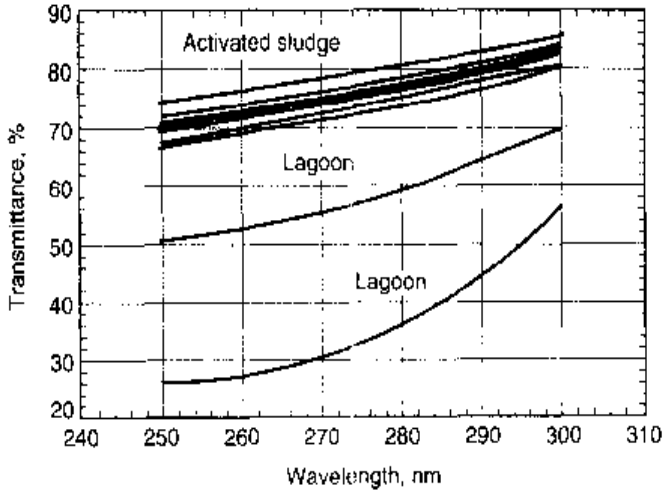
Collimated-beam device used to develop dose-response curves for UV disinfection (*a*) schematic and (*b*) view of two different types of collimated-beam devices. The collimated beam on the left is of European design; the collimated beam on the right is of the type shown schematically in (*a*).

5. Microfiltered secondary effluent = 0.15 to 0.3/cm
6. Reverse osmosis effluent = 0.05 to 0.2/cm

Knowledge of the average UV intensity and exposure time allows calculation of applied UV dose using Eq. (12–68). The UV dose is then correlated to the microorganism inactivation results, typically measured using an MPN procedure for bacteria, a plaque count procedure for viruses (see Chap. 2), or an animal infectivity procedure for protozoans.

The absorbance can also be derived from transmittance T measurements using the following relationship:



$$T, \% = 10^{-(\text{a.u./cm})} \times 100 \qquad (12\text{–}72)$$

Typical transmittance values over the entire UV spectrum for seven activated-sludge processes and two lagoon systems are shown on Fig. 12–41.

Reporting and Using Bioassay Collimated-Beam Test Results. The results of collimated-beam bioassays are reported in the form of dose-response curves (see Fig. 12–42). The inactivation curve shown on Fig. 12–42*a* is for discrete organisms exposed to UV light, whereas the curve shown on Fig. 12–42*b* is for wastewater containing particulate material. To assess both the inherent and process variability, as discussed in Sec. 15–2 in Chap. 15, the collimated-beam test must be repeated to obtain statistical significance. Because the radiation output of the medium-pressure high-intensity UV lamps is polychromatic (see Fig. 12–32), the inactivation performance of these lamps is often correlated to the performance of low-pressure (i.e., monochro-

Figure 12–41

Percent transmittance versus wavelength for seven activated-sludge plants and two wastewater lagoons.

matic wavelength) lamps for comparative purposes. An example of the process used to determine the required UV dose using collimated-beam test results is provided in Example 12–10.

EXAMPLE 12–10 Determination of Dose Requirement Using Results from Collimated-Beam Testing The following dose-response data were obtained by conducting collimated-beam tests once per month over a 12-month period for a given wastewater. Using these data, determine (1) the mean, standard deviation, and 75 percent confidence interval associated with the surviving number of total coliform bacteria at each UV dose investigated and (2) the dose required (site-specific) to comply with a permit limitation of 23 total coliform bacteria per 100 mL (30 d median) at a confidence level of 75 percent.

Test number	Survival at applied UV dose, mJ/cm²						
	0	20	40	60	80	100	120
1	3,500,000	280	43	6.8	5.5	5.4	6.0
2	79,000	920	23	6.8	5.5	36	22
3	920,000	58	17	13	10	1.8	1.8
4	430,000	540	110	24	430	14	8.1
5	9,200,000	2,800	540	24	46	1.8	21
6	210,000	54,000	9,200	920	110	2.0	5.5
7	16,000,000	36	23	13	5.5	17	5.5
8	1,700,000	180	46	4.0	4.0	69	4.5
9	920,000	540	49	21	1.8	3.6	5.5
10	5,600,000	2,400	31	69	19	24	1.8
11	79,000	920	280	280	81	12	1.8
12	4,400,000	110	9.1	84	22	54	95

Solution

1. Determine the mean, standard deviation, and confidence interval for the monthly dose-response data. Because biological UV dose-response data are generally log-normally distributed, log-transform the observed survival data to enable use of student-*t* statistics (student-*t* statistics must be used because there are not enough data to apply normal statistics; typically 30 samples are required).
   a. Log-transform the observed number of surviving total coliform bacteria. For example, for test 1 the log-transform data point associated with a UV dose of 40 is

      $$\log (43) = 1.63$$

   b. Determine the average and standard deviation for the log-transformed data for each investigated UV dose.
      For the UV dose of 20, the average is 2.75.
      For the UV dose of 20, the standard deviation is 0.86.
      The observed mean and standard deviation for each UV dose is provided in the following table.

Test number	Log survival at applied UV dose, mJ/cm²						
	0	20	40	60	80	100	120
1	6.54	2.45	1.63	0.83	0.74	0.73	0.78
2	4.90	2.96	1.36	0.83	0.74	1.56	1.34
3	5.96	1.76	1.23	1.11	1.00	0.26	0.26
4	5.63	2.73	2.04	1.38	2.63	1.15	0.91
5	6.96	3.45	2.73	1.38	1.66	0.26	1.32

(continued)

(*Continued*)

Test number	Log survival at applied UV dose, mJ/cm²						
	0	20	40	60	80	100	120
6	5.32	4.73	3.96	2.96	2.04	0.30	0.74
7	7.20	1.56	1.36	1.11	0.74	1.23	0.74
8	6.23	2.26	1.66	0.60	0.60	1.84	0.65
9	5.96	2.73	1.69	1.32	0.26	0.56	0.74
10	6.75	3.38	1.49	1.84	1.28	1.38	0.26
11	4.90	2.96	2.45	2.45	1.91	1.08	0.26
12	6.64	2.04	0.96	1.92	1.34	1.73	1.98
Average	6.08	2.75	1.88	1.48	1.25	1.01	0.83
Standard deviation	0.78	0.86	0.83	0.70	0.70	0.58	0.51

c. Determine the 75 percent confidence interval. Because the permit is based on a 30-day median value, designing based on the mean survival risks occasional permit violations. The 75 percent confidence interval is often used to ensure compliance with a median permit limit.

i. For a dose of 60 mJ/cm², the 75 percent confidence interval is calculated using the following expression (Larson and Faber, 2000):

$$75\%\ \text{confidence limit} = \bar{x} \pm t_{0.125}\left(\frac{s}{\sqrt{n}}\right)$$

where $\bar{x}$ = mean survival at a specific UV dose = 1.48

$t_{0.125}$ = student-t value associated with a 75 percent level of confidence
= 1.214 (obtained from statistical tables, Larson and Faber, 2000). Note that the degrees of freedom are $n - 1 = 12 - 1 = 11$

n = number of replicates = 12

s = sample standard deviation = 0.70

$$75\%\ \text{confidence limit} = 1.48 \pm 1.214\left(\frac{0.70}{\sqrt{12}}\right) = 1.48 \pm 0.245$$

ii. Transform the mean and confidence interval back to base 10. The mean and confidence interval associated with each investigated UV dose is provided in the table given below.

UV dose, mJ/cm²	Surviving total coliform per 100 mL		
	Average	Lower 75% C.I.	Upper 75% C.I.
0	1,200,000	623,000	2,320,000
20	560	280	1,200
40	76	38	150

(*continued*)

(*Continued*)

UV dose, mJ/cm²	Surviving total coliform per 100 mL		
	Average	Lower 75% C.I.	Upper 75% C.I.
60	30	17	54
80	18	10	32
100	10	6	17
120	7	4	10

2. Estimate the required UV dose.
   An inspection of the upper 75 percent confidence intervals in the above table leads to the conclusion that a design UV dose of 100 mJ/cm² is adequate to obtain a 30 d median survival of 23 total coliform bacteria per 100 mL.

Comment The variability in the data reported in Step 1 is representative of what will be observed in practice based on limited testing. To gain a better understanding of the variability associated with the wastewater of interest, it is recommended that replicate tests be conducted (a minimum of three tests is recommended).

Ultraviolet Disinfection Guidelines

Recently, the National Water Research Institute and the American Water Works Association Research Foundation published "Ultraviolet Disinfection Guidelines for Drinking Water and Wastewater Reclamation" (NWRI and AWWARF, 2000). The following elements are considered in the UV guidelines: (1) reactor design, (2) reliability design, (3) monitoring and alarm design, (4) the field commissioning test, (5) performance monitoring, and (6) an engineering report for unrestricted effluent reuse applications. Some of the items may not be applicable when utilizing UV disinfection for less demanding uses.

Application of UV Guidelines. The guidelines that cover reclaimed water are similar to those that cover drinking water systems. The primary difference is that recommended doses are provided for reclaimed water systems whereas there is no mention of recommended doses for drinking water systems. For reclaimed water systems, the recommended design UV doses are 100 mJ/cm² for granular medium filtration effluent, 80 mJ/cm² for membrane filtration effluent, and 50 mJ/cm² for reverse osmosis effluent. The different dose requirements reflect the different virus density concentrations expected within each type of process effluent. The dosages selected are intended to provide four logs of poliovirus inactivation with a factor of safety of about 2. In addition to differing dose recommendations as a function of effluent quality, there are differing design transmittance recommendations. For granular medium, microfiltration, and reverse osmosis effluents, the design transmittances are 55, 65, and 90 percent, respectively. The differing transmittance values are based on field observations made to date. All UV disinfection systems installed for either drinking water or unrestricted

reuse applications must undergo validation testing prior to their installation. Although the guidelines do not apply to the disinfection of secondary effluent, the general design issues addressed are applicable.

Relationship of UV Guidelines to UV System Design. The design of a UV disinfection system requires three general steps: (1) determination of the UV dose required, based on bioassay testing, for adequate inactivation of the target microorganism(s), (2) validation of manufacturer-specific UV disinfection system performance, and (3) determination of an optimal UV system configuration (e.g., the number of lamps per module, modules per bank, banks per channel, and the overall number of channels). The first two issues are addressed directly in the guidelines, and general guidance is provided on design aspects. Determination of the UV dose required to comply with a permit limitation was discussed previously and illustrated in Example 12–10. Specific details on the culture of the microorganisms and the conduct of the test are given in the guidelines. The determination of an optimal UV system configuration is considered following the discussion of the approach used for the validation of manufacturer-specific UV disinfection system performance presented below.

UV System Performance Validation. Validation testing consists of quantifying the inactivation of a virus surrogate (e.g., MS2 bacteriophage) as a function of flowrate through the disinfection system. The flowrate is normalized to the number of lamps within the system, such that the design of the UV disinfection systems can be based on the hydraulic loading rate (e.g., L/min·lamp). Validation testing is important because the test results can be used to compare competing UV disinfection technologies and it eliminates the need to make choices based on manufacturers' claims, often not verified by an independent third party. Validation testing of UV disinfection equipment consists of the following steps:

1. Selection of a representative test water for use in the validation testing of the disinfection system.
2. Selection of the configuration of the UV disinfection system to be tested (for low-pressure low-intensity UV systems, a minimum of two banks must be tested but typically more are used; see Fig. 12–43*a*). If the power to the UV lamps cannot

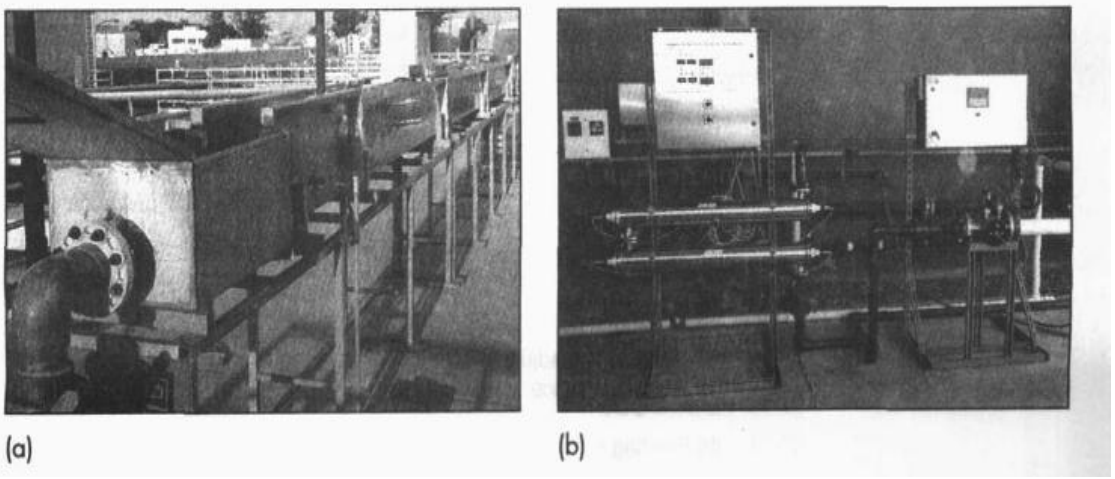

Figure 12–43
Typical pilot-scale UV disinfection test reactors used for performance validation: (*a*) low-pressure low-intensity, and (*b*) medium-pressure high-intensity.

be turned down to simulate the end of life lamp performance, then aged UV lamps must be used in the test.

3. Testing of the hydraulic performance of the UV disinfection system. Hydraulic testing is done to verify the uniformity of the approach and exit velocities.
4. Quantification of the inactivation of the viral indicator as a function of hydraulic loading rate through the UV test reactor. Two typical dosing arrangements are illustrated on Fig. 12–44.
5. Simultaneously conduct a collimated-beam test on the test water to determine the inactivation of the viral indicator as a function of applied UV dose.
6. Verify the accuracy of the laboratory collimated-beam dose-response test data. The laboratory test data must fall within the area bound by the following two equations:

$$-\log_{10}(N/N_o) = 0.040 \times [\text{UV dose, mJ/cm}^2] + 0.64 \quad (12\text{–}73)$$

$$-\log_{10}(N/N_o) = 0.033 \times [\text{UV dose, mJ/cm}^2] + 0.20 \quad (12\text{–}74)$$

7. Assign UV doses to the pilot reactor based on the measured inactivation observed during the conduct of the collimated-beam test as a function of applied UV dose.

The steps required in conducting a validation test are illustrated in Example 12–11.

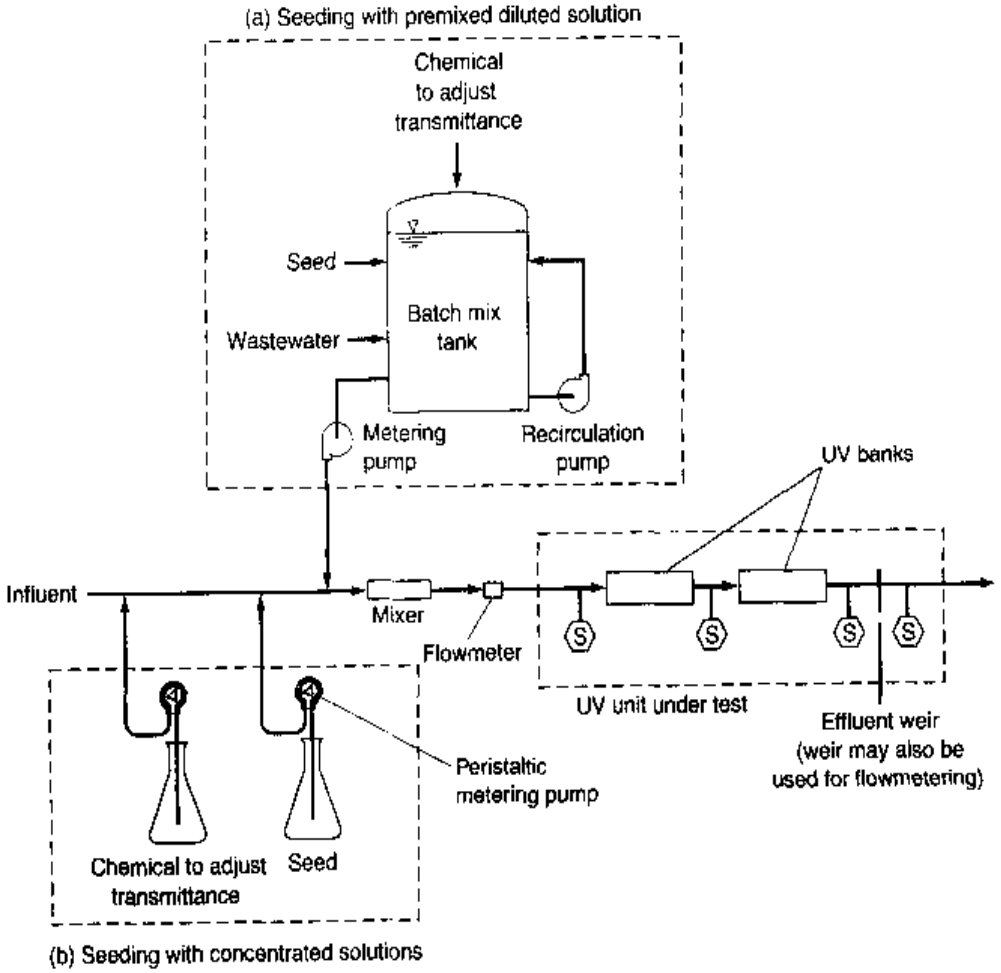

Figure 12–44

Schematic flow diagram for the conduct of field evaluation of UV systems using seeded microorganisms and UV transmittance adjustment: (a) seeding with premixed diluted solution from batch tank and (b) seeding with concentrated solutions.

EXAMPLE 12–11 Conduct a Pilot Test to Validate UV Disinfection System Performance The manufacturer has supplied a pilot-scale UV disinfection system to be tested for the assignment of UV doses as a function of lamp hydraulic loading rate. The steps involved are delineated below. Because the UV disinfection system will be used for filtered secondary effluent, determine the range of flows expressed as L/min·lamp over which the UV disinfection system will deliver a dose of 100 mJ/cm^2 at a confidence level of 75 percent.

Solution

1. Set up a pilot testing facility.
   a. The manufacturer chooses to make use of a four lamp per bank pilot facility with three banks in series for the total applied dose. Each bank of lamps is hydraulically independent of subsequent banks. Therefore, the results can be applied to full-scale reactors up to 40 lamps per bank (i.e., full-scale facility can utilize up to 10 times as many lamps per bank as the pilot facility tested).
   b. Aged lamps were placed in the pilot facility to simulate the performance of the UV lamps at the end of their warranted life.
   c. Testing was conducted on tertiary effluent from a local wastewater reclamation facility. Normal transmittance of the tertiary effluent is 75 percent. Transmittance reducing agent (e.g., instant coffee) was injected into the process stream until the transmittance was lowered to 55 percent.
   d. The manufacturer has specified that the UV disinfection system should be tested for hydraulic loading rates ranging from 20 to 80 L/min·lamp.
   e. The titer of the virus indicator (i.e., MS2 coliphage) to be used for performance testing was approximately 1×10^{11} phage/mL. Therefore, it was decided to test the system under the conditions outlined in the following table:

Hydraulic loading rate, L/min·lamp (1)	Process flow, L/min (2)	Virus titer concentration, phage/mL (3)	Virus titer injection flowrate, L/min (4)	Approximate resulting virus concentration in process flow, phage/mL (5)
20	240	1×10^{11}	0.024	1×10^{7}
40	480	1×10^{11}	0.048	1×10^{7}
60	720	1×10^{11}	0.072	1×10^{7}
80	960	1×10^{11}	0.096	1×10^{7}

Notes on column entries:

(1) Desired range to be tested as specified by the manufacturer.

(2) The pilot system contained three banks with 12 lamps total. Therefore, at a hydraulic loading rate of 20 L/min·lamp, the process flowrate needs to be (12 lamps)(20 L/min·lamp) = 240 L/min.

(3) Provided by the laboratory.

(4) It was desired to obtain a virus titer in the process flow of about 1×10^{7} phage/mL. Therefore, at 240 L/min, the solution containing the virus had to be injected at a rate of 0.024 L/min to obtain the desired initial titer.

2. Test the system.
   a. Each flowrate was tested randomly with respect to order. Three distinct replicate samples were collected per flowrate. An inlet sample (i.e., that containing the concentration of phage prior to any inactivation) was collected with each process replicate.
   b. Determine the inlet viral indicator concentration for each test. The results are provided in the following table.

Flowrate, L/min	Replicate	Inlet concentration, phage/mL	Log-transformed inlet conc. log (phage/mL)	Average log-transformed inlet conc. log (phage/mL)
240	1	5.25×10^6	6.72	
240	2	1.00×10^7	7.00	6.93
240	3	1.15×10^7	7.06	
480	1	1.00×10^7	7.00	
480	2	1.23×10^7	7.09	7.07
480	3	1.29×10^7	7.11	
720	1	1.23×10^7	7.09	
720	2	1.05×10^7	7.02	7.03
720	3	9.55×10^6	6.98	
960	1	1.23×10^7	7.09	
960	2	1.20×10^7	7.08	7.02
960	3	7.94×10^6	6.90	

   c. Determine the outlet concentration for each trial. The results are provided in the following table. Notice that at the low flowrate investigated (240 L/min), only two operational banks were investigated rather than three. Only two banks were tested because three operational banks resulted in no detectable viruses in the effluent. Because the banks were hydraulically independent, it is allowed under the UV Guidelines to investigate the inactivation for only two banks and extrapolate to performance expected for additional banks of lamps.

Flowrate, L/min	Replicate	Number of operational banks	Outlet concentration, phage/mL	Log-transformed outlet conc., log (phage/mL)
240	1	2	2.09×10^2	2.32
240	2	2	1.44×10^2	2.16
240	3	2	1.66×10^2	2.22

(continued)

(*Continued*)

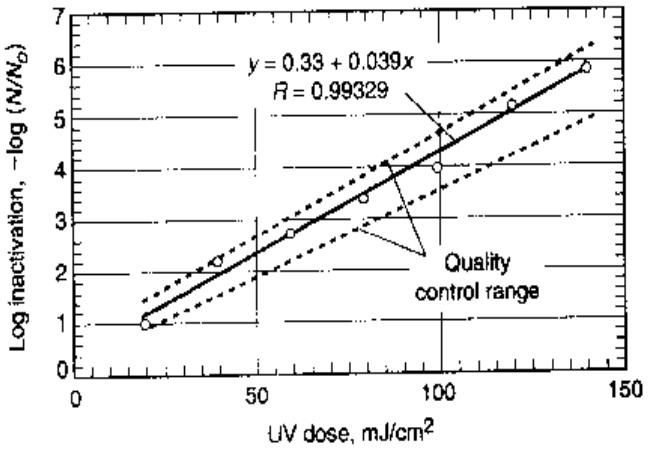
Flowrate, L/min	Replicate	Number of operational banks	Outlet concentration, phage/mL	Log-transformed outlet conc., log (phage/mL)
480	1	3	3.80×10^2	2.58
480	2	3	3.31×10^2	2.52
480	3	3	3.09×10^2	2.49
720	1	3	1.32×10^4	4.12
720	2	3	6.03×10^3	3.78
720	3	3	4.27×10^3	3.63
960	1	3	4.79×10^4	4.68
960	2	3	1.86×10^5	5.27
960	3	3	6.61×10^4	4.82

d. Determine the 75 percent level of confidence for each investigated flowrate. The results are provided in the following table. Note that the 75 percent level of confidence is determined using the student-*t* distribution (a minimum of 30 samples are required for use of the normal distribution).

Flowrate, L/min	Replicate	Log inactivation	Average log inactivation	Sample standard deviation	75% confidence log inactivation
240	1	4.61[a]			
240	2	4.77	4.69	0.08	4.63
240	3	4.71			
480	1	4.49			
480	2	4.55	4.54	0.05	4.50[b]
480	3	4.58			
720	1	2.91			
720	2	3.25	3.19	0.25	2.95
720	3	3.40			
960	1	2.34			
960	2	1.75	2.10	0.31	1.81
960	3	2.20			

[a] Sample calculation. From the previous table, the average inlet log concentration was observed to be 6.93. Therefore, the log inactivation for replicate 1 is 6.93 − 2.32 = 4.61.

[b] Sample calculation. For the flowrate of 480 L/min, the 75 percent level of confidence occurs at 4.50 as shown below.



$$75\% \text{ confidence limit} = \bar{x} \pm t_{0.125}\left(\frac{s}{\sqrt{n}}\right) = 4.54 - 1.214\,\frac{0.05}{\sqrt{3}} = 4.54 - 0.04 = 4.50$$

3. Conduct the required collimated-beam test. The results are provided in the following table:

Dose	Surviving concentration, phage/mL	Log survival, log (phage/mL)	Log inactivation
0	1.00×10^7	7.0	0.0
20	1.12×10^6	6.05	0.95[a]
40	6.76×10^4	4.83	2.17
60	1.95×10^4	4.29	2.71
80	4.37×10^3	3.64	3.36
100	1.20×10^3	3.08	3.92
120	7.08×10^1	1.85	5.15
140	1.48×10^1	1.17	5.83

[a] Sample calculation. Log inactivation = 7.00 − 6.05 = 0.95.

a. Plot the collimated-beam test results. Compare to the quality-control range provided in the UV Guidelines. A plot of the results is provided in the figure given below. All of the data points fall within the acceptable range. The equation of the linear regression used to determine the required dose as a function of log inactivation is given on the figure.

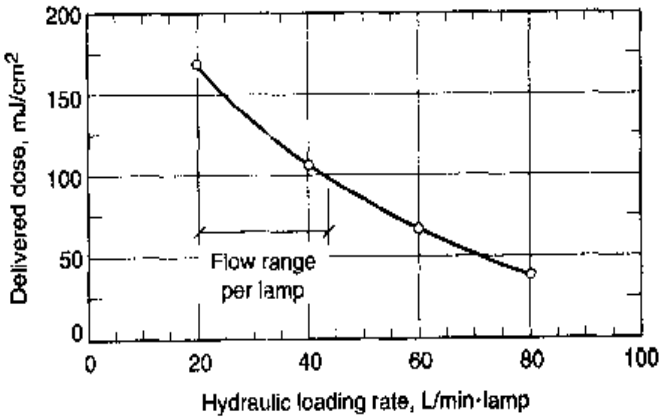
b. Assign doses to investigated hydraulic loading rates, and present results graphically. The calculated doses are provided in the table given below.

Flowrate, L/min	Hydraulic loading rate, L/min·lamp	75% confidence log-inactivation	Equivalent UV dose[b], mJ/cm²
240	20	(1.5)(4.63) = 6.95[a]	170
480	40	4.50	107

(continued)

(*Continued*)

Flowrate, L/min	Hydraulic loading rate, L/min·lamp	75% confidence log-inactivation	Equivalent UV dose[b], mJ/cm²
720	60	2.95	67.2
960	80	1.81	37.9



[a] The inactivation for this flowrate was extrapolated from the two-bank results. Because the system is a three-bank system, the inactivation for three banks is 150 percent greater than the inactivation observed with two operational banks.

[b] Sample calculation. Using the linear regression expression derived from the collimated-beam test, the equivalent UV dose at a flowrate of 480 L/min is

$$x(\text{UV dose}) = \frac{y\,(\log \text{ inactivation}) - 0.33}{0.039}$$

$$\text{Dose, mJ/cm}^2 = \frac{\log \text{ inactivation} - 0.33}{0.039} = \frac{4.50 - 0.33}{0.039} = 107 \text{ mJ/cm}^2$$

The results are plotted in the following figure.

4. Determine the flow per lamp over which the system will deliver 100 mJ/cm². From the plot given above, the system is capable of applying a dose of 100 mJ/cm² within the range of 20 to 43 L/min·lamp.

Comment Because aged lamps were used and the transmittance value was adjusted to 55 percent, the test results represent the performance of the UV disinfection system under the worst possible conditions, which provides a factor of safety under typical operating conditions. When the lamps are new, it may not be necessary to operate all three banks, depending on the test results. The curve given above in Step 3 will be used to determine the optimal configuration of the full-scale UV disinfection system, as will be discussed and illustrated below.

Selection and Sizing of a UV Disinfection System

Factors that affect the minimum number of UV lamps necessary for disinfection are (1) the hydraulic loading rate determined in the equipment validation test as outlined in the previous example, (2) the aging and fouling characteristics of the UV lamp/quartz sleeve assembly, (3) wastewater quality and its variability, and (4) the nature of the discharge permit itself and the level of confidence desired in meeting that permit. Hydraulic behavior has a significant impact on field reactor performance. The flow per lamp determined using the collimated-beam bioassay has a corresponding velocity that maintains that inactivation performance. The process configuration must maintain adequate system velocity to ensure that the bioassay results are applicable to the field installation. Although beyond the scope of this presentation, the UV Guidelines cited above should be reviewed carefully before undertaking the design of a UV system. The selection and sizing procedure is illustrated in Example 12–12.

EXAMPLE 12–12 Design of a UV Disinfection System Design a UV disinfection system that will deliver a minimum design dose of 100 mJ/cm^2. Assume for the purpose of this example that the following data apply:

1. Wastewater characteristics
   a. Minimum design flow = 6000 m^3/d = 4167 L/min (diurnal low flow)
   b. Maximum design flow = 21,000 m^3/d = 14,584 L/min (peak hour flow with recycle streams)
   c. Minimum transmittance = 55 percent
2. System characteristics
   a. Horizontal lamp configuration
   b. Validated system performance as determined in Example 12–11
   c. System headloss coefficient = 1.8 (manufacturer-specific)
   d. Lamp/sleeve diameter = 23 mm
   e. Cross-sectional area of quartz sleeve = 4.15×10^{-4} m^2
   f. Lamp spacing = 75 mm (center to center)
   g. One standby UV bank will be required per channel

Solution

1. Determine the number of UV channels.
   a. The manufacturer has provided validated information for a three-bank system at a flow range of 20 to 80 L/min·lamp. The system is capable of applying a dose of 100 mJ/cm^2 within the range of 20 to 43 L/min·lamp (see Example 12–11). Therefore, the system has an approximate 2:1 flow variation capacity for the design dose under consideration.
   b. Use two channels.
      i. From 4167 to 8000 L/min use one channel.
      ii. From 8000 to 14,584 L/min split the flow between two channels such that each channel is loaded between 4000 and 7300 L/min.
2. Determine the number of lamps required per channel.

At 8000 L/min, the total number of required lamps is

$$\text{Lamps required at 8000 L/min} = \frac{(8000\ \text{L/min})}{(43\ \text{L/lamp·min})} = 186\ \text{lamps}$$

3. Determine the minimum number of lamps per bank.

$$\frac{186\ \text{lamps}}{3\ \text{banks}} = 62\ \frac{\text{lamps}}{\text{bank}}$$

4. Configure the UV disinfection system.
Typically, 2, 4, 8, or 16 lamps per module are available. For an 8 lamp module, eight modules are required per bank for a total of 64 lamps per bank.
5. Check that the design falls within the manufacturer recommended range.
   a. At low flow:

$$\frac{(4167\ \text{L/min})}{192\ \text{lamps}} = 21.7\ \text{L/lamp·min}$$

   b. At high flow:

$$\frac{(14{,}584\ \text{L/min})}{384\ \text{lamps}} = 38.0\ \text{L/lamp·min}$$

Both of these hydraulic loading rates fall within the acceptable range for the UV disinfection system provided by the manufacturer.

6. Check whether the headloss for the selected configuration is acceptable.
   a. Determine the channel cross-sectional area.

$$\text{Cross-sectional area of channel} = (8 \times 0.075\ \text{m}) \times (8 \times 0.075\ \text{m})$$
$$= 0.36\ \text{m}^2$$

   b. Determine the net channel cross-sectional area by subtracting the cross-sectional area of the quartz sleeves (4.15×10^{-4} m^2/lamp).

$$A_{\text{channel}} = 0.36\ \text{m}^2 - [(8 \times 8)\ \text{lamps/bank}] \times (4.15 \times 10^{-4}\ \text{m}^2\text{/lamp})$$
$$= 0.33\ \text{m}^2$$

   c. Determine the maximum velocity in each channel.

$$v_{\text{channel}} = \frac{(14{,}584\ \text{L/min})}{(2\ \text{channel})(0.33\ \text{m}^2)(10^3\ \text{L/m}^3)(60\ \text{s/min})} = 0.37\ \text{m/s}$$

   d. Determine the headloss per UV channel.

$$h_{\text{channel}} = 1.8\ \frac{v^2}{2g}$$

$$h_{\text{channel}} = 1.8\ \frac{(0.37\ \text{m/s})^2(10^3\ \text{mm/m})}{2(9.81\ \text{m/s}^2)}(4\ \text{banks}) = 50\ \text{mm}$$

Note that four banks were used to determine system headloss. Use of four banks includes a redundant bank of lamps in each channel. Because the clear spacing between quartz sleeves is 52 mm (75 mm − 23 mm), the headloss cannot exceed 26 mm total (one-half the clear spacing between the quartz sleeves) without exposing the uppermost row of lamps to the air. To allow for the calculated 50 mm of total headloss, each UV channel will require a stepped channel bottom. A 24-mm step between the second and third bank of lamps is required to allow for the expected headloss and to allow the third and fourth banks of lamps to be set lower.

7. Summarize the system configuration.
   Minimum required system utilizes two channels, each channel containing four banks of lamps in series, three operational banks and one redundant bank. Each bank contains eight modules, each of which contains eight lamps.

Troubleshooting UV Disinfection Systems

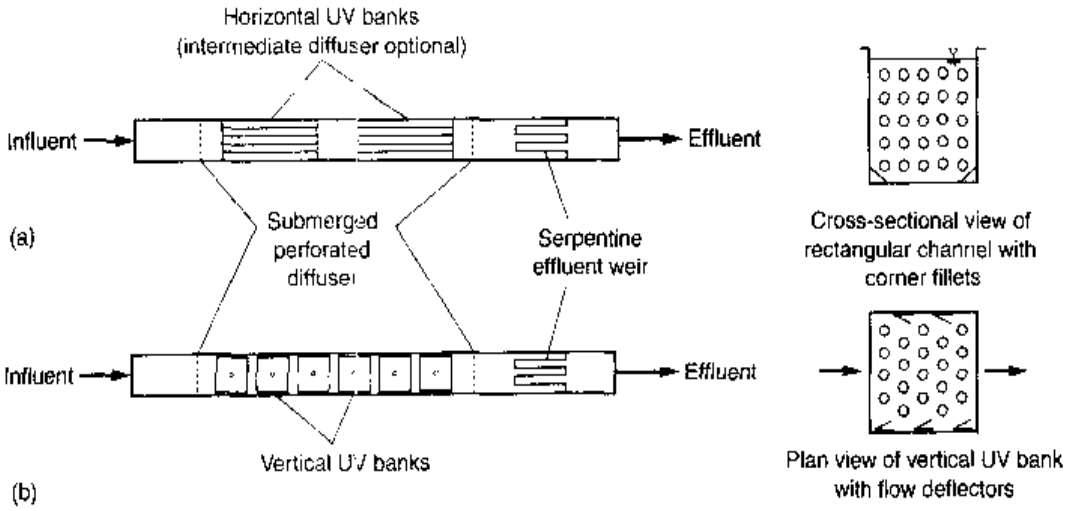
Problems associated with UV disinfection are related primarily to the inability to achieve permit limitations. Some issues that must be considered when diagnosing problems associated with UV disinfection systems are discussed below.

UV Disinfection System Hydraulics. Perhaps one of the most serious problems encountered in the field is erratic or reduced inactivation performance due to poor system hydraulics. The most common hydraulic problems are related to (1) the creation of density currents which can cause the incoming wastewater to move along the bottom or top of the UV lamp banks, resulting in short circuiting; (2) inappropriate entry and exit conditions which can lead to the formation of eddy currents, which ultimately create uneven velocity profiles that induce short circuiting; (3) the creation of dead spaces or zones within the reactor, resulting in short circuiting. The occurrence of short-circuiting or dead zones reduces the average contact time, leading to ineffective use of the UV system.

The principal hydraulic design features that can be used to improve system hydraulics in open channels include the use of (1) submerged perforated diffusers, (2) corner fillets in rectangular open-channel systems with horizontal lamp placement, (3) flow deflectors in open-channel systems with vertical lamp placement, and (4) serpentine effluent overflow weirs used in conjunction with perforated diffusers. In some cases, power input to mix the incoming flow may be necessary. Some of these corrective measures for open-channel UV disinfection systems are illustrated on Fig. 12–45. Submerged perforated baffles should have an open area of about 4 to 6 percent of the cross-sectional area of the flow channel. The headloss dissipated through a submerged baffle can be estimated using Eq. (12–56), presented previously in the discussion of the use of submerged baffles for chlorine contact basins (see Sec. 12–6). In closed UV disinfection systems, the use of perforated plates (see Fig. 12–46) is typically not required when the units are plumbed correctly. The use of computational fluid dynamics is of great value in studying the effect of various physical interventions in bringing about a more uniform approach velocity flow field.

Figure 12–45

Typical examples of physical features that can be used to improve the hydraulic performance of open-channel UV disinfection systems: (*a*) horizontal lamp placement and (*b*) vertical lamp placement.



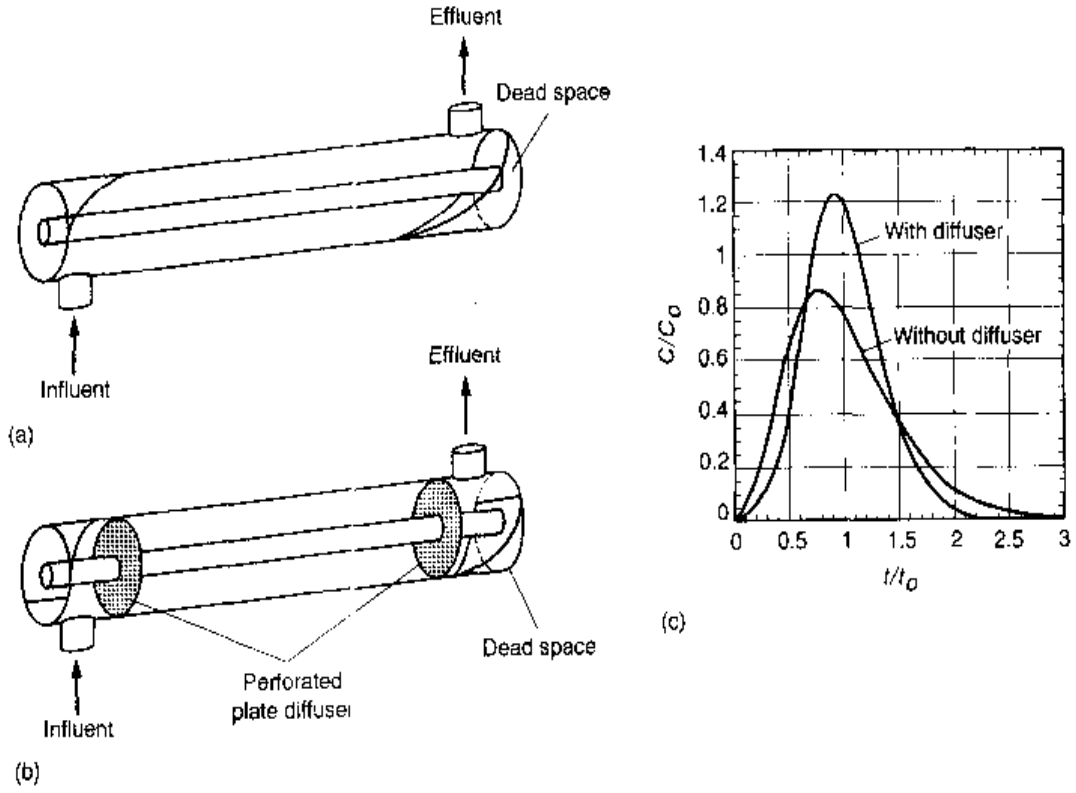


Figure 12–46

Use of perforated diffusers to improve the hydraulic performance of closed-channel UV disinfection system: (*a*) potential dead spaces without diffuser, (*b*) potential dead spaces with diffuser, and (*c*) relative improvement in hydraulic performance.

Biofilms on Walls of UV Channels and on UV Equipment. Another serious problem encountered with UV disinfection systems is the development of biofilms on the exposed surfaces of the UV reactor. The problem is especially serious in open-channel systems covered with standard grating. It has been found that if the UV channels are exposed to any light, even very dim light, biofilms (typically fungal and filamentous bacteria) will develop on the exposed surfaces. The problem with biofilms is that they can harbor and effectively shield bacteria. When the clumped biofilms break away from the attachment surface, bacteria can be shielded as the clumps pass through the disinfection system. The best control measure is to completely cover the UV channels. In addition, the channels can be occasionally cleaned and disinfected using hypochlorite, paracetic acid (see Sec. 12–8), or another suitable cleaning agent/disinfectant.

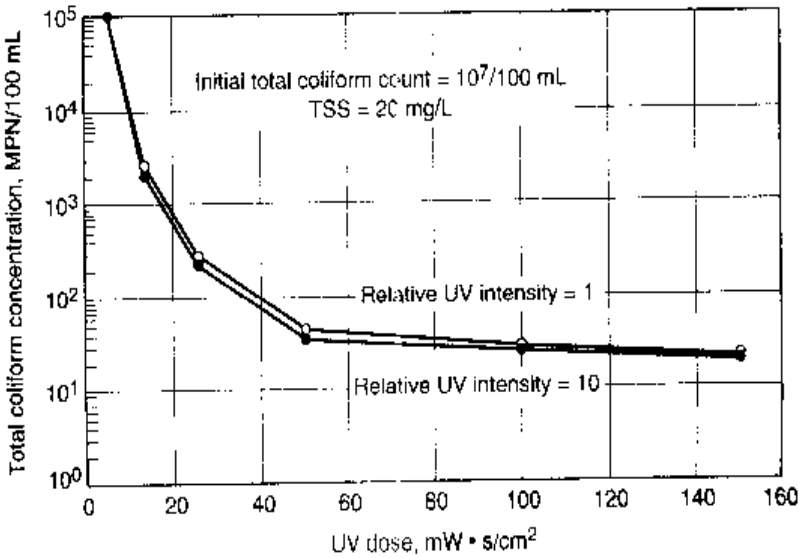
It should be noted that biofilm development can also occur in closed UV systems, but the severity is usually less, with the exception of UV systems in which medium-pressure high-intensity UV lamps are employed. Because medium-pressure high-intensity UV lamps emit some light in or near the visible light range (see Fig. 12–32), they can stimulate the growth of microorganisms on exposed surfaces. In some cases, growths approaching 300 mm in length have been found attached to the lamp support structure. The amount of light emitted in the visible light range will vary with each type of lamp (i.e., manufacturer). Removal of these growths with a suitable disinfectant must be conducted on a periodic basis.

Overcoming the Impact of Particles by Increasing the UV Intensity. It was thought at one time that the impact of particles on the performance of UV disinfection systems could be overcome by increasing the UV intensity. Unfortunately, it is not possible to increase the UV intensity enough to overcome the shading effect imparted by particles. An example is illustrated on Fig. 12–47. As shown, increasing the UV intensity tenfold has little effect on reducing the number of surviving particle-associated coliform bacteria because the absorption of UV radiation by wastewater particles is typically 10,000 times or more greater than the bulk liquid medium. Particles essentially block the transmission of UV light. Particles larger than some critical size (a function of the size of the target organism) will effectively shield the embedded microorganisms (Emerick et al., 1999; Emerick et al., 2000). Further, because large particles have little effect on turbidity, effluents with low measured turbidity values (i.e., ≤2 NTU) can still be difficult to disinfect due to the presence of large undetected particles (Ekster, 2001).

Because the effectiveness of UV disinfection is governed primarily by the number of particles containing coliform bacteria, to improve the performance of a UV disinfection system either the number of particles with associated coliform bacteria must be reduced (e.g., by selecting an appropriate upstream treatment process), or the particles themselves must be removed (e.g., by improved clarifier design or use of some form of filtration). Currently, to meet the stringent coliform bacteria requirements for body contact wastewater reuse applications (i.e., equal to or less than 2.2 MPN/100 mL), effluent filtration is required.

Figure 12–47

Impact of UV intensity on the effectiveness of UV disinfection of effluent from an air-activated sludge wastewater-treatment plant.



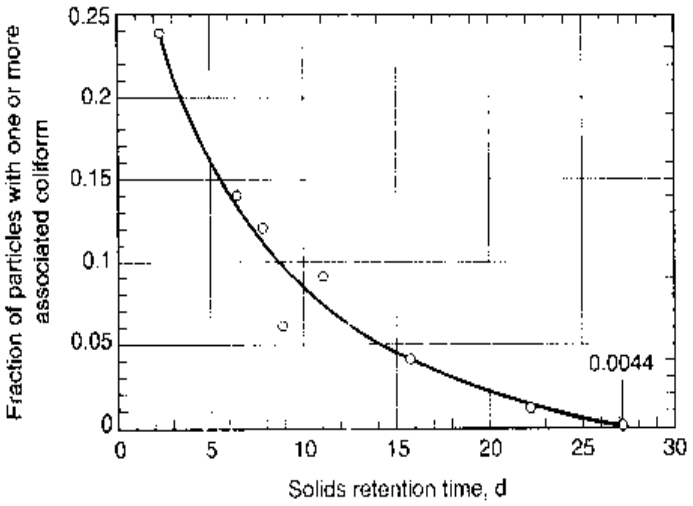


Figure 12–48
Fraction of particles in settled wastewater with one or more associated coliform organisms as function of the solids retention time (SRT).

Effect of Upstream Treatment Processes on UV Performance. The number of particles with associated coliform bacteria is another factor that will impact the performance of both chlorine and UV disinfection for unfiltered effluents (when coliform bacteria are used as the regulatory indicator). It has been observed that for activated-sludge plants the number of particles with associated coliform organisms is a function of the solids retention time (SRT). The relationship between the fraction of wastewater particles with one or more associated coliform organisms and the SRT is illustrated on Fig. 12–48. As illustrated, longer SRTs result in a decrease in the fraction of particles containing coliform bacteria. Without effluent filtration, the UV performance achieved will depend on the operation of the upstream processes (Darby et al., 1999). The use of deep final clarifiers will reduce the number of large particles that may shield bacteria. In general, without some form of filtration, it will be difficult to achieve extremely low coliform concentrations in the settled effluent from an activated-sludge plant operated at low SRT values (e.g., 1 to 2 d).

Environmental Impacts of UV Radiation Disinfection

On the basis of the evidence to date, it appears that the compounds formed at the UV dosages used for the disinfection (50 to 140 mJ/cm^2) of wastewater are harmless or are broken down into more innocuous forms. Thus, the disinfection of wastewater with ultraviolet light is considered to have no adverse environmental impacts. The environmental impacts and types of compounds formed when UV radiation is used for the destruction of trace organics such as NDMA and endocrine disruptors, typically at UV dosages greater than about 400 mJ/cm^2, is not known at present (2001). The use of hydrogen peroxide and UV for the destruction of selected organic compounds is considered in Sec. 11–10 in Chap. 11, which deals with *Advanced Oxidation Processes*.

12–10 COMPARISON OF ALTERNATIVE DISINFECTION TECHNOLOGIES

The advantages and disadvantages of the four technologies considered in this chapter for disinfection of wastewater (i.e., chlorine, chlorine dioxide, ozone, and UV) are reviewed briefly in the following discussion.

Germicidal Effectiveness

A general comparison of the germicidal effectiveness of the disinfection technologies by classes of organisms was presented previously in Table 12–11. Additional information was presented in Table 12–13 for chlorine, Table 12–22 for ozone, and Table 12–26 for UV. It is important to note that the values given in these tables are only meant to serve as a guide in assessing the effectiveness of these technologies. Because the characteristics of each wastewater and the degree of treatment will significantly impact the effectiveness of the various disinfection technologies, site-specific testing must be conducted to evaluate the effectiveness of alternative disinfection technologies and to establish appropriate dosing ranges.

Advantages and Disadvantages

The general advantages and disadvantages of using chlorine, chlorine dioxide, ozone, and UV for wastewater disinfection are summarized in Table 12–28.

Table 12–28
Advantages and disadvantages of chlorine, chlorine dioxide, ozone, and UV for the disinfection of wastewater[a]

Advantages	Disadvantages
Chlorine	
1. Well-established technology	1. Hazardous chemical that can be a threat to plant workers and the public; thus strict safety measures must be employed
2. Effective disinfectant	2. Relatively long contact time required as compared to other disinfectants
3. Chlorine residual can be monitored and maintained	3. Combined chlorine is less effective in inactivating some viruses, spores, cysts at low dosages used for coliform organisms
4. Combined chlorine residual can also be provided by adding ammonia	4. Residual toxicity of treated effluent must be reduced through dechlorination
5. Germicidal chlorine residual can be maintained in long transmission lines	5. Formation of trihalomethanes and other DBPs[b] (see Table 12–14)
6. Availability of chemical system for auxiliary uses such as odor control, dosing RAS lines, and disinfection plant water systems	6. Release of volatile organic compounds from chlorine contact basins
7. Oxidizes sulfides	7. Oxidizes iron, magnesium, and other inorganic compounds (consumes disinfectant)
8. Relatively inexpensive (cost is increasing with implementation of Uniform Fire Code regulations)	8. Oxidizes a variety of organic compounds (consumes disinfectant)
9. Available as calcium and sodium hypochlorite considered to be safer than chlorine gas	9. TDS level of treated effluent is increased
	10. Chloride content of the wastewater is increased
	11. Acid generation; pH of the wastewater can be reduced if alkalinity is insufficient
	12. Increased safety regulations, especially in light of the Uniform Fire Code
	13. Chemical scrubbing facilities may be required to meet Uniform Fire Code regulations

(continued)

Table 12-28 (*Continued*)

Advantages	Disadvantages
Chlorine dioxide	
1. Effective disinfectant	1. Unstable, must be produced onsite
2. More effective than chlorine in inactivating most viruses, spores, cysts, and oocysts	2. Oxidizes iron, magnesium, and other inorganic compounds (consumes disinfectant)
3. Biocidal properties not influenced by pH	3. Oxidizes a variety of organic compounds
4. Under proper generation conditions, halogen-substituted DBPs are not formed	4. Formation of DBPs (i.e., chlorite and chlorate)
5. Oxidizes sulfides	5. Potential for the formation of halogen-substituted DBPs
6. Provides residuals	6. Decomposes in sunlight
	7. Can lead to the formation of odors
	8. TDS level of treated effluent is increased
	9. Operating costs can be high (e.g., must test for chlorite and chlorate)
Ozone	
1. Effective disinfectant	1. No immediate measure of whether disinfection was successful
2. More effective than chlorine in inactivating most viruses, spores, cysts, and oocysts	2. No residual effect
3. Biocidal properties not influenced by pH	3. Less effective in inactivating some viruses, spores, cysts at low dosages used for coliform organisms
4. Shorter contact time than chlorine	4 Formation of DBPs (see Table 12-23)
5. Oxidizes sulfides	5. Oxidizes iron, magnesium, and other inorganic compounds (consumes disinfectant)
6. Requires less space	6. Oxidizes a variety of organic compounds (consumes disinfectant)
7. Contributes dissolved oxygen	7. Off-gas requires treatment
	8. Safety concerns
	9. Highly corrosive and toxic
	10. Energy-intensive
	11. Relatively expensive
	12. Highly operational and maintenance-sensitive
	13. Lack of chemical system that can be used for auxiliary uses such as dosing RAS lines
	14. May be limited to plant where generation of high-purity oxygen already exists

(*continued*)

Table 12-28 (*Continued*)

Advantages	Disadvantages
UV	
1. Effective disinfectant	1. No immediate measure of whether disinfection was successful
2. No residual toxicity	2. No residual effect
3. More effective than chlorine in inactivating most viruses, spores, cysts	3. Less effective in inactivating some viruses, spores, cysts at low dosages used for coliform organisms
4. No formation of DBPs at dosages used for disinfection	4. Energy-intensive
5. Does not increase TDS level of treated effluent	5. Hydraulic design of UV system is critical
6. Effective in the destruction of resistant organic constituents such as NDMA	6. Relatively expensive (price is coming down as new and improved technology is brought to the market)
7. Improved safety compared to the use of chemical disinfectants	7. Large number of UV lamps required where low-pressure low-intensity systems are used
8. Requires less space than chlorine disinfection	8. Low-pressure low-intensity lamps require acid washing to remove scale
9. At higher UV dosages than required for disinfection, UV radiation can be used to reduce the concentration of trace organic constituents of concern such as NDMA (see Sec. 11–10 in Chap. 11)	9. Lack of chemical system that can be used for auxiliary uses such as odor control, dosing RAS lines, and disinfection of plant water systems

[b] DBPs = disinfection byproducts.

PROBLEMS AND DISCUSSION TOPICS

12-1 Determine the inactivation rate constant for one of the following four waters (water to be selected by instructor) assuming Chick's law applies.

Log of organisms remaining	Time, min — Water A	B	C	D
7	0.0	0.0	0.0	0.0
6	2.0	6	4	3.0
5	4.0	12	8.1	5.9
4	6.5	18	12.6	8.6
3	8.5	23.9	17.5	12.5
2	10.0	30.1	20	15.2
Combined chlorine residual, mg/L	10	4	6	8

12–2 The following data were obtained for a 99 percent inactivation of a given bacterial strain for four different waters at 10°C. Using these data develop a general relationship that can be used to model the observed data for one of the waters (to be selected by instructor). Using the relationship developed, determine the chlorine dose required to achieve a 99.99 percent inactivation in 60 min at 25°C.

Combined chlorine residual, mg/L	Contact time, min			
	Water			
	A	B	C	D
2	12	240	90	38
3	4.0	92	30	10
4	1.9	47	12	4.2
5	1.0	28	7	2.1
6		18	4.1	1.2
7		12	2.8	
8		9	1.9	
9		6.8	1.2	
10		5.1	1.0	

12–3 Disinfection data were obtained for four different waters. Using these data, determine the coefficients for Eq. (12–31) (water to be selected by instructor). Using the equation developed, determine the time required to achieve a 4.5-log reduction.

$C_R t$, mg·min /L	$-\log N/N_o$			
	Water			
	A	B	C	D
0	0.0	0.0	0.0	0.0
5	0.0	0.4	0.0	0.8
10	0.0	1.2	0.0	1.8
20	0.0	2.2	1.0	2.8
50	1.0	3.0	2.0	3.8
100	2.0	3.9	2.8	4.8
200	3.0	4.8	3.6	5.6
500	4.0	6.0	4.6	—
Combined chlorine residual, mg/L	4.3	5.1	3.8	4.7

12–4 The data in the following table were obtained in a series of laboratory tests performed on an effluent from a secondary wastewater treatment process.

Chlorine dosage, mg/L	Residual fecal coliform count, no./100 mL; contact time, min.		
	15	30	60
1	10,000	2000	500
2	3,000	350	90
4	400	65	20
6	110	30	12
8	54	19	6
10	30	10	1

a. Plot the data on semilog paper. Using these data, determine the value of the exponent n and the constant in Eq. (12–6) for residual coliform counts of 200/100 mL and 1000/100 mL.

b. The following data apply to the wastewater treatment plant.

Item	Unit	May–Oct.	Nov.–Apr.
Average flow	m^3/d	20,000	26,000
Peak daily flow	m^3/d	40,000	52,000
Maximum permissible fecal coliform count in effluent	MPN100mL	200	1000

Determine the required volume in m^3 of a chlorine contact chamber designed to provide 60-min contact at the average winter flow. Using the equations developed in part a, determine the minimum dosage required in mg/L to give the required kill under each of the four flow conditions given above. Assuming that the yearly chlorine requirement can be computed on the basis of the average flow for each of the two 6-month periods, determine the minimum yearly chlorine requirement in kilograms. (Courtesy E. Foree.)

12–5 The chlorine residuals measured when various dosages of chlorine were added to four different wastewaters are given below. Determine (wastewater to be selected by instructor) (a) the breakpoint dosage and (b) the design dosage to obtain a residual of 1.0, 1.5, 2.0, and 2.5 mg/L (residual to be selected by instructor) free available chlorine.

Dosage, mg/L	Residual, mg/L			
	A	B	C	D
0	0.0	0.0	0.0	0.0
1	0.6	1.0	0.95	1.0
2	0.2	2.0	1.7	1.98
3	1.0	2.98	2.3	2.9
4	2.0	3.95	1.9	3.4
5	3.0	4.3	1.0	2.8

(continued)

(Continued)

Dosage, mg/L	Residual, mg/L			
	A	B	C	D
6		3.7	1.7	1.8
7		2.7	2.7	1.2
8		1.6	3.7	2.1
9		0.8		3.1
10		1.7		4.1
11		2.8		
12				

12-6 Compare the volume required for a complete-mix reactor to that for a plug-flow reactor to achieve a 10^4 reduction in the coliform count of a treated effluent. Assume that in both cases the chlorine residual to be maintained is 5 mg/L.

12-7 Using the following dose-response data for an enteric virus and the tracer data for four different chlorine contact basins, determine for one of the basins (to be selected by instructor) the expected effluent microorganism concentration using a segmented flow model. Also estimate the chlorine residual that would be required to achieve 4 logs of removal with the existing basins.

Dose-response data for enteric viruses

$C_R t$, mg/L·min[a]	Log number of organisms remaining
0	10^7
100	$10^{6.2}$
200	$10^{5.4}$
400	$10^{3.8}$
600	$10^{2.1}$
800	$10^{0.6}$
1000	10^{-1}

[a]Combined chlorine residual = 5.0.

Tracer data for chlorine contact basins

Time, min	Tracer concentration, mg/L			
	Chlorine contact basin			
	A	B	C	D
0	0.0	0.0	0.0	0.0
10	0.0	0.0	0.0	0.0
20	20.0	0.0	0.0	0.0

(continued)

(Continued)

	Tracer concentration, mg/L

12–8 Determine the amount of sulfur dioxide (SO_2), sodium sulfite (Na_2SO_3), sodium bisulfite ($NaHSO_3$), sodium metabisulfite ($Na_2S_2O_5$), and activated carbon (C) that would be required per year to dechlorinate treated effluent containing a chlorine residual of 4.0, 3.5, 6.0, or 5.2 mg/L as Cl_2 (residual to be selected by instructor) from a plant with an average flowrate of 1000, 3800 5000, or 8250 m^3/d (flowrate to be selected by instructor).

12–9 Review the current literature and prepare an assessment of the use of chlorine gas versus sodium hypochlorite for the disinfection of wastewater. A minimum of 4 articles and/or reports dating back to 1995 should be cited in your assessment.

12–10 Estimate the ozone dose needed to disinfect a filtered secondary effluent to an MPN value of 240/100 mL using the following disinfection data obtained from pilot-scale installation. Assume the starting coliform concentration will be 1×10^6/100 mL and that the ozone transfer efficiency is 80 percent.

Test number	Initial coliform count, N_o MPN/100 mL	Ozone transferred, mg/L	Final coliform count, MPN/100 mL	$-\log (N/N_o)$
1	95,000	3.1	1500	1.80
2	470,000	4.0	1200	2.59
3	3,500,000	4.5	730	3.68
4	820,000	5.0	77	4.03
5	9,200,000	6.5	92	5.00

12-11 Review the current literature and prepare an assessment of the use of ozone for the disinfection of wastewater. A minimum of 4 articles and/or reports dating back to 1995 should be cited in your assessment.

12-12 Determine the mean, standard deviation, and confidence interval for the following MS2 inactivation data, obtained using a collimated-beam device. What UV dose would be required to achieve a 4-log inactivation of MS2 with a confidence interval of 75 percent?

Log reduction, $-\log N/N_o$	Applied UV dose, mJ/cm^2				
	Test				
	1	2	3	4	5
1	17	21	26	24	20
2	37	43	51	47	40
3	56	66	80	70	60
4	75	89	105	94	80
5	94	110	131	120	100
6	114	133	160	143	121
7	131	155	185	170	142

12-13 If the intensity of the UV radiation measured at the water surface in a petri dish is 10 mW/cm^2, determine the average UV intensity to which a sample will be exposed if the depth of water in the petri dish is 10, 22, 14, 15, or 16 mm (water depth to be selected by instructor).

12-14 Assume the intensity of UV radiation measured at the water surface in a petri dish in Problem 12–12 is 5 mW/cm^2, and that the computed UV dose was based on a water depth of 10 mm. What would be the effect if the actual water depth in the petri dish were 20 mm? For one of the test runs (to be selected by instructor) plot the actual test results reported in Problem 12–12 and the corrected values using a water depth of 20 mm.

12-15 The following data were obtained for filtered wastewater with a transmittance of 65 percent at 254 nm with a UV pilot-test unit comprised of 4 UV lamps in each of two UV banks. Determine the mean, standard deviation, and 75 percent confidence interval for one of the tests (to be selected by instructor). For the test to be analyzed determine the range of flows expressed as L/min·lamp over which the UV disinfection system will deliver a dose of 90 mJ/cm^2.

Test	Pilot flowrate, L/min	Log_{10} MS2 bacteriophage survival		
		Replicate 1	Replicate 2	Replicate 3
1	200	4.51	4.47	4.48
1	400	3.48	3.50	3.53
1	700	2.50	2.57	2.45
2	300	5.55	5.50	5.60
2	500	4.51	4.44	4.53
2	800	3.05	2.90	3.20

(continued)

(Continued)

Test	Pilot flowrate, L/min	Log_{10} MS2 bacteriophage survival		
		Replicate 1	Replicate 2	Replicate 3
3	400	4.30	4.25	4.32
3	550	3.55	3.60	3.50
3	750	2.60	2.55	2.63
4	280	4.40	4.37	4.46
4	480	3.43	3.40	3.39
4	620	2.73	2.66	2.76

12-16 The following data were obtained for filtered wastewater with a transmittance of 55 percent at 254 nm with a UV pilot-test unit comprised of 6 UV lamps in a single UV bank operated at various ballast settings. Determine (1) the mean, standard deviation, and 75 percent confidence interval for one of the given ballast output settings (to be selected by instructor) and (2) the range of flows expressed as L/min·lamp over which the UV disinfection system will deliver a dose of 120 mJ/cm^2.

Pilot flowrate, L/min	Ballast output, %	Log_{10} MS2 bacteriophage survival		
		Replicate 1	Replicate 2	Replicate 3
400	100	6.58	6.62	6.53
	80	5.43	5.42	5.41
	60	4.94	4.98	4.93
	50	4.67	4.74	4.77
560	100	5.82	5.69	5.61
	80	4.62	4.85	4.61
	60	4.32	4.38	4.06
	50	4.11	4.07	4.14
732	100	5.54	5.5	5.44
	80	4.49	4.58	4.62
	60	4.22	3.96	3.76
	50	4.06	3.97	3.94

12-17 The following data were obtained in a pilot test of a UV disinfection system. If a UV dose of 30 mJ/cm^2 is to be maintained, determine the flowrate per lamp for each of the ballast settings. What is the lowest ballast setting that can be used to meet the required dosage?

Flowrate, L/min	Flowrate per lamp, L/lamp	Ballast output, %	Log inactivation	UV dose based on collimated beam, mJ/cm^2
100	25	60	1.15	26.2
140	35	60	1.01	21.8

(continued)

(Continued)

Flowrate, L/min	Flowrate per lamp, L/lamp	Ballast output, %	Log inactivation	UV dose based on collimated beam, mJ/cm²
188	47	60	0.93	20.5
100	25	80	1.66	34.6
140	35	80	1.45	28.5
188	47	80	1.51	29.4
100	25	100	1.85	40.7
140	35	100	1.59	31.7
188	47	100	1.5	29.2

12-18 Tests were conducted at the extreme hydraulic conditions to evaluate the independence of three different UV disinfection systems comprised of three UV banks in series. It is assumed that demonstration of hydraulic independence at the hydraulic extremes is adequate to allow testing to proceed on a single bank to evaluate UV performance versus ballast output. Using an analysis of variance, determine whether all three UV banks were operating similarly or differently. The test flowrate is to be selected by the instructor.

Flowrate, L/min	UV bank	Replicate			
		1	2	3	Average
380	1	1.26	1.16	1.10	1.17
	2	0.99	0.86	1.29	1.05
	3	1.31	1.01	1.09	1.14
				Average =	1.12
710	1	0.77	0.56	0.62	0.65
	2	0.67	0.69	0.61	0.66
	3	0.82	0.75	0.83	0.80
				Average =	0.70
1000	1	0.55	0.56	0.50	0.54
	2	0.57	0.65	0.61	0.61
	3	0.60	0.51	0.58	0.56
				Average =	0.57

12-19 Review the current literature and prepare an assessment of the use of low-pressure low-intensity versus low-pressure high-intensity UV disinfection systems for the disinfection of wastewater. A minimum of 4 articles and/or reports dating back to 1995 should be cited in your assessment.

12-20 Review the current literature and prepare an assessment of the use of medium-pressure high-intensity UV disinfection systems for the disinfection of wastewater. A minimum of 4 articles and/or reports dating back to 1995 should be cited in your assessment.

PROBLEMS AND DISCUSSION TOPICS 1439

REFERENCES 1443

Continued population growth, contamination of both surface water and groundwater, uneven distributions of water resources, and periodic droughts have forced water agencies to search for new sources of water supply. Use of highly treated wastewater effluent, now discharged to the environment from municipal wastewater treatment plants, is receiving more attention as a reliable water resource. In many parts of the country, water reuse is already an important element in water resources planning and implementation. While water reuse is a viable option, water conservation, efficient use of existing water supplies, and new water resources development and management are other alternatives that must be evaluated.

The purpose of this chapter is to introduce the basic concepts and issues involved in water reclamation and reuse. Because water reuse is a rapidly evolving field, especially with respect to water quality, emerging issues are considered in the epilogue to this chapter. The chapter is organized in 10 sections dealing with: (1) a general introduction to the water reuse, including the definition of terms commonly used, (2) public health and environmental considerations in water reuse, (3) risk assessment, (4) a brief review of the principal treatment technologies used for water reclamation, (5) storage of reclaimed water, (6) agricultural and landscape irrigation, (7) industrial water reuse,

(8) groundwater recharge with reclaimed water, (9) potable water reuse, and (10) planning considerations for water reclamation and reuse. Separate sections are devoted to agricultural and landscape irrigation, industrial water reuse, and groundwater recharge because these are the largest and most important users of reclaimed water. Although the quantities of water used for potable reuse are limited, potable reuse is discussed separately because it is a hotly debated subject that encompasses important issues related to advanced wastewater treatment, public health, and public acceptance.

13–1 WASTEWATER RECLAMATION AND REUSE: AN INTRODUCTION

The purpose of this section is (1) to introduce the technical terms used in water reuse practices, (2) to present the role of water reclamation and reuse in the context of the hydrologic cycle, (3) to provide a brief historical perspective on the subject of water reclamation and reuse, (4) to provide an introduction to the principal water reuse applications, and (5) to review briefly the need and status of water reuse.

Definition of Terms

Terms used frequently in the field of water reclamation, recycling, and reuse are summarized in Table 13–1. It should be noted that the definitions given in Table 13–1 have evolved from several water reuse regulations and in response to questions raised by consumers and the public at large.

The Role of Water Recycling in the Hydrologic Cycle

The inclusion of planned water reclamation, recycling, and reuse in water resource systems reflects the increasing scarcity of water sources to meet societal demands, technological advancements, increased public acceptance, and improved understanding of public health risks. As the link between wastewater, reclaimed water, and water reuse has become delineated more clearly, increasingly smaller recycle loops are possible (Asano and Levine, 1996). Traditionally, the hydrologic cycle has been used to represent the continuous transport of water in the environment. The water cycle consists of freshwater and saltwater surface resources, subsurface groundwater, water associated with various land use functions, and atmospheric water vapor. Many subcycles to the hydrologic cycle exist, including the engineered transport of water. Water reclamation, recycling, and reuse represent significant components of the hydrologic cycle in urban, industrial, and agricultural areas. A conceptual overview of the cycling of water from surface and groundwater resources to water treatment facilities, irrigation, municipal, and industrial applications, and to water reclamation and reuse facilities is shown on Fig. 13–1.

The major pathways of water reuse include irrigation, industrial use, surface water replenishment, and groundwater recharge. Surface water replenishment and groundwater recharge also occur through natural drainage and through infiltration of irrigation and stormwater runoff. The potential use of reclaimed water for a potable water source is also shown on Fig. 13–1. The quantity of water transferred via each pathway depends on the watershed characteristics, climatic and geohydrologic factors, the degree of water utilization for various purposes, and the degree of direct or indirect water reuse.

The water used or reused for agricultural and landscape irrigation includes agricultural, residential, commercial, and municipal applications. Industrial reuse is a general

Table 13–1 Definition of terms used in water reuse applications

Term	Description
Beneficial uses	The many ways water can be used, either directly by people, or for their overall benefit. Examples include municipal water supply, agricultural and industrial applications, navigation, fish and wildlife, and water contact recreation
Direct potable reuse	A form of reuse by the incorporation of reclaimed water directly into a potable water supply system, often implying the blending of reclaimed water with potable water
Direct reuse	The use of reclaimed water which has been transported from the wastewater reclamation plant to the water reuse site without intervening discharge to a natural body of water, including such uses as agricultural and landscape irrigation
Dual distribution system	Two sets of pipelines for water delivery, one for potable water and another for reclaimed water
Indirect potable reuse	Potable reuse by incorporation of reclaimed water into a raw water supply, allowing mixing and assimilation by discharge into an impoundment or natural body of water, such as in a domestic water supply reservoir or groundwater
Indirect reuse	Use of reclaimed water indirectly by passing through a natural body of water or use of groundwater that has been recharged with reclaimed water
Nonpotable water reuse	All reuse applications that do not involve either indirect or direct potable use
Planned reuse	Deliberate direct or indirect use of reclaimed water, without relinquishing control over the water during its delivery
Potable water reuse	An augmentation of drinking water supplies directly or indirectly by reclaimed water that is highly treated to protect public health
Reclaimed water	Water that, as a result of wastewater treatment, is suitable for a direct beneficial use or a controlled use that would not otherwise occur
Recycled water	Reclaimed water that has been used beneficially. The term recycled water is used synonymously with reclaimed water
Unplanned reuse	Reuse of treated wastewater following discharge (control relinquished), such as in the diversion of water from a river downstream of a discharge of treated wastewater
Water reclamation	Treatment or processing of wastewater to make it reusable. Also, this term is often used to include delivery of reclaimed water to place of use and its actual use
Water recycling	The use of wastewater that is captured and redirected back into the same water use scheme. Recycling is practiced predominantly in industries, such as manufacturing, and normally involves only one industrial plant or one user
Water reuse	The use of treated wastewater for a beneficial use, such as agricultural irrigation and industrial cooling

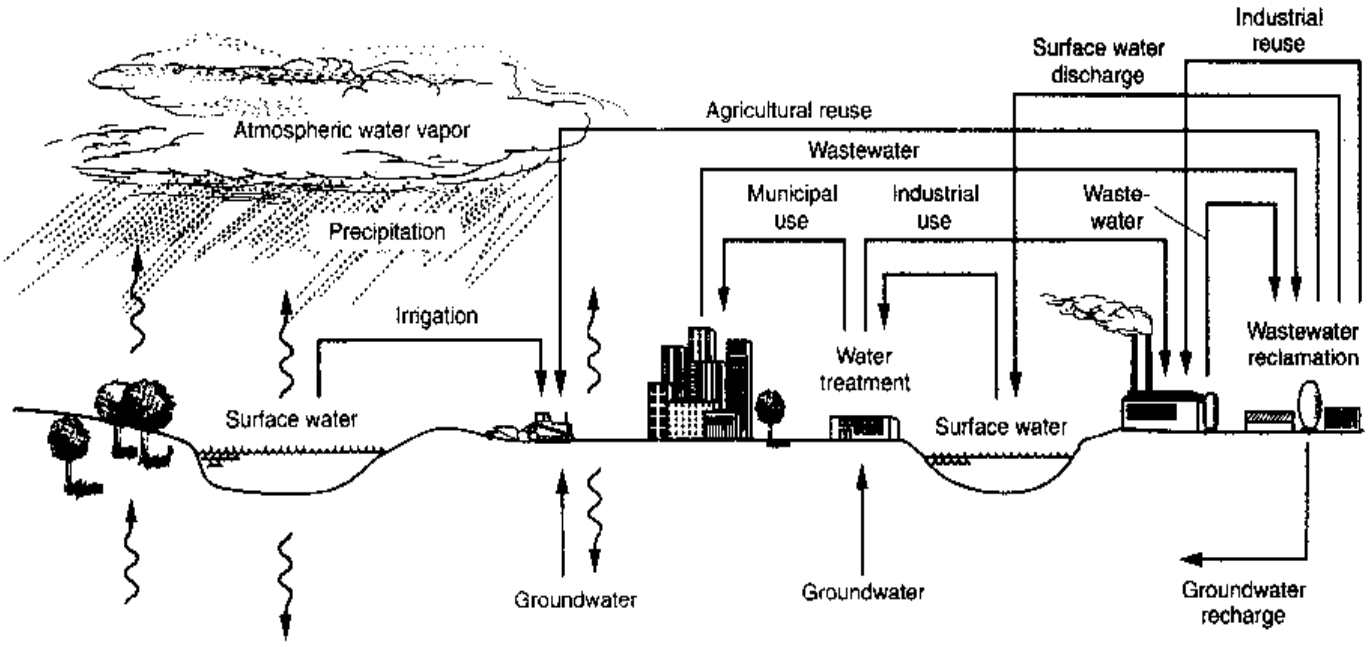

Figure 13–1

The role of engineered treatment, reclamation, and reuse facilities in the cycling of water through the hydrologic cycle. *(Adapted from Asano and Levine, 1996.)*

category encompassing water use for a diversity of industries that include power plants, pulp and paper, and other industries with high rates of water utilization. In some cases, closed-loop recycle systems have been developed that treat water from a single process stream and recycle the water back to the same process with some makeup water. In other cases, reclaimed municipal water is used for industrial purposes such as in cooling towers. The National Aeronautical and Space Administration has studied closed-loop systems for long-duration space missions and space stations.

How small this water-recycling loop should be will depend on public health, engineering, economics, aesthetics, and more importantly, public acceptance. Planned water reclamation and reuse have gained considerable attention worldwide in recent decades as an alternative and new water resource in the context of integrated water resources management.

Historical Perspective

Early developments in the field of water reuse are synonymous with the historical practice of land application for the disposal of wastewater. With the advent of sewerage systems in the nineteenth century, domestic wastewater was used at *sewage farms* and by 1900 there were numerous sewage farms in Europe and in the United States. While these sewage farms were used primarily for waste disposal, incidental use was made of the water for crop production or other beneficial uses (Veatch, 1938).

During the past century, a number of water reclamation and reuse projects have been developed as a matter of necessity to meet growing need for reliable water. Selected examples of historical development of water reuse in the United States are presented in Table 13–2.

Table 13-2
Selected examples of historic development of water reuse in the United States and other parts of the world

Year	Location	Water reuse application
	United States	
1912–1985	Golden Gate Park, San Francisco, CA	Watering lawns and supplying ornamental lakes
1926	Grand Canyon National Park, AZ	Toilet flushing, lawn sprinkling, cooling water, and boiler feed water
1929	City of Pomona, CA	Irrigation of lawns and gardens
1942	City of Baltimore, MD	Metals cooling and steel processing at the Bethlehem Steel Company
1960	City of Colorado Springs, CO	Landscape irrigation for golf courses, parks, cemeteries, and freeways
1961	Irvine Ranch Water District, CA	Irrigation and domestic water including toilet flushing in high-rise buildings
1962	County Sanitation Districts of Los Angeles County, CA	Groundwater recharge using spreading basins at the Montebello Forebay
1976	Orange County Water District, CA	Groundwater recharge by direct injection into the aquifers at the Water Factory 21
1977	City of St. Petersburg, FL	Irrigation of parks, golf courses, school yards, residential lawns, and cooling tower makeup water
1985	City of El Paso, TX	Groundwater recharge by direct injection into the Hueco Bolson aquifers, and power plant cooling water
1987	Monterey Regional Water Pollution Control Agency, Monterey, CA	Agricultural irrigation of food crops eaten uncooked including artichoke, celery, broccoli, lettuce, and cauliflower
	Outside of the United States	
1890	Mexico City, Mexico	Drainage canals were built to take untreated wastewater to irrigate an important agricultural area north of the city, a practice that still continues today. Untreated or minimally treated wastewater from Mexico City is delivered to the Valley of Mexico where it is used to irrigate about 90,000 ha of agricultural lands
1962	La Soukra, Tunisia	Irrigation with reclaimed water for citrus plants and groundwater recharge to reduce saltwater intrusion into groundwater
1968	City of Windhoek, Namibia	Advanced wastewater reclamation system to augment potable water supplies
1969	City of Wagga Wagga, Australia	Landscape irrigation of sporting fields, lawns, and cemeteries
1977	Dan Region Project, Tel-Aviv, Israel	Groundwater recharge via basins. Pumped groundwater is transferred via a 100-km-long conveyance system to southern Israel for unrestricted crop irrigation
1984	Tokyo Metropolitan Government, Japan	Water recycling project in Shinjuku District of Tokyo providing reclaimed water for toilet flushing in 19 high-rise buildings in highly congested metropolitan area
1989	Consorci de la Costa Brava, Girona, Spain	Golf course irrigation

Table 13–3
Estimates of water reclamation in the United States in 1995[a]

Category	Quantity	
	Mgal/d	Mm^3/d
Public supply	57	0.2157
Commercial	19	0.0719
Industrial	110	0.4164
Thermoelectric	100	0.3785
Mining	14	0.0530
Irrigation	718	2.7176
Total	1018	3.8531

[a] Adapted from Solley et al. (1998).

According to the most recent survey on estimated use of water in the United States, the use of reclaimed water in 1995 was 3.85×10^6 m^3/d (1018 Mgal/d), which was a 36 percent increase in 5 years (Solley et al., 1998). Estimates of water reclamation in the United States in 1995 by water use category are shown in Table 13–3. Most of the water reuse sites are located in the arid and semiarid western and southwestern states, including Arizona, California, Colorado, Nevada, Texas, and Utah. However, an increasing number of water reuse projects are being implemented in the humid regions of the United States, which include Florida, Maryland, and Missouri, for water pollution abatement as well as for water supply benefits. Because of costs of treatment, health issues, and safety concerns, water reuse applications have been limited primarily to nonpotable uses such as agricultural and landscape irrigation. However, where no other possibilities exist for expanding freshwater supplies, some communities are continuing to investigate and evaluate the potential for indirect and direct potable reuse options. While the quantities of reclaimed water involved in these potable water reuse projects are small, the technological, public health, aesthetic, and public acceptance issues are of fundamental importance and are a greater challenge in water reuse than in drinking water supply.

Wastewater Reuse Applications

In the planning and implementation of water reclamation and reuse, the reclaimed water application will usually govern the wastewater treatment needed to protect public health and the environment, and the degree of reliability required for the treatment processes and operations. The seven principal categories of municipal wastewater reuse are listed in Table 13–4 in descending order of projected volume of use along with potential constraints for their application.

- The first category, agricultural irrigation, is the largest current use of reclaimed water (see Fig. 13–2). This reuse category offers significant future opportunities for water reuse. Reviewing the base data for agricultural irrigation, California is by far the largest user of irrigation water, withdrawing about 110 million m^3/d (29 Bgal/d), 22 percent of the national total. California, together with Idaho, Colorado, Texas, and Montana, accounts for 54 percent of the national total (Solley et al., 1998).

Table 13–4 Categories of municipal wastewater reuse and potential issues/constraints

Wastewater reuse categories	Issues/constraints
1. Agricultural irrigation Crop irrigation Commercial nurseries	• Surface and groundwater contamination if not managed properly • Marketability of crops and public acceptance • Effect of water quality, particularly salts, on soils and crops • Public health concerns related to pathogens (e.g., bacteria, viruses, and parasites) • Use area control including buffer zone may result in high user costs
2. Landscape irrigation Parks School yards Freeway medians Golf courses Cemeteries Greenbelts Residential	
3. Industrial recycling and reuse Cooling water Boiler feed Process water Heavy construction	• Constituents in reclaimed water related to scaling, corrosion, biological growth, and fouling • Public health concerns, particularly aerosol transmission of pathogens in cooling water • Cross connection of potable and reclaimed water lines
4. Groundwater recharge Groundwater replenishment Saltwater intrusion control Subsidence control	• Possible contamination of groundwater aquifer used as a source of potable water • Organic chemicals in reclaimed water and their toxicological effects • Total dissolved solids, nitrates, and pathogens in reclaimed water
5. Recreational/environmental uses Lakes and ponds Marsh enhancement Stream-flow augmentation Fisheries Snowmaking	• Health concerns related to presence of bacteria and viruses (e.g., enteric infections and ear, eye, and nose infections) • Eutrophication due to nitrogen and phosphorus in receiving water • Toxicity to aquatic life
6. Nonpotable urban uses Fire protection Air conditioning Toilet flushing	• Public health concerns about pathogens transmitted by aerosols • Effects of water quality on scaling, corrosion, biological growth, and fouling • Cross connection of potable and reclaimed water lines
7. Potable reuse Blending in water supply reservoirs Pipe-to-pipe water supply	• Constituents in reclaimed water, especially trace organic chemicals and their toxicological effects • Aesthetics and public acceptance • Health concerns about pathogen transmission, particularly enteric viruses

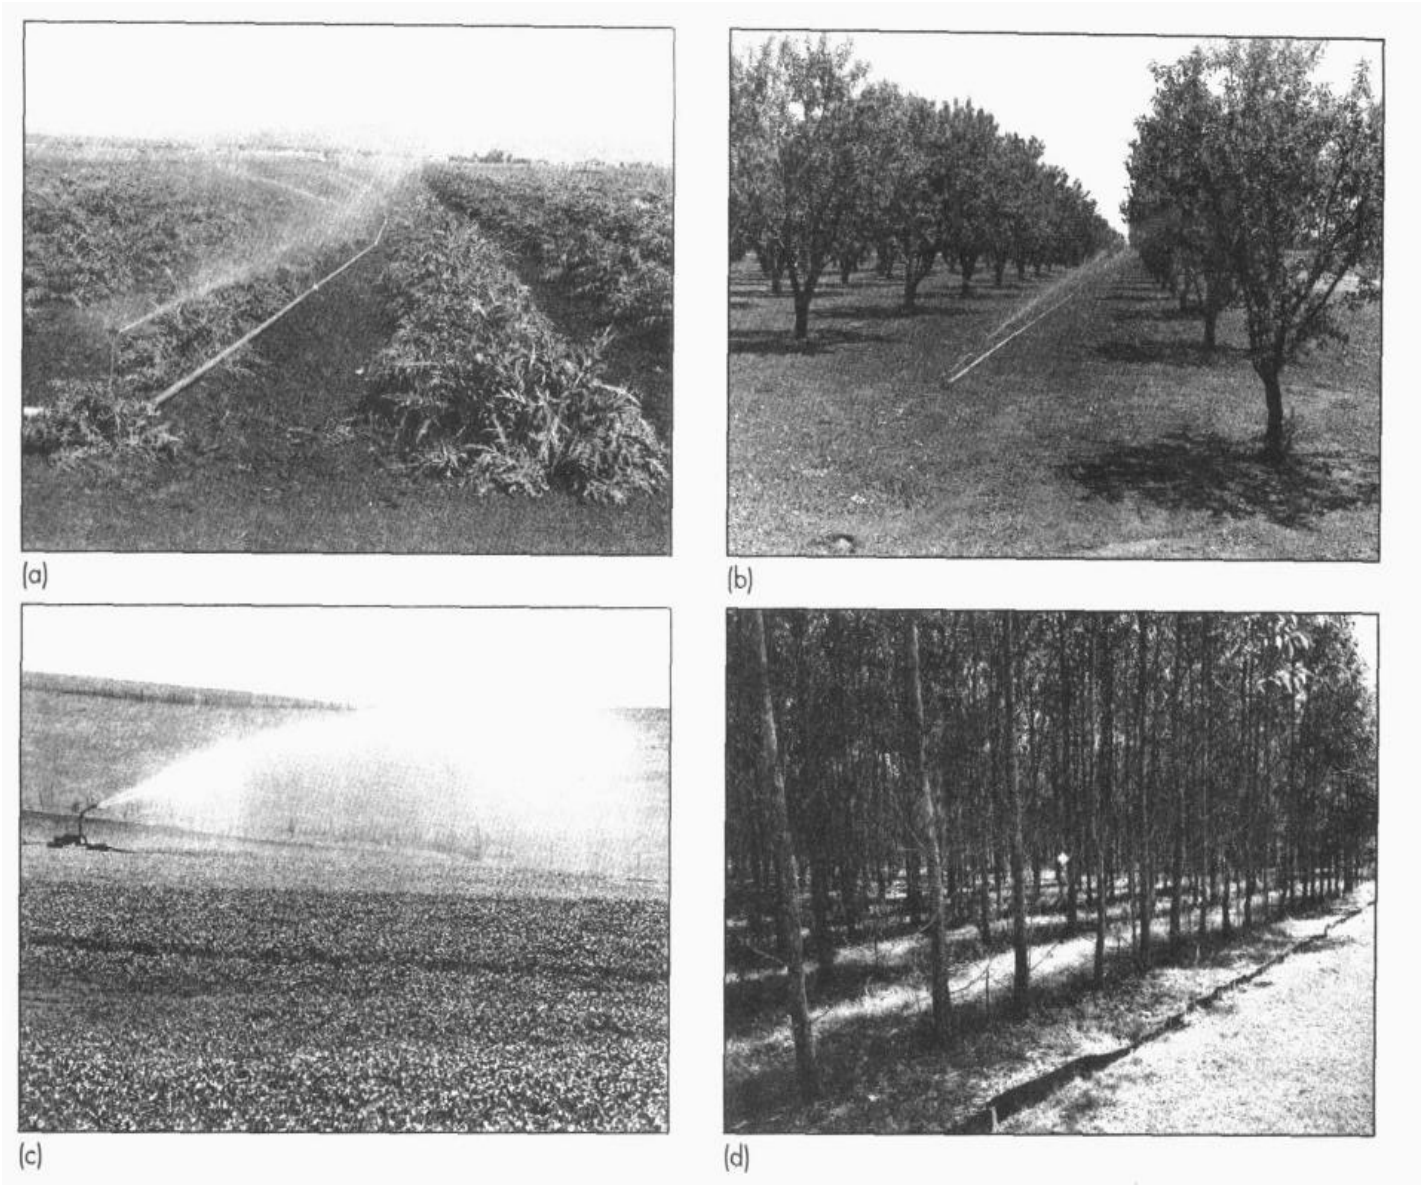

Figure 13-2

Typical irrigation of agricultural crops using reclaimed water: (*a*) artichokes using moveable impact-type sprinkler system, (*b*) orchard using fixed impact-type sprinkler system, (*c*) animal fodder using moveable water gun sprinkler system, and (*d*) experimental eucalyptus grove using impact-type sprinkler system (Australia). The experimental eucalyptus grove (*d*) is instrumented to assess the effect of nitrogen and other nutrients in reclaimed water.

- The second category, landscape irrigation, includes the irrigation of parks; playgrounds; golf courses (see Fig. 13–3); freeway medians; landscaped areas around commercial, office, and industrial developments; and landscaped areas around residences. Many landscape irrigation projects involve dual distribution systems—one distribution network for potable water and another for reclaimed water.
- The third major use of reclaimed water is in industrial activities, primarily for cooling and process needs. Cooling water is the predominant industrial water reuse and, for either cooling towers or cooling ponds, creates the single largest demand for water in many industries (see Fig. 13–22 in Sec. 13–7). Industrial uses vary greatly, and to provide adequate water quality, additional treatment is often required beyond conventional secondary wastewater treatment.

Figure 13–3
Typical golf course irrigated with reclaimed water.

- The fourth reuse application for reclaimed water is groundwater recharge, via either spreading basins (see Fig. 13–4) or direct injection to groundwater aquifers. Groundwater recharge involves assimilation of reclaimed water for replenishment, storage in groundwater aquifers, or establishing hydraulic barriers against saltwater intrusion in coastal areas.
- A fifth use of reclaimed water, recreational/environmental uses, involves a number of nonpotable uses related to land-based water features such as the development of recreational lakes, marsh enhancement, and stream-flow augmentation (see Fig. 13–5). Reclaimed water impoundments can be incorporated into urban landscape developments. Man-made lakes, golf course storage ponds, and water traps can be supplied with reclaimed water. Storage of reclaimed water is discussed in Sec. 13–5. Examples of recreational impoundments include Las Colinas, TX; Santee, CA; and Lubbock, TX. The use of reclaimed water in an environmental water feature is illustrated on Fig. 13–6. Reclaimed water has been applied to wetlands for a variety of reasons including creation, restoration, and enhancement of habitat, provision for additional treatment prior to discharge to receiving water, and provision for a wet weather disposal alternative for reclaimed water.
- The sixth reuse category, nonpotable urban uses, includes such uses as fire protection, air conditioning, toilet flushing, construction water, and flushing of sanitary sewers. Typically, for economic reasons, these uses are incidental depending on the location of the wastewater reclamation plant and whether these applications can be coupled with other ongoing reuse applications such as landscape irrigation.
- The seventh reuse opportunity involves potable reuse, which could occur by blending in water supply storage reservoirs or, in the extreme, by direct input into the water distribution system (i.e., so called "pipe-to-pipe" potable reuse).

While potentially large quantities of reclaimed municipal wastewater can be used in the first five categories, the quantities associated with the sixth and seventh reuse categories are minor at present; particularly potable water reuse.

Need for Water Reuse

To understand the potential and significance of water reuse, it is helpful to compare reclaimed water use with freshwater withdrawals on a national scale. The estimates of

Figure 13–4

Rio Hondo surface spreading basins in southern California. The spreading basins cover an area of 231 ha (570 ac). Water to be recharged is applied to the 20 shallow basins over a period of 7 days. The basins are then drained for 7 days and dried for an additional 7 days before being put back into service. *(Photo courtesy of County Sanitation Districts of Los Angeles County.)*

Figure 13–5

Stream flow augmentation with reclaimed water. During the summer months, the flow in the river shown in the photo is comprised essentially of reclaimed water. Streams in which a large fraction of the flow is reclaimed water are known as *effluent dominated waterways.*

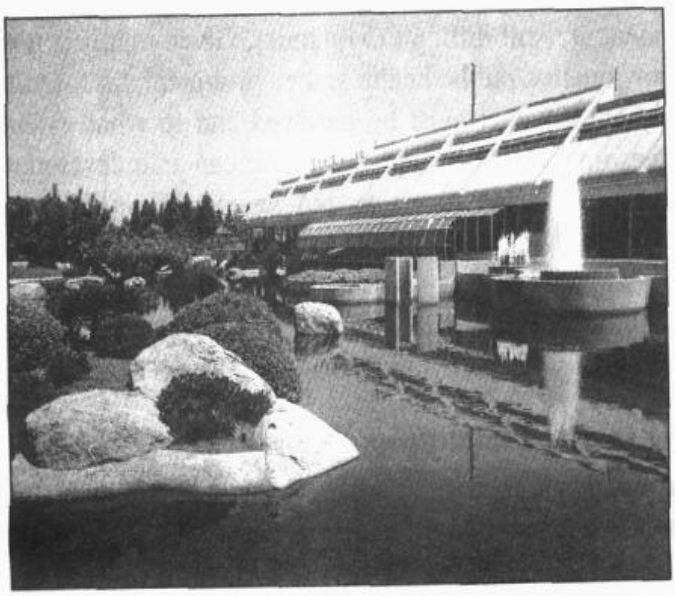

Figure 13–6

View of the stilling pond maintained with reclaimed wastewater at the Japanese Garden located adjacent to the Tillman Water Reclamation Plant in Los Angeles, CA.

Table 13–5 Estimates of freshwater withdrawals and water reclamation in the United States in years 1975, 1985, and 1995[a]

Category	Quantity, Mm^3/d (Bgal/d)		
	1975	1985	1995
Total freshwater withdrawals:			
Ground	310.37 (82)	277.06 (73.2)	289.17 (76.4)
Surface	984.10 (260)	1003.03 (265)	999.24 (264)
Reclaimed water	1.93 (0.5)	2.27 (0.6)	3.86 (1.02)

[a]Adapted from Solley et al. (1998).

freshwater withdrawals and quantity of reclaimed water used are reported in Table 13–5. The ratio of municipal wastewater reclamation and reuse to total freshwater withdrawals is expected to remain low in the near future. However, because the reclaimed water is a locally controllable water resource, the actual quantity of water reuse will increase significantly (see Table 13–5).

In recent years, the desirability and benefits of water reuse have been well recognized by several states. For example, in the California State Water Code it is clearly noted that "it is the intention of the Legislature that the State undertake all possible steps to encourage development of water recycling facilities so that recycled water may be made available to help meet the growing water requirements of the State." Today, technically proven wastewater treatment processes exist that can be used to produce water of almost any quality for water reuse. Thus, water reuse has a rightful place and has an important role in the planning and efficient use of water resources. However, public concerns about public health and environmental issues will need to be addressed in a more rigorous and transparent manner than has occurred in the past.

13–2 PUBLIC HEALTH AND ENVIRONMENTAL ISSUES IN WATER REUSE

Despite the existence of technically proven advanced wastewater treatment processes, as discussed in Chap. 11, long-term *safety* of reclaimed water and the *impact* on the environment are still difficult to quantify. Given that it is possible to produce water of almost any quality, public health and environmental issues that now must be addressed are: what constituents must be removed and to what extent must they be removed? These questions are of even greater significance in developing countries that are experiencing extreme water shortages and where high levels of treatment are not economically feasible. The purpose of this section is (1) to evaluate the impact of new scientific findings and knowledge concerning the constituents in water, (2) to examine the public health significance and environmental impact of the constituents in treated wastewater that is to be reused, and (3) to review existing water reuse criteria and guidelines.

Constituents in Reclaimed Water

The constituents in municipal wastewater subject to treatment may be classified as conventional, nonconventional, and emerging. Typical constituents included under each

Table 13–6
Classification of typical constituents found in wastewater

Classification	Constituent
Conventional	Total suspended solids
	Colloidal solids
	Biochemical oxygen demand
	Chemical oxygen demand
	Total organic carbon
	Ammonia
	Nitrate
	Nitrite
	Total nitrogen
	Phosphorus
	Bacteric
	Protozoan cysts and oocysts[a]
	Viruses[b]
Nonconventional	Refractory organics
	Volatile organic compounds
	Surfactants
	Metals
	Total dissolved solids
Emerging	Prescription and nonprescription drugs[c]
	Home care products
	Veterinary and human antibiotics
	Industrial and household products
	Sex and steroidal hormones
	Other endocrine disrupters

[a] Value per 100 mL.
[b] Plaque-forming units/100 mL.
[c] Pharmaceutically active substances.

category are described in Table 13–6. Expected concentrations in the reclaimed water after various levels of treatment are reported later in this chapter in Tables 13–16 through 13–18. The term *conventional* is used to define those constituents measured in mg/L that have served as the basis for the design of most conventional wastewater treatment plants. *Nonconventional* applies to those constituents that may have to be removed or reduced using advanced wastewater treatment processes before the water can be used beneficially. The term *emerging* is applied to those classes of compounds measured in the micro- or nanogram/L range that may pose long-term health concerns and environmental problems as more is known about the compounds. In some cases, these compounds cannot be removed effectively, even with advanced treatment processes.

Public Health Issues

Over the past 10 years, a variety of new analytical techniques have been developed (see Chap. 2) that can be used to measure extremely low concentrations (e.g., 10^{-12} g/m^3 or ng/L) of an ever-increasing variety of inorganic and organic constituents in water. As a consequence, hundreds of organic compounds have been detected in untreated and treated wastewater at relatively low concentrations. Further, it has been found that the effectiveness of conventional and advanced wastewater treatment processes varies considerably with respect to removal of these individual compounds.

For most of the *emerging* compounds listed in Table 13–6, there is little or no information concerning health or environmental effects. Unfortunately, some of the compounds that have been identified in reclaimed water are known to have both acute and chronic health effects, depending on their concentrations and exposure pathways. The dilemma posed by the presence of these trace amounts of organic compounds in reclaimed water is that the perceived or potential adverse health effects that may be caused by these compounds have not been quantified fully in current water reuse criteria and guidelines or drinking water standards. Where it is desired to conserve water resources via conservation and water reuse rather than to develop environmentally costly new water resources, the emphasis in the evaluation of water reuse options will be on public health protection, treatment process reliability, value of water, and public policy.

Environmental Issues

Environmental risks associated with previously unknown or unrecognized chemicals in treated effluents have long been a concern for environmental scientists and engineers. Ternes (1998), for example, investigated the occurrence of 32 drug residues in German municipal wastewater treatment plants. In general, more than 60 percent of the drug residues that were detected at parts per billion (ppb) or parts per trillion (ppt) levels in the wastewater influent were removed in the activated-sludge process. The long-term environmental effects of these compounds found in treated effluent are, for the most part, not well understood, and the true significance of these trace quantities of constituents in the aquatic environment and in water supplies is still an issue of concern. The most troubling finding is that the concentrations of these compounds that cause environmental effects to aquatic organisms are considerably lower than the concentrations that cause any measurable effects in humans.

The Evolution of Water Reuse Guidelines in the United States

To protect public health, considerable efforts have been made to establish conditions and regulations that would allow for safe use of reclaimed water for a variety of water reuse applications (see Table 13–4). Early guidelines and, to a large extent, current water reuse criteria and guidelines are based on the control of conventional parameters such as BOD, TSS, and coliforms used for the design and monitoring of wastewater treatment plants (Ongerth and Ongerth, 1982). Thus, most current criteria and guidelines do not include pathogenic bacteria such as *Salmonella* and enteric viruses such as *Hepatitis*, emerging pathogens, or the trace organic compounds discussed above.

Federal Guidelines. The U.S. Environmental Protection Agency (U.S. EPA, 1992) has suggested reclaimed water quality guidelines for the following reuse categories:

- Urban reuse
- Restricted-access-area irrigation
- Agricultural reuse—food crops
- Agricultural reuse—nonfood crops
- Recreational impoundments
- Landscape impoundments
- Construction uses
- Industrial reuse
- Groundwater recharge
- Indirect potable reuse

For each reuse category, levels of treatment, minimum reclaimed water quality, reclaimed water monitoring, and setback distances are suggested (U.S. EPA, 1992). The guidelines are summarized in Table 13–7 for the two principal levels of treatment—disinfected tertiary (filtered secondary effluent) and disinfected secondary effluents.

State Guidelines and Regulations. Regulations or guidelines adopted by individual states are summarized in Table 13–8. The listing includes 18 states with regulations and 18 states with guidelines on water reuse (U.S. EPA, 1992*a*). Both the regulations and the guidelines vary considerably from state to state. States such as California, Arizona, Florida, and Texas have developed comprehensive regulations that strongly encourage water reuse as an alternative water resource and a water conservation strategy. In these four states regulations have been developed for water quality requirements, treatment processes, and monitoring and reporting for the full spectrum of water reuse applications. California water reuse regulations have been developed progressively since 1918, and are the most comprehensive with regard to public health. In December 2000, the state of California revised the *Water Recycling Criteria* (Title 22 regulations), which are summarized in Table 13–9 (State of California, 2000). The representative uses and application methods are listed in Table 13–10.

Assessment of Water Reuse Guidelines. The goal of essentially virus-free reclaimed water (i.e., disinfected tertiary) contained in the *California Water Recycling Criteria* (see Tables 13–9 and 13–10) should not be interpreted to mean that the practice of using such water is risk-free. There is always a statistical probability of infection due to the exposure to reclaimed water. Because of the paucity of microbiological and infectious disease data, difficulties exist in correlating causative agents and the disease outcome and its epidemiological significance. However, the practice of water reclamation and reuse cannot be construed as *unsafe* compared to other sources of available water, such as polluted river and irrigation water. The *safety* of water reuse practice is defined by the acceptable level of risks developed by the regulatory agencies responsible for

Table 13–7
Summary of EPA suggested guidelines for water reuse[a]

Level of treatment	Types of reuse	Reclaimed water quality	Reclaimed water monitoring	Setback distances
1. Disinfected tertiary[b]	Urban reuse[c] Food crop irrigation Recreational impoundments	pH = 6–9 $BOD_5 \leq 10$ mg/L Turb. ≤ 2 NTU *E. coli* = none Res. $Cl_2 \geq 1$ mg/L	pH = weekly BOD = weekly Turb. = cont. *E. coli* = daily Res. Cl_2 = cont.	15 m (50 ft) to potable water supply wells[d]
2. Disinfected secondary	Restricted access area irrigation Food crop irrigation (commercially processed) Nonfood crop irrigation Landscape impoundments (restricted access) Construction Wetlands habitat	pH = 6–9 BOD_5 = 30 mg/L TSS = 30 mg/L *E. coli* = 200/100 mL Res. $Cl_2 \geq 1$ mg/L	pH = weekly BOD = weekly TSS = daily *E. coli* = daily Res. Cl_2 = cont.	30 m (100 ft) to areas accessible to the public (if spray irrigation) 90 m (300 ft) to potable water supply well

[a] From U.S. EPA (1992*a*).

[c] Uses include landscape irrigation, vehicle washing, toilet flushing, use in fire protection, and commercial air conditioners.
[d] Setback increases to 150 m (500 ft) if impoundment bottom is not sealed.

health and environmental risk management and endorsed by the public for the necessity of such undertaking in the integrated water resources management.

Although the *California Water Recycling Criteria* reported in Table 13–9 lack explicit epidemiological evidence to assess fully the associated health risks in water reuse practices, the criteria have been in effect since 1978 as attainable and enforceable regulations. Studies conducted using the available enteric virus monitoring data in California and quantitative microbiological risk assessment methodology appear to prove the validity of the *California Water Recycling Criteria* (Asano et al., 1992; Tanaka et al., 1998). Additional safety measures that have been used for nonpotable water reuse applications include (1) installation of separate storage and distribution systems for potable water, (2) use of color-coded pipes (normally purple) and labels to distinguish reclaimed water from potable water distribution piping, (3) cross-connection and backflow prevention devices, (4) periodic use of tracer dyes to detect the occurrence of cross contamination in potable supply lines, and (5) irrigation during off hours to further minimize the potential for human contact.

Water Reclamation Criteria in Other Countries

Reclaimed water quality criteria for protecting health in developing countries are often established in relation to the limited resources available for public works and other health delivery systems that may yield greater health benefits for the funds spent. Confined wastewater collection systems and wastewater treatment facilities are often nonexistent, and reclaimed water often provides an essential water supply and fertilizer source. For most developing countries, the greatest concern with the use of wastewater for irrigation is that untreated or inadequately treated wastewater contains numerous intestinal nematodes (e.g., *Ascaris* and *Trichuris* species and hookworms) and bacterial pathogens that are difficult to control. These infectious agents, as well as enteric viruses, can damage the health of both the general public consuming the crops contaminated with wastewater and farmworkers and their families.

The World Health Organization (WHO, 1989) has recommended that irrigation of crops likely to be eaten uncooked, sports fields, and public parks should be irrigated with wastewater treated by a series of stabilization ponds. The ponds are designed to achieve a microbiological quality of less than or equal to 1 intestinal nematode per liter and fecal coliforms of less than or equal to 1000 per 100 mL (geometric mean). In comparison, California's criteria are significantly more stringent (see Table 13–9). The criteria recommended by WHO for irrigation with reclaimed water have been accepted as

Table 13–9
California water recycling criteria[a]

Category of reclaimed water	Criteria for: Total coliform, MPN/100 mL	Criteria for: Turbidity, NTU	Suitable uses
Disinfected tertiary[b]	<2.2	2 average 5 maximum	All uses shown in Table 13–4
Disinfected secondary—2.2	<2.2	na	All uses shown in Table 13–4 except irrigation of parks and playgrounds,[c] food crops contacted by reclaimed water, nonrestricted impoundments
Disinfected secondary—23	<23	na	Same restrictions as disinfected secondary—2.2, except no food crop irrigation, no nonrestricted impoundment, and no watering of yards
Undisinfected secondary[d]	na	na	Drip or surface irrigation of fodder, fiber, seed orchard, and tree crops and sugar beets (commercially processed food crops)

[a] From California Code of Regulations, Title 22, Division 4, Chapter 3 Water Recycling Criteria, Sections 60301 et seq., Dec. 2, 2000.

[b] Filtered through natural undisturbed soils or filter media, such as sand or diatomaceous earth.

[c] Urban areas such as parks, playgrounds, school yards, residential yards, and golf courses associated with residences.

[d] Undisinfected wastewater means wastewater in which the organic matter has been stabilized, is nonputrescible, and contains dissolved oxygen.

na = not applicable.

Table 13–10
Representative uses and application methods for reclaimed water in California

General use	Conditions in which use is allowed[a]			
	Disinfected tertiary reclaimed water	**Disinfected secondary—2.2 reclaimed water**	**Disinfected secondary—23 reclaimed water**	**Undisinfected secondary reclaimed water**
All water uses other than potable use or food preparation;[b] and other than groundwater recharge (governed by other regulations)	Allowed[b]	Not allowed	Not allowed	Not allowed
Irrigation of:				
Parks, playgrounds, school yards, residential yards, and golf courses associated with residences	Spray, drip, or surface	Not allowed	Not allowed	Not allowed
Restricted-access golf courses, cemeteries, freeway landscapes	Spray, drip, or surface	Spray, drip, or surface	Spray, drip, or surface	Not allowed
Nonedible vegetation at other areas with limited public exposure[c]	Spray, drip, or surface	Spray, drip, or surface[c]	Spray, drip, or surface[c]	Not allowed
Sod farms	Spray, drip, or surface	Spray, drip, or surface	Spray, drip, or surface	Not allowed
Ornamental plants for commercial use	Spray, drip, or surface	Spray, drip, or surface	Spray, drip, or surface	Not allowed
All food crops	Spray, drip, or surface	Not allowed	Not allowed	Not allowed
Food crops that are above ground and not contacted by reclaimed water	Spray, drip, or surface	Drip or surface	Not allowed	Not allowed
Pasture for milking animals and other animals	Spray, drip, or surface	Spray, drip, or surface	Spray, drip, or surface	Not allowed
Fodder (e.g., alfalfa), fiber (e.g., cotton), and seed crops not eaten by humans	Spray, drip, or surface	Spray, drip, or surface	Spray, drip, or surface	Drip or surface
Orchards and vineyards bearing food crops	Spray, drip, or surface	Drip or surface	Drip or surface	Drip or surface
Orchards and vineyards not bearing food crops during irrigation	Spray, drip, or surface	Spray, drip, or surface	Spray, drip, or surface	Drip or surface
Christmas trees and other trees not bearing food crops	Spray, drip, or surface	Spray, drip, or surface	Spray, drip, or surface	Drip or surface
Food crop which must undergo commercial pathogen-destroying processing before consumption (e.g., sugar beets)	Spray, drip, or surface	Spray, drip, or surface	Spray, drip, or surface	Drip or surface

Table 13-10 (*Continued*)

General use	Conditions in which use is allowed[a]			
	Disinfected tertiary reclaimed water	Disinfected secondary—2.2 reclaimed water	Disinfected secondary—23 reclaimed water	Undisinfected secondary reclaimed water
Other uses:				
Washing aggregate and making concrete	Allowed	Allowed	Allowed	Not allowed
Dampening roads and other surfaces for dust control	Allowed	Allowed	Allowed	Not allowed
Dampening brushes and street surfaces in street sweeping	Allowed	Allowed	Allowed	Not allowed
Flushing sanitary sewers[f]	Allowed	Allowed	Allowed	Not allowed
Washing yards, lots, and sidewalks	Allowed	Allowed	Not allowed	Not allowed
Supply for decorative fountain	Allowed	Not allowed	Not allowed	Not allowed

[a] See California Code of Regulations, Title 22, Division 4, Chapter 3 Water Recycling Criteria, Sections 60301 et seq., Dec. 2, 2000.

[b] Disinfected tertiary effluent is suitable for all water uses that are not for potable use or food preparation, do not involve incorporation of reclaimed water into drink or food for humans, and do not conflict with provisions of the California Code of Regulations, federal regulations, statute, or other law.

[c] Disinfected secondary—2.2 reclaimed water and disinfected secondary—23 reclaimed water are suitable for irrigation of landscape vegetation and nonedible plants where (a) the public would have access and exposure to irrigation water similar to that which would occur at a golf course or cemetery, and (b) children do not have direct access and exposure to irrigation water. There is no concern regarding access and exposure when disinfected tertiary reclaimed water is used.

[d] The industrial process generates mist or could involve facial contact with reclaimed water.

[e] The industrial process does not generate mist or involve facial contact with reclaimed water.

[f] The regulatory agency may approve, for flushing sanitary sewers, the use of disinfected wastewater, notwithstanding the fact that the median concentration of total coliform bacteria is higher than that of disinfected secondary—23 reclaimed water. For example, suitable for such use is wastewater that is always disinfected so that the median concentration of total coliform bacteria does not exceed 240/100 mL.

an attainable goal for stabilization ponds in several Mediterranean and Latin American countries. In some Gulf Coast countries that have recently developed wastewater treatment facilities for water reuse, such as Abu Dhabi in the United Arab Emirates (whose population has grown from about 15,000 in the mid-1950s to almost one million in the late 1990s), more stringent water reuse criteria, similar to the California regulations, have been adopted. More stringent regulations were adopted to maintain an already high standard of health, and to transform the desert into a green environment, by planting numerous trees and shrubs for public parks and gardens.

What Level of Treatment Is Necessary?

Although water reuse guidelines were developed for protection of health, it is evident that they were based on the control of conventional parameters such as pH, BOD, TSS,

and pathogenic organisms (see Tables 13–7 and 13–9). Protozoan pathogens, helminths, or the trace organic compounds, as discussed above, are not included in current water reuse regulations. It is clear, as delineated in Chap. 11 and in the following section, that water of high quality can be produced using a combination of advanced wastewater treatment processes. Thus, important questions that must be asked are (1) should the technology-based highest level of treatment that can be achieved be specified for water reuse applications, regardless of different exposure to reclaimed water in various applications, or (2) should the decision to use reclaimed water be based on risk assessment related to the exposure to reclaimed water for a specific application? Is the science sufficiently advanced to undertake such risk-based decisions in water reuse practice? Although there are no definite answers to these questions, the issues surrounding reclaimed water quality and the corresponding exposure risks must nevertheless be addressed if the *safety* of water reuse practice is to be debated on a rational basis, especially with respect to water quality, public health, liability, and public acceptance. In fact, the same questions must be addressed with regard to the treated wastewater now discharged to the environment.

13–3 INTRODUCTION TO RISK ASSESSMENT

When health effects can occur as the result of an environmental action, risk analysis is used to quantify the corresponding risks. Typically, a complete risk analysis is divided into two parts: (1) risk assessment and (2) risk management. Risk assessment involves the study and analysis of the potential effect of certain hazards to human health. Using statistical information on cause and effect, risk assessment is intended to be a tool for making informed decisions. Risk management is the process of reducing risks that are determined to be unacceptable.

Both risk assessment and risk management are introduced in the following discussion to provide a perspective on the approaches used in risk analysis. Noncarcinogenic effects and ecological risk assessment are also considered briefly. Additional details may be found in Pepper et al. (1996) and U.S. EPA (1990). Finally, risk assessment for water reuse is discussed with respect to enteric viruses, which are a major concern in industrialized countries.

Risk Assessment

Environmental risk analysis takes place in four discrete steps, as diagramed on Fig. 13–7 (Neely, 1994).

1. Hazard identification
2. Exposure assessment
3. Dose response assessment
4. Risk characterization

These four steps are described below, along with a brief discussion of the use of risk assessment in setting standards.

Hazard Identification. This step involves weighing the available evidence and determining whether a substance or constituent exhibits a particular adverse health hazard. As part of hazard identification, evidence is gathered on the potential for a sub-

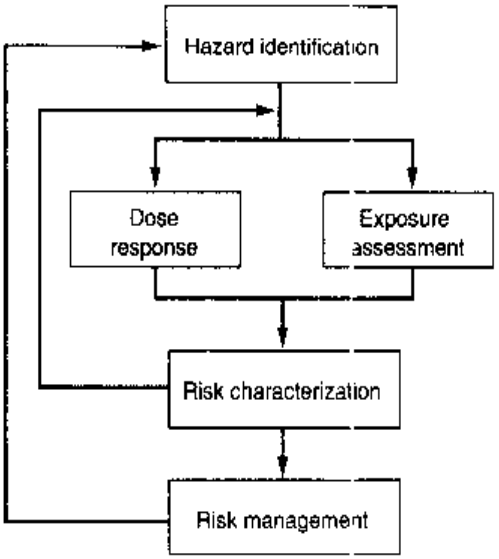

Figure 13–7
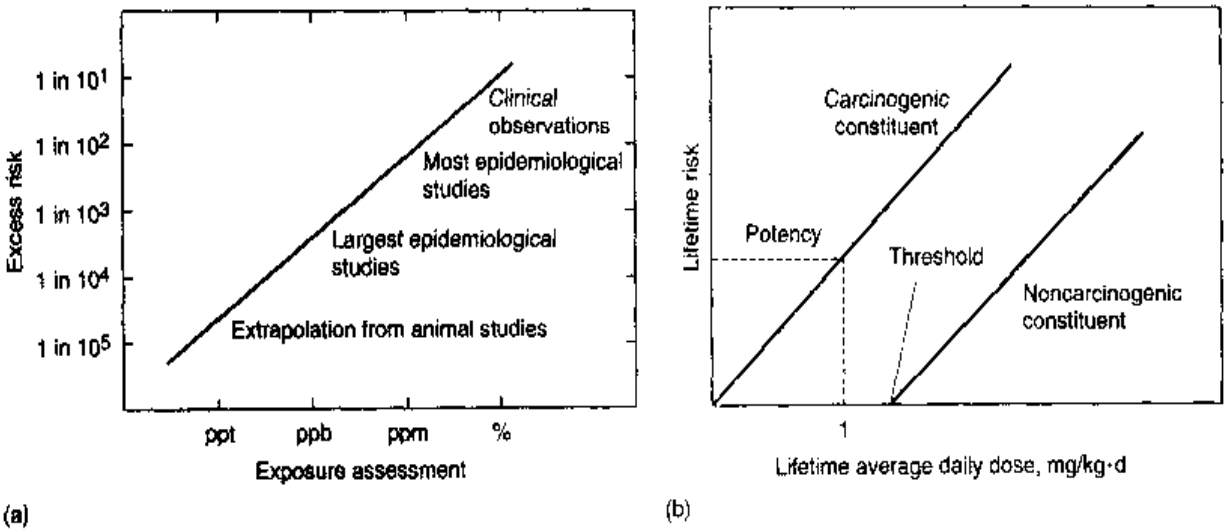
Definition sketch for the conduct of health effects risk assessment.

stance to cause adverse health effects in humans or unacceptable environmental impacts. For humans, the principal sources for this information are clinical studies, controlled epidemiological studies, experimental animal studies, and from evidence gathered from accidents and natural disasters.

Exposure Assessment. Exposure is the process by which an organism comes into contact with a hazard; exposure or access is what bridges the gap between a hazard and a risk (Kolluru et al., 1996). For humans, exposure can occur through different pathways including inhalation of air, ingestion of water or food, absorption through the skin via dermal contact, or absorption through the skin via radiation. The key steps in exposure assessment are identification of a potential receptor population, evaluation of exposure pathways and routes, and quantification of exposures. For example, an exposure scenario to assess the impacts of drinking groundwater that contains a known amount of trichloroethylene (TCE) would be as follows: an adult weighing 70 kg drinks 2 L of groundwater containing 50 μg/L of TCE every day for 70 years. In this case, the adult is the receptor, drinking groundwater is the pathway, and drinking 2.0 L/d containing 50 μg/L of TCE for 70 years is the quantification of exposure.

Dose-Response Assessment. The fundamental goal of a dose-response assessment is to define a relationship (typically mathematical) between the amount of a toxic constituent to which a human is exposed and the risk that there will be an unhealthy response to that dose in humans. The relative sensitivity of epidemiological studies in defining excess risk is illustrated on Fig. 13–8*a*. Typical dose-response relationships for carcinogenic and noncarcinogenic constituents are illustrated on Fig. 13–8*b*. It should be noted that it is assumed that there is no threshold for potentially carcinogenic constituents. Although the dose-response curve for a carcinogenic constituent is shown passing through the origin, data are not available at extremely low doses (see Fig. 13–9*a*). Therefore, mathematical models have been developed to define the dose response at low concentrations. Typical dose-response models that have been proposed and used for human exposure include (1) the single-hit model, (2) the multistage model, (3) the linear multistage model, (4) the multihit model, and (5) the probit model. The characteristics of these models are summarized in Table 13–11.



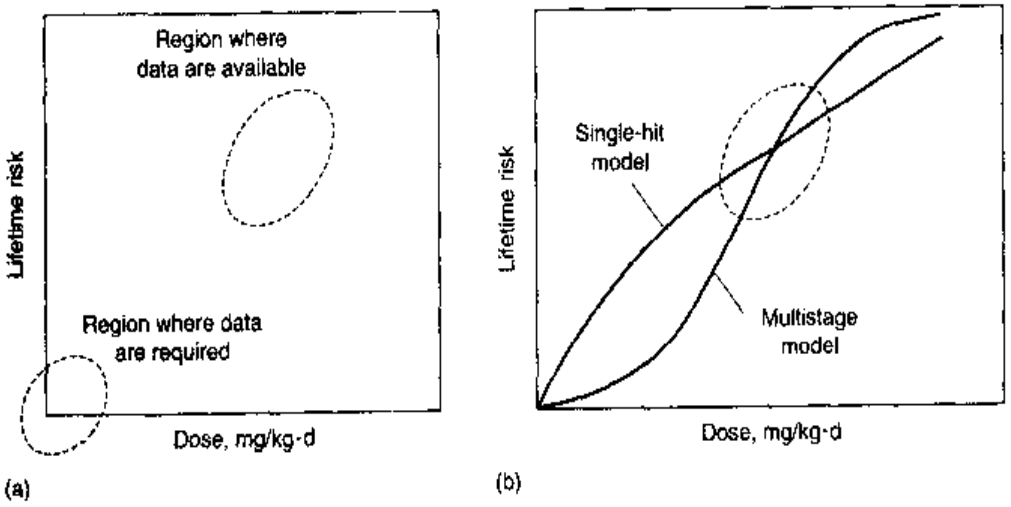


Figure 13–8

Definition sketches for risk assessment: (*a*) relative sensitivity of epidemiological studies in defining excess risk *(adapted from NRC, 1983)* and (*b*) dose-response curves for carcinogenic and noncarcinogenic constituents. As shown, it is assumed that the dose-response curve for a carcinogenic constituent has no threshold value.

Figure 13–9

Definition sketch for dose-response curves: (*a*) illustration of where data are available and where data are required, and (*b*) two different models used to define the dose-response relationship.

The mathematical function used to describe the relationship between risk and dose for the single-hit model is

$$P(d) = 1 - \exp\left[-(q_0 - q_1 d)\right] \tag{13-1}$$

where $P(d)$ = lifetime risk (probability) of developing cancer
q_0 and q_1 = empirical parameters picked to fit the data
d = dose

The mathematical formulation used to describe the relationship between risk and dose for the multistage model is

$$P(d) = 1 - \exp\left[-\sum_{i=0}^{n} q_i d^i\right] \tag{13-2}$$

Table 13–11
Models used to assess nonthreshold effects of toxic constituents[a]

Model[b]	Description
One-hit	A single exposure can lead to the development of a tumor
Multistage	The formation of a tumor is the result of a sequence of biological events
Linear multistage	Modification of the multistage model. The model is linear at low doses with a constant of proportionality that statistically will produce less than 5 percent chance of underestimating risk
Multihit	Several interactions are required before cell becomes transformed
Probit	Tolerance of exposed population is assumed to follow a log-normal (probit) distribution

[a] Adapted from Cockerham and Shane (1994), Pepper et al. (1996).

[b] In all of the models cited above, it is assumed that exposure to the toxic constituent will always produce an effect regardless of the dose.

where $P(d)$ = lifetime risk (probability) of developing cancer
q_i = positive empirical parameters picked to fit the data
d = dose

The relationship between these two models and the risk data given on Fig. 13–9*a* is shown on Fig. 13–9*b*. A variety of models have also been proposed to define the risk associated with low levels of microbial pathogens (Haas, 1983).

The U.S. EPA has defined lifetime risk as follows:

$$\text{Lifetime risk} = \text{CDI} \times \text{PF} \tag{13–3}$$

where CDI = chronic daily intake over a 70-year lifetime, mg/kg·d
PF = potency factor, $(\text{mg/kg·d})^{-1}$

The chronic daily intake (CDI) is computed as follows:

$$\text{CDI} = \frac{\text{total dose, mg}}{(\text{body weight, kg})(\text{lifetime, d})} \tag{13–4}$$

In its most general form, the total dose is defined as

$$\text{Total dose} = \begin{pmatrix}\text{constituent}\\ \text{concentration}\end{pmatrix}\begin{pmatrix}\text{intake}\\ \text{rate}\end{pmatrix}\begin{pmatrix}\text{exposure}\\ \text{duration}\end{pmatrix}\begin{pmatrix}\text{absorption}\\ \text{factor}\end{pmatrix} \tag{13–5}$$

Recommended standard values for daily intake calculations have also been developed by EPA. The average body weights used for an adult and child are 70 and 10 kg, respectively, and the corresponding rates of water ingestion are 2 and 1 liter(s) per day (U.S. EPA, 1986*b*).

The potency factor PF, often identified as the *slope factor*, is the slope of the dose-response curve, at very low doses (see Fig. 13–8*b*). The U.S. EPA has selected the linear multistage model as the basis for assessing risk. In effect, the PF corresponds to the risk resulting from a lifetime average dose of 1.0 mg/kg·d. The U.S. EPA maintains a database on toxic substances known as the Integrated Risk Information System (IRIS) (U.S. EPA, 1996). Typical toxicity data for several chemical constituents are reported in

Table 13–12
Toxicity data for selected potential carcinogenic chemical constituents[a,b]

Chemical constituent	CASRN[c]	Potency factor, PF	
		Oral route, $(mg/kg \cdot d)^{-1}$	Inhalation route, $(\mu g/kg \cdot d)^{-1}$
Arsenic, inorganic	7440-38-2	1.5 E+0	3.0 E−2
Benzene	71-43-2	1.5 to 5.5 E−2	1.54 to 5.45 E−5
Bromate	15541-45-4	7 E−1	na
Chloroform	67-66-3	6.1 E−3	1.6 E−4
Dieldrin	60-57-1	1.6 E+1	3.2 E−2
Heptachlor	76-44-8	4.5 E+0	9.1 E−3
N-Nitrosodiethylamine	55-18-5	1.2 E+2	3.0 E−1
N-Nitrosodimethylamine	62-75-9	5.1 E+1	9.8 E−2
Vinyl chloride[d]	75-01-4	7.2 E−1	3.1 to 6.2 E−5

[a]U.S. EPA IRIS database (1996) (http //www.epa.gov/iris).

[b]Because the data in the IRIS database is being revised continuously, it is important to check the database for the most current values.

[c]Chemical Abstracts Service Registry Number.

[d]Continuous lifetime exposure during adulthood.

Table 13–12. Comparing the magnitude of the given values listed in Table 13–12, the relative potency of the chemical constituents can be assessed (e.g., for the oral route, the potency of arsenic is about 245 times that of chloroform). Because of the numerous uncertainties involved in the development of the database, it is important to remember that the values given in the IRIS database cannot be used to predict the incidence of human disease or the type of effects a given chemical constituent will have on an individual. The data included extrapolations of animal data to humans and from high experimental dosages to the low environmental dosages encountered in real life. Use of the data given in Table 13–12 is illustrated in Example 13–1.

EXAMPLE 13–1 Risk Assessment for Drinking Groundwater Containing Trace Amounts of N-Nitrosodimethylamine (NDMA) Estimate the incremental cancer risk for an adult associated with drinking 2 L per day of groundwater containing 2.0 μg/L of N-nitrosodimethylamine (NDMA) using data from the Integrated Risk Information System (IRIS) (U.S. EPA, 1996). To limit NDMA exposure to acceptable cancer risk of 1 in 100,000, determine the concentration of NDMA that can be allowed in extracted groundwater.

Solution

1. Compute the CDI using Eq. 13–4.

$$\text{CDI} = \frac{\text{average daily dose, mg/d}}{\text{body weight, kg}}$$

$$\text{CDI} = \frac{(2.0\ \mu\text{g/L})(2\ \text{L/d})(1\ \text{mg}/10^3\ \mu\text{g})}{70\ \text{kg}} = 0.57 \times 10^{-4}\ \text{mg/kg·d}$$

2. Compute the lifetime risk using Eq. 13–3 and data from Table 13–12.

   Incremental lifetime risk = CDI × PF

   The potency factor from Table 13–12 for the oral route for NDMA is $5.1 \times 10\ (\text{mg/kg·d})^{-1}$. Thus,

   $$\text{Incremental lifetime risk} = (0.57 \times 10^{-4}\ \text{mg/kg·d})\ [5.1 \times 10\ (\text{mg/kg·d})^{-1}]$$
   $$= 2.9 \times 10^{-3}$$

   From the results of this analysis, the estimated probability of developing elevated cancer risks as a result of drinking the groundwater containing 2.0 μg/L of NDMA is 2.9 per 1000 persons.

3. Determine the concentration of NDMA to limit the acceptable cancer risk to 1 in 100,000

   a. Estimate the CDI

      $$10^{-5} = (\text{CDI})\ [5.1 \times 10\ (\text{mg/kg·d})^{-1}]$$

      $$\text{CDI} = 1.96 \times 10^{-7}\ \text{mg/kg·d}$$

   b. Estimate the concentration of NDMA

      $$\frac{(\text{C}\ \mu\text{g/L})(2\ \text{L/d})(1\ \text{mg}/10^3\ \mu\text{g})}{70\ \text{kg}} = 1.96 \times 10^{-7}\ \text{mg/kg·d}$$

      $$\text{C} = 0.0069\ \mu\text{g/L} = 6.9\ \text{ng/L}$$

Comment The U.S. EPA–proposed drinking water standard for NDMA is 2.0 ng/L. Because of concern over the carcinogenocity of NDMA, the Ontario, Canada, Drinking Water Objective has been set at 9 ng/L, based on a cancer risk to 1 in 100,000 estimated by the U.S. EPA (Andrews and Taguchi, 2001).

In addition to the carcinogenic dose-response information, the U.S. EPA has developed reference doses (RfD) for a number of constituents based on the assumption that thresholds exist for certain toxic effects (see Fig. 13–8), such as cellular *necrosis* (localized death of living tissue), but may not exist for other toxic effects, such as carcinogenicity. In general, RfDs are established based on reported results from human epidemiological data, long-term animal studies, and other available toxicological information. The RfD values represent an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime (U.S. EPA, 1989*a*). RfD values are available in the IRIS database (U.S. EPA, 1996) and in the Health Effects Assessment Summary Tables (U.S. EPA, 1991).

The RfD is used as a reference point for assessing the potential effects of other doses. Usually, doses that are less than the RfD are not likely to be associated with health

risks. As the frequency of exposure exceeds the RfD and the size of excess increases, the probability increases that adverse health effects may be observed in a human population. The RfD is derived using the following formula:

$$\text{RfD} = \frac{\text{NOAEL or LOAEL}}{(\text{UF}_1 \times \text{UF}_2 \ldots) \times \text{MF}} \tag{13–6}$$

where NOAEL = no observable adverse effect level
LOAEL = lowest observable adverse effect level
UF_1, UF_2 = uncertainty factors
MF = modifying factor

In the above equation, uncertainty factors are based on experimental species, effects, and duration of the study, while modifying factors represent professional assessments reflecting the confidence in the study. The LOAEL is used only when a suitable NOAEL is unavailable.

It must be recognized that the present state of knowledge concerning the impacts of specific constituents is incomplete. Thus, each step in risk assessment involves uncertainty. In hazard identification, most assessments depend on animal tests and yet animal biological systems are different from human ones. In dose response, it is often unknown whether safe levels or thresholds exist for any toxic chemical. Exposure assessment usually involves modeling, with the attendant uncertainty as to substance releases, release characteristics, meteorology, and hydrology. Because of the uncertainties associated with any risk assessment, the results of such an analysis should only be used as a guide in decision making (Haas et al., 1999).

Risk Characterization. The final step in risk assessment is risk characterization, in which the question of who is affected and what are the likely effects are defined to the extent they are known. Risk characterization involves the integration of exposure and dose-response assessments to arrive at the quantitative probabilities that effects will occur in humans for a given set of exposure conditions.

Risk Assessment in Standard Setting. Examples of risk assessment in wastewater management include health effects from consuming highly treated reclaimed water and health and environmental effects from land application of biosolids (see Sec. 14–17 in Chap. 14). An acceptable risk of 1 in 10,000 is often used in environmental risk assessment (U.S. EPA, 1986*a*). Risks of less than 1 in 10,000 are considered minimal.

Risk Management

Risk management involves the development of standards and guidelines and management strategies for specific constituents including both toxic constituents and infectious agents. For example, if a toxic constituent or infectious microorganisms are present at higher than the maximum allowable concentration based on the risk assessment, risk management involves the determination of what management and/or technology is necessary to limit the risk to an acceptable level. Thus, the development and screening of alternatives; selection, design, and implementation; and monitoring and review are important elements of health risk management.

Ecological Risk Assessment

Ecological risk assessment is similar to risk assessment for humans in that the ecological effects of exposure to one or more stressors are assessed. A stressor is defined as a substance, circumstance, or energy field that can cause an adverse effect on a biological system. It should be noted that ecological risk assessments are undertaken for a variety of reasons such as to assess the potential impacts of the discharge of treated effluent to an existing wetland or applying biosolids on land. The framework for ecological risk assessment is illustrated on Fig. 13–10 involving (1) problem formulation, in which the characteristics of the stressor are identified, (2) identification and characterization of the ecosystem at risk and the exposure modes, (3) identification of likely ecological risks, and (4) risk characterization, in which all of the information and data are integrated along with input from the risk manager (U.S. EPA, 1992*b*). Because the field of ecological risk assessment is continually undergoing change, the latest reports and publications should be consulted.

Risk Assessment for Water Reuse

In less-developed countries where advanced levels of wastewater treatment are not possible or are economically out of reach, a number of investigators have sought to assess the risk of using reclaimed water of varying quality in different reuse applications by controlling possible transmission routes of excreta-related infections. The WHO *Health Guidelines for the Use of Wastewater in Agriculture and Aquaculture* (1989) is such an example where high concentrations of pathogens exist in wastewater and partially treated effluents.

In the United States, the constituents in reclaimed water that have received the most attention are enteric viruses because of their low-dose infectivity, long-term survival in the environment, difficulties in monitoring them, and their low removal and inactivation

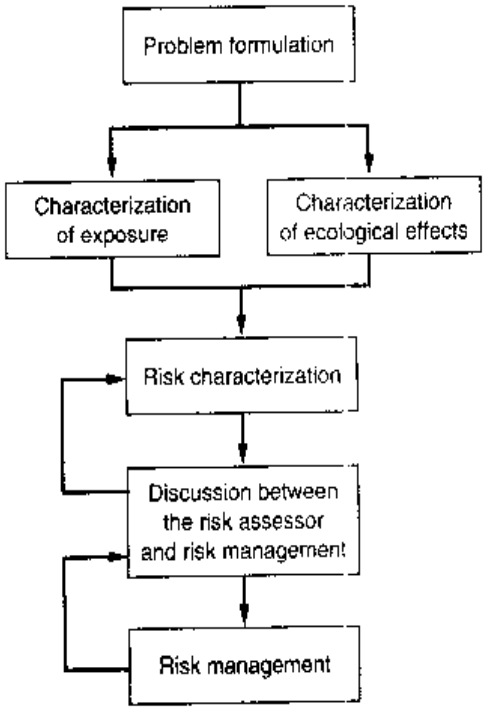

Figure 13–10

Definition sketch for the conduct of ecological risk assessment.

efficacy in conventional wastewater treatment. However, more recently, other inorganic and organic constituents that may be present in treated wastewater such as arsenic and NDMA have received considerable attention because of their significant potency factors (see Table 13–12).

Health risks associated with enteric viruses in reclaimed water that are typically encountered in the California water reuse conditions were analyzed by a quantitative microbial risk assessment approach (Tanaka et al., 1998). Past monitoring data from four wastewater treatment facilities in California on enteric virus concentrations in unchlorinated secondary effluents were used. To assess potential health risks associated with the use of reclaimed water in various reuse applications, four exposure scenarios were tested: (1) golf course irrigation, (2) food crop irrigation, (3) recreational impoundments, and (4) groundwater recharge. Because enteric virus concentrations in unchlorinated secondary effluents were found to vary over a wide range, characterizing their variability was found to be extremely important in this study.

Two concepts related to safety of water reuse were used: (1) the *reliability,* defined as the probability that the risk of infection does not exceed an acceptable risk, and (2) the *expectation,* defined by acceptable annual risk in which exposure to the enteric viruses may be estimated stochastically by numerical simulation such as the Monte Carlo methods. In the U.S. EPA Surface Water Treatment Rule (SWTR) (U.S. EPA, 1989*b*), it is assumed that one infection per 10,000 population per year due to pathogens is acceptable in the public water supply. Therefore, if 10^{-4} annual risk of infection (less than or equal to 1 infection per 10,000 population per year) is set as an acceptable risk for water reclamation and reuse. the reliability (percent of time that infection risk due to exposure to enteric viruses in reclaimed water is less than the acceptable risk) is presented in Table 13–13.

From the results of the analysis presented in Table 13–13, the reliability or relative safety of water reuse can be assessed in comparison to the domestic water supply meeting the SWTR. When the effluent from the full treatment with high chlorine dose of about 10 mg/L is used, there is virtually no difference in terms of a probability of enteric virus infection whether reclaimed water or domestic water is used for golf course irrigation, crop irrigation, and groundwater recharge. However, depending on the water quality of the secondary effluent, there is a considerable difference in water reuse for recreational impoundment where body contact sports and swimming may take place. Similar observations can be made for the use of chlorinated secondary effluent and the reclaimed water from contact filtration with low chlorine dose of less than 5 mg/L.

The utility of the study conducted by Tanaka et al. (1998), as described above, was that their findings were able to provide a basis for conservative assessment of microbiological requirements promulgated in the *California Wastewater Reclamation Criteria* (State of CA, 1978) for variety of water reuse applications. Based on the professional judgment and the research findings, California Department of Health Services was able to ensure safe and reliable water reuse practices.

Limitations in Risk Assessment for Water Reuse

Although risk assessment is used in a variety of settings as an aid to decision making, a number of serious limitations exist with the application of risk assessment to water

Table 13-13
Reliability of various water reuse applications meeting the criterion of one enteric virus infection per 10,000 populations per year[a]

Treatment process	Secondary effluent from plant	Reliability, %			
		Golf course irrigation	Crop irrigation	Recreational impoundment	Groundwater recharge
Full treatment or contact filtration with high chlorine dose removing 5.2 logs of viruses	A	100	100	77	100
	B	100	100	99	100
	C	100	100	98	100
	D	99	100	62	100
Chlorination of secondary effluent removing 3.9 logs of viruses	A	95	100	10	100
	B	100	100	81	100
	C	99	100	93	100
	D	84	100	11	100
Contact filtration with low chlorine removing 4.7 logs of viruses	A	100	100	48	100
	B	100	100	96	100
	C	100	100	97	100
	D	97	100	39	100

[a] Adapted from Tanaka et al. (1998).

reuse. The principal limitations of risk assessment as applied to water reuse are: (1) the relative nature of risk assessment as practiced currently, (2) inadequate consideration of secondary infections in microbial risk assessment, and (3) most importantly, the limited availability of valid dose-response data.

Because it is impossible to determine absolute risk, with the present state of knowledge, relative health risk as opposed to absolute risk, as illustrated above, must be used to assess the safety of water reuse practices and to evaluate alternative reuse applications. In a recently completed study, the relative human and ecological risks involved in three different effluent discharge options were examined using a Bayesian analysis, based on available information and expert opinion. Arsenic, *Cryptosporidium parvum*, rotavirus, and n-nitrosodimethylamine (NDMA) were used as indicators of human health risks. The three alternative discharge options evaluated were: (1) injection to a deep subsurface aquifer located below a drinking water aquifer, (2) discharge to surface canals where the treated effluent can infiltrate into and become mixed with the existing natural groundwater, and (3) discharge to the ocean where body contact sports including swimming and beach activities may be involved (Englehardt et al., 2001, 2002). The Bayesian approach used in this study may be applicable to reuse projects although it has not been attempted. Regardless of the approach used, risk assessment is not well understood by the public; thus, if project evaluation risk is influenced by risk assessment, it is imperative that the process be made as transparent as possible.

In chemical risk assessment, the basis for the analysis is the individual who is ingesting the constituent of concern. Although the same approach can be used for microbial risk assessment, as discussed above, more rigorous quantitative methodologies are required because enteric viruses can be transmitted from person to person. Because of the possibility of disease transmission from person to person, secondary infection must be considered in assessing microbial risks, especially where large populations are exposed (e.g., swimming in a pond containing reclaimed water). To describe the transmission of enteric virus infection and disease within an exposed population, it has been proposed that consideration must be given to the quantification of persons who are: (1) infectious and symptomatic, (2) infectious and not symptomatic, (3) not infectious and not symptomatic, and (4) not infectious and not symptomatic with short-term or partial immunity and their movement between these states (Olivieri et al., 1999). Such an approach has been applied in assessing the risk associated with the land application of digested sludge in a study conducted for the WEF (2001). Because of the complexity of disease transmission mechanisms involved in person-to-person contact, additional research must be conducted before microbial risk assessment can be considered routine undertaking in water reuse applications.

Finally, the most serious limitation in the application of risk assessment to water reuse is the limited availability of dose-response data for most of the constituents of concern in water reuse. As noted previously, numerous uncertainties are involved in the development of the dose-response data including extrapolations of animal data to humans and mathematical extrapolations from high experimental dosages to the extremely low dosages encountered in most water reuse risk assessments. Unfortunately, the current situation is often described as being *model rich* (i.e., mathematical models) and *data poor*. Because dose-response data serve as the basis for most mathematical modeling, the results obtained from modeling efforts must be used judiciously. At this time, what is critically needed is a national dialogue to develop a consensus on acceptable health and environmental risk.

13–4 WATER RECLAMATION TECHNOLOGIES

The required water quality for reclaimed water varies with each reuse application (see Tables 13–9 and 13–10). The focus of this section is to consider treatment concepts and technologies that are of particular importance to water reuse. The topics considered include (1) a review of constituent removal technologies, (2) a review of selected treatment process flow diagrams used in water reclamation applications, (3) predicting the performance of the combinations of treatment operations and processes, and (4) a discussion of treatment process reliability.

Constituent Removal Technologies

As noted in the previous section, the constituents in wastewater subject to treatment may be classified as conventional, nonconventional, and emerging (see Table 13–6). Conventional constituents are removed by the conventional treatment technologies discussed in Chaps. 5 through 10. Advanced treatment technologies, as discussed in Chap. 11, are used most commonly for the removal of nonconventional constituents. The removal of emerging constituents occurs in both conventional and advanced treatment processes, but the

Table 13–14
Treatment levels achievable with various combinations of unit operations and processes used for wastewater reclamation

Treatment process	Typical effluent quality, mg/L except turbidity, NTU						
	TSS	BOD_5	COD	Total N	NH_3-N	PO_4-P	Turbidity
Activated sludge + granular medium filtration	4–6	<5–10	30–70	15–35	15–25	4–10	0.3–5
Activated sludge + granular medium filtration + carbon adsorption	<5	<5	5–20	15–30	15–25	4–10	0.3–3

[a] Removal process occurs in the main flowstream as opposed to sidestream treatment.

levels to which individual constituents are removed are not well defined. Typical performance data for selected treatment process combinations are presented in Table 13–14.

Conventional Wastewater Treatment Process Flow Diagrams for Water Reclamation

Unrestricted urban water reuse involves the use of reclaimed water where frequent public exposure is likely in the water reuse application. Disinfected, filtered effluent (see Tables 13–7, 13–9, and 13–10) is required for unrestricted urban water reuse. The three principal treatment process flow diagrams used to produce the required effluent quality are (1) full treatment, (2) direct filtration, and (3) contact filtration.

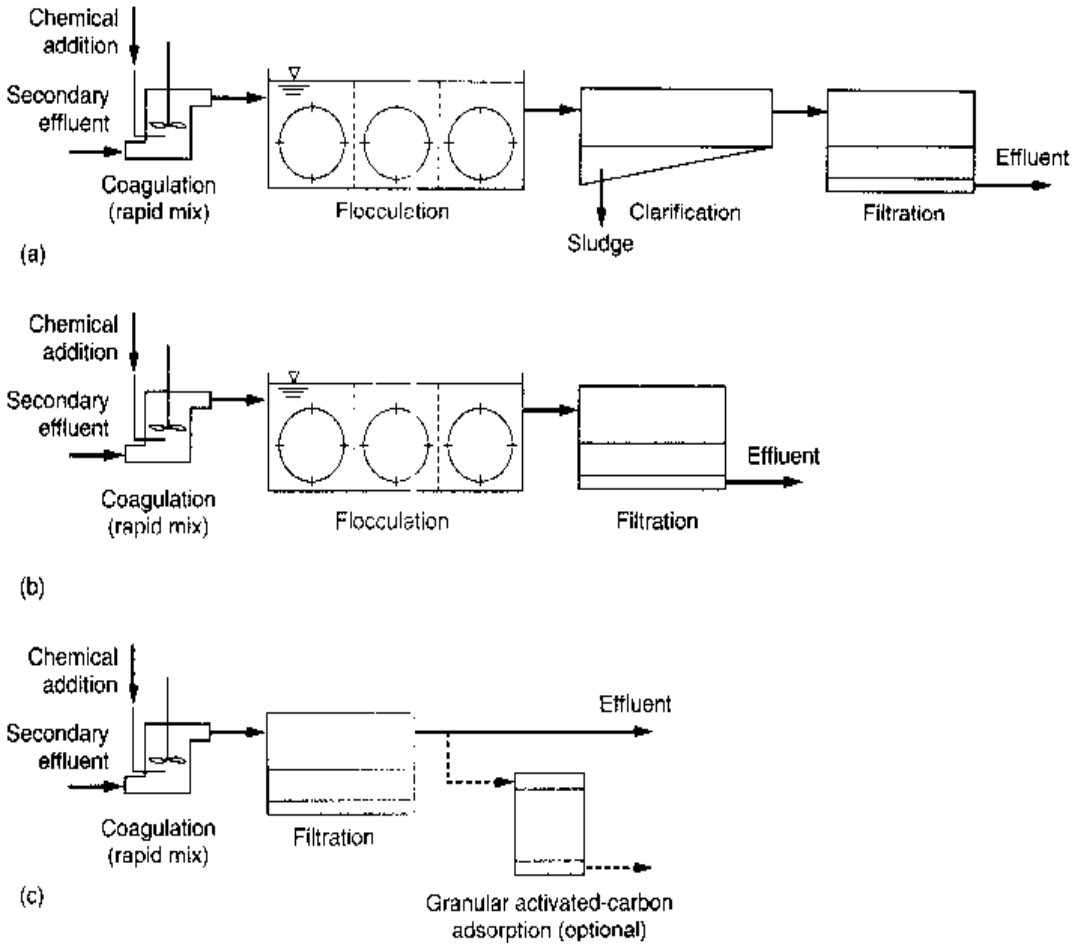

Figure 13–11
Comparison of tertiary treatment systems for wastewater reclamation: (*a*) complete treatment, (*b*) direct filtration, (*c*) contact filtration with optional granular activated-carbon adsorption.

Full Treatment. The full or complete treatment flow diagram, as shown on Fig. 13–11*a*, is essentially a water treatment flow diagram that involves coagulation, flocculation, clarification, filtration, and disinfection. Using secondary effluent as the feed source, the treatment efficacy for this flow diagram in terms of solids, bacteria, and enteric viruses is substantial, and essentially virus-free water can be attained following disinfection (Asano et al., 1992). The disadvantage of the full treatment flow diagram is the added cost of clarification and solids handling (Richards et al., 1993).

Direct Filtration. Direct filtration is the full treatment process flow diagram without the clarifier (see Fig. 13–11*b*). The flocculation basin is used to develop a floc with the addition of alum and polymer for coagulation. A turbidity value of 10 NTU in the conventional secondary effluent is typically used as the economic dividing line when deciding between the use of full treatment versus contact or direct filtration (Tchobanoglous and Burton, 1991). When the effluent from a waste-stabilization lagoon is being filtered, higher influent turbidities are expected; thus, air flotation and the use of chemicals are often required.

If the turbidity of the conventional secondary effluent is less than 10 NTU, contact or direct filtration can be used to meet the stringent turbidity requirement of 2 NTU imposed

by the *California Water Recycling Criteria* without the need for chemicals. When the turbidity of the secondary effluent is above 7 to 9 NTU, coagulant chemical addition will normally be required to obtain effluent turbidity value of 2 NTU and the filters may need to be operated at lower than a conventional loading rate of 200 L/m^2·min (5 gal/ft^2·min).

Contact Filtration. In contact filtration, flocculation and clarification facilities are omitted and the system relies on in-line coagulation prior to filtration (see Fig. 13–11*c*). In the "Pomona Virus Study" (CSDLAC, 1977), it was demonstrated that, with adequate disinfection contact time, the equivalent of full treatment virus attenuation/disinfection could be achieved.

Advanced Wastewater Treatment Process Flow Diagrams

Several examples of existing advanced wastewater treatment process flow diagrams for water reuse are illustrated on Figs. 13–12 through 13–14. A 38,000 m^3/d (10 Mgal/d) advanced wastewater treatment system in operation since 1985 at El Paso, TX, is shown on Fig. 13–12, where reclaimed water is injected directly into a potable water aquifer. At Orange County, CA, groundwater recharge with direct injection of reclaimed water has been in operation since 1976. A schematic flow diagram of the original 57,000 m^3/d (15 Mgal/d) Water Factory 21 water reclamation facility is shown on Fig. 13–13*a*. As shown, the advanced wastewater treatment process includes lime clarification for metals and nutrients removal, recarbonation, granular medium filtration, activated-carbon adsorption, demineralization by reverse osmosis, and chlorination (NRC, 1998). The replacement flow diagram currently (2001) under design is shown on Fig. 13–13*b*. The 3,800 m^3/d (1 Mgal/d) Denver Potable Water Reuse Demonstration Plant is illustrated on Fig. 13–14.

Performance Expectations for Water Reclamation Processes

Over the past 10 years, a considerable amount of operating data and information has become available concerning the performance and reliability of conventional and advanced wastewater treatment processes for the removal of conventional constituents. Limited information is available for the removal of nonconventional and emerging constituents. A summary of unit operations and processes used for the removal of conventional and nonconventional constituents is presented in Table 13–15.

Removal of Conventional Constituents. Typical performance data for conventional and advanced treatment processes for the removal of constituents are reported in Table 13–16. As reported in Table 13–16, it is clear that for conventional constituents a very high treatment efficacy can be attained using a variety of treatment process flow diagrams. The typical variability in the performance of treatment processes for conventional constituents is illustrated on Fig. 13–15 with respect to the effluent turbidity and TSS, and on Fig. 13–16 with respect to the removal of MS2 *bacteriophage (coliphage)*.

Removal of Nonconventional Emerging Constituents and Compounds. Corresponding data for the removal of nonconventional constituents are reported in Table 13–17 for complete treatment (as shown on Fig. 13–11*a*) plus reverse osmosis.

[b] Plaque-forming units/100 mL.

[c] Depends on specific metal and operation of biological treatment process.

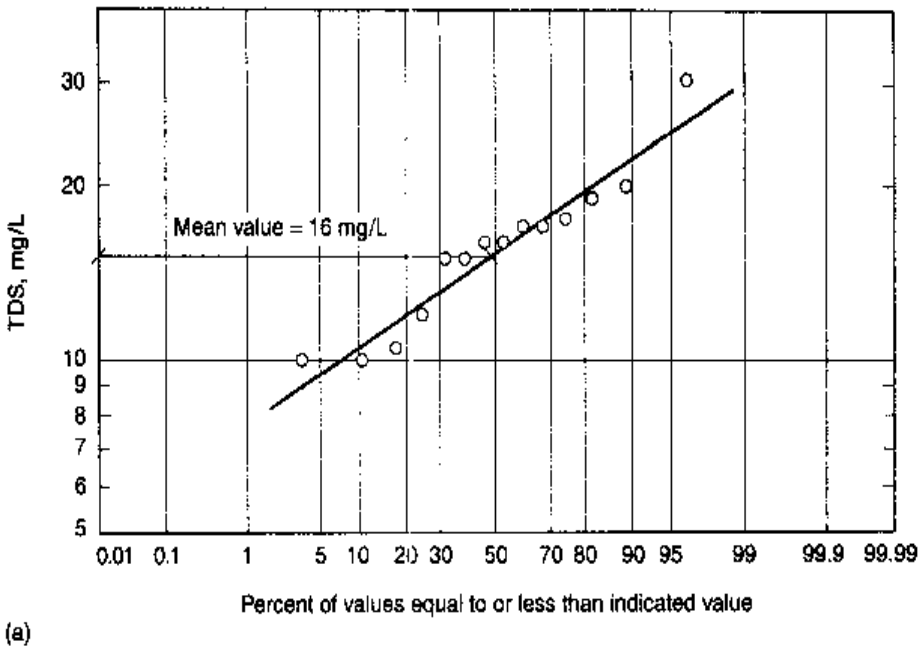
[d] Pharmaceutically active substances.

Table 13–18
Reported removal ranges for selected emerging constituents of concern

Constituent	Removal range, percent		
	Secondary treatment	Microfiltration	Reverse osmosis
N-nitrosodimethylamine (NDMA)	50–75	50–75	50–75
17β-Estradiol			50–100
Alkylphenols ethoxylates (APEOs)	40–80	40–80	40–80

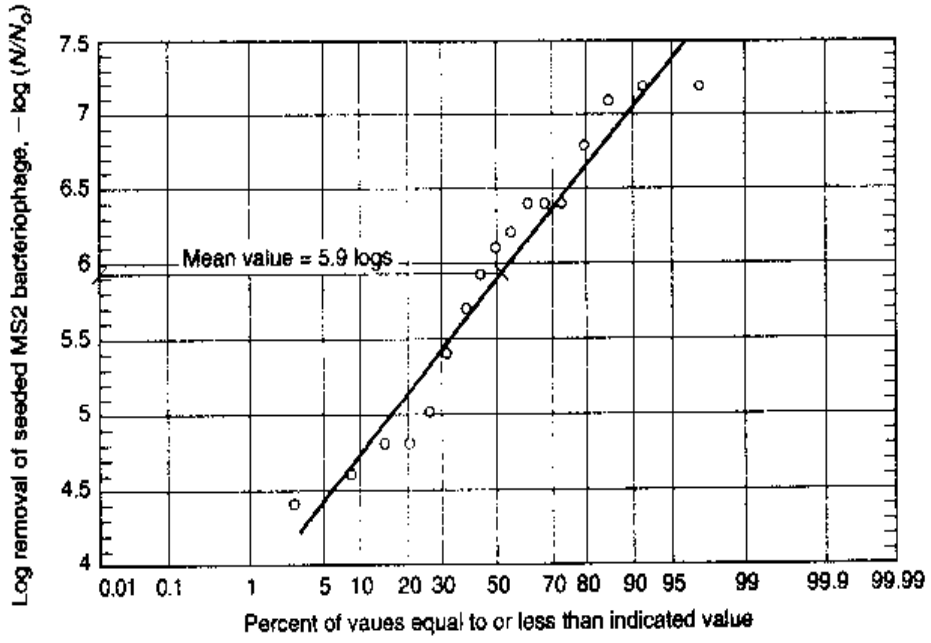
Note: Significant variations have been observed in the concentrations of these constituents in the influent wastewater.

In reviewing the data presented in Table 13–17, it can be concluded that the treatment performance for nonconventional constituents is quite variable and not as well defined. Limited data for emerging constituents are reported in Table 13–18. The impact of the constituents that remain after various treatment processes is of profound importance with respect to the long-term protection of public health and the environment. The emerging constituents were unable to be measured in the ppb or ppt range until just a few years ago, and their impacts are mostly unknown at present. The typical variability in the performance of treatment processes for nonconventional and emerging constituents and compounds is illustrated on Fig. 13–17 with respect to the removal of total dissolved solids (TDS) and seeded MS2 bacteriophage used as a surrogate parameter.



Predicting the Performance of Treatment Process Combinations

By logically combining the various unit processes and operations described in Table 13–15, and based on the experience obtained with the advanced wastewater treatment plants for water reuse shown on Figs. 13–12 through 13–14, it is now possible to produce nearly any quality of water from municipal wastewater. One of the problems, however, is that it is not possible to define directly the performance of the combined processes for selected constituents by field testing. For example, the combined performance of a treatment process for removing enteric viruses through advanced treatment processes, consisting of secondary treatment and advanced treatment—microfiltration and reverse osmosis followed by UV disinfection, cannot directly be tested because it is not possible to grow enteric viruses at high enough concentrations to test the removal in combined treatment process and operation.



It is possible, however, to test the processes individually and to synthesize the results stochastically to predict the performance of the combined process. The procedure for combining performance data from two processes may be outlined as follows. First sufficient data must be gathered to define the performance probability density function for each of the treatment process (see Fig. 13–18). The combined density function is obtained by randomly sampling both distributions and combining the results. The application of this approach is illustrated in Example 13–2.

Figure 13–17

(a)

(b)

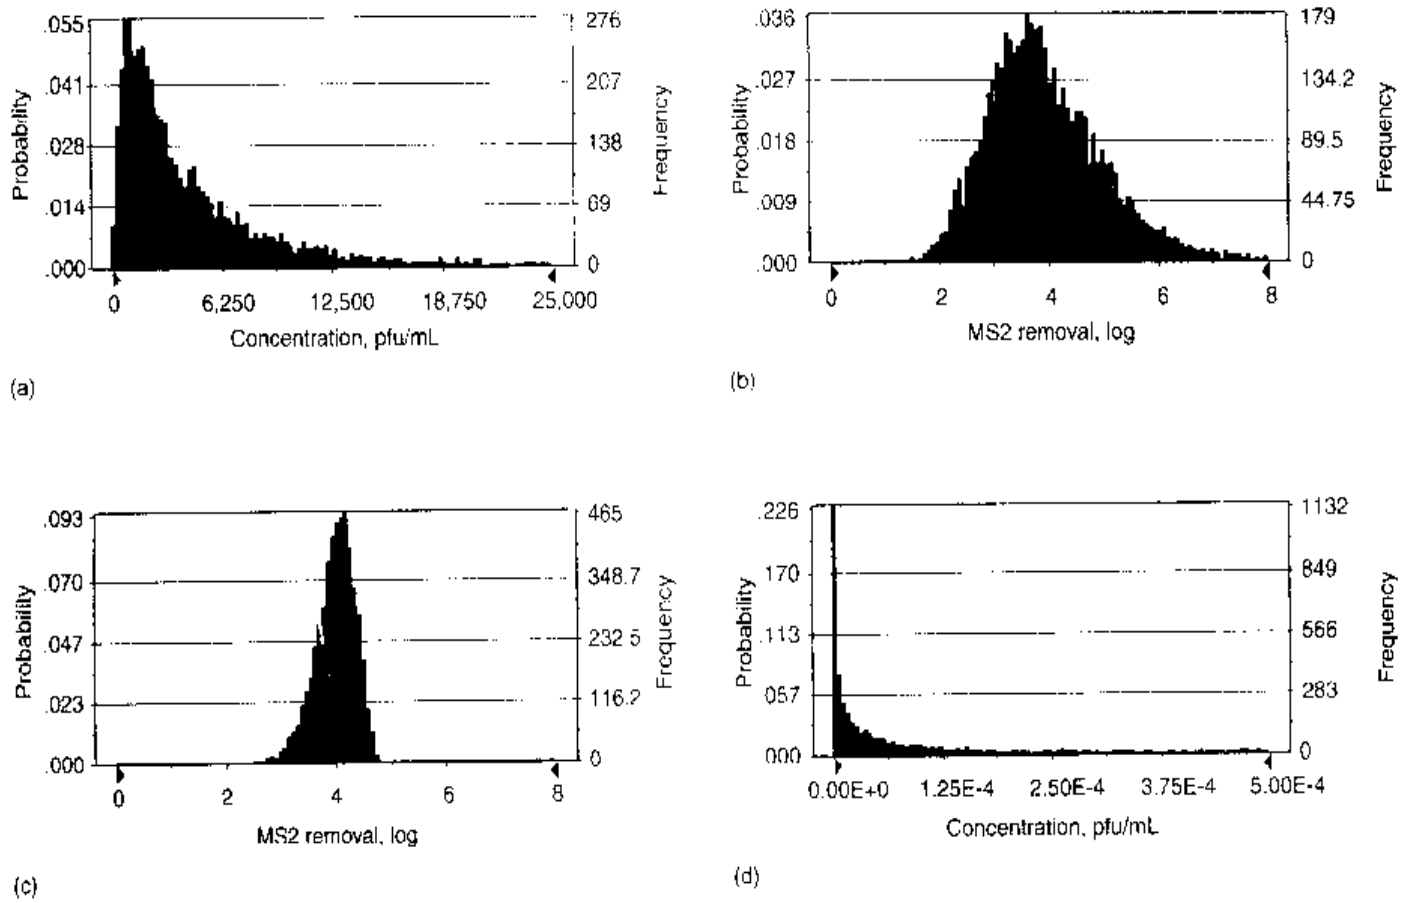

Figure 13–18

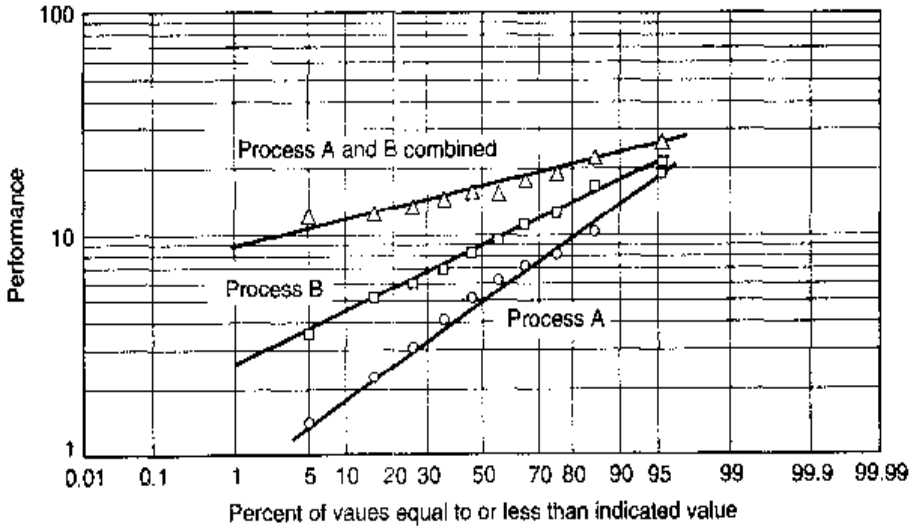
Prediction of effluent quality for combined processes by means of simulation. Probability frequency functions generated by 5000 Monte Carlo simulations based on measured performance data for: (a) influent MS2 coliphage concentration (log-normal distribution), (b) MS2 coliphage removal by ultrafiltration (log-normal distribution), and (c) MS2 coliphage removal by reverse osmosis (Weibull distribution). The predicted effluent quality frequency function, given in plot (d), is obtained by randomly sampling 5000 times from the distributions given in plots (a), (b), and (c). *(Adapted from Olivieri, et al., 1999.)*

EXAMPLE 13–2 Performance Estimation of Combined Treatment Processes Estimate the combined performance of the following two treatment processes. The performance of the individual processes for a given constituent has been measured and is reported below in unitless performance numbers.

Process A	Process B
1.4	3.5
2.2	5.0
3.0	6.0
4.0	6.7
5.0	8.0



(continued)

(*Continued*)

Process A	Process B
6.0	9.0
7.0	11.0
8.0	12.0
10.0	16.0
18.0	20.0

Solution

1. The first step is to determine the nature of the performance distributions. Plotting the performance distributions on both arithmetic and log-probability paper, it was found that the performance distributions were log-normal. The plots for the two processes are shown in the following plot.

2. The expected performance of the combined processes can be estimated by combining randomized performance values for the individual processes.
   a. The individual performance values are randomized using a random-number table or a random-number generator. The procedure is as follows. Starting at any random location within the table, proceed systematically to find the required numbers. The random sequence numbers correspond to the order in which the required numbers are found in the table. For example, starting in row five, the random numbers for Process A are as summarized in the following table. The random numbers for Process B were obtained by starting at row 16.
   b. The next step is to add the corresponding performance values for the two treatment processes as shown in column 5. For example, for the random number 1, the performance value for Process A is 5.0 and the value for Process B is 9.0 for a total of 14.0.
   c. The combined performance values are arranged in ascending order for plotting as shown in column 6.

d. The combined performance is plotted on the graph developed in Step 1.

Process A (1)	Random number (2)	Process B (3)	Random number (4)	Combined processes A and B (5)	Combined processes A and B[a] (6)
1.4	8	3.5	9	14.0	11.5
2.2	4	5.0	2	15.0	12.0
3.0	7	6.0	5	24.7	13.0
4.0	10	6.7	3	18.2	14.0
5.0	1	8.0	10	13.0	15.0
6.0	6	9.0	1	17.0	15.0
7.0	5	11.0	6	15.0	17.0
8.0	9	12.0	7	21.4	18.2
10.0	2	16.0	4	11.5	21.4
18.0	3	20.0	8	12.0	24.7

[a]Performance of combined processes based on random numbers arranged in ascending order.

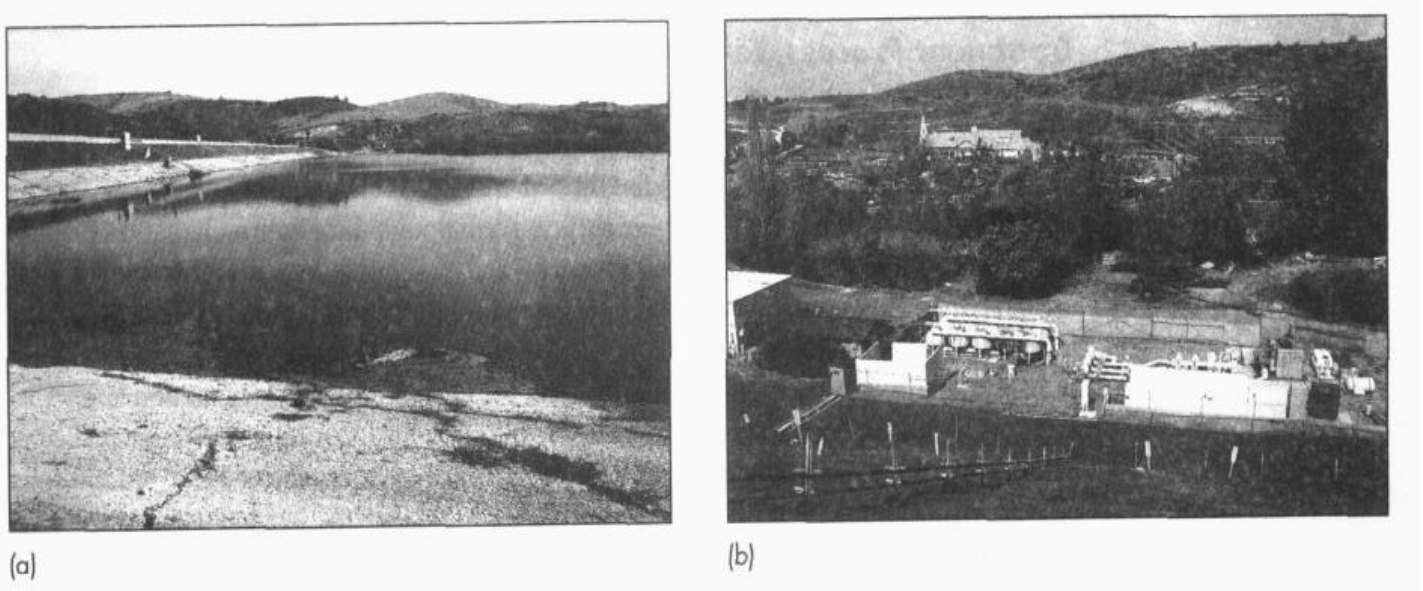
Comment The above procedure is used when it is not possible to field-test a series of processes that are to be used in combination.

Treatment Process Reliability

The reliability of a water reclamation plant can be assessed in terms of its ability to produce acceptable reclaimed water consistently. There are two categories of problems that can affect the performance and reliability of a water reclamation plant: (1) problems caused by the influent wastewater variability, even though the water reclamation plant is designed, operated, and maintained properly, and (2) problems caused by mechanical breakdown, design deficiencies, and operational failures. For the first category of problems, evaluation of the influent water quality variability and the corresponding operational reliability is of particular importance in the design of water reclamation and reuse systems. With respect to the second category of problems, operation and maintenance is cited most frequently as the leading cause of poor plant performance. Thus, reliability is a function of both the inherent process reliability as well as the mechanical process reliability. Each of these topics is considered further in Sec. 15–2 in Chap. 15.

13–5 STORAGE OF RECLAIMED WATER

The storage of reclaimed water has become an important issue in a number of reuse applications and especially where communities are moving toward zero discharge of treated effluent. Reservoirs used for the storage of reclaimed water can be either open or enclosed, with open reservoirs being the most common. To introduce some of the



issues involved in the storage of reclaimed water the following topics are considered in this section: (1) the need for storage, (2) meeting water quality discharge requirements, (3) operation of open storage reservoirs, (4) problems involved with storage of reclaimed water in open and enclosed reservoirs, and (5) management strategies that can be used to overcome the problems encountered in the storage of reclaimed water in open and enclosed reservoirs. The following discussion deals with the storage of reclaimed water for nonpotable applications, more specifically for agricultural, landscape, and industrial applications.

Need for Storage

In many reclaimed water reuse applications, storage facilities for reclaimed water have become an integral part of the water recycling facilities. In golf course watering and landscape irrigation, reclaimed water is applied in the evening or early morning hours. Because of low flow during these time periods, reclaimed water produced during the daytime hours must be stored to meet the irrigation demand. A typical storage reservoir and golf course application site is shown on Fig. 13–19. A large enclosed reservoir is also shown on Fig. 13–20. Because of increasingly restrictive discharge standards to streams and rivers, many communities are moving toward applying treated effluent to land, with the ultimate objective of zero discharge to water bodies. In some locations, treated effluent must be stored during the summer months, because of low-flow conditions in streams, and discharged during the winter high-flow months.

Meeting Water Quality Discharge Requirements

An issue involving water reuse applications where one or more storage reservoirs are involved is where the applicable discharge requirements from the treatment process

(a) (b)

Figure 13–19

Storage and irrigation facilities for reclaimed water: (a) example of large storage reservoir for reclaimed water. The top of the dam used to create the reservoir is shown on the left-hand side, and (b) view from the top of the dam. The battery of agricultural-type filters shown at the base of the dam (just left of center) are used to remove algae and other suspended matter before the reclaimed water is disinfected and applied to the golf course shown in the background behind the clubhouse.

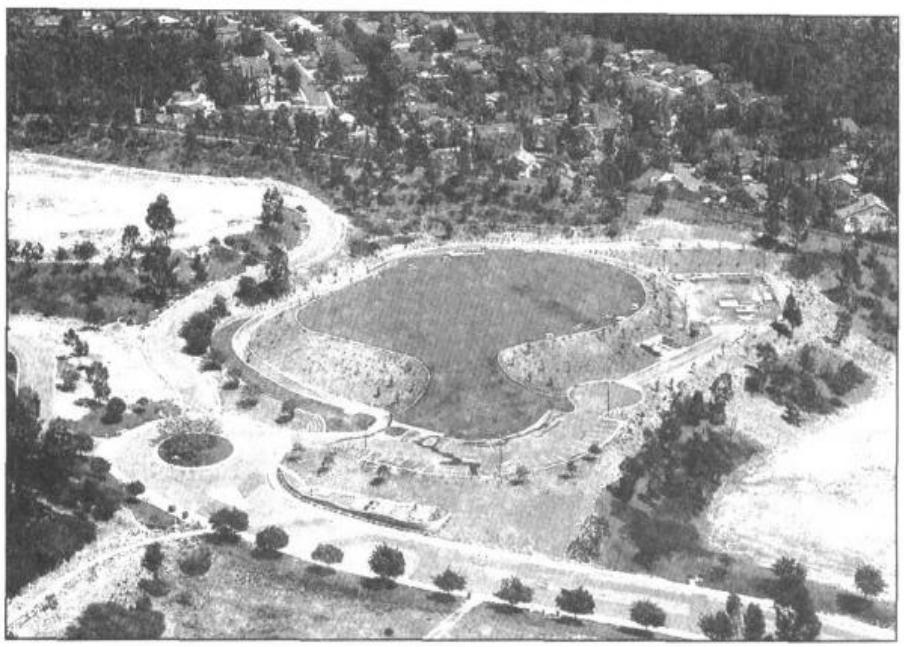


Figure 13–20

Aerial view of a large enclosed storage reservoir for reclaimed water located adjacent to a residential area. The top of the reservoir has been landscaped and is used as a soccer field. *(Photo courtesy Metropolitan Wastewater Department, City of San Diego, aerial photography by Jeran-Aero Graphics.)*

should be met. Historically, water quality discharge requirements were monitored at the point of discharge to the environment (i.e., the point of reuse if all of the water is recycled). In more recent times, it has become common to meet the applicable discharge requirements at the end of the treatment plant. However, where storage is used, it will still be necessary to meet the applicable requirements for reuse when the water is withdrawn. In many cases it will be necessary to disinfect again to meet applicable reuse requirements. To avoid the need to disinfect twice (i.e., at the treatment plant and at the point of reuse), it has been proposed that the reclaimed water storage reservoir be considered part of the treatment process. If the storage reservoir is considered to be part of the treatment process, the water would only have to be disinfected to meet the applicable discharge standards when it is withdrawn for use. If the effluent were not disinfected before being placed in storage, the number of organisms to be disinfected would be reduced by sedimentation and natural decay during storage, depending on the storage conditions. It should be noted, however, that many operating agencies choose to disinfect at the treatment plant to limit the growth of microorganisms on the walls of the transmission pipelines and other locations in the distribution systems.

Operation of Storage Reservoirs

Given the above applications, a number of operating schemes are in use for both open and enclosed reservoirs including (1) off-line storage of peak flows during the daytime hours for nighttime use, (2) flow-through in-line storage, (3) long-term storage of winter flows for summer discharge, and (4) long-term storage of summer flows for winter discharge. Off-line storage is common in water reuse applications to (1) meet the off-hour irrigation water requirements, and (2) minimize pumping costs associated with meeting peak water use demands. Long-term storage of winter flows for reuse during the summer irrigation period is quite common. Estimation of the irrigation area and reservoir capacity required for irrigation and storage requirements is illustrated in Example 13–3. Long-term storage of summer flows for winter discharge occurs where

there are limited local water reuse opportunities and low stream flow limits the amount of treated effluent that can be discharged during the summer months. The type of storage facility required will depend on the amount of storage required to fulfill the rate and duration of application as well as the schedule for reservoir filling.

EXAMPLE 13–3 Determination of Irrigation Area and Reservoir Storage Capacity Requirements for a No Discharge Reclaimed Water Reuse System Determine the irrigation area required for a wastewater land application system. Calculate the reservoir storage volume, assuming that effluent will be stored in the reservoir until the end of the irrigation season. Find the reservoir area, assuming that the reservoir depth may not exceed 6.0 m. Monthly average wastewater flowrates, rainfall, and crop evapotranspiration (ET) values for the system are provided below in Computation Table 1. Assume that water surface evaporation rates are approximately equal to crop ET rates. Based on percolation tests conducted in the land application area, the soil saturated hydraulic conductivity is 37 mm/d. Use a practical application rate of 10 percent of the saturated hydraulic conductivity when calculating maximum allowable percolation rate. The allowable application rate will depend on local soil conditions but will vary from about 10 to 15 percent.

Solution

1. Determine the monthly depth of wastewater that can be applied to the land application area. Follow the procedure shown in Computation Table 1.
   a. From Computation Table 1, *natural percolation* is defined as the portion of total percolation attributable to excess rainfall (i.e., rainfall that exceeds the evaporation rate). Calculate natural percolation by subtracting the crop ET value from the rainfall value for each month. Where crop ET exceeds rainfall, natural percolation equals zero.
   b. Determine the design total percolation depth for each month by multiplying the saturated hydraulic conductivity times the application factor (10 percent), times the number of days per month. For January:

$$\text{January design total percolation} = \left(\frac{37 \text{ mm}}{\text{d}}\right) \times (0.10) \times (31 \text{ d}) = 115 \text{ mm}$$

   Where natural percolation exceeds the design total percolation value for a given month (e.g., in January and February), total percolation is assumed to equal natural percolation.
   c. Calculate the applied percolation depth for each month by subtracting the natural percolation from the total percolation. Applied percolation refers to the portion of percolation attributable to applied wastewater.
   d. Net ET is defined as the crop ET requirement that is not met by rainfall (see Sec. 13–5). Calculate net ET for each month by subtracting rainfall from crop ET. Where rainfall exceeds crop ET, net ET equals zero.

e. Find the depth of applied wastewater for each month by adding applied percolation to net ET. As shown in col. 10 of Computation Table 1, the annual depth of applied wastewater is 1871 mm.

2. Follow the procedure shown in Computation Table 2 to determine the required size of the land application area and storage reservoir.
   a. Determine the wastewater inflow volume to the storage reservoir by multiplying the average monthly wastewater flowrate times the number of days for that month. For January:

$$\text{January wastewater inflow} = \left(\frac{8000\ \text{m}^3}{\text{d}}\right) \times (31\ \text{d}) = 248{,}000\ \text{m}^3$$

   b. Determine the monthly rainfall inflow volume to the storage reservoir by multiplying the monthly rainfall in col. 4 of Computation Table 1 times an assumed area for the storage reservoir. (The assumed area will be modified later to provide the desired depth. Changing assumed values to achieve a given objective is done most easily by using a spreadsheet program, such as the Microsoft Excel.)
   c. Determine the monthly evaporation outflow volume from the storage reservoir by multiplying the monthly crop ET depth in col. 5 of Computation Table 1 times the assumed area for the storage reservoir.
   d. Determine the monthly irrigation outflow volume from the storage reservoir by multiplying the applied wastewater depth in col. 10 of Computation Table 1 times an assumed area for the land application area. Like the assumed area for the storage reservoir, the assumed value for the land application area will be modified later.
   e. Calculate the monthly change in storage reservoir volume by adding the inflow values (wastewater + rainfall) and subtracting the outflow values (evaporation and irrigation) for each month.
3. In a water balance, the annual sum of inflow and outflow values to the storage reservoir should equal zero. Change the assumed value for the land application area until the sum is zero. If the sum is positive, the land application area should be made larger. Conversely, if the sum is negative, the land application area should be made smaller.
4. The annual sum of monthly volume changes for the storage reservoir (now zero) consists of both positive (net inflow) and negative (net outflow) values. Calculate the net volume of wastewater stored in the reservoir, beginning with the first positive volume change after summer. The running volume sum should terminate with zero volume (see the October value in col. 7 of Computation Table 2).
5. Determine the approximate monthly depth of wastewater in the storage reservoir by dividing the monthly storage volume by the assumed storage reservoir area. If the depth exceeds 6.0 m, increase the reservoir area. Conversely, if the depth is much less than 6.0 m, decrease the reservoir area. Due to changes in the reservoir size, the land application area may also have to be adjusted slightly to maintain a zero sum of volume changes.

6. Determine the final storage reservoir and land application area requirements, without construction and buffer allowances.
   a. Determine the storage area. From Computation Table 2, the critical month for storage is April. Thus,

$$\text{Storage reservoir area} = \left(\frac{975{,}319\ \text{m}^3}{6\ \text{m}}\right)\left(\frac{1\ \text{ha}}{10^5\ \text{m}^2}\right) = 16.26\ \text{ha}$$

   b. Determine the land application area. From Computation Table 2, the total amount of water applied is 1,883,738 m^3 and the depth of application from Computation Table 1 is 1.871 m. Thus,

$$\text{Land application area} = \left(\frac{1{,}883{,}738\ \text{m}^3}{1.871\ \text{m}}\right)\left(\frac{1\ \text{ha}}{10^5\ \text{m}^2}\right) = 100.7\ \text{ha}$$

Problems Involved with Storage of Reclaimed Water

The problems encountered with the storage of reclaimed water in open and enclosed reservoirs derive from the residual constituents remaining in the water after treatment and the chemical characteristics of the potable water supply.

Problems with Open Reservoirs. Changes in water quality during storage or impoundment can be significant. The most common problems encountered with the storage of reclaimed water in open reservoirs are listed in Table 13–19 under the categories of physical, chemical, and biological. As noted in Table 13–19, most of the physical parameters are also of aesthetic concerns. In many cases, aesthetic concerns will be the controlling factor in deciding whether the community will accept a proposed water-recycling program. The principal problems with the storage of reclaimed water in open reservoirs are:

- Release of odors, principally hydrogen sulfide
- Temperature stratification
- Loss of chlorine residual
- Low dissolved oxygen resulting in odors and fish kills
- Excessive growth of algae and phytoplankton
- High levels of turbidity and color
- Regrowth of microorganisms
- Water quality deterioration due to bird and rodent populations

Many of these problems are interrelated. For example, the production of hydrogen sulfide odors is related to reservoir stratification caused by temperature differences. The production of hydrogen sulfide is also related to the sulfate concentration in the potable water supply and the amount added during usage. If the sulfate levels in the reclaimed water are greater than about 50 mg/L, hydrogen sulfide production is likely to occur in stratified reclaimed water storage reservoirs. Unfortunately, the amount of residual

Table 13-19 Problems encountered in the operation of open reservoirs used for the storage of reclaimed water

Reservoir problem	Description
Physical/aesthetic:	
Color	The presence of color can affect the aesthetic acceptance of the water. Often caused by the presence of humic materials and fine silts and clays in runoff and the presence of color in the reclaimed water
Odors (primarily H_2S)	One of the most common problems encountered with the storage of reclaimed water. In addition to causing odors, H_2S has a chlorine demand
Temperature	Water may be unusable during certain times of the year
Temperature stratification	Usually occurs once or twice a year depending on the latitude
Turbidity	The presence of turbidity can affect the aesthetic acceptance of the water. Turbidity can be caused by runoff containing silt and clay and by algal growth
Chemical:	
Chlorine	Chlorine and compounds containing chlorine may be toxic to aquatic life in open reservoirs
Dissolved oxygen	Low DO can cause fish kills and allow the release of odors in open reservoirs
Nitrogen	Nutrient capable of stimulating phytoplankton
Phosphorus	Nutrient capable of stimulating phytoplankton
Biological:	
Algae	Presence of excess algae can cause odors, increase turbidity, and clog filters
Aquatic foul	The presence of excessive numbers of aquatic birds can degrade the water quality of the stored water
Bacteria	Regrowth is a common occurrence in open storage reservoirs. May affect possible applications
Chlorophyll	Presence of excess algae and plant matter
Helminths	May affect possible reuse applications
Insects (mosquitoes)	May require spraying of insecticides
Phytoplankton	Presence of excess algae can cause odors, increase turbidity, and clog filters
Protozoa	May affect possible reuse applications
Viruses	May affect possible reuse applications

nitrogen and phosphorus in most reclaimed waters is more than adequate for the growth of algae and other phytoplankton. Materials carried into the storage reservoir by local runoff often cause turbidity and color. Fine clays and silts are difficult to settle and color caused by humic substances is extremely difficult to remove. In some cases the reclaimed water may also have a high color content due to the presence of untreated humic substances that can pass through a treatment process.

Problems with Enclosed Reservoirs. The most common problems encountered with the storage of reclaimed water in enclosed reservoirs are listed in Table 13–20 under the categories of physical, chemical, and biological. The principal problems with the storage of reclaimed water in enclosed reservoirs are:

- Stagnation
- Release of odors, principally hydrogen sulfide
- Loss of chlorine residual (much slower compared to open reservoirs)
- Regrowth of microorganisms

Management Strategies for Open and Enclosed Reservoirs

Management strategies that have been used to overcome the problems cited in Tables 13–19 and 13–20, and discussed above, are summarized in Table 13–21. The strategies for open and enclosed reservoirs are considered in the following discussion.

Strategies for Open Reservoirs. Although all of the strategies listed in Table 13–21 have been used, the most effective strategy for open reclaimed water storage reservoirs has been the use of aeration to provide both oxygen and destratification. A variety of aeration systems have been used to provide oxygen and to eliminate stratification including surface aerators with high pumping capacity, brush aerators, static tube aerators, diffused aeration systems, and the Speece cone (see Secs. 5–4 and 5–12 in Chap. 5). Of these devices the Speece cone is superior with respect to the transfer of

Table 13–20
Problems encountered in the operation of enclosed reservoirs used for the storage of reclaimed water

Reservoir problem	Description
Physical/aesthetic:	
Color	Often caused by the presence of humic materials in reclaimed water
Odors (primarily H_2S)	One of the most common problems encountered with the storage of reclaimed water. In addition to causing odors, H_2S has a chlorine demand
Turbidity	The presence of turbidity can affect the aesthetic acceptance of the water
Chemical:	
Chlorine	Chlorine and compounds containing chlorine may cause odors. Chlorine is used commonly to control biological growths
Dissolved oxygen	Lack of oxygen can lead to the release of odors in enclosed reservoirs
Biological:	
Bacteria	Regrowth has occurred in enclosed storage reservoirs. May affect possible applications
Insects (mosquitoes)	Insects can enter improperly sealed reservoirs. May require spraying of insecticides
Viruses	May affect possible reuse applications

Table 13–21
Management strategies for open and enclosed reservoirs used for the storage of reclaimed water

Management strategies	Comments
Open storage reservoirs	
Aeration/destratification	Installation of aeration facilities can be used to maintain aerobic conditions and eliminate thermal stratification. May result in release of phosphorus from bottom sediments
Alum precipitation	Alum precipitation has been used to remove suspended solids and phosphorus. Can be used to stop release of phosphorus from sediments
Biomanipulation	Control of microorganism growth rates
Copper sulfate addition	Copper sulfate is applied to control the growth of algae. The use of copper may be eliminated because of toxicity concerns over accumulation of copper
Destratification (including recirculation)	Submerged or aspirating mixers can be used to eliminate thermal stratification. Recirculating pumps can also be used. May result in release of phosphorus from bottom sediments
Dilution	Water from other sources can be blended with water from the storage reservoir to manage the water quality
Dredging	Accumulated sediment can be removed annually to limit the formation of deposits and the generation of hydrogen sulfide
Filtration	Water from the storage reservoir can be filtered through a rock filter, a slow sand filter, or a disk-type filter to remove algae and to improve the clarity of the water
Natural microorganism decay	The effectiveness of natural decay will depend on the operation of the reservoir and the detention time
Photooxidation	With proper mixing, advantage can be taken of the beneficial effects of exposing the water to sunlight
Wetlands treatment	Water from the storage reservoir can be passed through a constructed wetland to improve the clarity of the effluent and to remove algae
Withdrawal from selected depths	Varying water quality can be obtained by drawing off water at selected depths within the reservoir
Enclosed storage reservoirs	
Aeration	Maintain residual level of DO to eliminate the formation of odors
Chlorination	Used to control the growth of microorganisms
Recirculation	Adequate recirculation can limit the growth of microorganisms and the formation of odors

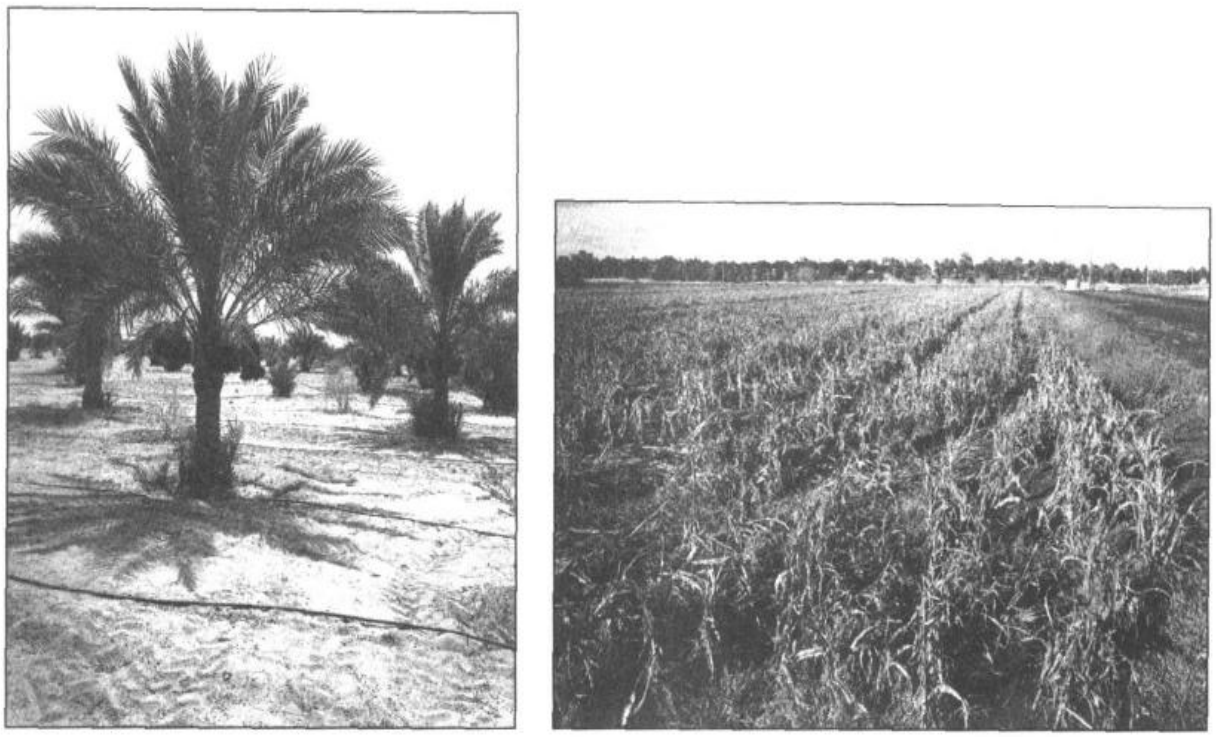
oxygen and for mixing the contents of the reservoir. The power input required for aeration and destratification is on the order of 0.30 to 0.50 kW/1000 m^3. Obviously, the actual power requirement will vary with the physical characteristics of the reservoir including surface area, aspect ratio, depth of the reservoir, and temperature.

The growth of plankton in reservoirs can be controlled using copper sulfate or more selective algicides. The use of chlorine in open reservoirs is not recommended as a control measure. Under certain circumstances chlorine can combine with odor-causing compounds present in the reservoir to form odors with greater intensity. The effective

use of these chemicals, such as copper sulfate, requires microscopic examination of the water to determine the number and type of organisms involved. Ideally, the control chemicals should be applied just at the time when the number of organisms starts to increase rapidly.

Treatment is usually needed when the number of organisms exceeds 500 to 1000 units per milliliter. The required dosage of copper sulfate is influenced by the temperature, alkalinity, and carbon dioxide content of the water. Based on operating experience with water supply storage reservoirs, a copper sulfate dose of 0.3 mg/L can be used without laboratory control. Safe dosages for most fish are 0.5 mg/L, with the exception of trout, for which the safe dosage is on the order of 0.10 mg/L. Because many of the organisms can be controlled with lower dosages, savings are possible with proper control. The dosage of copper sulfate is usually based on the volume of shallow reservoirs or on the upper circulating portion of the reservoir, where the plankton are typically found, in stratified reservoirs. If the depth of the circulation pattern is unknown, a rule of thumb is to use an active depth of about 4.5 m. The frequency of application should be based on microscopic examination.

Several methods are used to apply copper sulfate to reservoir waters. The most common methods are (1) the burlap bag method, (2) the spray method, (3) the blower method, and (4) the continuous dosing method. In the burlap bag method, copper sulfate is placed in a bag in a dose equivalent to 3.0 mg/L. The bag is then dragged through the water from the stern of a rowboat or a motorboat. In the spray and blower methods, copper sulfate is either sprayed or blown over the water surface from a boat, using tree spraying equipment or air blowers. In many reservoirs, copper sulfate is applied continuously using commercial or locally made dosing equipment (Tchobanoglous and Schroeder, 1985).



Strategies for Enclosed Reservoirs. In enclosed reservoirs, effective management strategies include providing facilities to (1) recirculate the contents of the storage basin and (2) add additional chlorine to maintain a residual. In addition to using aeration devices and pumps to promote circulation, the inlet and withdrawal piping can be configured to promote circulation. Generally, the addition of chlorine will be limited to small off-line storage reservoirs, typically used for landscape irrigation and some industrial reuse applications.

13–6 AGRICULTURAL AND LANDSCAPE IRRIGATION

Irrigation of crops was developed in the United States, along with the settlement of the arid West, because irrigation was needed to raise crops and livestock. In the humid eastern United States, irrigation was used to supplement natural rainfall, to increase the number of plantings per year and yield of crops, and to reduce the risk of crop failures during drought periods. Irrigation is also used to maintain recreational lands such as parks and golf courses. An important use of reclaimed water in recent years is for the irrigation of landscaped areas and golf courses in the urban environment.

Evaluation of Irrigation Water Quality

Although irrigation has been practiced throughout the world (see Fig. 13–21) for several millennia, it is only in the last century that the importance of the quality of the irrigation

(a) (b)

Figure 13–21

Typical examples of worldwide use of reclaimed water for agricultural crops (a) date palms using drip irrigation in Acaba Jordan and (b) fodder crop (recently harvested) using flood irrigation in Australia near Brisbane.

water has been recognized. The design approach to irrigation with reclaimed municipal wastewater depends upon whether emphasis is placed on water supply for irrigation or on wastewater treatment via land treatment and disposal.

Physical and Chemical Characteristics. The physical and chemical characteristics of irrigation water are of particular importance in arid zones where extremes of temperature and low humidity result in high rates of evapotranspiration (ET). Evapotranspiration refers to the water lost through evaporation from the soil and surface water bodies and transpiration from plants. Water used for irrigation can vary greatly in quality depending upon type and quantity of dissolved salts. The consequence of evapotranspiration is salt deposition from the applied water, which tends to accumulate in the soil profile. The physical and mechanical properties of the soil, such as degree of dispersion of the soil particles, stability of aggregates, soil structure, and permeability, are sensitive to the types of exchangeable ions present in irrigation water. Thus, when irrigation with reclaimed water is being planned, not only is the crop yield important, but also soil properties must be taken into consideration. The problems, however, are no different from those caused by salinity or trace elements in any water supply and are of concern only if they restrict the use of the water or require special management to maintain acceptable crop yields.

Numerous irrigation water quality guidelines have been proposed. The guidelines presented in Table 13–22 were developed by the University of California Committee of

Table 13-22
Guidelines for interpretations of water quality for irrigation[a]

Potential irrigation problem	Units	Degree of restriction on use: None	Slight to moderate	Severe
Salinity (affects crop water availability):				
EC_w	dS/m or mmho/cm	<0.7	0.7–3.0	>3.0
TDS	mg/L	<450	450–2000	>2000
Permeability (affects infiltration rate of water into the soil. Evaluate using EC_w and SAR or adj R_{Na} together)[b]				
adj R_{Na} = 0–3		and EC_w ≥0.7	0.7–0.2	<0.2
3–6		≥1.2	1.2–0.3	<0.3
6–12		≥1.9	1.9–0.5	<0.5
12–20		≥2.9	2.9–1.3	<1.3
20–40		≥5.0	5.0–2.9	<2.9
Specific ion toxicity (affects sensitive crops):[c]				
Sodium (Na)				
Surface irrigation	SAR	<3	3–9	>9
Sprinkler irrigation	mg/L	<70	>70	
Chloride (Cl)				
Surface irrigation	mg/L	<140	140–350	>350
Sprinkler irrigation	mg/L	<100	>100	
Boron (B)	mg/L	<0.7	0.7–3.0	>3.0
Trace elements (see Table 13–23)				
Miscellaneous effects (affects susceptible crops):				
Nitrogen (total-N)	mg/L	<5	5–30	>30
Bicarbonate (HCO_3) (overhead sprinkling only)	mg/L	<90	90–500	>500
pH	unit		Normal range 6.5–8.4	
Residual chlorine (overhead sprinkling only)	mg/L	<1.0	1.0–5.0	>5.0

[a] Adapted from Ayers and Westcot (1985) and Pettygrove and Asano (1985).

[b] For wastewater irrigation, it is recommended that SAR be adjusted to include a more correct estimate of calcium in the soil water. A procedure is given in Eq. (13–11) and Table 13–24. The adjusted sodium adsorption ratio (adj R_{Na}) calculated by this procedure is to be substituted for the SAR value in this table.

[c] See also Table 13–23.

Consultants and were expanded subsequently by Ayers and Westcot (1985). The long-term influence of water quality on crop production, soil conditions, and farm management is emphasized, and the guidelines are applicable to both freshwater and reclaimed water. Four categories of potential management problems associated with water quality in irrigation are (1) salinity, (2) specific ion toxicity, (3) water infiltration rate, and (4) other problems.

Salinity. Salinity of an irrigation water is determined by measuring its electrical conductivity and is the most important parameter in determining the suitability of a water for irrigation. The electrical conductivity (EC) of a water is used as a surrogate measure of total dissolved solids (TDS) concentration. The electrical conductivity is expressed as decisiemens per meter (dS/m) or mmho/cm. It should be noted that one dS/m is equivalent to one mmho/cm. Values for salinity are also reported as TDS in mg/L. For most agricultural irrigation purposes, the values for EC and TDS are related to each other and can be converted within an accuracy of about 10 percent using Eq. (13–7) (Pettygrove and Asano, 1985).

$$\text{TDS (mg/L)} \approx \text{EC (dS/m or mmho/cm)} \times 640 \tag{13–7}$$

The presence of salts affects plant growth in three ways: (1) osmotic effects, caused by the total dissolved salt concentration in the soil water; (2) specific ion toxicity, caused by the concentration of individual ions; and (3) soil particle dispersion, caused by high sodium and low salinity. With increasing soil salinity in the root zone, plants expend more of their available energy on adjusting the salt concentration within the tissue (osmotic adjustment) to obtain needed water from the soil. Consequently, less energy is available for plant growth.

In irrigated areas, salts originate from the local groundwater or from salts in the applied water. Salts tend to concentrate in the root zone due to evapotranspiration, and plant damage is tied closely to an increase in soil salinity. Establishing a net downward flux of water and salt through the root zone is the only practical way to manage a salinity problem. Under such conditions, good drainage is essential to allow a continuous movement of water and salt below the root zone. Long-term use of reclaimed water for irrigation in which only the conventional constituents have been removed is not possible without adequate drainage.

If more water is applied than the plant uses, the excess water will percolate below the root zone, carrying with it a portion of the accumulated salts. Consequently, the soil salinity will reach some constant value dependent on the leaching fraction. The fraction of applied water that passes through the entire rooting depth and percolates below is called the leaching fraction (LF)

$$\text{LF} = \frac{D_d}{D_i} = \frac{(D_i - \text{ET}_c)}{D_i} \tag{13–8}$$

where LF = leaching fraction
D_d = depth of water leached below the root zone, mm (in)
D_i = depth of water applied at the surface, mm (in)
ET_c = crop evapotranspiration, mm (in)

A high leaching fraction results in less salt accumulation in the root zone. If the salinity of irrigation water (EC_w) and the leaching fraction are known, salinity of the drainage water that percolates below the rooting depth can be estimated by using Eq. (13–9):

$$EC_{dw} = \frac{EC_w}{LF} \tag{13–9}$$

where EC_{dw} = salinity of the drainage water percolating below the root zone
EC_w = salinity of irrigation water

The EC_{dw} value is used to assess the potential effects on crop yield and on groundwater. For salinity management, it is often assumed that EC_{dw} is equal to the salinity of the saturation extract of the soil sample, EC_e. This assumption is, however, conservative in that EC_{dw} occurs at the soil-water potential of field capacity and EC_e occurs at a potential of zero, by definition, at laboratory condition. For a quick check, the value of EC_{dw} can be estimated as twice the value of EC_e for most soils.

EXAMPLE 13–4 Calculation of Drainage Water Quality A crop is irrigated with reclaimed water whose salinity (EC_w), measured by electrical conductivity, is 1.0 dS/m. If the crop is irrigated to achieve a leaching fraction of 0.15 (i.e., 85 percent of the applied water is used by the crop or lost through evapotranspiration): (1) Calculate the salinity of the deep percolate water, and (2) Determine the appropriate leaching fraction to maintain crop yield. The crop is known to suffer significant loss in yield when TDS of the soil water exceeds 5000 mg/L.

Solution

1. After many successive irrigations, the salt accumulation in the soil will approach an equilibrium concentration based on the salinity of the applied irrigation water and the leaching fraction. Thus, the salinity of the water (drainage water) that percolates below the root zone can be estimated using Eq. (13–9).

$$EC_{dw} = \frac{EC_w}{LF} = \frac{1.0}{0.15} = 6.7 \text{ dS/m}$$

2. Estimate the TDS of the drainage water using Eq. (13–7).

TDS (mg/L) = EC (mmho/cm or dS/m) × 640

TDS (mg/L) = 6.7 × 640 = 4290 mg/L (ok less than 5000 mg/L)

3. Determine the leaching fraction using Eq. (13–9).

$$LF = \frac{EC_w}{EC_{dw}} = \frac{1.0 \times 640}{4290} = 0.15$$

Thus, to prevent loss in yield, a minimum of 15 percent of the applied water will be needed to carry salts below root zone and 85 percent will be consumed by evapotranspiration.

Specific Ion Toxicity. If the decline of crop growth is due to excessive concentrations of specific ions, rather than osmotic effects alone, it is referred to as "specific ion toxicity." As shown in Table 13–22, the ions of most concern in wastewater are sodium, chloride, and boron. The most prevalent toxicity from the use of reclaimed water is from boron. The source of boron is usually household detergents or discharges from industrial plants. The quantities of chloride and sodium also increase as a result of domestic usage, especially where water softeners are used.

For sensitive crops, specific ion toxicity is difficult to correct short of changing the crop or the water source. The problem is also accentuated by hot and dry climatic conditions due to high evapotranspiration rates. The suggested maximum trace element concentrations for irrigation waters are reported in Table 13–23. In severe cases, these elements tend to accumulate in plants and soils, which could result in human and animal health hazards or cause phytotoxicity in plants (Ayers and Westcot, 1985).

Water Infiltration Rate. In addition to the sodium toxicity discussed above, another indirect effect of high sodium content is the deterioration of the physical condition of a soil (formation of crusts, waterlogging, reduced soil permeability). If the infiltration rate is greatly reduced, it may be impossible to supply the crop or landscape plant with enough water for good growth. In addition, reclaimed water irrigation systems are often located on less desirable soils or soils already having permeability and management problems. It may be necessary, in these cases, to modify soil profiles by excavating and rearranging the affected land.

The water infiltration problem occurs within the top few centimeters of the soil and is mainly related to the structural stability of the surface soil. To predict a potential infiltration problem, the sodium adsorption ratio (SAR) is often used (Ayers and Westcot, 1985).

$$\text{SAR} = \frac{\text{Na}^+}{\sqrt{\dfrac{\text{Ca}^{2+} + \text{Mg}^{2+}}{2}}} \tag{13–10}$$

where the cation concentrations are expressed in meq/L.

The adjusted sodium adsorption ratio (adj R_{Na}) is a modification of Eq. (13–10), which takes into account changes in calcium solubility in the soil water (Ayers and Westcot, 1985; and Suarez, 1981).

$$\text{adj } R_{Na} = \frac{\text{Na}^+}{\sqrt{\dfrac{\text{Ca}_x^{2+} + \text{Mg}^{2+}}{2}}} \tag{13–11}$$

where Na^+ and Mg^{2+} concentrations are expressed in meq/L, and the value of Ca_x^{2+}, also expressed in meq/L, is obtained from Table 13–24.

Use of the adj R_{Na} value is preferred in irrigation applications with reclaimed water because it reflects the changes in calcium in the soil water more accurately. At a given sodium adsorption ratio, the infiltration rate increases as salinity increases or decreases as salinity decreases. Therefore, SAR, or adj R_{Na} and electrical conductivity (EC_w) of

Table 13–23
Recommended maximum concentrations of trace elements in irrigation waters[a]

Element	Recommended maximum concentration,[b] mg/L	Remarks
Al (aluminum)	5.0	Can cause nonproductivity in acid soils (pH < 5.5), but more alkaline soils at pH > 5.5 will precipitate the ion and eliminate any toxicity
As (arsenic)	0.10	Toxicity to plants varies widely, ranging from 12 mg/L for Sudan grass to less than 0.05 mg/L for rice
Be (beryllium)	0.10	Toxicity to plants varies widely, ranging from 5 mg/L for kale to 0.5 mg/L for bush beans
Cd (cadmium)	0.010	Toxic to beans, beets, and turnips at concentrations as low as 0.1 mg/L in nutrient solutions. Conservative limits recommended because of its potential for accumulation in plants and soils to concentrations that may be harmful to humans
Co (cobalt)	0.050	Toxic to tomato plants at 0.1 mg/L in nutrient solution. Tends to be inactivated by neutral and alkaline soils
Cr (chromium)	0.10	Not generally recognized as an essential growth element. Conservative limits recommended because of lack of knowledge on toxicity to plants
Cu (copper)	0.20	Toxic to a number of plants at 0.1 to 1.0 mg/L in nutrient solutions
F (fluoride)	1.0	Inactivated by neutral and alkaline soils
Fe (iron)	5.0	Not toxic to plants in aerated soils but can contribute to soil acidification and loss of reduced availability of essential phosphorus and molybdenum. Overhead sprinkling may result in unsightly deposits on plants, equipment, and buildings
Li (lithium)	2.5	Tolerated by most crops up to 5 mg/L; mobile in soil. Toxic to citrus at low levels (>0.075 mg/L). Acts similar to boron
Mn (manganese)	0.20	Toxic to a number of crops at a few tenths mg to a few mg/L, but usually only in acid soils
Mo (molybdenum)	0.010	Not toxic to plants at normal concentrations in soil and water. Can be toxic to livestock if forage is grown in soils with high levels of available molybdenum
Ni (nickel)	0.20	Toxic to a number of plants at 0.5 to 1.0 mg/L; reduced toxicity at neutral or alkaline pH
Pb (lead)	5.00	Can inhibit plant cell growth at very high concentrations
Se (selenium)	0.020	Toxic to plants at concentrations as low as 0.025 mg/L and toxic to livestock if forage is grown in soils with relatively high levels of added selenium. An essential element for animals but in very low concentrations
Sn (tin)	—	Effectively excluded by plants; specific tolerance unknown
Ti (titanium)	—	(See remark for tin)
W (tungsten)	—	(See remark for tin)
V (vanadium)	0.10	Toxic to many plants at relatively low concentrations
Zn (zinc)	2.0	Toxic to many plants at widely varying concentrations; reduced toxicity at pH > 6.0 and in fine-textured or organic soils

[a] Adapted from Ayers and Westcot (1985) and NAS (1972).

[b] The maximum concentration is based on a water application rate of 1.25 m/yr (4 ft/yr) that is consistent with good agricultural practice.

Table 13–24
Values of Ca_x^{2-} used in Eq. (13–11) as a function of the HCO_3/Ca^{2+} ratio and solubility[a]

[a] Adapted from Pettygrove and Asano (1985).

irrigation water should be used in combination to evaluate the potential permeability problem as shown in Table 13–22.

Reclaimed water is normally high in calcium, and there is little concern for the water dissolving and leaching too much calcium from the surface soil (see Example 13–5). However, reclaimed water is sometimes high in sodium; the resulting high SAR is a major concern in planning irrigation projects with reclaimed water.

EXAMPLE 13-5 Calculation of Adjusted Sodium Adsorption Ratio and Evaluation of Potential Water Infiltration Problems The following water quality analyses were reported on an aerated lagoon effluent which will be used for irrigating agricultural land. Using the reported water quality data: (1) calculate adj R_{Na}, and (2) determine whether an infiltration problem may develop by using this effluent for irrigation.

Water quality parameter	Concentration, mg/L
BOD	39
TSS	160
Total N	4.4
Total P	5.5
pH[a]	7.7
Cations:	
Ca^{2+}	37
Mg^{2+}	46
Na^{+}	410
K	27
Anions:	
HCO_3^-	295
SO_4^{2-}	66
Cl	526
Electrical conductivity (dS/m)	2.4
TDS	1536
Boron	1.2
Alkalinity (total, as $CaCO_3$)	242
Hardness (total, as $CaCO_3$)	281

[a]Unitless.

Solution

1. Calculate the adj R_{Na} using Eq. (13–11) and the values given in Table 13–24.
   a. Convert the concentrations of the related water quality parameters to meq/L

Ca^{2+} = 37/20.04 = 1.85 meq/L

Mg^{2+} = 46/12.15 = 3.79 meq/L

Na^{+} = 410/23 = 17.83 meq/L

HCO_3^- = 295/61 = 4.84 meq/L

b. Determine the value of Ca_x^{2+} in Eq. (13–11) using the given water quality data.
   i. Salinity of applied water (EC_w) = 2.4 dS/m
   ii. Ratio of HCO_3/Ca^{2+} = 4.84/1.85 = 2.62
   iii. From Table 13–24, the value of Ca_x^{2+} = 1.20 meq/L
c. The adj R_{Na} is

$$\text{adj } R_{Na} = \frac{Na^+}{\sqrt{\frac{Ca_x^{2+} + Mg^{2+}}{2}}} = \frac{17.83}{\sqrt{\frac{1.20 + 3.79}{2}}} = 11.29$$

2. Determine whether an infiltration problem will develop.

Entering Table 13–22 with adj R_{Na} = 11.29 and EC_w = 2.4 dS/m, no restrictions are indicated for use of this reclaimed wastewater.

Nutrients. The nutrients in reclaimed water provide fertilizer value for crop or landscape production. However, in certain instances, when nutrients are in excess of plant needs they can cause problems, as described below. Nutrients that are important to agriculture and landscape management include N, P, and occasionally K, Zn, B, and S. The most beneficial and the most frequently excessive nutrient in reclaimed water is nitrogen.

The nitrogen in reclaimed water can replace equal amounts of commercial fertilizer during the early to midseason crop-growing period. Excessive nitrogen in the latter part of the growing period may be detrimental to many crops, causing excessive vegetative growth, delayed or uneven maturity, or reduced crop quality. If alternate low-nitrogen water is available, a switch in water supplies or blending of reclaimed water with other water supplies has been used to keep nitrogen under control, otherwise expensive seasonal denitrification would be required.

Other Problems

Clogging problems with sprinkler and drip irrigation systems have been reported, particularly with oxidation pond effluent. Biological growth (slimes) in the sprinkler head, emitter orifice, or supply line causes plugging, as do heavy concentrations of algae and suspended solids. The most frequent clogging problems occur with drip irrigation systems. From the standpoint of public health, such systems are often considered ideal, as they are totally enclosed, minimizing the problems of worker exposure to reclaimed water or spray drift.

In reclaimed water that is chlorinated, chlorine residuals of less than 1 mg/L do not affect plant foliage, but chlorine residuals in excess of 5 mg/L can cause severe plant damage when reclaimed water is sprayed directly on foliage.

EXAMPLE 13–6 Suitability and Effects of Various Irrigation Waters Analyses of four representative waters in California are presented in the following data table. The waters are: (1) the relatively unpolluted Sacramento River, (2) a moderately saline groundwater in San Joaquin County, and (3) two reclaimed municipal wastewaters from the cities of Fresno and Bakersfield. Assuming the following conditions are applicable, determine the suitability of these waters for irrigation.

1. Daily crop water demand varies during the growing season and among crop types. The range of water demand may be from a low of 2 mm (0.08 in/d) to a high of 7.6 to 10 mm/d (0.3 to 0.4 in/d).
2. On-farm management of reclaimed wastewater must take crop water demand into account, and the irrigation objective should be to use the reclaimed wastewater efficiently to produce a crop.

Constituents[a]	Sacramento River	San Joaquin County groundwater	Fresno wastewater effluent	Bakersfield wastewater effluent
EC (dS/m)	0.11	1.25	0.69	0.77
pH	7.1	7.7	8.6	7.0
Ca^{2-}	10	100	24.0	47
Mg^{2+}	5	33	12.8	5
Na^{+}	6	92	80	109
K^{-}	1.5	3.9	13.8	26
SAR	0.4	2.0	3.3	4.1
HCO_3^-	42	190	236	218
SO_4^{2-}	7.3	110	—	62
Cl^-	2.2	200	70	107
$NO_3^- + NH_3$-N	0.08	5.9	14[b]	0.5[c]
B	—	1.4	0.43	0.38
TDS[d]	72	800	442	477
As			<0.002	
Cd			<0.002	<0.01
Cr			<0.02	
Pb			<0.05	

[a] All concentrations are expressed in mg/L except electrical conductivity (EC) and pH.

[b] Total Kjeldahl-N.

[c] NO_3^--N. A total-N of 20 to 25 mg/L was reported.

[d] TDS values estimated using Eq. (13–7).

Solution

1. Evaluation for the suitability of various irrigation waters is made based on the information given in Table 13–22.

Problem area	Degree of problem[a]			
	Sacramento River	San Joaquin County groundwater	Fresno wastewater effluent	Bakersfield wastewater effluent
Salinity	N	S–M	N	S–M
Infiltration	SV	N	S–M	S–M
Toxicity (sensitive crops only)				
Na^+				
Surface irrigation	N	N	S–M	S–M
Sprinkler irrigation	N	S–M	S–M	S–M
Cl^-				
Surface irrigation	N	S–M	N	N
Sprinkler irrigation	N	S–M	N	S–M
B	—	S–M	N	N
Miscellaneous (susceptible crops only)				
N	N	S–M	S–M	N
HCO_3	N	S–M	S–M	S–M

[a]N = no problem, S–M = slight to moderate problem, and SV = severe problem expected when using respective water for a long period of time.

2. Although the water quality of the two reclaimed waters is such that minor water infiltration, toxicity, and miscellaneous problems may be anticipated from use, normal agronomic practice used in the area has proved to be adequate to allow full production of adapted crops. The cities of Fresno and Bakersfield have a long history of using reclaimed water for irrigation.

13–7 INDUSTRIAL WATER REUSE

Industrial water use includes water for such purposes as processing, washing, and cooling in facilities that manufacture products. Major water-using industries include steel, chemical and allied products, paper and allied products, and petroleum refining. Industrial water reuse represents a significant potential application for reclaimed water in the United States and other industrialized countries. Industrial uses of reclaimed water from external sources such as reclaimed municipal wastewater include evaporative cooling water, boiler feedwater, process water, and landscaping and maintenance of industrial grounds. Water recycling within an industrial plant is normally an integral part of the

industrial process, and treated and reclaimed water is recycled to conserve water and avoid stringent discharge requirements.

Industrial Water Use

Total industrial water use during 1995 was estimated to be 103 × 10^6 m^3/d (27,100 Mgal/d). Industrial freshwater use was an estimated 97 × 10^6 m^3/d (25,500 Mgal/d) during 1995, and represents about 7 percent of freshwater use for all off-stream categories. Self-supplied industrial withdrawals were an estimated 78 × 10^6 m^3/d (20,700 Mgal/d) of freshwater and 6 × 10^6 m^3/d (1660 Mgal/d) of saline water. Surface water was the source for 82 percent of self-supplied industrial withdrawals; groundwater, 18 percent; and reclaimed wastewater less than 1 percent. Public-supply deliveries to industries were about 18 × 10^6 m^3/d (4750 Mgal/d) and accounted for 12 percent total public-supply withdrawals. The Great Lakes and Ohio water resources regions had the largest fresh- and saline-water withdrawals for industrial purposes in 1995 (Solley et al., 1998).

Cooling Tower Makeup Water

Among several industrial water reuse applications, cooling tower makeup water (see Fig. 13–22) represents a significant water use for many industries and is currently the predominant industrial water reuse application. For industries such as electric power generating stations, oil refining, and many other types of manufacturing plants, one-quarter to more than one-half of the total water use may be cooling tower makeup water. Because a cooling tower normally operates as a closed-loop system, it can be viewed as a separate water system with its own specific set of water quality requirements, largely independent of the particular industry involved. Thus, using reclaimed water for cooling tower makeup water is relatively easy and is practiced in many locations in the United States.

The onsite water reclamation plant for the cooling tower operations at the Palo Verde Nuclear Generating Station in Arizona is shown on Fig. 13–23. Secondary effluent from the cities of Tolleson and Phoenix is pumped 61 km (38 miles) to this site. Before using the effluent, it is subjected to advanced treatment consisting of (1) biological nitrification, (2) lime and soda ash addition for softening and phosphorus

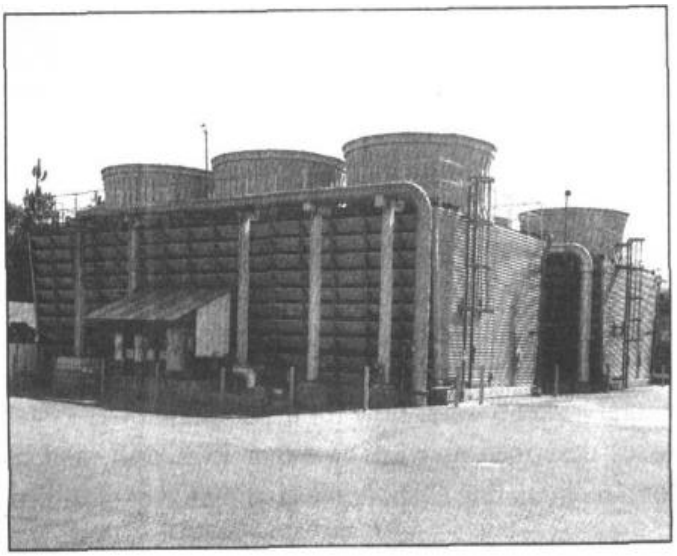

Figure 13–22

Typical industrial cooling towers operated with reclaimed wastewater.

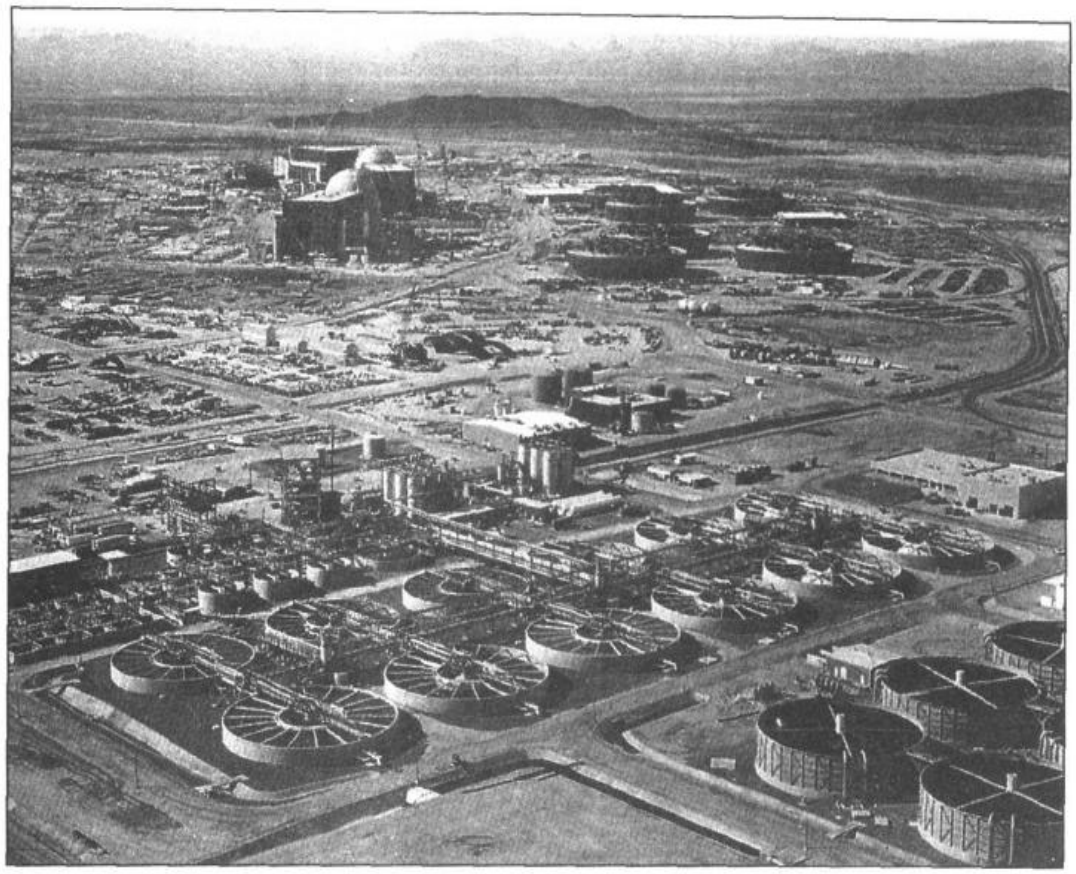

Figure 13–23

Onsite wastewater reclamation plant for the cooling tower operations at the Palo Verde Nuclear Generating Station. The secondary treated effluents from cities of Tolleson and Phoenix, AZ, are pumped 61 km (38 mi) to this site and undergo advanced wastewater treatment. *(Photo courtesy of Arizona Nuclear Power Project.)*

removal, (3) filtration, and (4) chlorination. The purpose of the advanced treatment is to reduce corrosion and scaling in the cooling tower systems.

Water and Salt Balances in Cooling Tower

The basic principle of cooling tower operation is that of evaporative condensation and exchange of sensible heat. The air and water mixture releases latent heat of vaporization. Water exposed to the atmosphere evaporates and as the water changes to vapor, heat is consumed, which amounts to approximately 2.3 kJ/g (1000 Btu/lb) of water evaporated.

Under normal operating conditions, the loss of water discharged from the cooling tower to the atmosphere as hot, moist vapor amounts to approximately 1.2 percent for each 5.5°C (10°F) of cooling range. Drift, or water lost from the top of the tower to the wind, is the second mechanism by which water is lost from the cooling system. About 0.005 percent of the recirculating water is lost in this way. While evaporation results in a loss of water from the system, the salt concentration is increased because salts are not removed by evaporation. To prevent the formation of precipitates in the resulting more-concentrated tower water, a portion of the concentrated cooling water is bled off and replaced with low-salt-makeup water to maintain a proper salt balance. This highly saline water bled off from the cooling tower system is called *blowdown*.

The total makeup water flow for the cooling tower system includes all three of the water losses described above (i.e., vapor loss, drift, and blowdown). The definition sketch for a recirculating evaporative cooling tower is shown on Fig. 13–24.

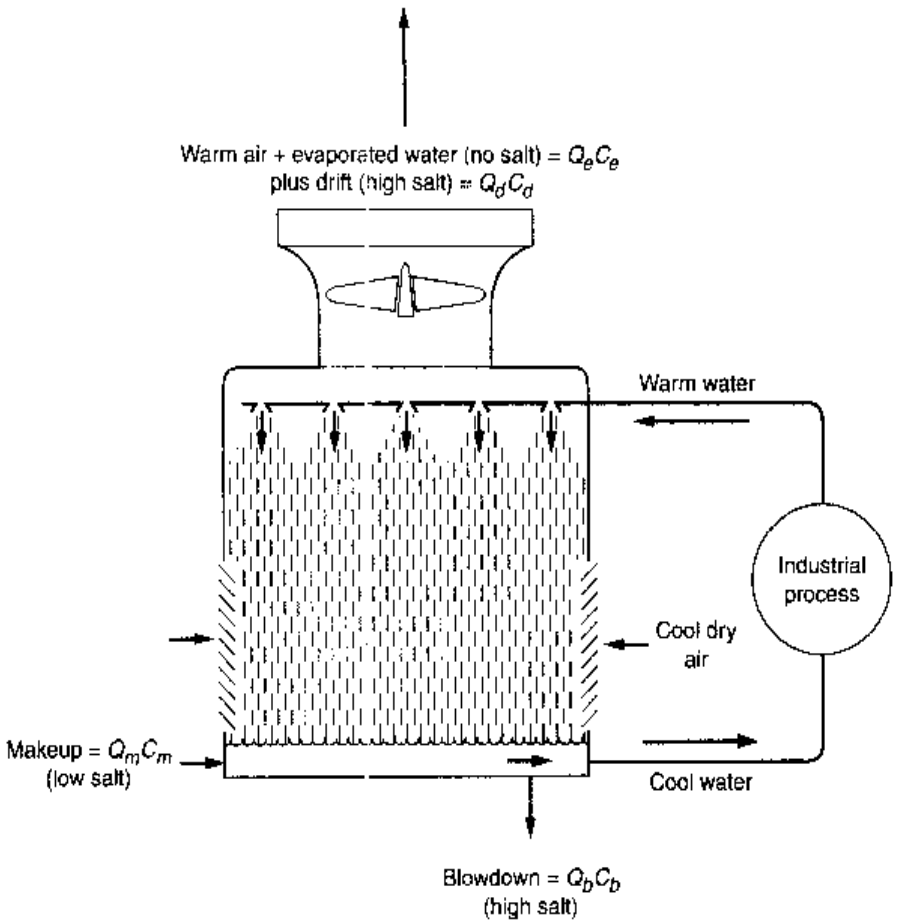

Figure 13–24
Definition sketch for salt balance in the recirculating, evaporative cooling tower.

The water balance around the cooling tower is

Accumulation = in − out

At steady state the accumulation term is equal to zero and

$$Q_m = Q_b + Q_d + Q_e \tag{13–12}$$

where Q_m = makeup water flow, L/min
Q_b = blowdown flow, L/min
Q_d = drift flow, L/min
Q_e = evaporation loss, L/min

Drift flow Q_d is normally small enough to be ignored, as noted previously (<0.005 percent).

In a similar way, the salt balance in the cooling tower is

$$Q_mC_m = Q_bC_b + Q_dC_d + Q_eC_e \tag{13–13}$$

where C_m = salt concentration in makeup water flow, mg/L
C_b = salt concentration in blowdown flow, mg/L
C_d = salt concentration in drift flow, mg/L
C_e = salt concentration in evaporation loss, mg/L

Because Q_d is negligible, the term $Q_d C_d$ can be omitted without serious error. Further, because the concentration of salts in the evaporation water is also negligible under normal operating conditions Eq. (13–13) can be reduced to Eq. (13–14).

$$Q_m C_m = Q_b C_b \tag{13–14}$$

The magnitude of the blowdown flow (and thus the makeup flow) is dependent upon the concentration of potential precipitants in the makeup water. The ratio of the concentration of the salt C_b in the blowdown to its concentration C_m in the makeup water is known as the cycles of concentration.

$$\text{Cycles of concentration} = C_b/C_m \tag{13–15}$$

Combining Eqs. (13–14) and (13–15) yields

$$\text{Cycles of concentration} = Q_m/Q_b \tag{13–16}$$

It can be seen in Eq. (13–16) that the cycles of concentration also equal the ratio of the makeup flow to the blowdown flow.

When the cycles of concentration are on the order of 3 to 7, some of the dissolved solids in the circulating water can exceed their solubility limits and precipitate, causing scale formation in pipes and coolers. To avoid scale formation, sulfuric acid is often used to convert calcium and magnesium carbonates into more soluble sulfate compounds. The amount of acid used must be limited to maintain some residual alkalinity in the system. If the pH of the system is reduced too far below 7, accelerated corrosion can occur (see Example 13–6).

Common Water Quality Problems in Cooling Tower Systems

Four general water quality problems are encountered in industrial cooling tower operations: (1) scaling, (2) metallic corrosion, (3) biological growths, and (4) fouling in heat exchanger and condensers. Both freshwater and reclaimed water contain constituents that can cause these problems, but their concentrations in reclaimed water are generally higher.

Scaling. Scaling refers to the formation of hard deposits, usually on hot surfaces, which reduce the efficiency of heat exchange. Calcium scales (calcium carbonate, calcium sulfate, and calcium phosphate) are the principal cause of cooling tower scaling problems. Magnesium scales (magnesium carbonate and phosphate) can also be a problem. Silica deposits are particularly difficult to remove from heat exchanger surfaces; however, most waters contain relatively small quantities of silica.

Reducing the potential for scaling in wastewater is achieved by controlling the formation of calcium phosphate, which is the first calcium salt to precipitate if phosphate is present. Treatment is usually accomplished by removing phosphates by precipitation (see Chap. 11). Other treatment methods, such as ion exchange, reduce scale formation by the removal of calcium and magnesium; however, these techniques are comparatively expensive and their use is limited.

Metallic Corrosion. In cooling systems, corrosion can occur when an electrical potential between dissimilar metal surfaces is created. The corrosion cell consists of an anode, where oxidation of one metal occurs, and a cathode, where reduction of another

metal takes place. Water quality greatly affects metallic corrosion. Contaminants such as TDS increase the electrical conductivity of the solution and thereby accelerate the corrosion reaction. Dissolved oxygen and certain metals (manganese, iron, and aluminum) promote corrosion because of their relatively high oxidation potential.

The corrosion potential of cooling water can be controlled by the addition of chemical corrosion inhibitors. The chemical requirements to control corrosion in reclaimed water are usually much higher than for freshwater because the concentration of TDS is often two to five times higher in wastewater.

Biological Growth. The warm, moist environment inside the cooling tower makes an ideal environment for promoting biological growth. Nutrients, particularly N and P, and available organics further encourage the growth of microorganisms that can attach and deposit on heat-exchanger surfaces, inhibiting heat transfer and water flow. Biological growths may also settle and bind other debris present in the cooling water, which may further inhibit effective heat transfer. Certain microorganisms also create corrosive byproducts during their growth. Biological growths are usually controlled by the addition of biocides as part of the internal chemical treatment process that may include the addition of acid for pH control, the use of biocides, and scale and biofoul inhibitors. Because reclaimed water contains a greater concentration of organic matter, it may require larger dosages of biocides. It is possible, however, that most of the nutrients and available organic matter are removed from the reclaimed water during biological and chemical treatment.

When reclaimed water is used for cooling, the assurance of adequate disinfection is a primary concern to protect the health of workers. The disinfection requirements for use of reclaimed water in industrial processes are made on a case-by-case basis. The most stringent requirement, similar to unrestricted reclaimed water use in food crop irrigation, would be appropriate if exposure to spray were possible. Protection of the neighboring public as well as plant operators is of prime importance.

Fouling. Fouling refers to the process of attachment and growth of deposits of various kinds in cooling tower recirculation systems. The deposits consist of biological growths, suspended solids, silt, corrosion products, and inorganic scales. Inhibition of heat transfer in the heat exchangers can result. Control of fouling is achieved by the addition of chemical dispersants that prevent particles from aggregating and subsequently settling. Dispersants are also added at the point of use, as is the usual case for freshwater cooling systems. Also, the chemical coagulation and filtration processes required for phosphorus removal are effective in reducing the concentration of contaminants that contribute to fouling.

In most cases, disinfected secondary effluent is supplied for noncritical, once-through cooling. For recirculating cooling tower operation, most wastewaters contain constituents which, if not removed, would limit industries to very low cycles of concentration in their cooling towers. Additional treatment includes lime clarification, alum precipitation, or ion exchange. Treatment processes used for both external and internal treatment of cooling or boiler makeup water are summarized in Table 13–25. In many cases, the water quality requirements for the use of reclaimed water are the same as those for freshwater. Water quality requirements at the point of use for cooling waters for both once-through and makeup for recirculation are reported in Table 13–26.

Table 13-25 Processes used in treating water for cooling or boiler makeup

Note: Unless otherwise indicated, units are mg/L and values that normally should not be exceeded. No one water will have all the maximum values shown.

[a] From NAS (1972).

[b] Brackish water—dissolved solids more than 1000 mg/L.

[c] Accepted as received (if meeting other limiting values); has never been a problem at concentrations encountered.

[d] Zero, not detectable by test.

[e] Controlled by treatment for other constituents.

[f] No floating oil.

EXAMPLE 13–7 Estimation of Blowdown Water Composition Reclaimed water with the chemical characteristics given below is being considered for use as makeup water for a cooling tower. Calculate the composition of the blowdown flow if 5 cycles of concentration are to be used. Assume that the temperature of the hot water entering the cooling tower is 50°C (120°F) and the solubility of $CaSO_4$ is about 2200 mg/L as $CaCO_3$ at this temperature.

Constituent	Concentration, mg/L
Total hardness (as $CaCO_3$)	118
Ca^{2+} (as $CaCO_3$)	85
Mg^{2+} (as $CaCO_3$)	33
Total alkalinity (as $CaCO_3$)	90
SO_4^{2-}	20
Cl^-	19
SiO_2	2

Where mw of $CaCO_3$ = 100, $CaSO_4$ = 136, H_2SO_4 = 98, and SO_4 = 96.

Solution

1. Determine the total hardness in the circulating water.
   a. When the total alkalinity is less than total hardness, Ca and Mg are also present in forms other than carbonate hardness.
   b. Setting the cycles of concentration equal to 5 and using Eq. (13–15), the total hardness in circulating water is

$$C_b = (\text{cycles of concentration})\,(C_m)$$
$$= 5 \times 118 = 590 \text{ mg/L } CaCO_3$$

2. Determine the total amount of H_2SO_4 that must be added to convert the $CaCO_3$ to $CaSO_4$.
   a. To convert from $CaCO_3$ to $CaSO_4$, sulfuric acid is injected into the circulating water and the following reaction occurs:

$$\underset{100}{CaCO_3} + \underset{98}{H_2SO_4} \rightarrow \underset{136}{CaSO_4} + H_2O + CO_2$$

   b. The alkalinity in the circulating water, if not converted into sulfates, is $5 \times 90 = 450$ mg/L as $CaCO_3$.
   c. If 10 percent of the alkalinity is left unconverted to avoid corrosion, the amount of alkalinity remaining is $0.1 \times 450 = 45$ mg/L as $CaCO_3$.
   d. The amount of alkalinity that must be converted is $450 - (0.1 \times 450) = 405$ mg/L as $CaCO_3$.
   e. The amount of sulfate that must be added for the conversion is

$$SO_4^{2-} = (405 \text{ mg/L})\left(\frac{96}{100}\right) = 389 \text{ mg/L}$$

f. Converting to mg/L $CaSO_4$ yields

$$CaSO_4 = (389 \text{ mg/L})\left(\frac{136}{96}\right) = 551 \text{ mg/L}$$

3. Determine the required sulfuric acid concentration in the circulating water.

$$H_2SO_4 = (389 \text{ mg/L } SO_4)\left(\frac{98}{96}\right) = 397 \text{ mg/L}$$

4. Determine the sulfate concentration in the circulating water contributed by the makeup water.
   a. Sulfate from makeup water is $5 \times 20 = 100$ mg/L as SO_4.
   b. If combined with Ca^{2+}, the concentration is $CaSO_4 = (100 \text{ mg/L})\left(\frac{136}{96}\right) = 142$ mg/L.
5. The solubility of $CaSO_4$ at 50°C (120°F) is about 2200 mg/L. In the circulating water, 142 mg/L $CaSO_4$ was originally present after 5 cycles of concentration and 551 mg/L was formed by the addition of sulfuric acid. Therefore, an additional 1507 mg/L of $CaSO_4$ formation is theoretically permissible before the solubility limit is exceeded. The cycles of concentration could have been carried out much higher before $CaSO_4$ would precipitate in the system.
6. Determine the concentrations of Cl and SiO_2 in the circulating water.
   a. Chloride

   $$Cl^- = 5 \times 19 = 95 \text{ mg/L}$$

   b. Silica

   $$SiO_2 = 5 \times 2 = 10 \text{ mg/L}$$

7. Summarize the composition of the blowdown flow after 5 cycles of concentration.

	Concentration, mg/L	
Parameter	**Initial**	**Final**
Total hardness (as $CaCO_3$)	118	590
Total alkalinity (as $CaCO_3$)	90	45
SO_4^{2-}	20	489
Cl^-	19	95
SiO_2	2	10

13–8 GROUNDWATER RECHARGE WITH RECLAIMED WATER

Groundwater recharge has been used to (1) reduce, stop, or even reverse declines of groundwater levels, (2) protect underground freshwater in coastal aquifers against

saltwater intrusion from the ocean, and (3) store surface water, including flood or other surplus water, and reclaimed water for future use. Groundwater recharge is also achieved incidentally in land treatment and disposal systems where municipal and industrial wastewater is disposed of via percolation and infiltration.

Groundwater recharge with reclaimed water is an approach to water reuse that results in the planned augmentation of groundwater supplies. There are several advantages to storing water underground: (1) the cost of artificial recharge may be less than the cost of equivalent surface reservoirs; (2) the aquifer serves as an eventual distribution system and may eliminate the need for surface pipelines or canals; (3) water stored in surface reservoirs is subject to evaporation, to potential taste and odor problems due to algae and other aquatic productivity, and to pollution; (4) suitable sites for surface reservoirs may not be available or environmentally acceptable; and (5) the inclusion of groundwater recharge in an indirect potable reuse project may also provide health, psychological, and aesthetic secondary benefits as a result of the transition between reclaimed water and groundwater.

Groundwater Recharge Methods

Two methods of groundwater recharge are used commonly with reclaimed water: (1) surface spreading in basins, and (2) direct injection into groundwater aquifers.

Groundwater Recharge by Surface Spreading. Surface spreading (see Figs. 13–4, 13–25, and 13–26) is the simplest, oldest, and most widely used method of groundwater recharge. In surface spreading, recharge waters percolate from the spreading basins through an unsaturated groundwater (vadose) zone. Infiltration basins are the most favored methods of recharge because they allow efficient use of space and require relatively little maintenance. Based on recent findings, the assumption that the vadose zone can be counted for treatment of trace organics has come into question. It appears, based on large-scale tracer studies, that much of the flow moves down through the soil column in preferential flow paths and receives little or no treatment as it passes through the soil.

Where hydrogeological conditions are favorable for groundwater recharge with spreading basins, water reclamation can be implemented relatively simply by the rapid infiltration (also known as the soil-aquifer treatment (SAT) system or geopurification). Typical SAT system schematics are shown on Fig. 13–27, where the necessary treatment for conventional constituents can be obtained by filtration as the treated effluent (normally the secondary treated effluent) percolates through the soil and the vadose zone, down to the groundwater, and then some distance through the aquifer. The extracted groundwater can be used for irrigation for a variety of food crops.

Because recharged groundwater may be an eventual source of potable water supply, groundwater recharge with reclaimed water often involves treatment beyond the conventional secondary treatment. For surface spreading operations practiced in California, common wastewater reclamation processes prior to recharge include primary and secondary wastewater treatment, and tertiary granular-medium filtration followed by disinfection with chlorine or UV radiation. The RIX (rapid infiltration/extraction) spreading ground in San Bernardino County, CA, is shown on Fig. 13–28. The water extracted from the area surrounding the spreading basin, which has been filtered by passage through the soil, is disinfected by UV radiation before being discharged to the Santa Ana River.

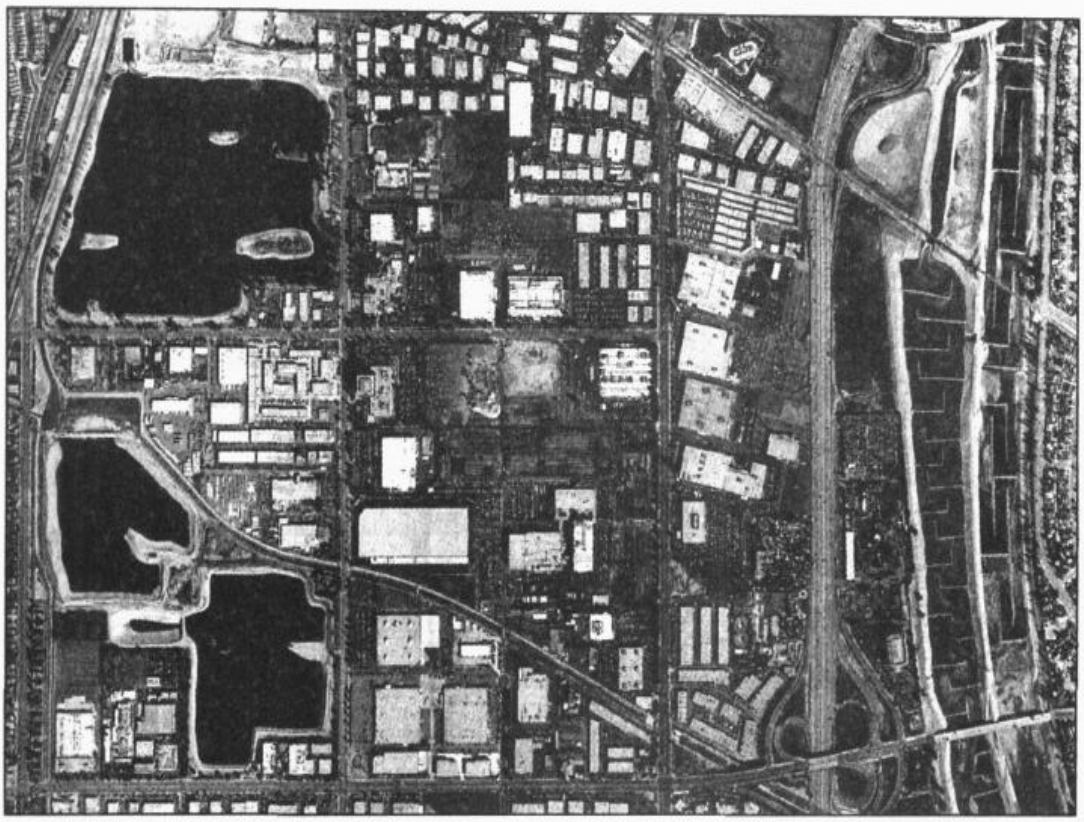

Figure 13–25

Groundwater replenishment facilities operated by the Orange County Water District in southern CA. Anaheim Lake, Kraemer Basin, and Miller Basin, shown top to bottom on the left-hand side of the photo, are spreading basins where Santa Ana River water and imported water is recharged to replenish the Orange County Groundwater Basin. The three basins can recharge up to 1.11×10^5 m^3/yr (90,000 ac-ft/yr). In the future, the Groundwater Replenishment System, a joint project of the Orange County Water District and the Orange County Sanitation District, will be used to recharge reclaimed water, treated by secondary treatment, microfiltration, reverse osmosis, and ultraviolet light, at Kraemer Basin. Infiltration facilities used to recharge about 8.6×10^4 m^3/yr (70,000 ac-ft/yr) of Santa Ana River water are shown on the right hand side of the photo. *(Photo courtesy of the Orange County Water District, aerial photography by Robert J. Lung, Associates.)*

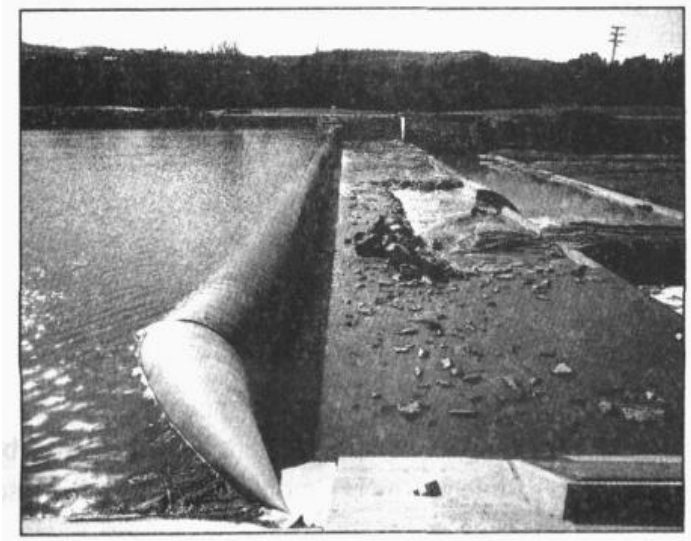

Figure 13–26

Inflatable rubber dam used to divert flow from the Santa Ana River in southern California to groundwater spreading basins. In the summer the flow in the river is comprised almost entirely of treated effluent from upstream treatment plants.

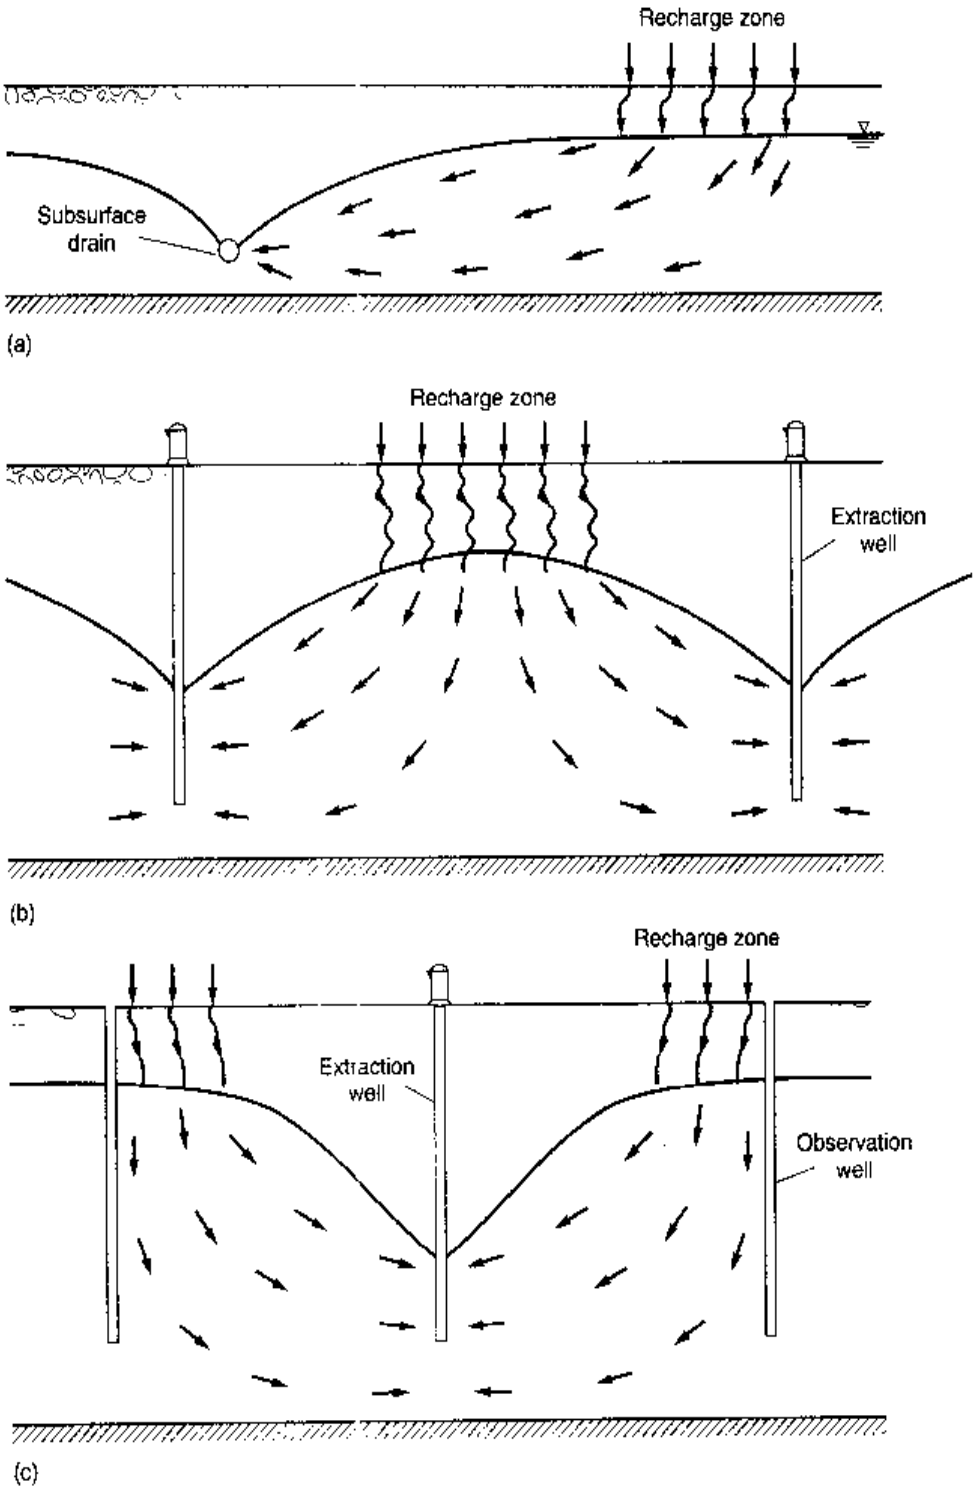

Figure 13-27

Typical schematics of soil-aquifer treatment (SAT) systems with recovery of renovated water by: (*a*) subsurface drains, (*b*) wells surrounding the spreading basins, and (*c*) wells midway between two parallel strips of basins.

Groundwater Recharge by Direct Injection. Direct subsurface recharge is achieved when water is conveyed and injected directly into groundwater aquifer. In direct injection, generally, highly treated reclaimed water is injected directly into the saturated groundwater zone, usually into a well-confined aquifer. Groundwater recharge by direct injection is practiced, in most cases, where groundwater is deep or where the topography or existing land use makes surface spreading impractical or too expensive. This method of groundwater recharge is particularly effective in creating freshwater barriers in coastal aquifers against intrusion of saltwater from the sea.

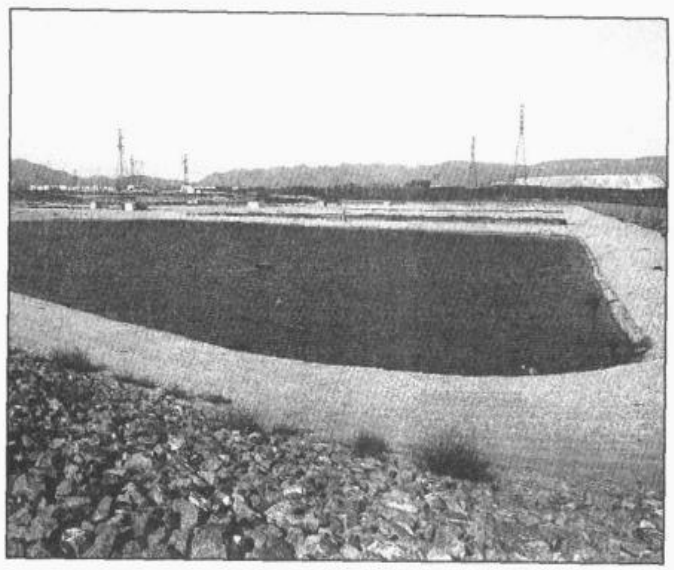

Figure 13–28

Rapid infiltration and extraction surface spreading basins. Reclaimed water that has infiltrated is pumped out from a series of wells surrounding the spreading basins, disinfected with ultraviolet irradiation, and released to the Santa Ana River.

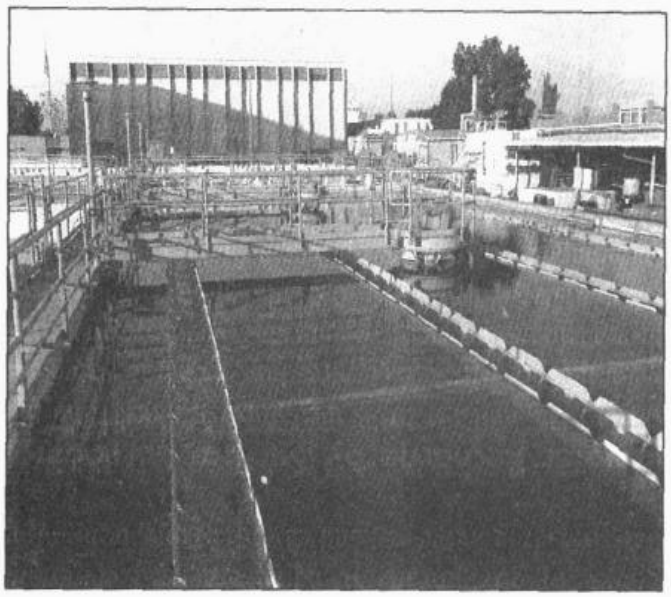

Figure 13–29

View (from effluent end) of lime clarification facilities used for the pretreatment of secondary effluent for reverse osmosis filtration. The flocculation basins are located at the head end of the clarification facilities. Lime storage and slaking facilities are located in the building just behind the flocculation facilities. In the future, lime clarification will be replaced by microfiltration (see Fig. 13–13*b*).

Pretreatment Requirements for Groundwater Recharge

Pretreatment requirements for groundwater recharge vary considerably, depending on the purpose of groundwater recharge, sources of reclaimed water, recharge methods, and location (see Fig. 13–29). For example, pretreatment for municipal wastewater for application to a SAT system may include only primary treatment or treatment in a stabilization pond. However, pretreatment processes that leave high algal concentrations in the recharge water should be avoided. Algae can severely clog the soil of infiltration basins. While the water recovered from the SAT system has much better water quality than the influent water, it could still be lower quality than the native groundwater. Thus, the SAT system should be designed and managed to avoid encroachment into the native groundwater and to use only a portion of the aquifer as shown on Fig. 13–27. The dis-

tance between infiltration basins and wells or drains should be as large as possible, usually at least 45 to 106 m (150 to 350 ft) to allow for adequate soil-aquifer treatment.

More detailed discussions regarding the capability of various advanced wastewater treatment process combinations are found in Sec. 13–4. To avoid potential health risks, careful attention must be paid to groundwater recharge operations when a possibility exists to augment substantial portions of potable groundwater supplies. Both in surface spreading and in direct injection, locating the extraction wells as great a distance as possible from the spreading basins or the injection wells increases the flow path length and residence time of the recharged water. These separations in space and in time contribute to the assimilation of the recharged reclaimed water with the other aquifer contents, and the loss of identity of the recharged water originated from municipal wastewater.

Fate of Contaminants in Groundwater

Understanding of the behavior of stable organic constituents and bacterial and viral pathogens is crucial in evaluating the feasibility of groundwater recharge using reclaimed water. Treated effluents contain trace quantities of nonconventional and emerging constituents and compounds even when the most advanced treatment technology is used. The transport and fate of these substances in the subsurface environment are governed by various mechanisms, which include biodegradation by microorganisms, chemical oxidation and reduction, sorption and ion exchange, filtration, chemical precipitation, dilution, volatilization, and photochemical reactions (in spreading basins) (see Table 4–5 in Chap. 4).

Particulate Constituents. Particulate constituents including microorganisms in reclaimed water are removed by filtration and retained effectively by the soil matrix. Factors affecting the movement, removal, and inactivation of viruses in groundwater are discussed in Bitton and Gerba (1984) and Ward et al. (1985).

Dissolved Inorganic and Organic Constituents. In addition to the common dissolved mineral constituents, reclaimed water contains many dissolved trace elements. The physical action of filtration does not, however, accomplish the removal of these dissolved inorganic contaminants. For trace metals to be retained in the soil matrix, physical, chemical, or microbiological reactions are required to immobilize the dissolved constituents. In a groundwater recharge system, the impact of microbial activities on the attenuation of inorganic constituents is small. Physical and chemical reactions in the soil that are important with respect to trace metal elements include cation exchange, precipitation, surface adsorption, and chelation and complexation. Although soils do not possess unlimited capability in attenuating inorganic constituents, it has been found in experimental studies that soils do have capacities for retaining large amounts of trace metal elements. Therefore, it is conceivable that a site used for groundwater recharge may be effective in retaining trace metals for extended periods of time.

Removal of dissolved organic constituents is affected primarily by biodegradation and adsorption during groundwater recharge operations. Biodegradation offers the potential of permanent conversion of toxic organic substances into harmless products. The rate and extent of biodegradation are strongly influenced by the nature of the organic substances, as well as by the presence of electron acceptors such as dissolved oxygen, nitrate, and sulfate. Biodegradation of easily degradable substances takes place

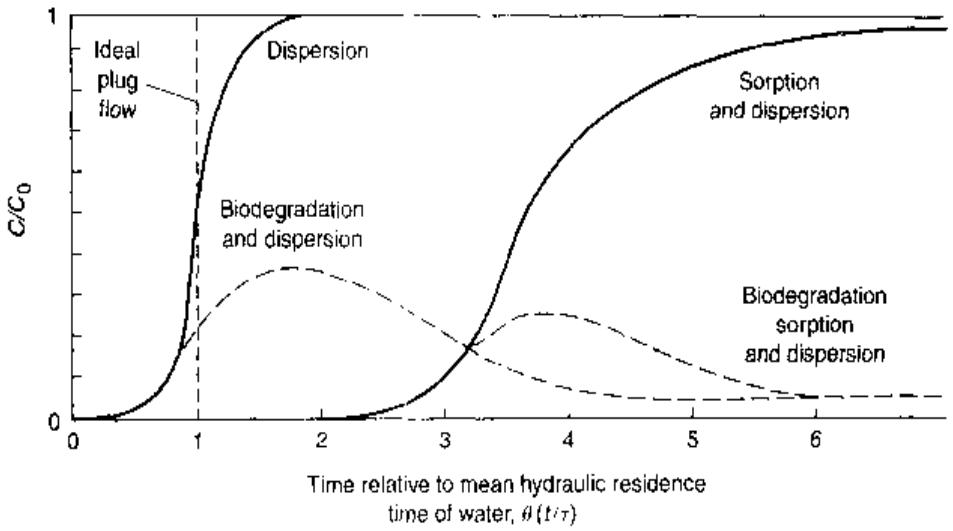

Figure 13–30
Effect of dispersion, sorption, and biodecomposition on the time change in concentration of an organic compound. Expected responses to a step change in concentration are shown. *(From McCarty et al., 1981.)*

almost exclusively in the first one or 0.6 m (2 ft) of travel. There is increasing evidence that a significant portion of the observed degradation occurs in the biological mat (*Schmutzdecke*) that forms on the infiltrating surface in a spreading basin. The fate of some of the more resistant organic compounds found in recharge water is still poorly understood. The effects of dispersion, sorption, and biodecomposition on the time change in concentration of an organic compound at an aquifer observation well are illustrated on Fig. 13–30. The observed concentration is C, and C_o represents the concentration in the injection water (McCarty et al., 1981).

Among the end products of complete biodegradation of dissolved organic constituents are carbon dioxide and water under aerobic conditions, or carbon dioxide, nitrogen, hydrogen sulfide, and methane under anaerobic conditions. However, the degradation process does not necessarily proceed to completion. Degradation may terminate at an intermediate stage, leaving a residual organic product that, under the particular conditions, cannot be degraded further at an appreciable rate.

Pathogen Removal. Groundwater contamination by pathogenic microorganisms has not received as much attention as surface water. It has been generally assumed that groundwater is free of pathogenic microorganisms. However, a number of well-documented disease outbreaks have been traced to contaminated groundwater. The fate of bacterial pathogens and viruses in the subsurface environment is determined by their survival characteristics and their retention in the soil matrix. Both survival and retention are largely determined by (1) climate, (2) nature of the soil, and (3) nature of microorganisms.

Temperature and rainfall are two important climatic factors that will affect viral and bacterial survival and movement. At higher temperatures, inactivation or natural die-off is fairly rapid. For bacteria, and probably viruses, the die-off rate is approximately doubled with each 10°C rise in temperature between 5 and 30°C. Rainwater, because of its lower pH value, can elute adsorbed virus particles, which may then move with the groundwater. The physical and chemical characteristics of the soil will also play a major role in determining survival and retention of microorganisms. Soil properties influence moisture-holding capacity, pH, and organic matter. All of these factors control the survival of bacteria and viruses in the soil.

Resistance of microorganisms to environmental factors varies among different species as well as strains. Bacteria are removed largely by filtration processes in the soil while adsorption appears to be the major factor controlling virus retention.

Groundwater Recharge Guidelines

The major concern with groundwater recharge with reclaimed water is the potential adverse health effects that may be caused by the introduction of pathogens and trace amounts of toxic constituents. Because of the increasing concern for long-term health effects, every effort should be made to reduce the number of chemical species and concentration of specific organic constituents in the recharge water.

A source control program to limit the quantities of potentially harmful constituents entering the collection system must be an integral part of any groundwater recharge project. Extreme caution is necessary in controlling the quality of the treated effluent to be recharged, because restoring a groundwater basin once it is contaminated is difficult and expensive. Additional cost would be incurred if groundwater quality changes resulting from recharge necessitated the treatment of extracted groundwater or the development of additional water sources. The level of municipal wastewater treatment necessary to produce a suitable reclaimed water for groundwater recharge depends upon the groundwater quality objectives, hydrogeologic characteristics of the groundwater basin, and the amount of reclaimed water recharged in relation to other waters recharged. Factors to be considered in the formulation of the groundwater recharge guidelines are summarized in Table 13–27.

In the United States, federal requirements for groundwater recharge in the context of water reclamation and reuse have not been established. As a consequence, water reuse requirements for groundwater recharge are presently regulated by state agencies on a case-by-case determination. The state of California initially considered developing statewide groundwater recharge regulations with reclaimed water in the mid-1970s (Nellor et al., 1985). As interest in indirect potable reuse via groundwater recharge grew, the state of California agencies (State Water Resources Control Board, Department of Water Resources, and Department of Health Services) formed a Scientific Advisory Panel on Groundwater Recharge with Reclaimed Water, and its report was issued in 1987 (State of California, 1987). Proposed regulations by the Department of Health Services have undergone several iterations and, when adopted, will replace the more general groundwater recharge regulations that are included in the current *Water Recycling Criteria* (State of California, 2000). A conceptual framework for the proposed regulations on groundwater recharge is summarized in Table 13–28. Some issues remain to be resolved, for example, nitrogen limits, criteria to identify impairment of groundwater suitable for use as drinking water source, and unregulated trace organics.

13–9 PLANNED INDIRECT AND DIRECT POTABLE WATER REUSE

With the increased attention being paid to drinking water quality, much of the research on drinking water is of relevance to planned indirect and direct potable reuse. Three classes of constituents of special concern in water reclamation and reuse where potable water supply may be affected are (1) enteric viruses, (2) organic constituents including both industrial chemicals and home products and medicines, and (3) heavy metals. The

Table 13-27
Factors to be considered in the formulation of groundwater recharge guidelines in the United States

	Surface spreading
Treatment	Source control of toxic chemicals
	Primary sedimentation and secondary biological treatment
	Tertiary granular-medium filtration (possibly activated-carbon adsorption for organics removal)
	Disinfection
Depth to groundwater	Percolation through an unsaturated zone of undisturbed soil
	Depth to groundwater in the range of 3 to 15 m (10 to 50 ft) depending on percolation rate of the soils
Retention time in ground	6 to 12 months depending on the type of pretreatment
Maximum percent reclaimed wastewater	20 to 50 percent on the annual basis at extraction wells, depending on organics removal
Horizontal distance	150 to 300 m (500 to 1000 ft) depending on pretreatment
Monitoring	Extensive, including the contaminants in the drinking water regulations
	Direct injection
Treatment	Source control of toxic chemicals
	Primary sedimentation and secondary biological treatment
	Chemical coagulation, clarification, and granular-medium filtration
	Activated-carbon adsorption
	Volatile organics removal
	Reverse osmosis or other membrane process
	Disinfection
Depth to groundwater	Not applicable (direct injection to groundwater aquifers)
Retention time in ground	12 months
Maximum percent reclaimed wastewater	20 percent on the annual basis at extraction wells
Horizontal distance	300 to 600 m (1000 to 2000 ft)
Monitoring	Quite extensive, including the contaminants in the drinking water regulations

ramification of many of these constituents with respect to health effects is not well understood, and, as a result, regulatory agencies are proceeding with extreme caution in permitting water reuse applications that affect potable water supplies. Where little possibility exists for developing additional freshwater supplies, some communities are developing plans for indirect potable reuse (Crook et al., 1999). Although the quantities involved in potable reuse are small, the technological and public health interests are the greatest, and hence considerable research has been directed toward potable water reuse in recent years. Both planned indirect and direct reuse are considered in this section.

Table 13–28
Conceptual frameworks for the proposed California groundwater recharge criteria[a]

Contaminant type	Type of recharge	
	Surface spreading	Subsurface injection
Pathogenic microorganisms:		
Secondary treatment	TSS ≤30 mg/L	
Filtration	≤2 NTU	
Disinfection	4-log virus inactivation, ≤2.2 total coliform per 100 mL	
Retention time underground	6 months	12 months
Horizontal separation	152 m (500 ft)	61 m (2000 ft)
Regulated contaminants	Meet all drinking water MCLs	
Unregulated contaminants:		
Secondary treatment	BOD ≤30 mg/L, TOC ≤16 mg/L	
Reverse osmosis	Four options available depending on meeting 1 mg/L TOC requirement	100 percent treatment to: $TOC \leq \frac{1\ mg/L}{RWC^b}$
Spreading criteria for SAT 50 percent TOC removal credit	Depth to groundwater at initial percolation rates of: <5 mm/min = 0.9 m (<0.2 in/min = 10 ft) <7.5 mm/min = 3.1 m (<0.3 in/min = 20 ft)	NA
Mound monitoring option	Demonstrate feasibility of mound compliance point	NA
Reclaimed water contributior	≤50 percent	

[a]Adapted from California Department of Health Services Working Paper (2000).
[b]RWC = percent reclaimed water contribution in groundwater extracted by drinking water wells.

Planned Indirect Potable Water Reuse

While direct potable reuse is not practiced in the United States, indirect potable reuse is implemented to augment several drinking water systems through groundwater recharge, and several pilot facilities have been constructed to evaluate the potential for indirect and direct potable reuse. Several examples are shown below (Asano, 1998; NRC, 1998):

- The Denver Water Department's Direct Potable Water Reuse Demonstration Project, 1979–1990
- The Potomac Estuary Experimental Water Treatment Plant, 1980–1983
- The County Sanitation Districts of Los Angeles County Ground Water Recharge Projects, 1962–present
- The Orange County Water District, California, Water Factory 21, 1972–present

- The Fred Hervey Water Reclamation Plant, El Paso, TX, Groundwater Recharge, 1985–present
- The city of San Diego's Total Resource Recovery Project, 1984–1999
- The city of Tampa, FL, Water Resources Recovery Project, 1993

Planned indirect potable reuse systems in operation today include such groundwater recharge operations as the Whittier Narrows Groundwater Recharge Project in Los Angeles County, CA; Orange County Water District in Orange County, CA, and in El Paso, TX. Another example of indirect potable reuse is the Occoquan Reservoir in northern Virginia. Highly treated effluent from the 57,000 m^3/d (15 Mgal/d) Manassas, VA, advanced wastewater treatment plant is discharged directly into the Occoquan Reservoir, a principal drinking water reservoir for more than 660,000 people.

Planned Direct Potable Water Reuse

The only well-studied case of a planned direct potable reuse system in operation is in Windhoek, Namibia. For nearly 30 years, this facility has been used intermittently to forestall water emergencies during drought conditions. The current treatment process sequences involve primary, secondary treatment, and maturation ponds at the Gammans wastewater treatment plant. The secondary effluent is then directed to the Goreangab water reclamation plant, which includes alum addition, dissolved air flotation, chlorination, and lime addition, followed by settling, sand filtration, chlorination, carbon filtration, and final chlorination. The final effluent is then blended with other drinking water sources before distribution (Harhoff and van der Merwe, 1996).

In almost all the cases where potable water reuse has been implemented, alternative sources of water have been developed in the ensuing years and the need to adopt direct (e.g., pipe-to-pipe) potable water reuse has been avoided. In proposing direct potable water reuse, serious consideration must be given to whether the need is for a short-term emergency or for normal use over a prolonged period. The major emphasis placed upon the potable water reuse today concerns the chronic health effects that might result from ingesting the mixture of unregulated inorganic and organic contaminants in trace amounts that remain in water, even after subjecting it to the most advanced treatment methods such as microfiltration and reverse osmosis.

Planned Potable Water Reuse Criteria

It has been argued that there should be a single water quality standard for potable water and that if reclaimed water can meet this standard, it should be acceptable. It must be recognized, however, that current drinking water standards have evolved on the presumption of water supplies derived from relatively unpolluted freshwater sources. While great advances have been made in analytical methods to identify chemical contaminants in water, only a small fraction of the contaminants present in surface water and groundwater can be identified (see discussion in Sec. 2–7 in Chap. 2). This analytical limitation has frustrated attempts to develop comprehensive potable water reuse criteria for various sources of water. In assessing water being considered for possible potable reuse, comparison should be made with the highest-quality water available locally to rationalize the selection.

While the implementation of direct potable use of reclaimed water is obviously limited to extreme situations, research relating to potable reuse has continued in several loca-

tions as identified in the previous section. As the proportional quantities of treated wastewater discharged into the nation's waters increase, as experienced in New Orleans, LA, on the Mississippi River, much of the research that addressed only potable water reuse is becoming of equal relevance to *unplanned indirect potable reuse* such as municipal water intakes downstream from wastewater discharges or from increasingly polluted rivers.

What Is the Ultimate Water Reuse Goal?

While many technological advances have been made in producing high-quality treated wastewater, a number of obstacles remain to be overcome before potable reuse is accepted. Much of the objection to planned potable reuse in the United States arises from concerns in the scientific community whether drinking water standards are adequate to ensure the safety of all waters "regardless of source." Some argue that drinking water standards apply only to—and were designed only for—waters derived from a relatively pristine source. Although this argument has a long-standing basis in public health and normal sanitation practice, it is becoming more difficult to determine what is the best available water source (NRC, 1998). Some lessons learned from implementing indirect potable reuse projects were reviewed by Hartling (2001).

Support from the public sector is also lacking; some of the reasons may be (1) the immediate need for potable reuse has not been demonstrated convincingly, (2) few *champions* for water reuse have rallied support, (3) political leaders prefer not to be advocates for a potentially controversial issue, (4) few media presentations make an appealing case for supporting potable reuse, and (5) few forums are available for public education and informed discussions of the issues surrounding water reuse.

Beyond engineering feasibility for indirect potable reuse, future research by social and political scientists may involve an effort to answer the following questions:

- Why were planned indirect potable water reuse projects not approved and implemented? What were the main influences on public opinion in each case?
- What should be the roles and strategies of the media, government officials, and other interested parties with respect to the indirect potable reuse projects?
- To what extent do public concerns about health effects, growth inducement, and cost influence community acceptance of potable water reuse projects as compared to the prospects of diminished water resources?

13–10 PLANNING FOR WASTEWATER RECLAMATION AND REUSE

In effective planning for water reclamation and reuse, the objectives and basis for conducting the planning should be defined clearly. The optimum water reclamation and reuse project is best achieved by integrating both wastewater treatment and water supply needs into one plan. This integrated approach is somewhat different from planning for conventional wastewater treatment facilities where planning is done only for conveyance, treatment, and disposal of municipal wastewater.

Planning Basis

Effective water reclamation and reuse facilities plans should include the following elements: (1) assessment of wastewater treatment and disposal needs, (2) assessment of

water supply and demand, (3) assessment of water supply benefits based on water reuse potential, (4) analysis of reclaimed water market, (5) engineering and economic analyses of alternatives, (6) implementation plan with financial analysis, and (7) a public information program. Important factors that should be considered in the planning process are briefly introduced in this section.

Project Objectives. Water reclamation and reuse can serve the functions of both water pollution control and water supply. It has been only in the last three decades that increased attention has been given to the water supply benefits in the facilities planning process for the municipal wastewater treatment. Ignoring the water supply potential of municipal wastewater has often resulted in facilities that now hinder the development of this alternative water resource. For example, in some locations optimum water reuse would have been better achieved if smaller satellite wastewater treatment plants had been constructed with reuse in mind, instead of a large regional wastewater treatment facility.

Because many water and wastewater agencies are established with a single-purpose function, planning by these agencies tends to be single-purpose as well. Optimum water reclamation and reuse is best achieved in a framework of multiple-purpose planning and with cooperative efforts of both wastewater management and water supply agencies. Once these multiple benefits and beneficiaries of water reuse are recognized, additional options may be available for sharing project responsibilities and costs among project sponsors.

Project Study Area. The project study area is another critical planning issue. There are two study area horizons to consider in project planning. The first planning horizon is established based on the direct service area of the project facilities plan. The second horizon extends to the area that accrues less direct costs or benefits from a project, which should be accounted for in evaluating the project. Thus, the study area for facilities design includes (1) the collection system area to be served by the wastewater treatment facilities and (2) the area that can potentially be served by reclaimed water. To evaluate project benefits and costs, the project study area must include (1) the area impacted by the environmental effects of the wastewater, and (2) the area benefiting from the supplemental or alternative water supply of the reclaimed water.

The traditional approach to planning is to equate the study area with the project sponsor's jurisdictional boundaries. Such boundaries, however, may not suit the optimum design of a water reuse project or include the areas of benefit. Because water supply is typically dependent on regional water resources outside of the facilities study area, it is essential to look beyond this study area to obtain an understanding of the water resources situation. For instance, overdrafted groundwater basins may be having their most serious impacts on communities at great distances beyond the project area. Thus, implementing a water reuse project in one community that reduces groundwater overdraft could result in benefits to a water supply in another community.

Market Assessment

In planning a water reclamation project, it is essential to find potential customers who are capable and willing to use reclaimed water. The success of water reuse projects is

Table 13–29
Reclaimed wastewater market assessment: background information and survey[a]

1. Inventory potential users and uses of reclaimed wastewater
2. Determine health-related requirements regarding water quality and application requirements (e.g., treatment reliability, backflow prevention, use area controls, irrigation methods) for each type of application of reclaimed wastewater
3. Determine regulatory requirements to prevent nuisance and water quality problems, such as restrictions to protect groundwater
4. Develop assumptions regarding probable water quality that would be available in the future with various levels of treatment and compare those to regulatory and user requirements
5. Develop an estimate of future freshwater supply costs to potential users of reclaimed wastewater
6. Survey potential reclaimed wastewater users, obtaining the following information:
   a. Specific potential uses of reclaimed wastewater
   b. Present and future quantity needs
   c. Timing and reliability of needs
   d. Water quality needs
   e. Onsite facilities modifications to convert to reclaimed wastewater and meet regulatory requirements for protection of public health and prevention of pollution problems from reclaimed wastewater
   f. Capital investment of the user for onsite facilities modifications, changes in operational costs, desired pay-back period or rate of return, and desired water cost savings
   g. Plans for changing use of site in future
7. Inform potential users of applicable regulatory restrictions, probable water quality available with different levels of treatment, reliability of the reclaimed water, future costs, and quality of freshwater compared to reclaimed water
8. Determine the willingness of potential users to use reclaimed wastewater now or in the future

[a]Developed from Asano and Mills (1990).

largely dependent on securing of markets for the reclaimed water. A market assessment consists of three parts: (1) background information including potential uses of reclaimed water, (2) a survey of potential reclaimed water users and their needs, and (3) community support. Background and survey information necessary for a market assessment for reclaimed water is listed in Table 13–29. The results of this assessment form the basis for developing alternatives and determining financial feasibility of a project.

Monetary Analyses

In many cases, monetary factors tend to be the overriding concern in determining whether and how to implement a water reuse project, even though the *make or break* for most projects will be based on technical, environmental, and social factors. Greater emphasis must be placed on environmental considerations, public acceptance, and public policy issues rather than mere cost-effectiveness as a measure of the feasibility of a water reuse project.

Economic and Financial Analyses. Monetary analyses, based on established water resources economics, fall into two categories: economic analysis and financial analysis. The economic analysis is focused on the value of the resources invested in a project to construct and operate it, measured in monetary terms. The financial analysis is focused on the perceived costs and benefits of a project from the viewpoints of the project sponsor, participants, and others impacted by a project. These perceived costs and benefits may not reflect the actual value of resources invested due to subsidies or monetary transfers.

Whereas economic analysis evaluates water reclamation and reuse projects in the context of impacts on society, financial analysis focuses, instead, on the local ability to raise money from project revenues, government grants, loans, and bonds to pay for the project. The basic result of the economic analysis is to answer the question, *should* a water reuse project be constructed? Equally important, however, is the question, *can* a water reuse project be constructed? Both orientations, therefore, are necessary. However, only water reuse projects that are viable in the economic context are given further consideration for a financial analysis (Asano and Mills, 1990).

Cost and Price of Water. An important factor in the monetary analysis of water reuse projects is to distinguish between the cost and the price of water. In an economic analysis, only the future flow of resources invested in or derived from a project is considered. Past resource investments are considered sunk costs that are irrelevant to future investment decisions. Thus, debt service on past investments is not included in an economic analysis. The price of water is the purchase price paid to a water wholesaler or retailer to purchase water. Water price usually reflects a melding of current and past expenditures for a combination of projects, as well as water system administration costs, which are generally fixed costs. The costs of relevance to an economic analysis are only costs for future construction, operations, and maintenance.

To determine the water supply benefit of a water reuse project in an economic analysis, the project is usually compared to the development of a new freshwater supply. In performing such an analysis, the relevant costs for comparison are the future stream of costs (1) to construct new freshwater facilities, and (2) to operate and maintain all of the facilities needed to treat and deliver the new increment of water supply developed. In this case, the present and future price charged for freshwater would not provide a valid basis of comparison to judge the water supply benefit of a water reuse project.

On the other hand, consideration of prices charged for freshwater and reclaimed water are important to determine financial feasibility. The perceived cost of water to customers is the price charged, and thus prices will be evaluated by potential reclaimed water users in determining willingness to participate in a water reuse project.

Other Planning Factors

In addition to the monetary analyses, a number of factors have to be evaluated during the planning for a water reclamation and reuse project. Factors of particular significance in project development are related to (1) water demand characteristics, (2) supplemental water supply and emergency backup systems, (3) water quality requirements, and (4) determination of optimum project size. In essence, a water reuse project is a relatively small-scale water supply project with considerations of matching supply and

Table 13–30
Outline for wastewater reclamation and reuse facilities plan[a]

1. Study area characteristics: geography, geology, climate, groundwater basins, surface waters, land use, population growth
2. Water supply characteristics and facilities: agency jurisdictions, sources and qualities of supply, description of major facilities, water use trends, future facilities needs, groundwater management and problems, present and future freshwater costs, subsidies and customer prices
3. Wastewater characteristics and facilities: agency jurisdictions, description of major facilities, quantity and quality of treated effluent, seasonal and hourly flow and quality variations, future facilities needs, need for source control of constituents affecting reuse, description of existing reuse (users, quantities, contractual and pricing agreements)
4. Treatment requirements for discharge and reuse and other restrictions: health and water quality–related requirements, user-specific water quality requirements, use area controls
5. Potential water reuse customers: description of market analysis procedures, inventory of potential reclaimed water users, and results of user survey
6. Project alternative analysis: capital and operation and maintenance costs, engineering feasibility, economic analysis, financial analysis, energy analysis, water quality impacts, public and market acceptance, water rights impacts, environmental and social impacts, comparison of alternatives and selection
   a. Treatment alternatives
   b. Alternative markets: based on different levels of treatment and service areas
   c. Pipeline route alternatives
   d. Alternative reclaimed water storage locations and options
   e. Freshwater alternatives
   f. Water quality management alternatives
   g. No project alternative
7. Recommended plan: description of proposed facilities, preliminary design criteria, projected cost, list of potential users and commitments, quantity and variation of reclaimed water demand in relation to supply, reliability of supply and need for supplemental or backup water supply, implementation plan, operational plan
8. Construction financing plan and revenue program: sources and timing of funds for design and construction; pricing policy of reclaimed water; cost allocation between water supply benefits and pollution control purposes; projection of future reclaimed water use, freshwater prices, reclamation project costs, unit costs, unit prices, total revenue, subsidies; sunk costs and indebtedness; analysis of sensitivity to changed conditions

[a]Developed from Asano and Mills (1990).

demand, appropriate levels of wastewater treatment, reclaimed water storage, and supplemental or backup freshwater supply.

Planning Report

The results of the completed planning effort are documented in a facilities planning report on water reclamation and reuse. An outline is shown in Table 13–30, which also serves as a checklist for planning considerations. All of the items listed in Table 13–30 have been found at one time or another to affect the evaluation of water reclamation and reuse projects. Thus, while all of the factors shown do not deserve an in-depth analysis,

they should at least be considered in the planning process. While the emphasis on the wastewater treatment or water supply aspects will vary depending on whether a project is single- or multiple-purpose, the nature of water reclamation and reuse is such that both aspects must be considered.

13–11 EPILOGUE ON WATER REUSE ISSUES

Inadequate water supply and water quality deterioration represent serious contemporary concerns for many municipalities, industries, agriculture, and the environment in various parts of the world. Several factors have contributed to these problems such as continued population growth in urban areas, contamination of surface water and groundwater, uneven distribution of water resources, and frequent droughts caused by the extreme global weather patterns. For more than a quarter century, a recurring thesis in environmental and water resources engineering has been that improved wastewater treatment provides a treated effluent of such quality that it should not be wasted but put to beneficial use. This conviction in responsible engineering, coupled with the vexing problem of increasing water shortage and environmental pollution, provides a realistic framework for considering reclaimed water as a water resource in many parts of the world. Water reuse has been dubbed as the *greatest challenge of the 21st century* as water supplies remain practically the same and water demands increase because of increasing population and per capita consumption. Water reuse accomplishes two fundamental functions: (1) the treated effluent is used as a water resource for beneficial purposes, and (2) the effluent is kept out of streams, lakes, and beaches; thus reducing pollution of surface water and groundwater.

The main concerns in water reuse are: (1) reliable treatment of wastewater to meet strict water quality requirements for the intended reuse, (2) protection of public health, and (3) gaining public acceptance. Water reuse also requires close examinations of infrastructure and facilities planning, and water utility management involving effective integration of water and reclaimed water supply functions. Whether water reclamation and reuse will be appropriate in a specific locale depends upon careful economic considerations, potential uses for the reclaimed water, and stringency of waste discharge requirements. Public policy wherein the desire to conserve and reuse rather than develop additional water resources with considerable environmental expenditures may be an important consideration. Through integrated water resources planning, the use of reclaimed water may provide sufficient flexibility to allow a water agency to respond to short-term needs as well as increase long-term water supply reliability.

Groundwater recharge with reclaimed water and direct potable water reuse share many of the public health concerns encountered in drinking water withdrawn from polluted rivers and reservoirs. Three classes of constituents are of special concern where reclaimed water is used in such applications: (1) enteric viruses and other emerging pathogens; (2) organic constituents including industrial chemicals, home products, and medicines; and (3) heavy metals The impact of many of these constituents in trace quantity are not well understood with respect to long-term health effects, and, as a result, regulatory agencies are proceeding with extreme caution in permitting water reuse applications that affect potable water supplies. In all the cases in the United States

where potable water reuse has been contemplated, alternative sources of water have been developed in the ensuing years and the need to adopt direct potable water reuse has been avoided. As the proportional quantities of treated wastewater discharged into the nation's waters increase, as experienced in New Orleans, Louisiana, on the Mississippi River, much of the research that addresses groundwater recharge and potable water reuse is becoming of equal relevance to *unplanned indirect potable reuse* such as municipal water intakes located downstream from wastewater discharges or from increasingly polluted rivers and reservoirs. At this time, what is critically needed is a national dialogue to develop a consensus on acceptable health and environmental risk.

Reclaimed water is a locally controllable water resource that exists right at the doorstep of the urban environment, where water is needed the most and priced the highest. Closing the water cycle not only is technically feasible in industries and municipalities but also makes economic sense. While potable reuse is still a distant possibility and may never be implemented in the United States, groundwater recharge with advanced wastewater treatment technologies is a viable option backed by the decades of experiences in Arizona, California, New York, and Texas as well as in Australia, Israel, Germany, the Netherlands, and the United Kingdom. Water reuse has become an essential element of future water resources development and management but with more challenges.

PROBLEMS AND DISCUSSION TOPICS

13-1 Using the data given in Table 13–12, estimate the incremental cancer risk for an adult associated with drinking groundwater containing 2.0 μg/L of one of the following constituents (to be selected by the instructor): inorganic arsenic, benzene, bromate, chloroform, dieldrin, heptachlor, n-nitrosodiethylamine, or vinyl chloride. To limit the constituent exposure to an acceptable cancer risk of 1 in 100,000, determine the concentration of the constituent that can be allowed in extracted groundwater. Compare your computed value to the value given in the U.S. EPA IRIS database (http://www.epa.gov/iris).

13-2 The removal performance for 5 individual processes for a given constituent has been measured and is reported below. If process A is to be combined with one of the other processes, estimate the performance of the combined processes A and B, A and C, A and D, or A and E (process combination to be selected by the instructor). Using the performance for combined processes, estimate the combined removal at the 90 and 99 percent probability levels.

Process	Geometric removal, M_g	Geometric standard deviation, s_g
A	2.0	1.40
B	5.0	1.40
C	2.5	1.26
D	4.2	1.31
E	3.4	1.29

13–3 The performance of 5 individual treatment processes for a given constituent has been measured and is reported below. For the processes studied, it was observed that the percentage removal was independent of the initial concentration. Estimate the performance for one of the following process combinations A + B + C, B + C + D, C + D + E, or D + E + A (to be selected by the instructor) and plot the resulting probability distribution. Using the performance for combined processes, estimate the combined removal at the 88 and 95 percent probability levels.

Process	Arithmetic mean removal, %	Arithmetic standard deviation
A	60	12
B	30	17
C	55	5
D	40	10
E	50	5

13–4 The following average monthly performance data were obtained for a wastewater reclamation plant before effluent filtration. Compare and contrast the reported performance data to similar data in the literature. Cite a minimum of three references in your review.

	Concentration, mg/L	
Month	CBOD	COD
Jan	8.1	47.0
Feb	10.0	58.5
Mar	9.0	49.2
Apr	6.5	42.0
May	5.0	44.0
Jun	5.0	43.3
Jul	4.5	54.5
Aug	5.2	53.8
Sep	6.7	73.6
Oct	7.1	62.1
Nov	7.5	50.5
Dec	7.7	44.6

13–5 The following wastewater flowrate data are from four different activated-sludge plants. Assuming the information and data given in Example 13–3 are applicable, use the procedure outlined in Example 13–3 to determine the land area required for storage and land application. The treatment plant will be selected by the instructor.

Month	Days	Daily wastewater flowrate, m^3/d			
		Treatment plant			
		A	B	C	D
Jan	31	5000	7000	4000	7400
Feb	28	4750	6000	3750	6850
Mar	31	4500	5400	3470	6400
Apr	30	4200	5000	3200	6100
May	31	4000	4700	3000	5800
Jun	30	4000	4600	3000	5600
Jul	31	4000	4550	3000	5450
Aug	31	4000	4570	3000	5400
Sep	30	4000	4700	3200	5500
Oct	31	4000	4950	3700	5600
Nov	30	4300	5400	4400	5900
Dec	31	4600	6000	5400	6300
Total	365				—

13–6 The following effluent water quality data were obtained from 4 different activated-sludge plants.

Water quality constituent	Concentration, mg/L			
	Treatment plant			
	A	B	C	D
BOD	5	7	6	11
COD	55	45	60	42
TSS	4	8	7	10
NH_3–N	5	1.0	0.5	1.4
NO_3^-–N	9	10	27.5	5
Total – P	6.3	7.3	6.9	6
pH	?	?	?	?
Cations				
Ca^{2+}	60	140	175	85
Mg^{2+}	40	37	60	33
Na^+	25	33	45	151
K^-	16	12	19	15
Anions				
HCO_3^-	320	440	550	272
SO_4^{2-}	68	132	240	168
Cl^-	35	65	74	210

(continued)

(Continued)

Water quality constituent	Concentration, mg/L			
	Treatment plant			
	A	B	C	D
EC (mmhos/cm)	1.0	1.4	1.9	1.6
TDS	640	930	1265	1000
B	0.55	0.8	1.0	0.7
Temperature °C	20	28	24	26

For one of these effluents (to be selected by instructor): (1) determine the SAR and adj R_{Na}, (2) estimate the pH, (3) determine whether infiltration problems will develop in using these effluents for irrigation, (4) estimate the salinity (expressed as EC) of drainage water if the crop is irrigated to achieve a leaching fraction of 0.1, and (5) estimate also the TDS concentration of the drainage water from the crop irrigation.

13–7 For the waters given in Problem 13–6, determine the appropriate leaching fraction to maintain crop yield, if the crop is known to suffer significant loss in yield when TDS of the soil water exceeds 3000, 4000, 5000, or 6000 mg/L (TDS value to be selected by instructor).

13–8 A common chemical precipitation reaction in water softening is shown in the following equation:

$$Ca(HCO_3)_2 + Ca(OH)_2 \rightarrow 2CaCO_3 + 2H_2O$$

Given a treated wastewater flowrate of 3500, 4000, 4200, and 5500 m^3/d (to be selected by instructor), determine how much $Ca(OH)_2$ is required each day to reduce the Ca^{2+} concentration from 175 mg/L as $CaCO_3$ to 35, 50, 65, and 80 mg/L as $CaCO_3$ (to be selected by instructor) so that the treated wastewater can be used for industrial cooling. Determine also the kilograms of $CaCO_3$ and the sludge volume produced each day if the solids are settled to 1 percent by weight and the specific gravity of $CaCO_3$ is 2.8.

13–9 Reclaimed water with the chemical characteristics given below is being considered for use as makeup water for a cooling tower. Calculate the composition of the blowdown flow if 3, 4, or 5 cycles of concentration are to be used (cycles of concentration and water to selected by instructor). Assume that the temperature of the hot water entering the cooling tower is 55°C. Estimate the solubility of $CaCO_3$ using the data in Table 6–16.

Constituent	Concentration, mg/L			
	A	B	C	D
Ca^{2+} (as $CaCO_3$)	120	90	88	65
Mg^{2+} (as $CaCO_3$)	25	30	12	25
Alkalinity (as $CaCO_3$)	120	100	150	145
SO_4^{2-}	20	15	25	18
Cl^-	16	14	20	18
SiO_2	2.2	2.5	3.1	5.0

13-10 In your state which federal, state, or local agencies are involved in setting water reclamation regulations? Discuss the pros and cons of the federal government establishing national water reuse criteria.

13-11 Review the current literature (a minimum of five articles should be reviewed and cited) and list health and regulatory factors affecting implementation of water reuse projects. What is the rationale for setting less stringent microbiological standards in developing countries where enteric diseases are rampant among the population?

13-12 Discuss the feasibility of wastewater reclamation and reuse by means of decentralized wastewater treatment facilities.

PROBLEMS AND DISCUSSION TOPICS 1623

REFERENCES 1628

The constituents removed in wastewater-treatment plants include screenings, grit, scum, solids, and biosolids. The solids and biosolids (formerly collectively called sludge) resulting from wastewater-treatment operations and processes are usually in the form of a liquid or semisolid liquid, which typically contains from 0.25 to 12 percent solids by weight, depending on the operations and processes used. The term *biosolids*, as defined by the Water Environment Federation (WEF 1998), reflects the fact that wastewater solids are organic products that can be used beneficially after treatment with processes such as stabilization and composting. The term *sludge* is used only before beneficial use criteria (discussed in Sec. 14–2) have been achieved. The term *sludge* is generally used in conjunction with a process descriptor, such as *primary sludge*, *waste-activated sludge*, and *secondary sludge*. In cases where it is uncertain whether beneficial use criteria have been met, the term *solids* is used.

Of the constituents removed by treatment, solids and biosolids are by far the largest in volume, and their processing, reuse, and disposal present perhaps the most complex problem facing the engineer in the field of wastewater treatment. For this reason, a separate chapter has been devoted to this subject. The disposal of grit and screenings is discussed in Chap. 5.

The problems of dealing with solids and biosolids are complex because (1) they are composed largely of the substances responsible for the offensive character of untreated wastewater; (2) the portion of biosolids produced from biological treatment requiring disposal is composed of the organic matter contained in the wastewater but in another form, and it, too, will decompose and become offensive; and (3) only a small part is solid matter. The principal purpose of this chapter is to describe the solids operations and the processes that are used (1) to reduce the water and organic content and (2) to render the processed solids suitable for reuse or final disposal.

The principal methods used for solids processing are listed in Table 14–1. Thickening (concentration), conditioning, dewatering, and drying are used primarily to remove

Table 14–1
Solids processing methods

Unit operation, unit process, or treatment method	Function	See Sec.
Pumping	Transport of sludge and liquid biosolids	14–4
Preliminary operations:		
Grinding	Particle size reduction	14–5
Screening	Removal of fibrous materials	14–5
Degritting	Grit removal	14–5
Blending	Homogenization of solids streams	14–5
Storage	Flow equalization	14–5
Thickening:		
Gravity thickening	Volume reduction	14–6
Flotation thickening	Volume reduction	14–6
Centrifugation	Volume reduction	14–6
Gravity-belt thickening	Volume reduction	14–6
Rotary-drum thickening	Volume reduction	14–6
Stabilization:		
Alkaline stabilization	Stabilization	14–8
Anaerobic digestion	Stabilization, mass reduction	14–9
Aerobic digestion	Stabilization, mass reduction	14–10
Autothermal aerobic digestion (ATAD)	Stabilization, mass reduction	14–10
Composting	Stabilization, product recovery	14–11
Conditioning:		
Chemical conditioning	Improve dewaterability	14–12
Other conditioning methods	Improve dewaterability	14–12
Dewatering:		
Centrifuge	Volume reduction	14–13
Belt-filter press	Volume reduction	14–13
Filter press	Volume reduction	14–13

Dedicated land disposal	Disposal, land reclamation	14–17
Landfilling	Disposal	
Conveyance and storage	Solids transport and storage	14–18

moisture from solids; digestion, composting, and incineration are used primarily to treat or stabilize the organic material in the solids. To make the study of these operations and processes more meaningful, the first two sections of this chapter are devoted to a discussion of the sources, characteristics, and quantities of solids; the current regulatory environment; and a presentation of representative solids-treatment process flow diagrams. Because the pumping of sludge is a fundamental part of wastewater-treatment plant design, a separate discussion (Sec. 14–4) is devoted to sludge and scum pumping. The various methods used in the processing of solids are discussed in Secs. 14–5 through 14–15. Stabilization of solids and biosolids is introduced in Sec. 14–7 and is divided into four subsequent sections for more detailed discussion: alkaline stabilization, anaerobic digestion, aerobic digestion, and composting (see Secs. 14–8 through 14–11). The preparation of solids balances for treatment facilities is described in Sec. 14–16. The application of biosolids to land and conveyance and storage of biosolids after processing is discussed in Secs. 14–17 and 14–18.

14–1 SOLIDS SOURCES, CHARACTERISTICS, AND QUANTITIES

To design solids processing, treatment, and disposal facilities properly, the sources, characteristics, and quantities of the solids to be handled must be known. Therefore, the purpose of this section is to present background data and information on these topics that will serve as a basis for the material to be presented in the subsequent sections of this chapter.

Sources

The sources of solids in a treatment plant vary according to the type of plant and its method of operation. The principal sources of solids and the types generated are reported in Table 14–2. For example, in a complete mix activated-sludge process, if the wasting of solids is accomplished from the mixed liquor line or aeration chamber, the activated-sludge settling tank is not a source of solids. On the other hand, if wasting is accomplished from the activated-sludge return line, the activated-sludge settling tank constitutes a solids source. Processes used for thickening, digesting, conditioning, and dewatering of solids produced from primary and secondary settling tanks also constitute sources.

Characteristics

To treat and dispose of the solids produced from wastewater-treatment plants in the most effective manner, it is important to know the characteristics of the solids that will be processed. The characteristics vary depending on the origin of the solids, the amount of aging that has taken place, and the type of processing to which they have been subjected (see Table 14–3).

General Composition. Typical data on the chemical composition of untreated sludge and digested biosolids are reported in Table 14–4. Many of the chemical constituents, including nutrients, are important in considering the ultimate disposal of the processed solids and the liquid removed during processing. The measurement of pH,

Table 14–2
Sources of solids from conventional wastewater-treatment plants

Unit operation or process	Types of solids	Remarks
Screening	Coarse solids	Coarse solids are removed by mechanical and hand-cleaned bar screens. In small plants, screenings are often comminuted for removal in subsequent treatment units
Grit removal	Grit and scum	Scum-removal facilities are often omitted in grit-removal facilities
Preaeration	Grit and scum	In some plants, scum-removal facilities are not provided in preaeration tanks. If the preaeration tanks are not preceded by grit-removal facilities, grit deposition may occur in preaeration tanks
Primary sedimentation	Primary solids and scum	Quantities of solids and scum depend upon the nature of the collection system and whether industrial wastes are discharged to the system
Biological treatment	Suspended solids	Suspended solids are produced by the biological conversion of BOD. Some form of thickening may be required to concentrate the waste sludge stream from the biological treatment system
Secondary sedimentation	Secondary biosolids and scum	Provision for scum removal from secondary settling tanks is a requirement of the U.S. EPA
Solids processing facilities	Solids, compost, and ashes	The characteristics of the end products depend on the characteristics of the solids treated and the operations and processes used. Regulations for the disposal of residuals are stringent

alkalinity, and organic acid content is important in process control of anaerobic digestion. The content of heavy metals, pesticides, and hydrocarbons has to be determined when incineration and land application methods are contemplated. The thermal content of solids is important where a thermal reduction process such as incineration is considered.

Specific Constituents. Solids characteristics that affect their suitability for application to land and for beneficial use include organic content (usually measured as volatile solids), nutrients, pathogens, metals, and toxic organics. The fertilizer value of the sludge and solids, which should be evaluated where they are to be used as a soil conditioner, is based primarily on the content of nitrogen, phosphorus, and potassium (potash). Typical nutrient values of wastewater biosolids as compared to commercial fertilizers are reported in Table 14–5. In most land application systems, biosolids provide sufficient nutrients for good plant growth. In some applications, the phosphorus and potassium content may be low and require augmentation.

Trace elements are those inorganic chemical elements that, in very small quantities, can be essential or detrimental to plants and animals. The term "heavy metals" is used to denote several of the trace elements present in sludge and biosolids. Concentrations of heavy metals may vary widely, as indicated in Table 14–6. For the application of biosolids to land, concentrations of heavy metals may limit the application rate and the useful life of the application site (see Sec. 14–17).

Table 14–3
Characteristics of solids and sludge produced during wastewater treatment

Solids or sludge	Description
Screenings	Screenings include all types of organic and inorganic materials large enough to be removed on bar racks. The organic content varies, depending on the nature of the system and the season of the year
Grit	Grit is usually made up of the heavier inorganic solids that settle with relatively high velocities. Depending on the operating conditions, grit may also contain significant amounts of organic matter, especially fats and grease
Scum/grease	Scum consists of the floatable materials skimmed from the surface of primary and secondary settling tanks and from grit chambers and chlorine contact tanks, if so equipped. Scum may contain grease, vegetable and mineral oils, animal fats, waxes, soaps, food wastes, vegetable and fruit skins, hair, paper and cotton, cigarette tips, plastic materials, condoms, grit particles, and similar materials. The specific gravity of scum is less than 1.0 and usually around 0.95
Primary sludge	Sludge from primary settling tanks is usually gray and slimy and, in most cases, has an extremely offensive odor. Primary sludge can be readily digested under suitable conditions of operation
Sludge from chemical precipitation	Sludge from chemical precipitation with metal salts is usually dark in color, though its surface may be red if it contains much iron. Lime sludge is grayish-brown. The odor of chemical sludge may be objectionable but is not as objectionable as the odor of primary sludge. While chemical sludge is somewhat slimy, the hydrate of iron or aluminum in it makes it gelatinous. If the sludge is left in the tank, it undergoes decomposition similar to primary sludge, but at a slower rate. Substantial quantities of gas may be given off and the sludge density increased by long residence times in storage
Activated sludge	Activated sludge generally has a brown flocculent appearance. If the color is dark, the sludge may be approaching a septic condition. If the color is lighter than usual, there may have been underaeration with a tendency for the solids to settle slowly. Sludge in good condition has an inoffensive "earthy" odor. The sludge tends to become septic rapidly and then has a disagreeable odor of putrefaction. Activated sludge will digest readily alone or when mixed with primary sludge
Trickling-filter sludge	Humus sludge from trickling filters is brownish, flocculent, and relatively inoffensive when fresh. It generally undergoes decomposition more slowly than other undigested sludges. When trickling-filter sludge contains many worms, it may become inoffensive quickly. Trickling-filter sludge digests readily
Aerobically digested biosolids	Aerobically digested biosolids are brown to dark brown and have a flocculent appearance. The odor of aerobically digested sludge is not offensive; it is often characterized as musty. Well-digested aerobic sludge dewaters easily on drying beds
Anaerobically digested biosolids	Anaerobically digested biosolids are dark brown to black and contain an exceptionally large quantity of gas. When thoroughly digested, they are not offensive, the odor being relatively faint and like that of hot tar, burnt rubber, or sealing wax. Primary sludge, when anaerobically digested, produces about twice as much methane gas as does waste activated sludge. When drawn off onto porous beds in thin layers, the solids first are carried to the surface by the entrained gases, leaving a sheet of comparatively clear water. The water drains off rapidly and allows the solids to sink down slowly onto the bed. As the solids dry, the gases escape, leaving a well-cracked surface with an odor resembling that of garden loam
Compost	Composted solids are usually dark brown to black, but the color may vary if bulking agents such as recycled compost or wood chips have been used in the composting process. The odor of well-composted solids is inoffensive and resembles that of commercial garden-type soil conditioners

Note: kJ/kg × 0.4303 = Btu/lb.

Table 14–5
Comparison of nutrient levels in commercial fertilizers and wastewater biosolids[a]

Product	Nutrients, %		
	Nitrogen	Phosphorus	Potassium
Fertilizers for typical agricultural use[a]	5	10	10
Typical values for stabilized wastewater biosolids (based on TS)	3.3	2.3	0.3

[a]The concentrations of nutrients may vary widely depending upon the soil and crop needs.

Quantities

Data on the quantities of solids produced from various processes and operations are presented in Table 14–7. Although the data in Table 14–7 are useful as presented, it should be noted that the quantity of solids produced would vary widely. Corresponding data on the solids concentrations to be expected from various processes are given in Table 14–8.

Table 14–6
Typical metal content in wastewater solids[a]

Metal	Dry solids, mg/kg	
	Range	Median
Arsenic	1.1–230	10
Cadmium	1–3410	10
Chromium	10–99,000	500
Cobalt	11.3–2490	30

Selenium	1.7–17.2	5
Tin	2.6–329	14
Zinc	101–49,000	1700

[a]U.S. EPA (1984).

Quantity Variations. The quantity of solids entering the wastewater-treatment plant daily may be expected to fluctuate over a wide range. To ensure capacity capable of handling these variations, the designer of solids processing and disposal facilities should consider (1) the average and maximum rates of solids production, and (2) the potential storage capacity of the treatment units within the plant. The variation in daily quantity that may be expected in large cities is shown on Fig. 14–1. The curve is characteristic of large cities having a number of large collection lines laid on flat slopes; even greater variations may be expected at small plants.

A limited quantity of solids may be stored temporarily in the sedimentation and aeration tanks. Where digestion tanks with varying levels are used, their large storage capacity provides a substantial dampening effect on peak digested solids loads. In solids-treatment systems where digestion is used, the design is usually based on maximum monthly loadings; however, digesters that have a 15 d solids residence time frequently use maximum 15 d loadings. Where digestion is not used, the solids-treatment process should be designed based on the inherent storage capacity available in the solids handling system. For example, the mechanical dewatering system following gravity thickening could be based on the maximum 1 or 3 d solids production. Certain components of the solids operations system, such as sludge pumping and thickening, may need to be sized to handle the maximum-day conditions.

Volume-Mass Relationships. The volume of sludge depends mainly on its water content and only slightly on the character of the solid matter. A 10 percent sludge, for example, contains 90 percent water by weight. If the solid matter is composed of

Table 14–7
Typical data for the physical characteristics and quantities of sludge produced from various wastewater-treatment operations and processes

Treatment operation or process	Specific gravity of solids	Specific gravity of sludge	Dry solids, lb/10³ gal		Dry solids, kg/10³ m³	
			Range	Typical	Range	Typical
Primary sedimentation	1.4	1.02	0.9–1.4	1.25	110–170	150

Primary sludge	2.5–7	3.5
Primary sludge and waste activated sludge	1.5–4	2.5
Primary sludge and trickling-filter humus	0.8–2.5	1.3

Figure 14–1

Peak sludge loading as a percentage of the average daily load.

where W_s = weight of solids
S_s = specific gravity of solids
ρ_w = density of water
W_f = weight of fixed solids (mineral matter)
S_f = specific gravity of fixed solids
W_v = weight of volatile solids
S_v = specific gravity of volatile solids

Therefore, if one-third of the solid matter in a sludge containing 90 percent water is composed of fixed mineral solids with a specific gravity of 2.5, and two-thirds is composed of volatile solids with a specific gravity of 1.0, then the specific gravity of all solids S_s would be equal to 1.25, as follows:

$$\frac{1}{S_s} = \frac{0.33}{2.5} + \frac{0.67}{1} = 0.802$$

$$S_s = \frac{1}{0.802} = 1.25$$

If the specific gravity of the water is taken to be 1.0, the specific gravity of the sludge S_{sl} is 1.02, as follows:

$$\frac{1}{S_{sl}} = \frac{0.1}{1.25} + \frac{0.9}{1.0} = 0.98$$

$$S_{sl} = \frac{1}{0.98} = 1.02$$

The volume of sludge may be computed with the following expression:

$$V = \frac{M_s}{\rho_w S_{sl} P_s} \tag{14–2}$$

where V = volume, m^3
M_s = mass of dry solids, kg
ρ_w = specific weight of water, 10^3 kg/m^3

S_{sl} = specific gravity of the sludge
P_s = percent solids expressed as a decimal

For approximate calculations for a given solids content, it is simple to remember that the volume varies inversely with the percent of solid matter contained in the sludge as given by

$$\frac{V_1}{V_2} = \frac{P_2}{P_1} \qquad \text{(approximate)}$$

where V_1, V_2 = sludge volumes
P_1, P_2 = percent of solid matter

The application of these volume and weight relationships is illustrated in Example 14–1.

EXAMPLE 14–1 Volume of Untreated and Digested Sludge Determine the liquid volume before and after digestion and the percent reduction for 500 kg (dry basis) of primary sludge with the following characteristics:

	Primary	Digested
Solids, %	5	10
Volatile matter, %	60	60 (destroyed)
Specific gravity of fixed solids	2.5	2.5
Specific gravity of volatile solids	≈1.0	≈1.0

Solution

1. Compute the average specific gravity of all the solids in the primary sludge using Eq. (14–1).

$$\frac{1}{S_s} = \frac{0.4}{2.5} + \frac{0.6}{1.0} = 0.76$$

$$S_s = \frac{1}{0.76} = 1.32 \qquad \text{(primary solids)}$$

2. Compute the specific gravity of the primary sludge.

$$\frac{1}{S_{sl}} = \frac{0.05}{1.32} + \frac{0.95}{1}$$

$$S_{sl} = \frac{1}{0.99} = 1.01$$

3. Compute the volume of the primary sludge using Eq. (14–2).

$$V = \frac{500 \text{ kg}}{(1000 \text{ kg/m}^3)(1.01)(0.05)}$$

$$= 9.9 \text{ m}^3$$

4. Compute the percentage of volatile matter after digestion.

$$\text{Volatile matter, \%} = \frac{\text{total volatile solids after digestion}}{\text{total solids after digestion}} \times 100$$

$$= \frac{0.4(0.6 \times 1000)}{400 - 0.4\,(600)} \times 100 = 37.5\%$$

5. Compute the average specific gravity of all the solids in the digested sludge using Eq. (14–1).

$$\frac{1}{S_s} = \frac{0.625}{2.5} + \frac{0.375}{1} = 0.625$$

$$S_s = \frac{1}{0.625} = 1.6 \qquad \text{(digested solids)}$$

6. Compute the specific gravity of the digested sludge (S_{ds}).

$$\frac{1}{S_{ds}} = \frac{0.1}{1.6} + \frac{0.90}{1} = 0.96$$

$$S_{ds} = \frac{1}{0.96} = 1.04$$

7. Compute the volume of digested sludge using Eq. (14–2).

$$V = \frac{200\text{ kg} + 0.4(300\text{ kg})}{(1000\text{ kg/m}^3)(1.04)(0.10)}$$

$$= 3.1\text{ m}^3$$

8. Determine the percentage reduction in the sludge volume after digestion.

$$\text{\% reduction} = \frac{(9.9 - 3.1)\text{ m}^3}{9.9\text{ m}^3} \times 100 = 68.7$$

14–2 REGULATIONS FOR THE REUSE AND DISPOSAL OF SOLIDS IN THE UNITED STATES

In selecting the appropriate methods of solids processing, reuse, and disposal, consideration must be given to the appropriate regulations. In the United States, regulations (40 CFR Part 503) were promulgated in 1993 by the U.S. Environmental Protection Agency that established pollutant numerical limits and management practices for the reuse and disposal of solids generated from the processing of municipal wastewater and septage (Federal Register, 1993). The regulations were designed to protect public health and the environment from any reasonably anticipated adverse effects of pollutants contained in the biosolids.

The regulations addressed by 40 CFR Part 503 cover specifically (1) land application of biosolids, (2) surface disposal of biosolids, (3) pathogen and vector reduction in treated biosolids, and (4) incineration. Each of these subjects is discussed below. The regulations directly affect selection of many of the processes used in solids treatment, especially for sludge stabilization, i.e., alkaline stabilization, anaerobic digestion, aerobic digestion, and composting. In some cases, to achieve compliance, appropriate treatment requirements or methods are stipulated by the regulations. Additional discussion regarding regulations for applying biosolids on land is provided in Sec. 14–17.

Land Application

Land application relates to biosolids reuse and includes all forms of applying bulk or bagged biosolids to land for beneficial uses at agronomic rates, i.e., rates designed to provide the amount of nitrogen needed by crop or vegetation while minimizing the amount that passes below the root zone. The regulations establish two levels of biosolids quality with respect to heavy metals concentrations—pollutant ceiling and pollutant concentrations ("high" quality biosolids); two levels of quality with respect to pathogen densities—Class A and Class B; and two types of approaches for meeting vector attraction—biosolids processing or use of physical barriers. Vector attraction reduction decreases the potential for spreading infectious disease by vectors such as rodents, insects, and birds.

Surface Disposal

The surface disposal part of the Part 503 regulations apply to (1) dedicated surface disposal sites; (2) monofills, i.e., solids-only landfills; (3) piles or mounds; and (4) impoundments or lagoons. Disposal sites and solids placed on those sites for final disposal are addressed in the surface disposal rules. Surface disposal does not include placement of solids for storage or treatment purposes. Where surface disposal sites do not have a liner or leachate collection system, limits are established for pollutants such as arsenic and nickel and vary based on the distance of the active surface disposal site boundary from the site property line (see Federal Register, 1993).

Pathogen and Vector Attraction Reduction

The 40 CFR Part 503 regulations divide the quality of biosolids into two categories, referred to as Class A and Class B (see definitions in Table 1–1). Class A biosolids must meet specific criteria to ensure they are safe to be used by the general public and for nurseries, gardens, and golf courses. Class B biosolids have lesser treatment requirements than Class A, and typically are used for application to agricultural land or disposed of in a landfill.

When biosolids are prepared for sale or given away for land application to lawns and home gardens or are marketed in containers, they must meet one of the following Class A biosolids criteria:

- A fecal coliform density of less than 1000 MPN/g total dry solids
- *Salmonella* sp. density of less that 3 MPN per 4 g total dry solids (3 MPN/4 g TS)

Bulk biosolids applied to lawns and home gardens or sold or given away in bags or other containers must meet the Class A criteria for pathogen reduction (see Table 14–9)

Table 14-9
Pathogen reduction alternatives[a]

Class A:	
In addition to meeting the requirements in one of the six alternatives listed below, fecal coliform or *Salmonella* sp. bacterial levels must meet specific densities at the time of biosolids use or disposal, when prepared for sale or giveaway in a bag or other container for application to the land, or when prepared to meet the requirements in 503.10(b), (c), (e), or (f)	
Alternative 1	Thermally treated biosolids: use one of four time-temperature regimes
Alternative 2	Biosolids treated in a high pH–high temperature process: specifies pH, temperature, and air-drying requirements
Alternative 3	For biosolids treated in other processes: demonstrate that the process can reduce enteric viruses and viable helminth ova. Maintain operating conditions used in the demonstration
Alternative 4	Biosolids treated in unknown processes: demonstration of the process is unnecessary. Instead, test for pathogens—*Salmonella* sp. bacteria, enteric viruses, and viable helminth ova—at the time the biosolids are used or disposed of or are prepared for sale or giveaway in a bag or other container for application to the land, or when prepared to meet the requirements in 503.10(b), (c), (e), or (f)
Alternative 5	Use of PFRP: Biosolids are treated in one of the processes to further reduce pathogens (PFRP)
Alternative 6	Use of a process equivalent to PFRP: biosolids are treated in a process equivalent to one of the PFRPs, as determined by the permitting authority
Class B:	
The requirements in one of the three alternatives below must be met in addition to Class B site restrictions for the application of biosolids to land	
Alternative 1	Monitoring of indicator organisms: test for fecal coliform density as an indicator for all pathogens at the time of biosolids use or disposal
Alternative 2	Use of PSRP: biosolids are treated in one of the processes to significantly reduce pathogens (PSRP)
Alternative 3	Use of processes equivalent to PSRP: biosolids are treated in a process equivalent to one of the PSRPs, as determined by the permitting authority

[a] From U.S. EPA (1992).

and one of several vector attraction reduction processing options (see Table 14–10). In addition, other requirements that must be met that are related to either (1) time/temperature for heat drying, (2) alkaline treatment, or (3) testing for virus. Alternatively, biosolids can be treated by a prescribed process that reduces pathogens beyond detectable levels (see Process to Further Reduce Pathogens discussed below).

Class B pathogen requirements are the minimum level of pathogen reduction for land application and surface disposal. The only exception to achieving at least Class B level occurs when the solids are placed in a surface disposal facility that is covered daily. Biosolids that do not qualify as Class B cannot be land applied. To meet Class B requirements, biosolids must be treated by a process that reduces but does not eliminate pathogens (see PSRP, also discussed below), or that must be tested to meet fecal coliform limits of less than 2.0×10^6 MPN/g TS or less than 2.0×10^6 CFU/g TS.

Table 14–10
Vector attraction reduction[a]

Requirement	What is required?	Most appropriate for
Option 1 503.33(b)(1)	At least 38% reduction in volatile solids during biosolids treatment	Biosolids processed by Anaerobic biological treatment Aerobic biological treatment Chemical oxidation
Option 2 503.33(b)(2)	Less than 17% additional volatile solids loss during bench-scale anaerobic batch digestion of the biosolids for 40 additional days at 30–37°C (86–99°F)	Only for anaerobically digested biosolids
Option 3 503.33(b)(3)	Less than 15% additional volatile solids reduction during bench-scale aerobic batch digestion for 30 additional days at 20°C (68°F)	Only for aerobically digested biosolids with 2% or less solids—e.g., biosolids treated in extended aeration plants
Option 4 503.33(b)(4)	SOUR at 20°C (68°F) is 1.5 mg O_2/h·g total solids	Biosolids from aerobic processes (should not be used for composted sludges). Also for biosolids that have been deprived of oxygen for longer than 1–2 h
Option 5 503.33(b)(5)	Aerobic treatment of the biosolids for at least 14 d at over 40°C (104°F) with an average temperature of over 45°C (113°F)	Composted biosolids (Options 3 and 4 are likely to be easier to meet for biosolids from other aerobic processes)
Option 6 503.33(b)(6)	Addition of sufficient alkali to raise the pH to at least 12 at 25°C (77°F) and maintain a pH of 12 for 2 h and a pH of 11.5 for 22 more hours	Alkali-treated biosolids (alkalies include lime, fly ash, kiln dust, and wood ash)
Option 7 503.33(b)(7)	Percent solids of 75% prior to mixing with other materials	Biosolids treated by an aerobic or anaerobic process (i.e., biosolids that do not contain unstabilized solids generated in primary wastewater treatment)
Option 8 503.33(b)(8)	Percent solids of 90% prior to mixing with other materials	Biosolids that contain unstabilized solids generated in primary wastewater treatment (e.g., any heat-dried sludges)
Option 9 503.33(b)(9)	Biosolids are injected into soil so that no significant amount of biosolids is present on the land surface 1 hour after injection, except Class A biosolids, which must be injected within 8 h after the pathogen reduction process	Liquid biosolids applied to the land. Domestic septage applied to agricultural land, a forest, or a reclamation site
Option 10 503.33(b)(10)	Biosolids are incorporated into the soil within 6 h after application to land. Class A biosolids must be applied to the land surface within 8 h after the pathogen reduction process, and must be incorporated within 6 h after application.	Biosolids applied to the land. Domestic septage applied to agricultural land, forest, or a reclamation site

[a]From U.S. EPA (1992).

To meet pathogen and vector reduction requirements, two levels of preapplication treatment are required, and have been defined by the U.S. EPA as Processes to Further Reduce Pathogens (PFRP) and Processes to Significantly Reduce Pathogens (PSRP). These processes are defined in Tables 14–11 and 14–12. Because PSRPs reduce but do not eliminate pathogens, PSRP-treated biosolids still have the potential to transmit disease. Because PFRPs reduce pathogens below detectable levels, there are no pathogen-related restrictions for land application. Minimum frequency of monitoring, record-keeping, and reporting requirements must be met, however.

Incineration

The Part 503 regulations establish requirements for wastewater biosolids-only incinerators. The regulations cover incinerator feed solids, the furnace itself, operation of the furnace, and exhaust gases from the stack. The rule indirectly limits emissions of heavy metals and directly limits total hydrocarbon emissions from incinerator stacks. Pollutant limits for wastewater solids fired in an incinerator are established for beryllium, mercury, lead, arsenic, cadmium, chromium, and nickel. Incinerators must also meet a monthly average limit of 100 ppm for total hydrocarbons (THCs), corrected for moisture level (0 percent) and oxygen content (to 7 percent) to control toxic organic compound emissions (Federal Register, 1993). Monitoring and reporting are also required.

Table 14–11
Regulatory definition of processes to further reduce pathogens (PFRP)[a]

Process	Definition
Composting	Using either within-vessel or static aerated pile composting, the temperature of the biosolids is maintained at 55°C or higher for 3 d. Using windrow composting, the temperature of the wastewater sludge is maintained at 55°C or higher for 15 d or longer. During this period, a minimum of five windrow turnings is required
Heat drying	Dewatered biosolids are dried by direct or indirect contact with hot gases to reduce the moisture content to 10 percent or lower. Either the temperature of solids particles exceeds 80°C or the wet-bulb temperature of the gas stream in contact with the biosolids as the biosolids leave the dryer exceeds 80°C
Heat treatment	Liquid biosolids are heated to a temperature of 180°C or higher for 30 min
Thermophilic aerobic digestion	Liquid biosolids are agitated with air or oxygen to maintain aerobic conditions, and the MCRT is 10 d at 55 to 60°C
Beta-ray irradiation	Biosolids are irradiated with beta rays from an accelerator at dosages of at least 1.0 megarad (Mrad) at room temperature (approximately 20°C)
Gamma-ray irradiation	Biosolids are irradiated with gamma rays from certain isotopes such as 60-cobalt or 135-cesium at dosages of at least 1.0 Mrad at room temperature (approximately 20°C)
Pasteurization	The temperature of the biosolids is maintained at 70°C or higher for at least 30 min

[a]Federal Register (1993).

Table 14–12
Regulatory definition of processes to significantly reduce pathogens (PSRP)[a]

Process	Definition
Aerobic digestion	Biosolids are agitated with air or oxygen to maintain aerobic conditions for an SRT and temperature between 40 d at 20°C and 60 d at 15°C
Air drying	Biosolids are dried on sand beds or on paved or unpaved basins for a minimum of 3 months. During 2 of the 3 months, the ambient average daily temperature exceeds 0°C
Anaerobic digestion	Biosolids are treated in the absence of air between an SRT of 15 d at temperatures of 35 to 55°C and an SRT of 60 d at a temperature of 20°C. Times and temperatures between these endpoints may be calculated by linear interpolation
Composting	Using either within-vessel, static aerated pile, or windrow composting, the temperature of the biosolids is raised to 40°C or higher for 5 d. For 4 h during the 5 d, the temperature in the compost pile exceeds 55°C
Lime stabilization	Sufficient lime is added to raise the pH of the biosolids to pH 12 and maintained for 2 h of contact

[a]Federal Register (1993).

14–3 SOLIDS PROCESSING FLOW DIAGRAMS

A generalized flow diagram incorporating the unit operations and processes to be discussed in this chapter is presented on Fig. 14–2. As shown, an almost infinite number of combinations are possible In practice, the most commonly used process flow diagram for biosolids processing involves biological treatment. Typical flow diagrams incorporating biological processing are presented on Fig. 14–3. Thickeners may be used depending upon the source of sludge and the method of sludge stabilization, dewatering, and disposal. Following biological digestion, any of the several methods shown may be used to dewater the sludge; the choice depends on economic evaluation, beneficial use requirements, and local conditions. In instances where biological stabilization is not used, dewatered biosolids undergo thermal decomposition in either multiple-hearth or fluidized-bed incinerators.

14–4 SLUDGE AND SCUM PUMPING

Sludge produced in wastewater-treatment plants must be conveyed from point to point in the plant in conditions ranging from a watery sludge or scum to a thick sludge. Sludge may also be pumped off-site for long distances for treatment and disposal. For each type of sludge and pumping application, a different type of pump may be needed (see Table 14–13).

Pumps

Pumps used most frequently to convey sludge include the plunger, progressive cavity, centrifugal, torque flow, diaphragm, high-pressure piston, and rotary-lobe types. Other types of pumps such as peristaltic (hose or rotor) pumps and concrete slurry pumps

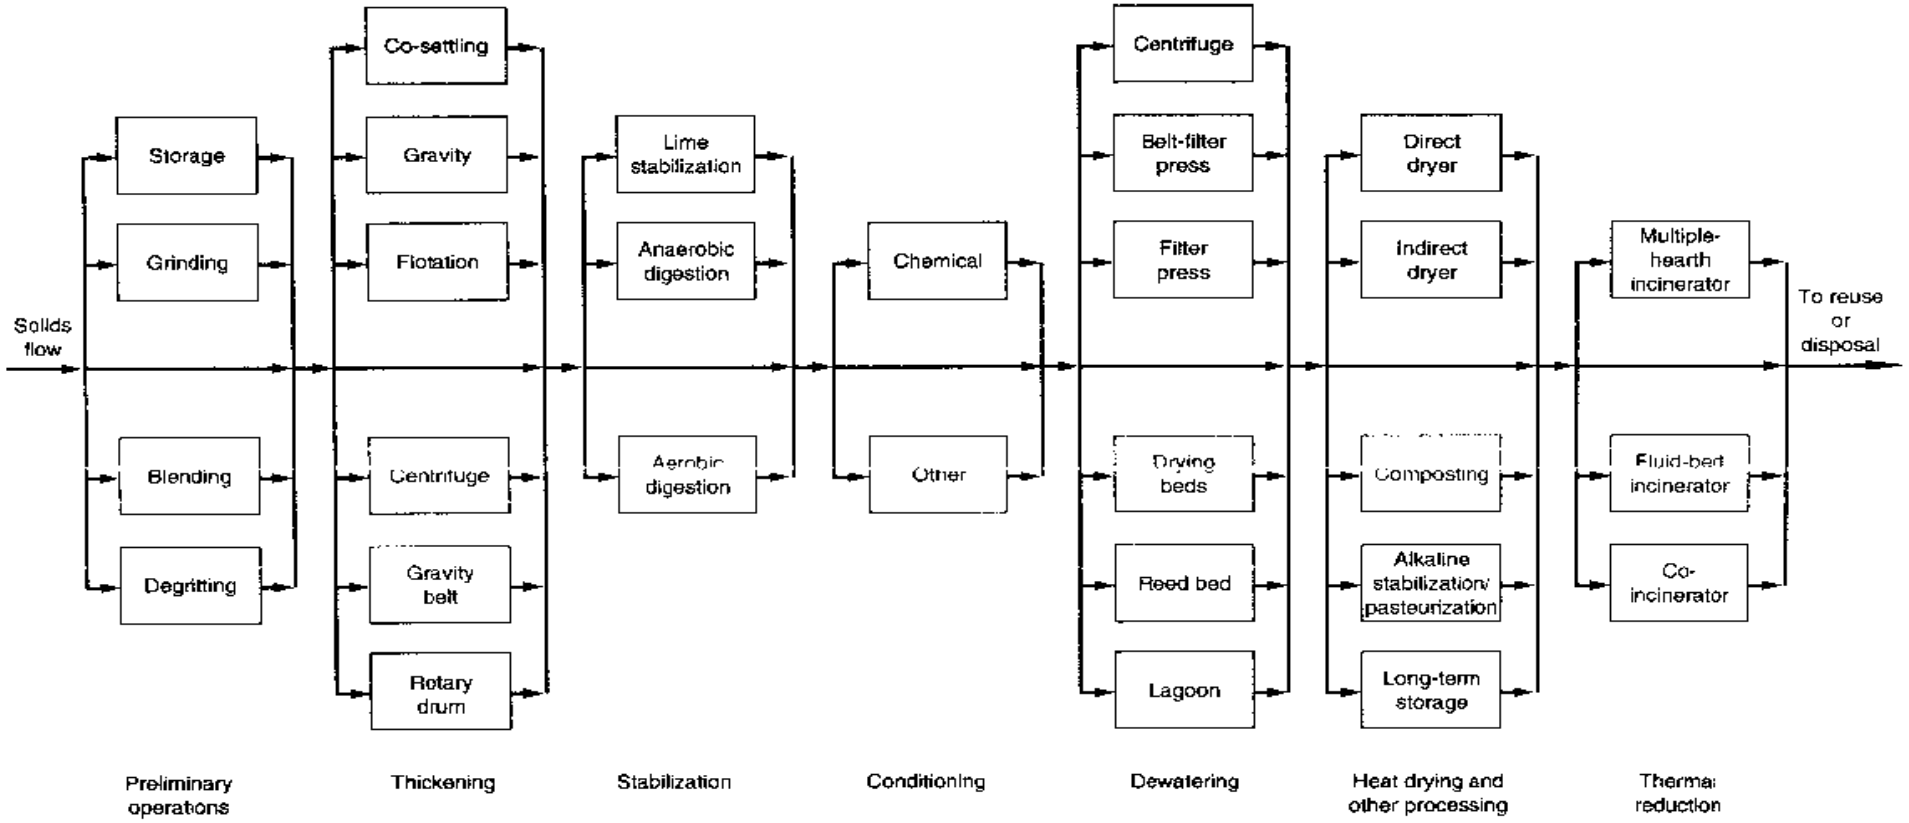

Figure 14–2

Generalized sludge-processing flow diagram.

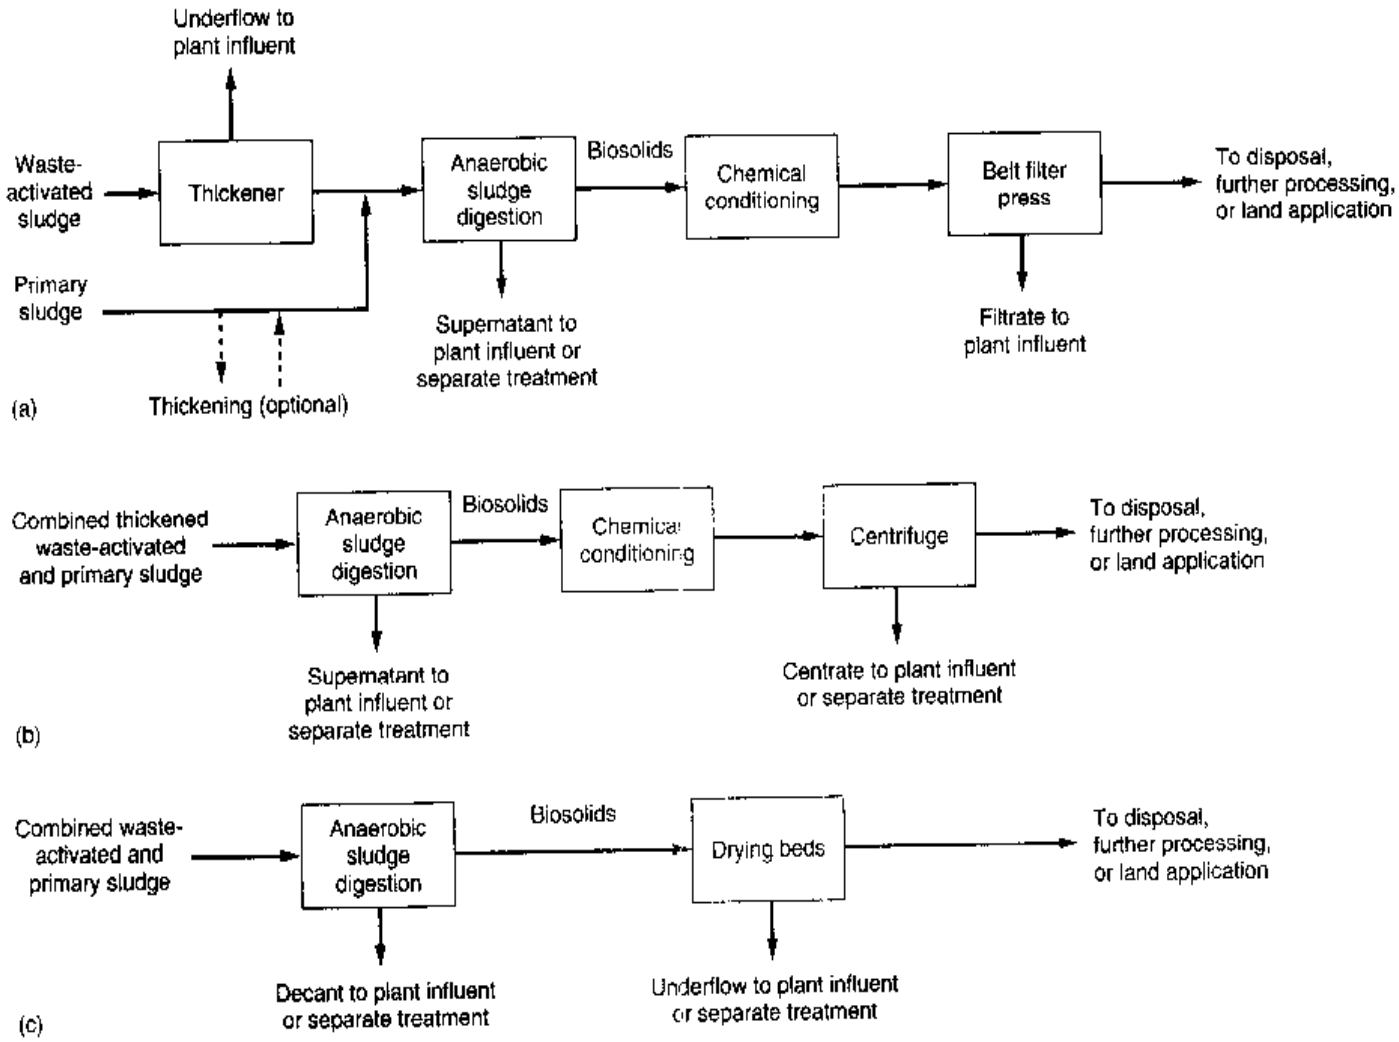

Figure 14–3

Typical sludge treatment flow diagrams with biological digestion and three different sludge dewatering processes: (*a*) belt-filter press, (*b*) centrifuge, (*c*) drying beds. In some plants, flows that are to be returned to the headworks are stored in equalization basins for return to the treatment process during the early morning hours when the plant load is reduced.

have also been used to pump sludge. Diaphragm and centrifugal pumps also are used extensively for pumping scum. "Chopper" type centrifugal pumps are also used for pumping sludge and scum containing rags, plastics, and other fibrous materials that require shredding. The advantages and disadvantages of each type of pump are summarized in Table 14–14.

Plunger Pumps. Plunger pumps (see Fig. 14–4*a*) have been used frequently, and if rugged enough for the service, have proved to be quite satisfactory. The advantages of plunger pumps are as follows:

1. Pulsating action of simplex and also duplex pumps tends to concentrate the sludge in the hoppers ahead of the pumps and resuspend solids in pipelines when pumping at low velocities.
2. They are suitable for suction lifts up to 3 m (10 ft) and are self-priming.

Table 14–13
Application of pumps to types of sludge and biosolids[a]

Type of sludge or solids	Applicable pump	Comment
Ground screenings	Pumping screenings should be avoided	Pneumatic ejectors may be used
Grit	Torque flow centrifugal	The abrasive character of grit and the presence of rags make grit difficult to handle. Hardened casings and impellers should be used for torque flow pumps. Pneumatic ejectors may also be used
Scum	Plunger; progressive cavity; diaphragm; centrifugal; chopper	Scum is often pumped by the sludge pumps; valves are manipulated in the scum and sludge lines to permit this. In larger plants separate scum pumps are used. Scum mixers are often used to ensure homogeneity prior to pumping. Pneumatic ejectors may also be used
Primary sludge	Plunger; centrifugal torque flow; diaphragm progressive cavity; rotary lobe; chopper; hose	In most cases, it is desirable to obtain as concentrated a sludge as practicable from primary sedimentation tanks, usually by collecting the sludge in hoppers and pumping intermittently, allowing the solids to collect and consolidate between pumping periods. The character of untreated primary solids will vary considerably, depending on the characteristics of the solids in the wastewater, and the types of treatment units and their efficiency. Where biological treatment follows, the quantity of solids from (1) waste-activated sludge, (2) humus sludge from settling tanks following trickling filters, (3) overflow liquors from digestion tanks, (4) and centrate or filtrate return from dewatering operations will also affect the sludge characteristics. In many cases, the character of the sludge is not suitable for the use of conventional nonclog centrifugal pumps. Where sludge contains rags, chopper pumps may be used
Sludge from chemical precipitation	Same as primary sludge	May contain large amounts of inorganic constituents depending on the type and amount of chemicals used
Trickling-filter humus	Nonclog and torque flow centrifugal; progressive cavity; plunger; diaphragm	Humus is usually of homogeneous character and can be easily pumped
Return or waste-activated sludge	Nonclog and torque flow centrifugal; progressive cavity; plunger; diaphragm	Sludge is dilute and contains only fine solids so that nonclog pumps may be used. For nonclog pumps, slow speeds are recommended to minimize the breakup of flocculent particles
Thickened or concentrated sludge	Plunger; progressive cavity; diaphragm; high-pressure piston; rotary lobe; hose	Positive-displacement pumps are most applicable for concentrated sludge because of their ability to generate movement of the sludge mass. Torque flow pumps may be used but may require the addition of flushing or dilution facilities
Digested biosolids	Plunger; torque flow centrifugal; progressive cavity; diaphragm; high-pressure piston; rotary lobe	Well-digested biosolids are homogeneous, containing 5 to 8% solids and a quantity of gas bubbles, but may contain up to 12% solids. Poorly digested biosolids may be difficult to handle. If good screening and grit removal are provided, nonclog centrifugal pumps may be considered

[a]Adapted, in part, from U.S. EPA (1979).

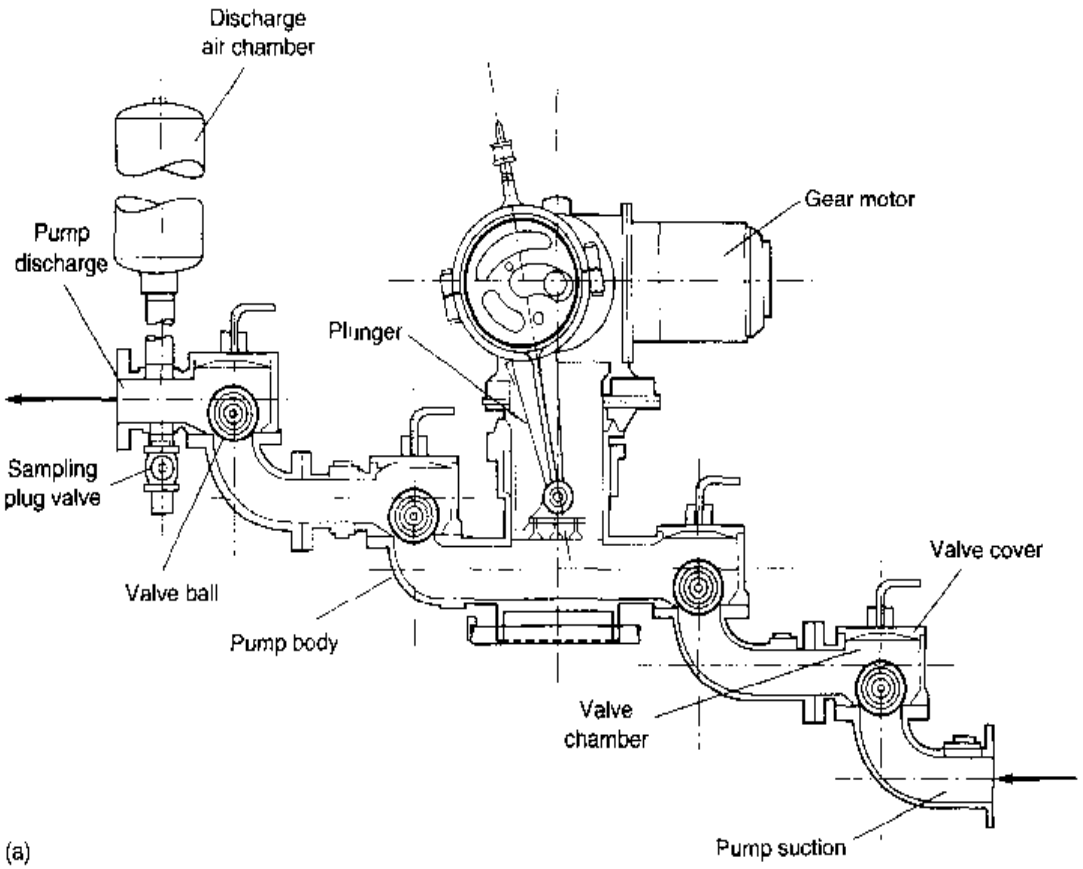
Table 14–14
Advantages and disadvantages of various types of sludge pumps[a]

Type of pump	Advantages	Disadvantages
Plunger	Can pump heavy solids concentrations (up to 15%)	Low efficiency
	Self-priming and can handle suction lifts up to 3 m (10 ft)	High maintenance if operated continuously
	Constant but adjustable capacity regardless of variations in head	Depending on downstream processes, pulsating flow may not be acceptable
	Cost-effective choice for flowrates up to 30 L/s (500 gal/min) and heads up to 60 m (200 ft)	
	Pulsating action of simplex and duplex pumps sometimes helps to concentrate sludge in hoppers ahead of pumps and resuspend solids in pipelines when pumping at low velocities	
	High-pressure capability	
Progressing cavity	Provides a relatively smooth flow	Stator will burn out if pump is operated dry; needs a run dry protection system
	Pumps greater than 3 L/s (50 gal/min) capacity can pass solids of about 20 mm (0.8 in) in size	Smaller pumps usually require grinders to prevent clogging
	Easily controlled flowrates	Power cost escalates when pumping heavy sludge
	Minimal pulsation	Grit in sludge may cause excessive stator wear
	Relatively simple operation	Seals and seal water required
	Stator/rotor tends to act as a check valve, thus preventing backflow through pump. An external check valve may not be required	
Diaphragm	Pulsating action may help to concentrate sludge in hoppers ahead of pumps and resuspend solids in pipelines when pumping at low velocities	Depending on downstream processes, pulsating flow may not be acceptable
	Self-priming with suction lifts up to 3 m (10 ft)	Requires a source of compressed air
	Can pump grit with relatively minimum wear	Operation may be excessively noisy
	Relatively simple operation	Low head and efficiency
		High maintenance if operated continuously
Centrifugal		
Nonclog (mixed flow)	Has high volume and excellent efficiency for activated-sludge pumping applications	Not recommended for other sludge pumping applications because of potential clogging due to rags and other debris
	Relatively low cost	
Recessed impeller	Because of recessed impeller design, pump can pass large solids and grit	Low efficiency—about 5 to 20% lower than standard nonclog pump
	Can pump digested sludges up to approximately 4%	Limited to raw sludges with solids concentrations of 2.5% and less
		Abrasion-resistant impellers cannot be trimmed to modify pumping characteristics

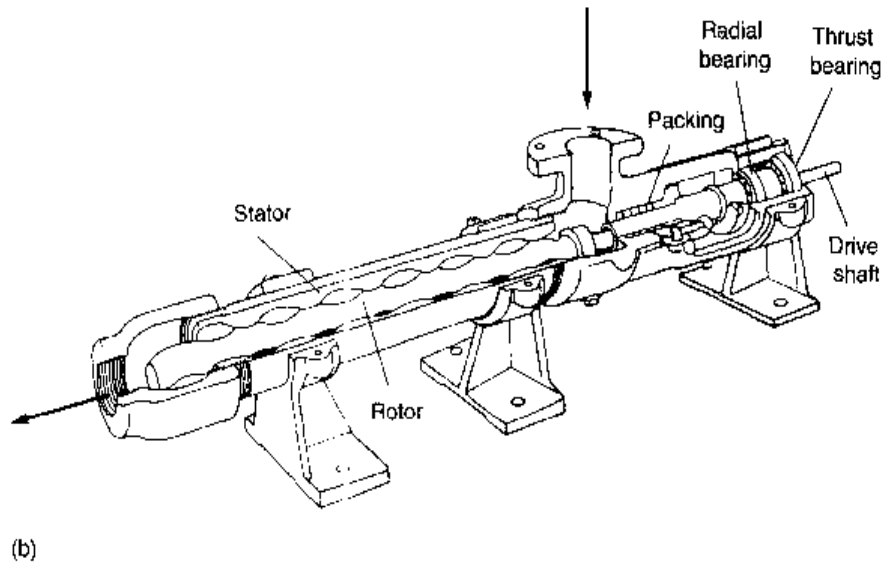
(continued)

Table 14–14 (*Continued*)

Type of Pump	Advantages	Disadvantages
Chopper	Reduces clogging at pump suction May eliminate need for grinder or comminutor Can handle higher solids concentrations than nonclog pumps	Relatively low efficiency—efficiency ranges from about 40 to 60% Requires a level of maintenance similar to grinders
Rotary lobe	Provides a relatively smooth flow Does not require a check valve in most applications with low to moderate discharge static heads Able to run dry for short periods of time without significant damage Low speed and low maintenance	Because of close tolerances between rotating lobes, grit will cause excessive wear, thus reducing pumping efficiency Fluid pumped must act as a lubricant Cost of pumping increases with volume
Peristaltic hose	Has self-priming capabilities Because it is a positive-displacement pump, it is capable of metering flow Relatively simple to maintain Can pump sludge with abrasive grit	Depending on downstream processes, pulsating flow may not be acceptable High starting torque (two to three times running torque) Replacement hoses may be expensive
High-pressure piston	Can be used to pump thickened sludge long distances Can pump at rates of 30 L/s (500 gal/min) at pressures up to 13,800 kPa (2000 lb_f/in^2) Can run dry without major damage Unobstructed internal flow path; can pass large solids	High capital cost Requires skilled maintenance personnel



[a]Adapted, in part, from WEF (1998).

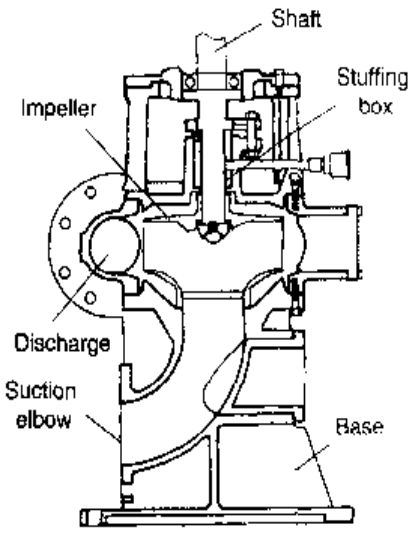


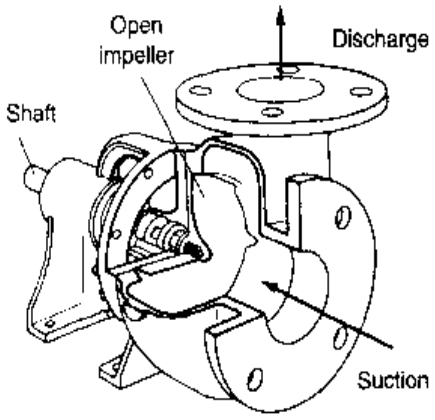
3. Low pumping rates can be used with large port openings.
4. Positive delivery is provided unless some object prevents the ball check valves from seating.
5. They have constant but adjustable capacity, regardless of large variations in pumping head.
6. High discharge heads may be provided for.
7. Heavy solids concentrations may be pumped if the equipment is designed for the load conditions.

Plunger pumps come with one, two, or three plungers (called simplex, duplex, or triplex units) with capacities of 2.5 to 3.8 L/s (40 to 60 gal/min) per plunger, and larger models are available. Pump speeds should be between 40 and 50 r/min. The pumps should be designed for a minimum head of 24 m (80 ft) in small plants and 35 m (115 ft) or more in large plants, because grease accumulations in sludge lines cause a progres-

Figure 14–4

Typical sludge and scum pumps used in wastewater-treatment plants: (a) plunger, (b) progressive cavity. *(Figure continues on next page)*





sive increase in head with use. Heavy-duty pumps are rated at 450 kPa (100 lb_f/in^2) up to 730 kPa (165 lb_f/in^2). Capacity is decreased by shortening the stroke of the plunger; however, the pumps seem to operate more satisfactorily at or near full stroke. For this reason, many pumps are provided with variable-speed drives for speed control of capacity. A plunger pump differs from a centrifugal or torque-flow pump in that its discharge is pulsing due to the action of a piston; consequently, the actual flow while sludge is moving in the pipeline is greater than average pumping capacity. The headloss calculations,

Table 14–15
Factors for computing peak pulsating flow when using plunger pumps

Type of plunger pump	Actual pulsating peak flow
Simplex	3.1 × design flow
Duplex	1.55 × design flow
Triplex	1.2 × design flow

therefore, must be based on the peak pulsating flow rather than the design flow. The factors given in Table 14–15 illustrate how the actual peak pulsating flow can be determined.

Progressive Cavity Pumps. The progressive cavity pump (see Fig. 14–4*b*) has been used successfully on almost all types of sludges. The pump is composed of a single-threaded rotor that operates with a minimum of clearance in a double-threaded helix stator made of rubber. A volume or "cavity" moves progressively from suction to discharge when the rotor turns. The pump is self-priming at suction lifts up to 8.5 m (28 ft), but it must not be operated dry or it will burn out the rubber stator. Progressive cavity

pumps are available in capacities up to 75 L/s (1200 gal/min) and may be operated at discharge heads of 135 m (450 ft) with sludge. For primary sludges, a grinder normally precedes these pumps. The pumps are expensive to maintain because of wear of the rotors and the stators, particularly in primary sludge pumping applications where grit is present. Advantages of the pumps are (1) the flowrates are controlled easily, (2) pulsation is minimal, and (3) operation is relatively simple.

Centrifugal Pumps. Centrifugal pumps of nonclog design (see Fig. 14–4*c*) are commonly used to pump sludge. In centrifugal pumping applications, the problem is choosing the proper size. At any given speed, centrifugal pumps operate well only if the pumping head is within a relatively narrow range; the variable nature of sludge, however, causes pumping heads to change. The selected pumps must have sufficient clearance to pass the solids without clogging and have a small enough capacity to avoid pumping a sludge diluted by large quantities of wastewater overlying the sludge blanket. Throttling the discharge to reduce the capacity is impractical because of frequent stoppages; hence it is absolutely essential that these pumps be equipped with variable-speed drives. Centrifugal pumps of special design: torque-flow and "chopper" type have been used for pumping primary sludge.

Torque-flow pumps (see Fig. 14–4*d*) have impellers that are fully recessed and are very effective in conveying sludge. The size of particles that can be handled is limited only by the diameter of the suction or discharge openings. The rotating impeller develops a vortex in the sludge so that the main propulsive force is the liquid itself. Most of the fluid does not actually pass through the vanes of the impeller, thereby minimizing abrasive contact; however, pumps used in sludge service are recommended to have nickel or chrome abrasion-resistant volute and impellers. The pumps can operate only over a narrow head range at a given speed, so the system operating conditions must be carefully evaluated. Variable speed control is recommended where the pumps are expected to operate over a wide range of head conditions. For high-pressure applications, multiple pumps may be used, connected together in series.

Chopper-type pumps have a cutter knife attached to a nonclog impeller that agitates and breaks up large solids that tend to block the pump suction. Incoming solids are chopped by sharpened impeller blades that turn across the cutter bar. Chopper pumps are manufactured in sizes up to 150 L/s (2400 gal/min) in both horizontal and vertical configurations.

Slow-speed centrifugal and mixed-flow pumps are commonly used for returning activated sludge to the aeration tanks. Screw pumps are also being used for this service.

Diaphragm Pumps. Diaphragm pumps use a flexible membrane that is pushed and pulled to contract and enlarge an enclosed cavity (see Fig. 14–4*e*). Flow is directed through this cavity by check valves, which may be either ball or flap type. The capacity of a diaphragm pump is altered by changing either the length of the diaphragm stroke or the number of strokes per minute. Pump capacity can be increased and flow pulsations smoothed out by providing two pump chambers and using both strokes of the diaphragm for pumping. Diaphragm pumps are relatively low capacity and low head; the largest available air-diaphragm pump delivers 14 L/s (220 gal/min) against 15 m (50 ft) of head.

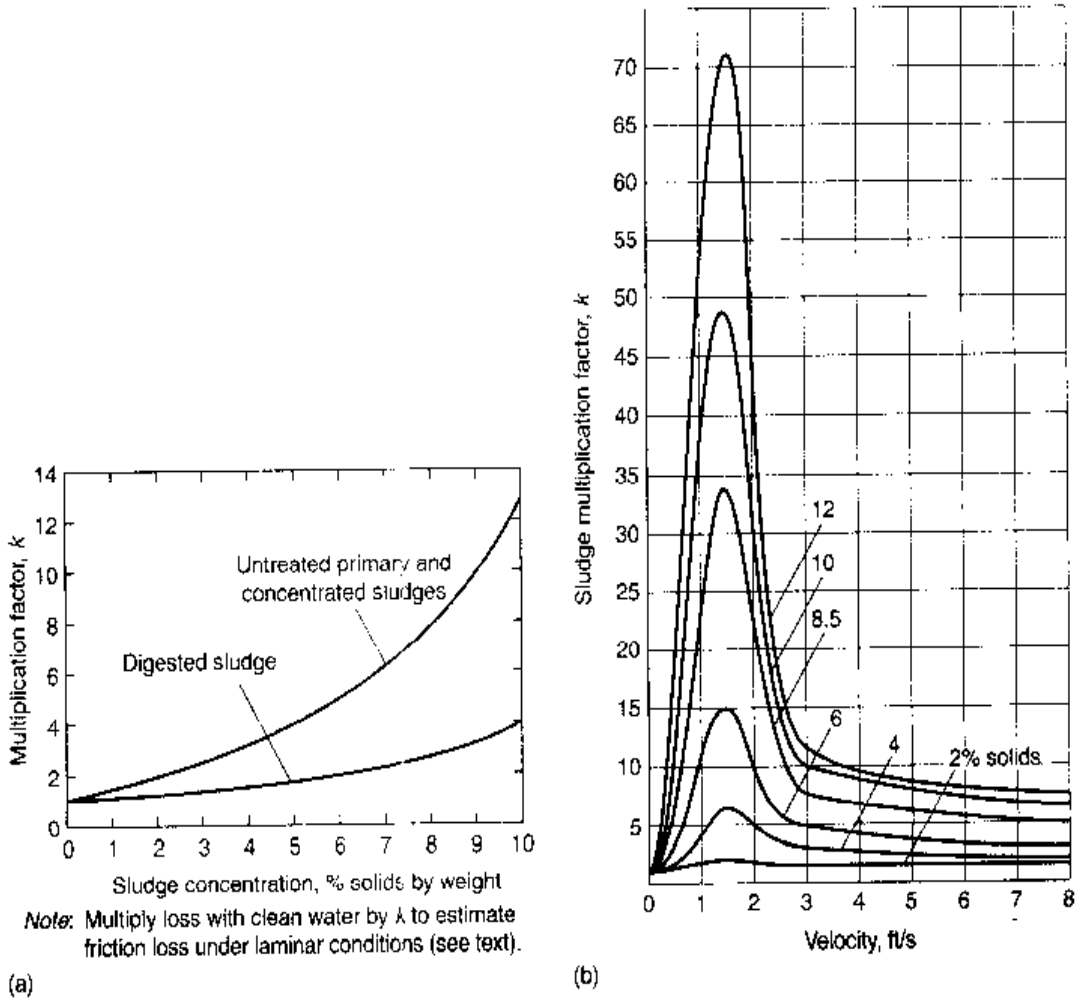
High-Pressure Piston Pumps. High-pressure piston pumps are used in high-pressure applications such as pumping sludge long distances. Several types of piston pumps have been developed for high-pressure applications, and are similar in action to plunger pumps. The high-pressure piston pumps use separate power pistons or membranes to separate the drive mechanisms from contacting the sludge. A piston membrane type of pump is shown on Fig. 14–4*f*. Advantages of these types of pumps are (1) they can pump relatively small flowrates at high pressures, up to 13,800 kN/m^2 (2000 lb$_f$/in^2), (2) large solids up to the discharge pipe diameter can be passed, (3) a range of solids concentrations can be handled, and (4) the pumping can be accomplished in a single stage. The pumps, however, are very expensive.

Rotary-Lobe Pumps. Rotary-lobe pumps (see Fig. 14–4*g*) are positive-displacement pumps in which two rotating synchronous lobes push the fluid through the pump. Rotational speed and shearing stresses are low. For sludge pumping, lobes are made of hard metal or hard rubber. An advantage cited for the rotary-lobe pump is that lobe replacement is less costly than rotor and stator replacement for progressive cavity pumps. Rotary-lobe pumps, like other positive-displacement pumps, must be protected against pipeline obstructions.

Hose Pumps. Peristaltic hose pumps (see Fig. 14–4*h*) have also been used to a limited extent for pumping sludge. The pump works by alternately compressing and relaxing a specially designed resilient hose. The hose is compressed between the inner wall of the pump housing and the compression shoes on the rotor. A lubricant is used to reduce heat and wear on the hose. The pumped sludge only comes in contact with the inner wall of the hose, which cushions entrained abrasives during compression. The pumps are available in capacities ranging from 36 to 1250 L/min (10 to 330 gal/min). As a positive-displacement pump, the pump output is directly proportional to speed at either high or low discharge pressures. The primary disadvantages of the hose pump are the pulsating flow, hose wear, and the relatively high cost of hose replacement.

Headloss Determination

The headloss encountered in the pumping of sludge depends on the flow properties (rheology) of sludge, the pipe diameter, and the flow velocity. It has been observed that headlosses increase with increased solids content, increased volatile content, and lower temperatures. When the percent volatile matter multiplied by the percent solids exceeds 600, difficulties may be encountered in pumping sludge.



Water, oil, and most other fluids are "Newtonian," which means that the pressure drop is proportional to the velocity and viscosity under laminar flow conditions. As the velocity increases past a critical value, the flow becomes turbulent. Dilute sludges such as unconcentrated activated and trickling-filter sludges behave similar to water. Concentrated wastewater sludges, however, are non-Newtonian fluids. The pressure drop under laminar conditions for non-Newtonian fluids is not proportional to flow, so the viscosity is not a constant. Special procedures may be used to determine headloss under laminar-flow conditions, and the velocity at which turbulent flow begins. In this section both the simplified approach of calculating headloss and a method using the sludge rheology will be discussed.

The headloss in pumping unconcentrated activated and trickling-filter sludges may be from 10 to 25 percent greater than for water. Primary, digested, and concentrated sludges at low velocities may exhibit a plastic-flow phenomenon in which a definite pressure is required to overcome resistance and start flow. The resistance then increases approximately with the first power of the velocity throughout the laminar range of flow, which extends to about 1.1 m/s (3.5 ft/s), the lower critical velocity. Above the higher critical velocity at about 1.4 m/s (4.5 ft/s), the flow may be considered turbulent. In the turbulent range, the losses for well-digested sludge may be more than two to three times the losses for water. The losses for primary and concentrated sludges, especially those conditioned with polymer, and scum may be considerably greater. The risk of underestimating the headloss also increases as the piping distance and solids concentrations increase. Where possible, particularly in long-distance sludge pumping, hydraulic studies should be conducted to confirm the ranges of headloss characteristics.

Simplified Headloss Computations. Relatively simple procedures are used to compute headloss for short sludge pipelines. The accuracy of these procedures may be adequate, especially at solids concentrations less than 3 percent by weight. To determine the headloss, the factor k is obtained from Fig. 14–5*a* for a given solids content and type of sludge. The headloss when pumping sludge is computed by multiplying the headloss of water, determined by using the Darcy-Weisbach, Hazen-Williams, or Manning equations, by k.

Figure 14–5

Headloss multiplication factors: (*a*) for different sludge types and concentrations, (*b*) for different pipeline velocities and sludge concentrations.

The values given on Fig. 14–5*a* should be used only when (1) velocities are at least 0.8 m/s (2.5 ft/s), (2) velocities do not exceed 2.4 m/s (8 ft/s), (3) thixotropic behavior is not considered, and (4) the pipe is not obstructed by grease or other materials.

Another approximate method makes use of empirical multiplication factor charts (see Fig. 14–5*b*). The approximate method involves only velocity and percent solids consideration.

Usually, the consistency of untreated primary sludge changes during pumping. At first, the most concentrated sludge is pumped. When most of the sludge has been pumped, the pump must handle a dilute sludge that has essentially the same hydraulic characteristics as water. The change in characteristics causes a centrifugal pump to operate farther out on its head-capacity curve, beyond the areas of best efficiency. The pump motor should be sized for the additional load, and a variable-speed drive should be considered to reduce the flow under changing sludge characteristics. If the pump motor is not sized for the maximum load when pumping water at top speed, it is likely to be overloaded or damaged if the overload devices do not function or are set too high.

To determine the operating speeds and motor power required for a centrifugal pump handling sludge, system curves should be computed (1) for the most dense sludge anticipated, (2) for average conditions, and (3) for water. The curves should be plotted on a graph of the pump curves for a range of available speeds. The maximum and minimum speeds required of a particular pump are obtained from the intersection of the pump head-capacity curves with the system curves at the desired capacity. Where the maximum speed head-capacity curve intersects the system curve for water determines the power required. In constructing the system curves for sludge for velocities from 0 to 1.1 m/s (3.5 ft/s), the headloss can be considered constant at the figure computed for 1.1 m/s. The intersection of the pump curves with the system curve for average conditions can be used to estimate hours of operations, average speed, and power costs.

Because the usual flow formulas cannot be used in the plastic and laminar range, the engineer must rely on judgment and experience. In this range, capacities will be small, and plunger, progressive cavity, or rotary-lobe pumps should be used with ample head and capacity as recommended previously.

Application of Rheology to Headloss Computations. For pumping sludge over long distances, an alternative method of computing headloss characteristics has been developed based on the flow properties of the sludge. A method of computing headloss for laminar-flow conditions was derived originally by Babbitt and Caldwell (1939), based on the results of experimental and theoretical studies. Additional studies have been performed for the transition from laminar to turbulent flow (Mulbarger et al., 1981; U.S. EPA, 1979) and are summarized in Sanks et al. (1998). Long-distance pumping of mixtures of untreated (raw) primary and secondary sludge is discussed by Carthew et al. (1983). The approach used in those studies for turbulent flow, which is of critical importance for long pipelines, is described below. For laminar and transitional flow, computational procedures described in Sanks et al. (1998) are recommended.

As stated previously, water, oil, and most other common fluids are "Newtonian," which means the pressure drop is directly proportional to the velocity and viscosity under laminar-flow conditions. As the velocity increases past a critical value, the flow becomes turbulent. The transition from laminar to turbulent flow depends on the Reynolds number, which is inversely proportional to the fluid viscosity. Wastewater sludge, however, is a

non-Newtonian fluid. The pressure drop under laminar conditions is not proportional to flow, so the viscosity is not a constant. The precise Reynolds number at which turbulent-flow characteristics are encountered is uncertain for sludges.

Sludge has been found to behave much like a Bingham plastic, a substance with a straight-line relationship between shear stress and flow only after flow begins. A Bingham plastic is described by two constants: the yield stress s_y and the coefficient of rigidity η. Typical ranges of values for yield stress and coefficient of rigidity are shown on Fig. 14–6*a* and *b*. If the two constants can be determined, the pressure drop over a wide range of velocities can be obtained using ordinary equations for water and the use of Fig. 14–6*c*. As observed on Fig. 14–6*a* and *b*, published data quantifying yield stress and the coefficient of rigidity values for wastewater sludges are highly variable. Pilot studies should be conducted to determine the rheological data for specific applications. Procedures for developing yield stress and the coefficient of rigidity using a pipeline viscometer and rotational viscometer are also given by Carthew et al. (1983).

Two dimensionless numbers can be used to determine the pressure drop due to friction for sludge: Reynolds number and Hedstrom number. Reynolds number is calculated by using the following expression:

$$N_R = \frac{\rho V D}{\eta} \qquad \text{SI units} \tag{14–3a}$$

$$N_R = \frac{\gamma V D}{\eta} \qquad \text{U.S. customary units} \tag{14–3b}$$

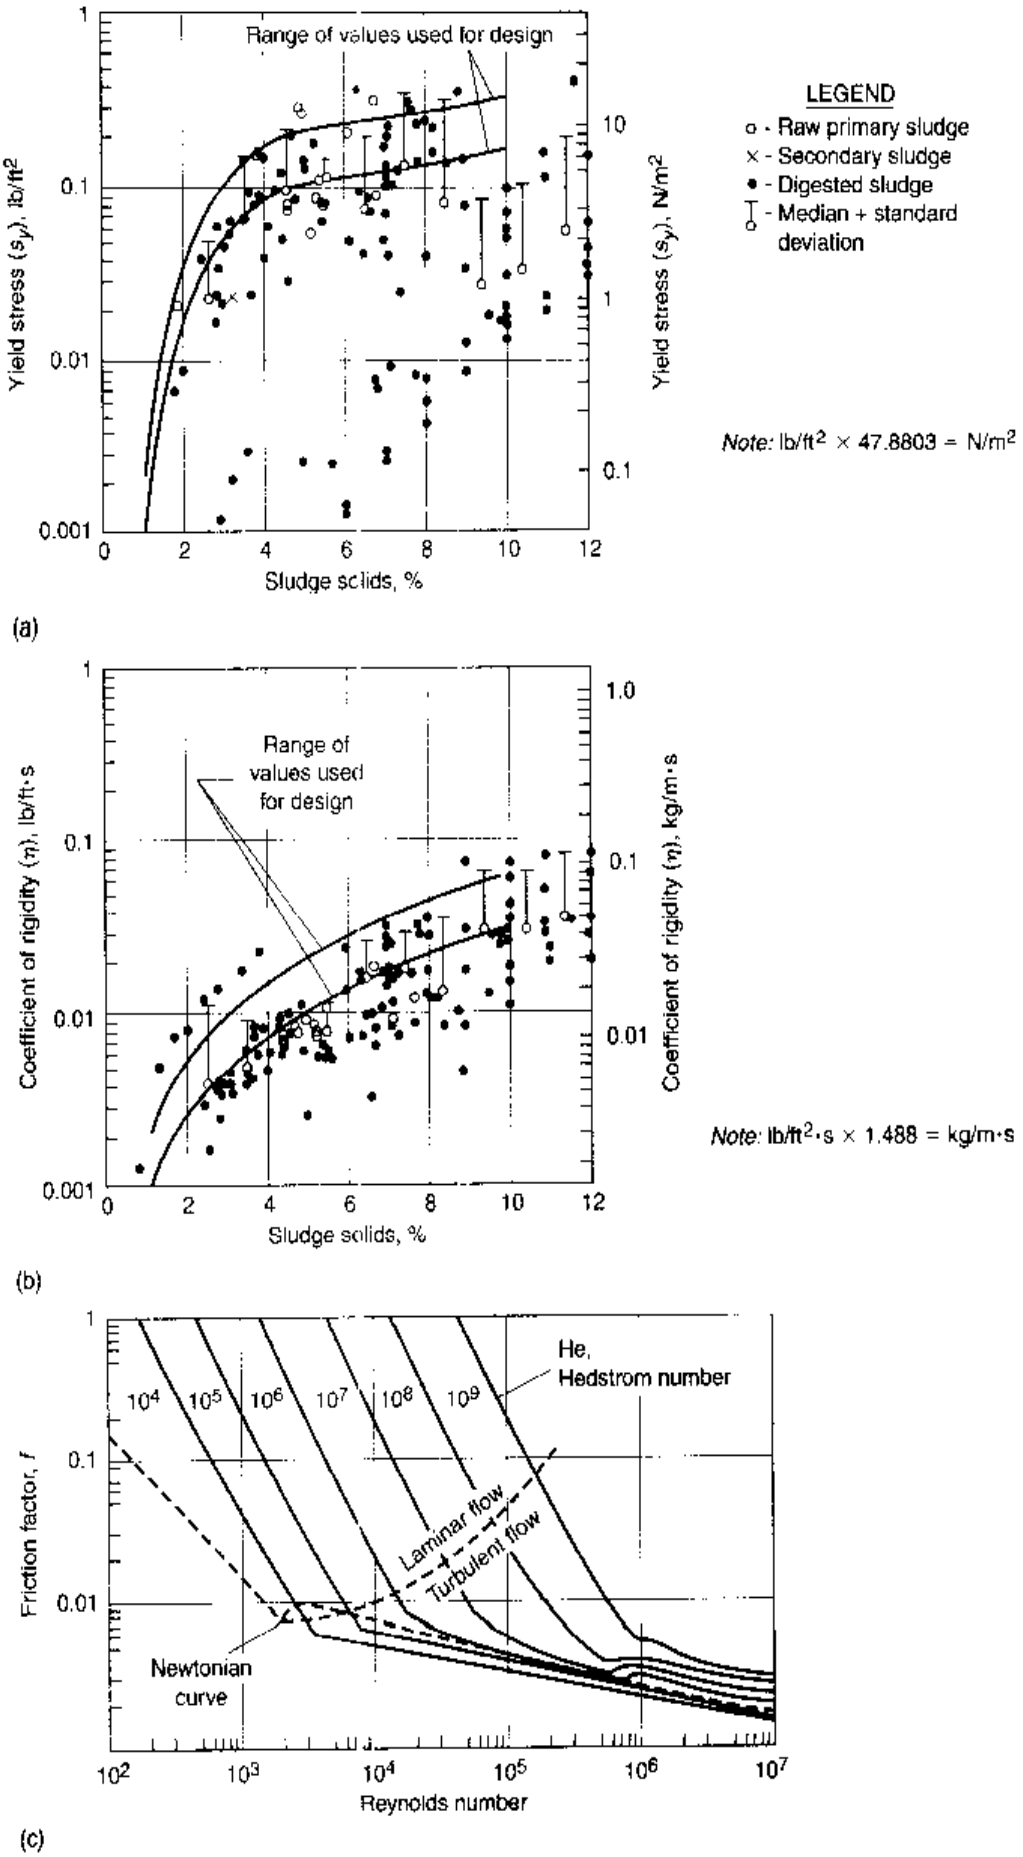
where N_R = Reynolds number, dimensionless
ρ = density of sludge, kg/m^3
γ = specific weight of sludge, lb/ft^3
V = average velocity, m/s (f/s)
D = diameter of pipe, m (ft)
η = coefficient of rigidity, kg/m·s (lb/ft·s)

Hedstrom number, which is reviewed by Hill et al. (1986), is calculated as follows:

$$\text{He} = \frac{D^2 s_y \rho}{\eta^2} \qquad \text{SI units} \tag{14–4a}$$

$$\text{He} = \frac{D^2 s_y g_c \gamma}{\eta^2} \qquad \text{U.S. customary units} \tag{14–4b}$$

where He = Hedstrom number, dimensionless
s_y = yield stress, N/m^2 (lb$_f$/ft^2)
g_c = 32.2 lb$_m$·ft/lb$_f$·s^2



Other terms are as defined previously.

Using the calculated Reynolds number and the Hedstrom number, the friction factor f can be determined from Fig. 14–6*c*. The pressure drop for turbulent conditions can then be calculated from the following relationship:

$$\Delta p = \frac{2 f \rho L V^2}{D} \qquad \text{SI units} \tag{14–5a}$$

Figure 14–6

Curves for computing pipeline headloss by the sludge rheology method: (*a*) yield stress vs. percent sludge solids, (*b*) coefficient of rigidity vs. percent sludge solids, and (*c*) friction factor for sludge analyzed as a Bingham plastic. *(Adapted from Carthew et al., 1983.)*

$$\Delta p = \frac{2f\rho LV^2}{g_c D} \qquad \text{U.S. customary units} \tag{14-5b}$$

where Δp = pressure drop due to friction, N/m^2 (lb$_f$/ft^2)
f = friction factor (from Fig. 14–6*c*)
L = length of pipeline, m (ft)
Other terms as defined previously.

In using Eqs. (14–3), (14–4), and (14–5), it should be noted that the Reynolds number is not the same as the Reynolds number based on viscosity. In plastic flow, an effective viscosity may be defined, but it is variable and can be much greater than the coefficient of rigidity. Consequently, the two Reynolds numbers can differ greatly. The friction factor f will usually differ significantly from the f values reported in standard hydraulic texts for clear water, which may be four times the values used on Fig. 14–6*c*. These equations apply to the entire range of laminar and turbulent flows, except that Fig. 14–6*c* does not allow for pipe roughness. To allow for pipe roughness, if customary water formulas for headloss give a higher pressure drop than Eq. (14–5), then roughness is dominant, the flow is fully turbulent, and the pressure drop given by the water headloss formula will be reasonably accurate. A safety factor on the order of 1.5 is recommended for worst-case design conditions (Mulbarger et al., 1981). The use of Eqs. (14–3), (14–4), and (14–5) is illustrated in Example 14–2.

EXAMPLE 14–2 Computation of Headloss Using Sludge Rheology Calculate the headloss in a 200-mm-diameter pipeline 10,000 m long conveying untreated (raw) sludge at an average flowrate 0.04 m^3/s. Determine also if the flow is turbulent. By testing, the following sludge rheology data were found:

Yield stress s_y = 1.3 N/m^2

Coefficient of rigidity η = 0.035 kg/m·s

Specific gravity = 1.01

Solution

1. Calculate the pipeflow velocity
   a. Determine the pipe cross-sectional area.

$$A = \pi \frac{D^2}{4} = 3.14 \frac{(0.2\text{ m})^2}{4} = 0.031\text{ m}^2$$

   b. Determine velocity.

$$V = \frac{Q}{A} = \frac{(0.04\text{ m}^3/\text{s})}{0.031\text{ m}^2} = 1.29\text{ m/s}$$

2. Compute sludge specific weight.

$$\rho = 1000\text{ kg/m}^3 \times 1.01 = 1010\text{ kg/m}^3$$

3. Compute Reynolds number using Eq. (14–3).

$$N_R = \frac{\rho VD}{\eta} = \frac{(1010\ \text{kg/m}^3)(1.29\ \text{m/s})(0.2\ \text{m})}{(0.035\ \text{kg/m·s})} = 7.4 \times 10^3$$

4. Compute Hedstrom number using Eq. (14–4).

$$\text{He} = \frac{D^2 s_y \rho}{\eta^2} = \frac{(0.2\ \text{m})^2(1.3\ \text{N/m}^2)(1010\ \text{kg/m}^3)}{(0.035\ \text{kg/m·s})^2} = 4.29 \times 10^4$$

5. Determine friction factor f from Fig. 14–6*c* using the computed Reynolds and Hedstrom numbers.

   $f = 0.007$

   Note, on Fig. 14–6*c*, that the flow is in the turbulent zone.

6. Compute pressure drop using Eq. (14–5).

$$\Delta p = \frac{2f\rho LV^2}{D} = \frac{2(0.007)(1010\ \text{kg/m}^3)(10{,}000\ \text{m})(1.29\ \text{m/s})^2}{0.2\ \text{m}}$$

$$= 1{,}176{,}519\ \text{kg·m/s}^2\ (\text{N/m}^2)$$

   Convert to meters of water.

$$\Delta p = \frac{1{,}176{,}159\ \text{kg·m/s}^2}{(1000\ \text{kg/m}^3)(9.81\ \text{m/s}^2)} = 120\ \text{m}$$

Comment In this example, only one set of rheology data was used. In actual design, test data should be used for a range of probable conditions so that a family of headloss curves can be developed for the range of operating conditions. In addition, appropriate safety factors should be used for worst-case conditions. Comparison of the headloss to the headloss for water using the Hazen-Williams formula is left as a homework problem.

Sludge Piping

In wastewater treatment plants, conventional sludge piping should not be smaller than 150 mm (6 in) in diameter although smaller-diameter glass-lined pipe has been used successfully. Sludge piping may not need to be larger than 200 mm (8 in), unless the velocity exceeds 1.5 to 1.8 m/s (5 to 6 ft/s), in which case the pipe is sized to maintain that velocity. Gravity sludge withdrawal lines should not be less than 200 mm (8 in) in diameter. It is common practice to install a number of cleanouts in the form of plugged tees or crosses instead of elbows so that the lines can be rodded if necessary. Pump connections should not be smaller than 100 mm (4 in) in diameter.

A liberal number of hose gates should be installed in the piping, and an ample supply of high-pressure flushing water should be available for clearing stoppages. The flushing water should be plant effluent. The flushing water system should have a capacity of not less than 0.010 m^3/s (150 gal/min) at 500 kN/m^2 (~70 lb_f/in^2). In large plants

with larger piping, a greater capacity should be available, and the available pressure should be increased to 700 kN/m^2 (100 lb$_f$/in^2).

Grease has a tendency to coat the inside of piping used for transporting primary sludge and scum. Grease accumulation is more of a problem in large plants than in small ones. The coating results in a decrease in effective diameter and a large increase in pumping head. For this reason, low capacity positive-displacement pumps are designed for heads greatly in excess of the theoretical head. Centrifugal pumps, with their larger capacity, usually pump a more dilute sludge, often containing some wastewater, and head buildup due to grease accumulations appears to occur more slowly. In some plants, provisions have been made for melting the grease by circulating hot water, steam, or digester supernatant through the main sludge lines.

In treatment plants, friction losses are low because the pipe runs are short; consequently, there is little difficulty in providing an ample safety factor. In the design of long sludge lines, however, special design features should be considered including (1) providing two pipes unless a single pipe can be shut down for several days without causing problems; (2) providing for external corrosion and pipe loads; (3) adding facilities for applying dilution water for flushing the line; (4) providing means to insert a pipe cleaner; (5) including provisions for steam injection, especially in cold climates and where excessive grease accumulation occurs; (6) providing air relief and blowoff valves for the high and low points, respectively, and (7) considering the potential effects of waterhammer. A discussion of waterhammer in force mains is provided in the companion volume to this text (Metcalf & Eddy, 1981).

14–5 PRELIMINARY OPERATIONS

Grinding, degritting, blending, and storage of solids and biosolids are necessary to provide a relatively constant, homogeneous feed to subsequent processing facilities. Blending and storage can be accomplished either in a single unit designed to do both or separately in other plant components. Screening of raw sludge or digested biosolids is sometimes required in reuse applications for the removal of plastics, rags, and other material. Each of these preliminary operations is discussed in this section.

Grinding

Sludge grinding is a process in which large and stringy material contained in sludge is cut or sheared into small particles to prevent clogging or wrapping around rotating equipment. A typical sludge grinder is shown on Fig. 14–7. Some of the processes that must be preceded by sludge grinders and the purposes of grinding are reported in Table 14–16. Grinders historically have required high maintenance, but newer designs of slow-speed grinders have been more durable and reliable. These designs include improved bearings and seals, hardened steel cutters, overload sensors, and mechanisms that reverse the cutter rotation to clear obstructions or shut down the unit if the obstruction cannot be cleared.

Screening

Because raw wastewater screens can allow significant quantities of solids to pass through, sludge screening is an alternative to grinding. Screening is advantageous in that

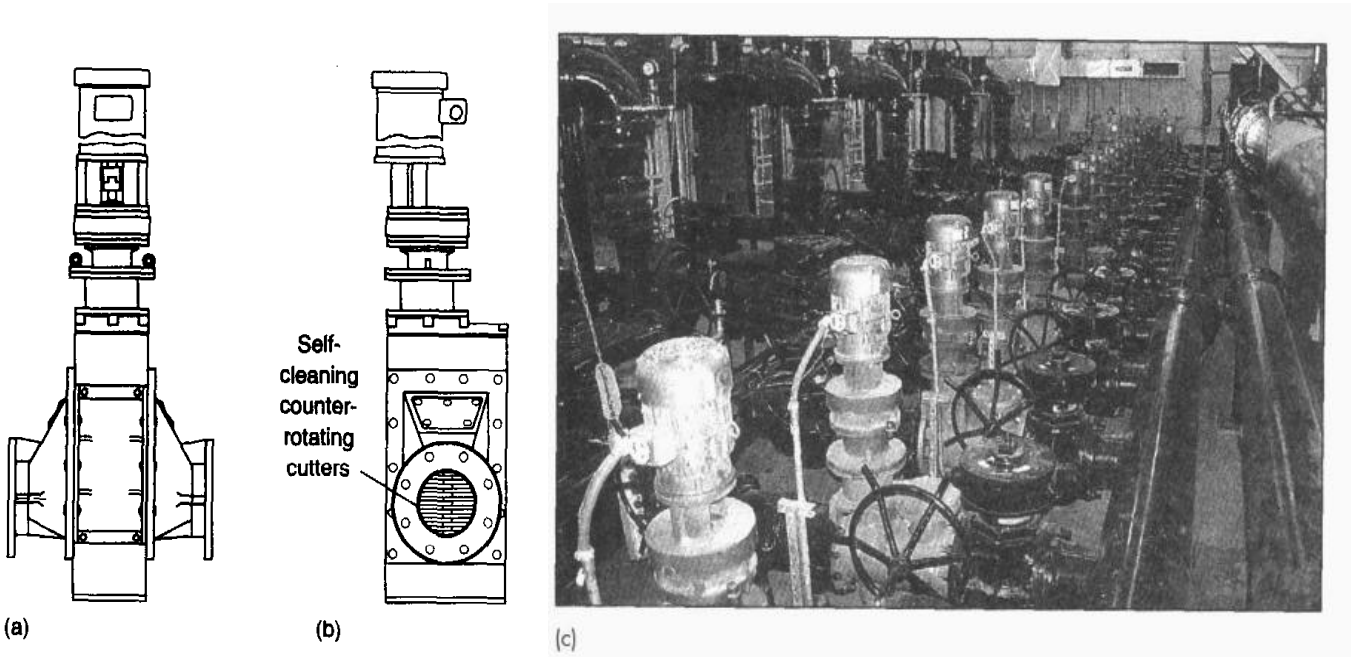


Figure 14–7

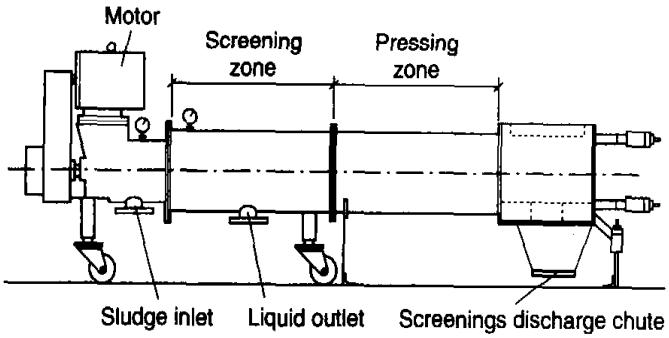
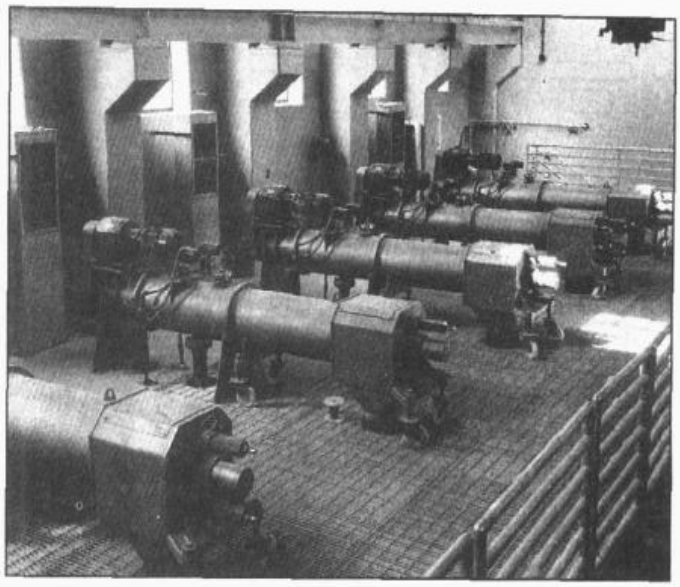


Typical in-line sludge grinder: (*a*) side view, (*b*) end view, and (*c*) view of typical installation with multiple grinders. *(Courtesy Franklin Miller.)*

Table 14–16
Operations and processes requiring the grinding of sludge



Operation or process	Purpose of grinding
Pumping with progressive cavity pumps	Prevent clogging and reduce wear
Solid-bowl centrifuges	Prevent clogging. Large solid bowl units generally can handle larger particles and may not require sludge grinding
Belt-filter press	Prevent clogging of the sludge distribution system, prevent warping of rollers, reduce wear on belts, and provide more uniform dewatering

nuisance material is removed from the solids stream. Step screens, shown on Fig. 5–4*c* in Chap. 5, can be used for the removal of fine solids from septage, primary sludge, or biosolids. Screen openings normally range from 3 to 6 mm (0.12 to 0.24 in), although openings up to 10 mm (0.4 in) can be used.

Another type of sludge screen is an in-line screen that can be installed in a pipeline (see Fig. 14–8). The screen removes material by passing the flow stream through a screen with 5-mm (0.2-in) openings. Material captured by the screen moves by a screw conveyor onto a finer screen [2-mm (0.08-in) -diameter perforations] where it is dewatered and compacted. Material is ejected from the screen when sufficient solids build up to overcome the force on the unit's discharge cone. Screenings solids concentrations range from 30 to 50 percent. Allowable operating pressure is reported to be 100 kPa (14 lb_f/in^2) (Arakaki et al., 1998). The screened sludge is dilute and may require thickening.

Sludge screenings press: (*a*) schematic and (*b*) view of a large installation. *(Courtesy City of San Diego.)*

Degritting

In some plants where separate grit-removal facilities are not used ahead of the primary sedimentation tanks, or where the grit-removal facilities are not adequate to handle peak flows and peak grit loads, it may be necessary to remove the grit before further processing of the sludge. Where further thickening of the primary sludge is desired, a practical consideration is sludge degritting. The most effective method of degritting sludge is through the application of centrifugal forces in a flowing system to achieve separation of the grit particles from the organic sludge. Such separation is achieved through the use of cyclone degritters, which have no moving parts. The sludge is applied tangential to a cylindrical feed section, thus imparting a centrifugal force. The heavier grit particles move to the outside of the cylinder section and are discharged through a conical feed section. The organic sludge is discharged through a separate outlet.

The efficiency of the cyclone degritter is affected by pressure and by the concentration of the organics in the sludge. To obtain effective grit separation, the sludge must be relatively dilute 1 to 2 percent TS. As the sludge concentration increases, the particle size that can be removed decreases. The general relationship between sludge concentration and effectiveness of removal for primary sludges is shown in Table 14–17.

Blending

Sludge is generated in primary, secondary, and advanced wastewater-treatment processes. Primary sludge consists of settleable solids carried in the raw wastewater. Secondary sludge consists of biological solids as well as additional settleable solids. Sludge produced in the advanced wastewater may consist of biological and chemical solids. Sludge is blended to produce a uniform mixture to downstream operations and processes. Uniform mixtures are most important in short-detention-time systems, such as sludge dewatering, heat treatment, and incineration. Provision of well-blended sludge

Table 14–17
Grit-removal efficiency using cyclone degritters for primary sludge[a]

Primary sludge concentration, % total solids	Mesh of removal[b]
1	150
2	100
3	65
4	28–35

[a] For a 300-mm (12-in) hydroclone at 42 kN/m² (6 lb_f/in^2 gage) at 13 L/s (200 gal/min).

[b] About 95 percent or more of indicated particle size is removed.

Note: Normal design range is for 1 to 1.5 percent feed solids.

with consistent characteristics to these treatment units will enhance greatly plant operability and performance.

Sludge from primary, secondary, and advanced processes can be blended in several ways:

1. *In primary settling tanks.* Secondary or tertiary sludges can be returned to the primary settling tanks where they will mix and co-settle with the primary sludge.
2. *In pipes.* Blending in pipes requires careful control of sludge sources and feed rates to ensure the proper blend. Without careful control, wide variations in sludge consistency may be expected.
3. *In sludge-processing facilities with long detention times.* Aerobic and anaerobic digesters (complete-mix type) can blend the feed sludges uniformly.
4. *In a separate blending tank.* This practice provides the best opportunity to control the quality of the blended sludges.

In treatment plants of less than 0.05 m^3/s (~1 Mgal/d) capacity, blending is accomplished usually in the primary settling tanks. In large facilities, optimum efficiency is achieved by separately thickening sludges before blending.

Storage

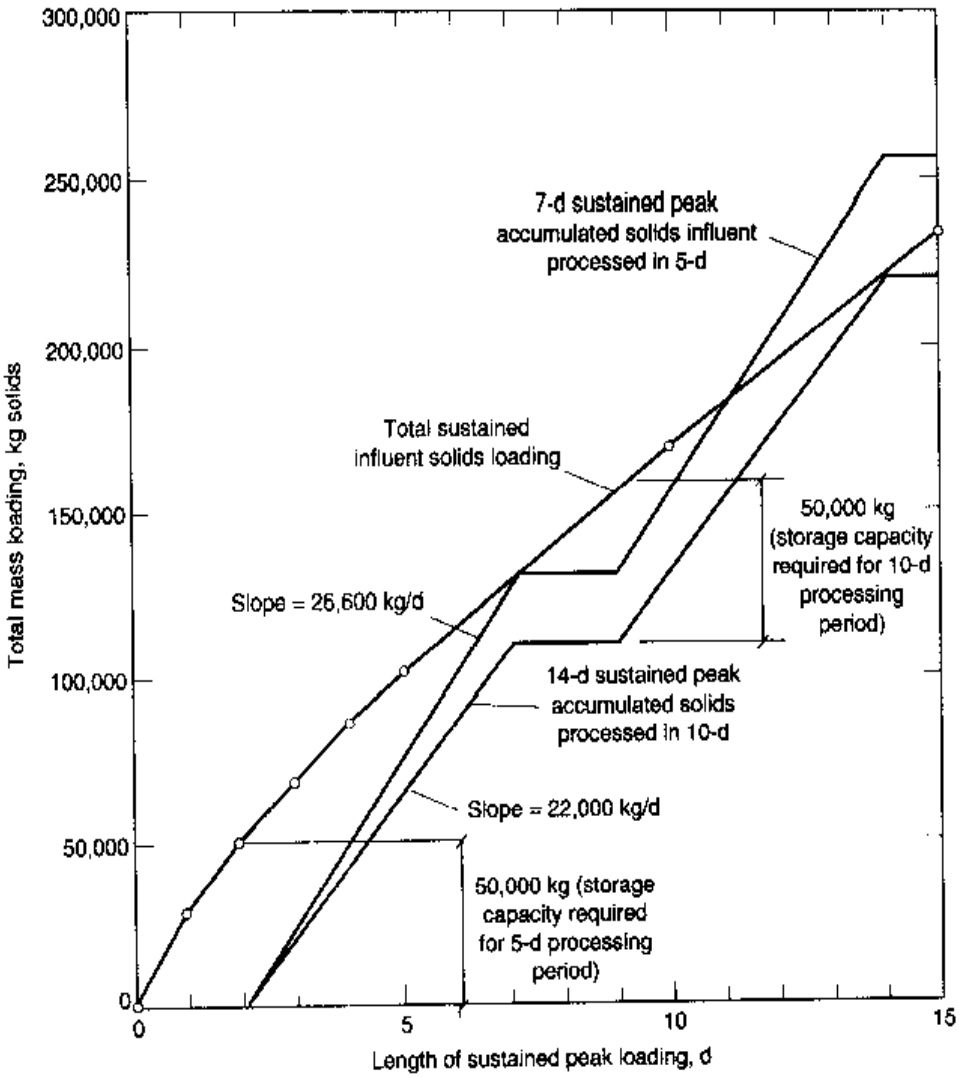
Storage should be provided to smooth out fluctuations in the rate of solids and biosolids production and to allow solids to accumulate during periods when subsequent processing facilities are not operating, e.g., night shifts, weekends, and periods of unscheduled equipment downtime. Storage is particularly important in providing a uniform feed rate ahead of the following processes: mechanical dewatering, lime stabilization, heat drying, and thermal reduction.

Short-term solids storage may be accomplished in wastewater settling tanks or in thickening tanks. Long-term solids storage may be accomplished in stabilization processes with long detention times, e.g., aerobic and anaerobic digestion, or in specially designed separate tanks. In small installations, sludge is usually stored in the settling tanks and digesters. In large installations that do not use aerobic and anaerobic digestion, sludge is often stored in separate blending and storage tanks. Such tanks may be sized to retain the sludge for a period of several hours to a few days. If sludge is stored longer than 2 to 3 days, it will deteriorate, become odorous, and be more difficult to dewater.

The determination of the required storage volume is illustrated in Example 14–3. Sludge is often aerated to prevent septicity and to promote mixing. Mechanical mixing may be necessary to assure complete blending of the sludge. Chlorine, iron salts, potassium permanganate, and hydrogen peroxide have been used with limited success to arrest septicity and to control the odors from sludge storage and blending tanks. Sodium hydroxide or lime may also be used for odor control by raising the pH and keeping the hydrogen sulfide in solution. In cases where sludge storage occurs in enclosed tanks, ventilation should be provided along with appropriate odor-control technologies such as chemical scrubbers or biofilters (see Chap. 15).

EXAMPLE 14–3 Determination of Volume Required for Sludge Storage Assume that the yearly average rate of sludge production from an activated-sludge treatment plant is 12,000 kg/d. Develop a curve of sustained sludge mass loading rates that can be used to determine the size of sludge-storage facilities required with various downstream sludge-processing units. Then, using the developed curve, determine the volume required for sludge storage, assuming that sludge accumulated for 7 d is to be processed in 5 working days, and that sludge accumulated for 14 d is to be processed in 10 working days. Note that the 5- and 10-d work periods correspond to 1 and 2 weeks, respectively, assuming that certain sludge-processing facilities, such as belt-filter presses, will not be operated on the weekends.

Solution



1. Develop a curve of sustained sludge mass loadings.
   a. Because no information is specified, it will be assumed that the sustained sludge production will mirror the sustained BOD plant loadings given on Fig. 5–6*a* and used in Example 5–3.
   b. Set up an appropriate computation table and compute the values necessary to plot the curve.

Length of sustained peak, d (1)	Peaking factor[a] (2)	Peak solids mass loading, kg/d (3)	Total sustained loading, kg[b] (4)
1	2.4	28,800	28,800
2	2.1	25,200	50,400
3	1.9	22,800	68,400
4	1.8	21,600	86,400
5	1.7	20,400	102,000
10	1.4	16,800	168,000
15	1.3	15,600	234,000
365	1.0	12,000	

[a]From Fig. 3–7*a*.

[b]Total mass produced for the corresponding sustained period given in col. 1.

   c. Plot the sustained solids loading curve (see following figure).

2. Determine the sludge storage volume required for the stated operating conditions.
   a. Determine the daily rate at which sludge must be processed to handle the 7-d sustained peak (from figure) in 5 working days.

$$\text{kg/d} = \frac{133{,}000}{5\text{ d}} = 26{,}600\text{ kg/d}$$

   b. Determine the daily rate at which sludge must be processed to handle the 14–d sustained peak (from figure) in 10 working days.

$$\text{kg/d} = \frac{220{,}000}{10\text{ d}} = 22{,}000\text{ kg/d}$$

   c. Assuming that the sludge storage facilities are empty on Friday just before the weekend, plot on the figure the average daily rate at which sludge must be processed during the 5- and 10-d periods.
   d. From the figure, the required storage capacity in pounds of solids is
      i. Capacity based on 5 working days = 50,000 kg
      ii. Capacity based on 10 working days = 50,000 kg

Comment The downstream processing equipment can now be sized using the daily rate at which sludge must be processed. For example, if the number of kilograms per hour that can be processed with a belt-filter press is known, then the size and number of units can be computed from the number of shifts to be used per day and the assumed value of the actual working hours per shift. In sizing equipment, a trade-off analysis should always be performed between the cost of storage and processing facilities versus labor costs (for both one shift and two shifts) to determine the most cost-effective combination.

14–6 THICKENING

The solids content of primary, activated, trickling filter, or mixed sludge (i.e., primary plus waste activated) varies considerably, depending on the characteristics of the sludge, the sludge removal and pumping facilities, and the method of operation. Representative values of percent total solids from various treatment operations or processes were shown previously in Table 14–8. Thickening is a procedure used to increase the solids content of sludge by removing a portion of the liquid fraction. To illustrate, if waste-activated sludge, which is typically pumped from secondary settling tanks with a content of 0.8 percent solids, can be thickened to a content of 4 percent solids, then a fivefold decrease in sludge volume is achieved. Thickening is generally accomplished by physical means, including co-settling, gravity settling, flotation, centrifugation, gravity belt, and rotary drum. Typical sludge-thickening methods are described in Table 14–18.

Application

The volume reduction obtained by sludge concentration is beneficial to subsequent treatment processes, such as digestion, dewatering, drying, and combustion from the following standpoints: (1) capacity of tanks and equipment required, (2) quantity of chemicals required for sludge conditioning, and (3) amount of heat required by digesters and amount of auxiliary fuel required for heat drying or incineration, or both.

For large facilities where sludge must be transported a significant distance, such as to a separate plant for processing, a reduction in sludge volume may result in a reduction of pipe size and pumping costs. For smaller facilities, the requirements of a minimum practicable pipe size and minimum velocity may necessitate pumping of significant volumes of wastewater in addition to sludge, thereby diminishing the value of volume reduction. Volume reduction is very desirable when liquid sludge is transported by tank trucks for direct application to land as a soil conditioner.

Sludge thickening is achieved at all wastewater treatment plants in some manner—in the primary clarifiers, in sludge-digestion facilities, or in specially designed separate units. If separate units are used, the recycled flows are returned normally to the wastewater treatment facilities. In treatment plants of less than 4000 m^3/d (~1 Mgal/d) capacity, separate sludge thickening is seldom practiced. In small plants, gravity thickening is accomplished in the primary settling tank or in the sludge-digestion units, or both. In larger treatment facilities, the additional costs of separate sludge thickening are often justified by the improved control over the thickening process and the higher concentrations attainable.

Table 14–18
Occurrence of thickening methods in solids processing

Method	Type of solids	Frequency of use and relative success
Gravity, co-settling in clarifier	Primary and waste activated	Occasional use; may negatively impact the effectiveness of primary clarifier
Gravity, thickening in separate tank	Untreated primary sludge	Commonly used with excellent results; sometimes used with hydroclone degritting of sludge. Can be odorous
	Untreated primary and waste-activated sludge	Often used. For small plants, generally satisfactory results with solids concentrations in the range of 4 to 6 percent. For large plants, results are marginal. Can be odorous in warm weather
	Waste-activated sludge	Seldom used; poor solids concentration (2 to 3 percent)
Dissolved air flotation	Untreated primary and waste-activated sludge	Limited use; results similar to gravity thickeners
	Waste-activated sludge	Commonly used, but use is decreasing because of high operating cost; good results (3.5 to 5 percent solids concentration)
Solid-bowl centrifuge	Waste-activated sludge	Often used in medium to large plants; good results (4 to 6 percent solids concentration)
Gravity-belt thickener	Waste-activated sludge	Often used; good results (3 to 6 percent solids concentration)
Rotary-drum thickener	Waste-activated sludge	Limited use; good results (3 to 6+ percent solids concentration)

Description and Design of Thickeners

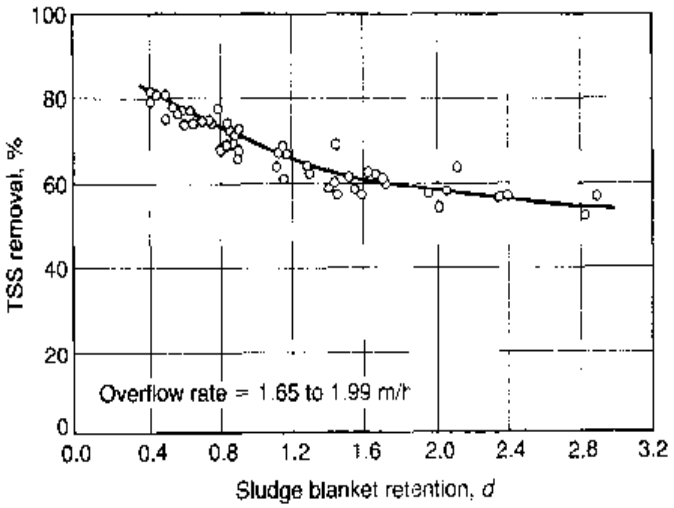
The following discussion is intended to introduce the reader to the operations used for the thickening of sludges. Most of the equipment is mechanical; therefore, the design engineer usually is more concerned with its proper application to meet a given treatment objective than with the theory of mechanical design.

In designing thickening facilities, it is important to (1) provide adequate capacity to meet peak demands and (2) prevent septicity, with its attendant odor problems, during the thickening process. The six methods of thickening discussed in this section are co-settling thickening, gravity, dissolved air flotation, centrifugal, gravity belt, and rotary drum.

Co-settling Thickening. Primary clarifiers are often used to thicken solids for downstream processing. To thicken solids, a sludge blanket must be created to consolidate the solids without allowing the clarified water to be pulled through. Oftentimes solids retention times of 12 to 24 h or more are maintained in clarifiers to achieve thickened solids concentration levels in the clarifier underflow. Excessive retention of solids in the clarifier can cause septic conditions and gasification, and reduce the levels of TSS and BOD removal. Typical effects of sludge blanket retention on TSS removal are illustrated on Fig. 14–9.

Figure 14–9

Effect of sludge blanket retention time on TSS removal for cothickening of primary sludge. *(Albertson and Walz, 1997.)*



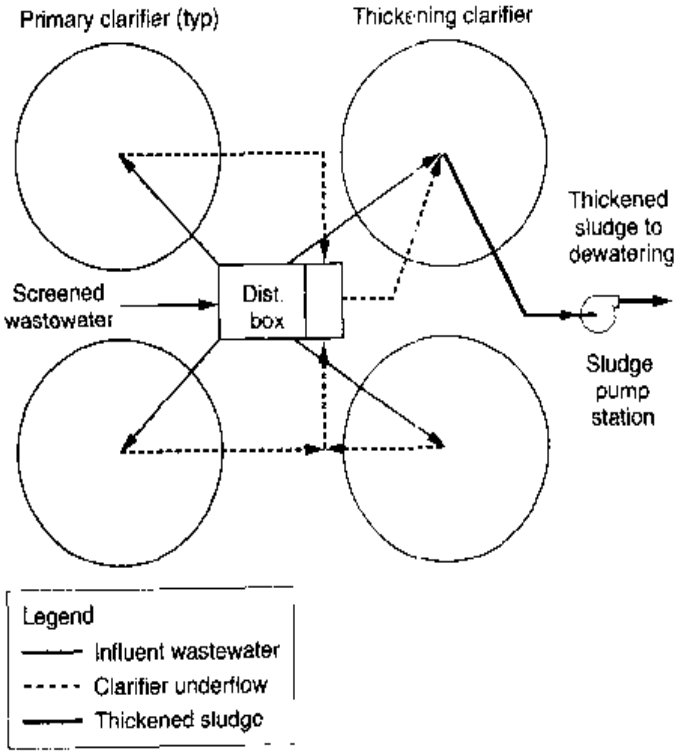


Figure 14–10

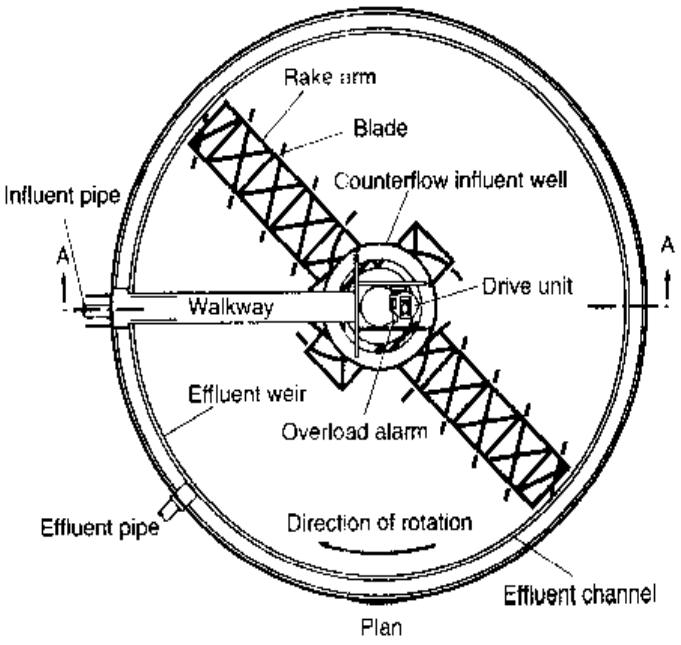
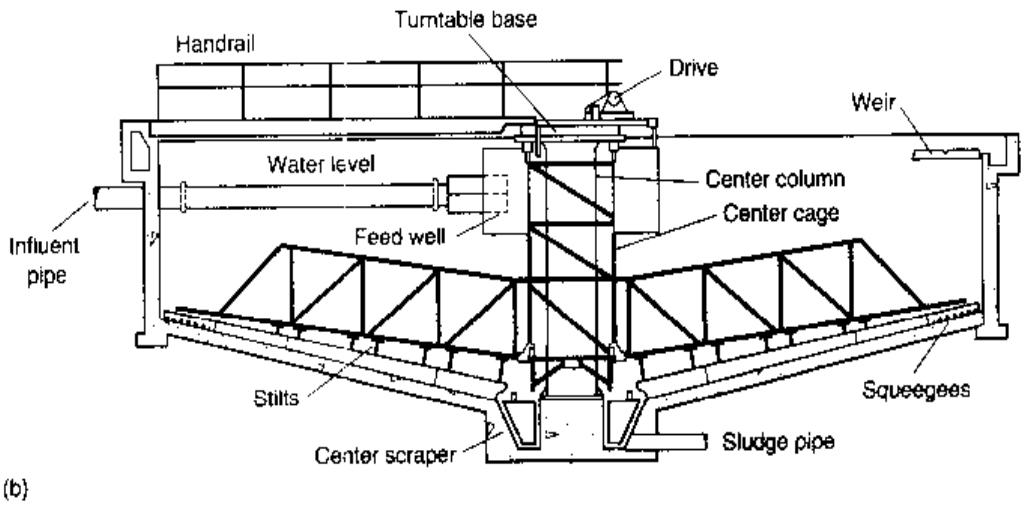
Schematic diagram of a sludge co-settling thickening system.



Successful thickening of solids in primary clarifiers has been achieved by a combination of the following: (1) using one clarifier in a bank of clarifiers for co-settling thickening; dilute solids underflow (less that 1 percent solids) from the other clarifers is discharged to the thickening clarifier, (2) maintaining the solids inventory for about 6 to 12 h, and (3) providing for the addition of coagulating chemicals such as polymer and ferric chloride to condition the solids to enhance settling. The need for chemical addition depends upon the clarifer overflow rates. Underflow solids concentrations on the order of 3 to over 5 percent have been reported (Albertson and Walz, 1997). By controlling the sludge blanket within the above solids retention parameters, clarifier removal rates are enhanced and solids thickening is achieved. A schematic diagram of the co-settling thickening system is shown on Fig. 14–10.



Gravity Thickening. Gravity thickening is one of the most common methods used and is accomplished in a tank similar in design to a conventional sedimentation tank. Normally, a circular tank is used, and dilute sludge is fed to a center feed well. The feed sludge is allowed to settle and compact, and the thickened sludge is withdrawn from the conical tank bottom. Conventional sludge-collecting mechanisms with deep trusses (see Fig. 14–11) or vertical pickets stir the sludge gently, thereby opening up channels for water to escape and promoting densification. The supernatant flow that results is drawn off and returned to either the primary settling tank, the influent of the treatment plant, or a return-flow treatment process. The thickened sludge is pumped to the digesters or dewatering equipment as required; thus, storage space must be provided for the sludge. As indicated in Table 14–18, gravity thickening is most effective on primary sludge. Gravity thickeners are designed on the basis of solids loading and thickener overflow rate. Typical solids loadings based on existing data are listed in Table 14–19. Recommended maximum hydraulic overflow rates range from 15.5 to 31 $m^3/m^2 \cdot d$

Figure 14–11

Table 14–19
Typical concentrations of unthickened and thickened sludges and solids loadings for gravity thickeners[a]

Type of sludge or biosolids	Solids concentration, %		Solids loading	
	Unthickened	Thickened	lb/ft²·d	kg/m²·d
Separate:				
Primary sludge	2–6	5–10	20–30	100–150
Trickling-filter humus sludge	1–4	3–6	8–10	40–50
Rotating biological contactor	1–3.5	2–5	7–10	35–50
Air-activated sludge	0.5–1.5	2–3	4–8	20–40
High-purity oxygen-activated sludge	0.5–1.5	2–3	4–8	20–40
Extended aeration-activated sludge	0.2–1.0	2–3	5–8	25–40
Anaerobically digested primary sludge from primary digester	8	12	25	120
Combined:				
Primary and trickling-filter humus sludge	2–6	5–9	12–20	60–100
Primary and rotating biological contactor	2–6	5–8	10–18	50–90
Primary and waste-activated sludge	0.5–1.5	4–6	5–14	25–70
	2.5–4.0	4–7	8–16	40–80
Waste-activated sludge and trickling-filter humus sludge	0.5–2.5	2–4	4–8	20–40
Chemical (tertiary) sludge:				
High lime	3–4.5	12–15	24–61	120–300
Low lime	3–4.5	10–12	10–30	50–150
Iron	0.5–1.5	3–4	2–10	10–50

[a]Adapted from WEF (1996).

(380 to 760 gal/ft²·d) for primary sludges, 4 to 8 m³/m²·d (100 to 200 gal/ft²·d) for waste-activated sludge, and 6 to 12 m³/m²·d (150 to 300 gal/ft²·d) for combined primary and waste-activated sludge (WEF, 1980). High hydraulic loadings can cause excessive solids carryover. Conversely, low hydraulic loadings can cause septic conditions and odors and floating sludge can result.

Provisions for dilution water and occasional chlorine addition are frequently included to improve process performance by maintaining the hydraulic loading. Polymer addition is frequently provided. To maintain aerobic conditions in gravity thickeners, especially when wastewater is warm (22 to 28°C), provisions should be included for adding up to 24 to 30 m³/m²·d (600 to 750 gal/ft²·d) of dilution water (final effluent) to the thickening tank. The dilution water may also remove certain soluble organic and inorganic compounds that consume large amounts of conditioning chemicals used in dewatering. Dilution water that is part of supernatant returned and recycled to the liquid process must be considered in process design.

Because the thickening characteristics of wastewater solids can vary considerably, it is desirable to design a thickening facility using criteria based on a testing program. Testing programs that can be used include batch settling tests, bench-scale settling tests, and pilot-scale testing. The latter method is recommended wherever possible because data can be obtained from a variety of operating parameters. Test methods are described in WEF (1998).

In operation, a sludge blanket is maintained on the bottom of the thickener to aid in concentrating the sludge. An operating variable is the sludge volume ratio, which is the volume of the sludge blanket held in the thickener divided by the volume of the thickened sludge removed daily. Values of the sludge volume ratio normally range between 0.5 and 20 d; the lower values are required during warm weather. Alternatively, sludge blanket depth should be measured. Blanket depths may range from 0.5 to 2.5 m (2 to 8 ft); shallower depths are maintained in the warmer months.

EXAMPLE 14–4 Design a Gravity Thickener for Combined Primary and Waste-Activated Sludge Design a gravity thickener for a wastewater treatment plant having primary and waste-activated sludge with the following characteristics:

Type of sludge	Specific gravity	Solids, %	Flowrate, m^3/d
Average design conditions:			
Primary sludge	1.03	3.3	400
Waste activated	1.005	0.2	2250
Peak design conditions:			
Primary sludge	1.03	3.4	420
Waste activated	1.005	0.23	2500

Solution

1. Compute the dry solids at peak design conditions.
   a. Primary sludge

$$\text{kg/dry solids} = (420\ \text{m}^3/\text{d})(1.03)(0.034\ \text{g/g})(10^3\ \text{kg/m}^3)$$
$$= 14{,}708\ \text{kg/d}$$

   b. Waste-activated sludge

$$\text{kg/dry solids} = (2500\ \text{m}^3/\text{d})(1.005)(0.0023\ \text{g/g})(10^3\ \text{kg/m}^3)$$
$$= 5779\ \text{kg/d}$$

   c. Combined sludge mass = 14,708 + 5779 = 20,487 kg/d
   d. Combined sludge flowrate = 2,500 + 420 = 2,920 m^3/d
2. Compute solids concentration of the combined sludge, assuming the specific gravity of the combined sludge is 1.02.

$$\%\ \text{solids} = \frac{(20{,}487\ \text{kg/d})}{(2920\ \text{m}^3/\text{d})(1.02)(10^3\ \text{kg/m}^3)} \times 100\% = 0.69\%$$

3. Compute surface area based on solids loading rate. Because the solids concentration is between 0.5 and 1.5%, select a solids loading rate of 50 kg/m²·d from Table 14–19.

$$\text{Area} = \frac{(20{,}487\ \text{kg/d})}{(50\ \text{kg/m}^2\cdot\text{d})} = 409.7\ \text{m}^2$$

4. Compute hydraulic loading rate.

$$\text{Hydraulic loading} = \frac{(2920\ \text{m}^3/\text{d})}{409.7\ \text{m}^2} = 7.13\ \text{m}^3/\text{m}^2\cdot\text{d}$$

5. Compute diameter of thickener; assume two thickeners.

$$\text{Diameter} = \sqrt{\frac{4 \times 409.7\ \text{m}^2}{2 \times \pi}} = 16.15\ \text{m}$$

Comment The hydraulic loading rate of 7.13 m³/m²·d at peak design flow is at the lower end of the recommended rate. To prevent septicity and odors, dilution water should be provided. Calculation of the dilution water requirements for average design flow is a homework problem. The thickener size of 16.15 m is within the maximum size of 20 m customarily recommended by thickener equipment manufacturers for use in municipal wastewater treatment. In actual design, round the thickener diameter to the nearest 0.5 m, or, in this case, 16 m.

Flotation Thickening. In dissolved-air flotation, air is introduced into a solution that is being held at an elevated pressure. A typical unit used for thickening waste-activated sludge is shown on Fig. 14–12. When the solution is depressurized, the dissolved air is released as finely divided bubbles carrying the sludge to the top, where it is removed. In locations where freezing is a problem or where odor control is of concern, flotation thickeners are normally enclosed in a building.

Flotation thickening is used most efficiently for waste sludges from suspended-growth biological treatment processes, such as the activated-sludge process or the suspended-growth nitrification process. Other sludges such as primary sludge, trickling-filter humus, aerobically digested sludge, and sludges containing metal salts from chemical treatment have been flotation thickened.

The float solids concentration that can be obtained by flotation thickening of waste-activated sludge is influenced primarily by the air-to-solids ratio, sludge characteristics (in particular the sludge volume index, SVI), solids loading rate, and polymer application. Although float solids concentrations have ranged historically between 3 and 6 percent by weight, float solids concentration is difficult to predict during the design stage without bench- or pilot-plant testing. The air-to-solids ratio is probably the most important factor affecting performance of the flotation thickener, and is defined as the weight ratio of air available for flotation to the solids to be floated in the feed

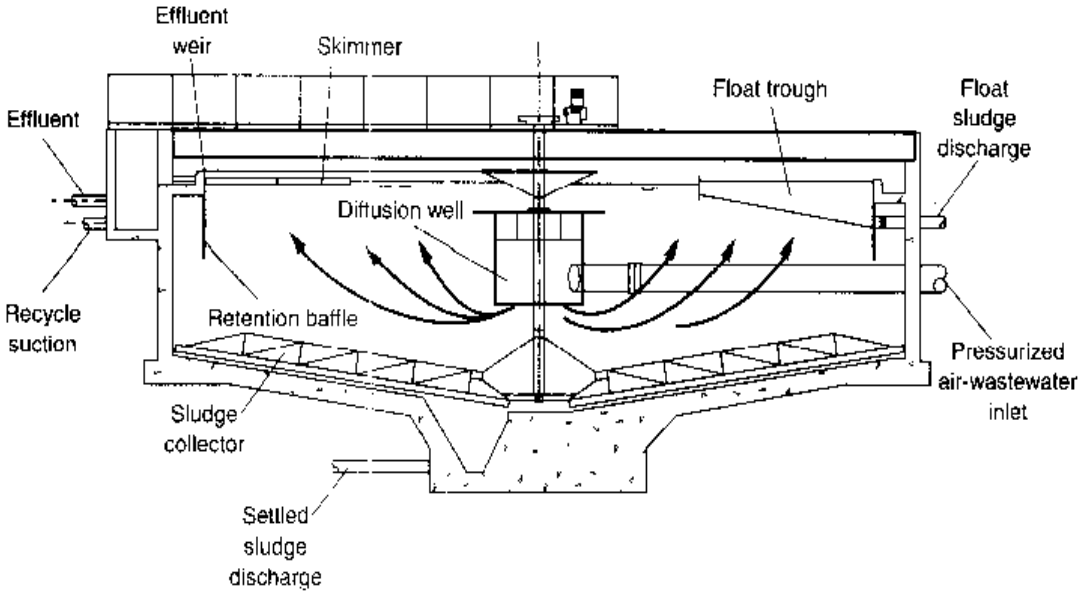

Figure 14–12
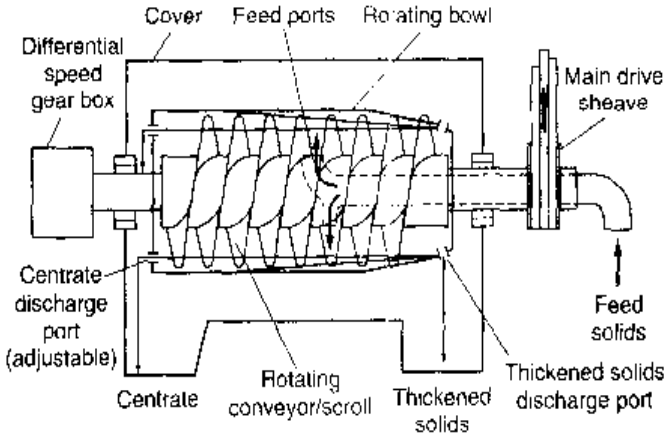
Typical dissolved air flotation unit used for thickening waste-activated sludge.

stream. The air-to-solids ratio at which float solids are maximized varies from 2 to 4 percent. The SVI is also important because better thickening performance has been reported when the SVI is less than 200, using nominal polymer dosages. At high SVIs, the float concentration deteriorates and high polymer dosages are required.

Higher loadings can be used with dissolved-air flotation thickeners than are permissible with gravity thickeners, because of the rapid separation of solids from the wastewater. Flotation thickeners typically are designed for the solids loadings given in Table 14–20. For design without the benefit of pilot studies, the minimum loadings should be used. The higher solids loadings generally result in lower concentrations of thickened sludge. Operational difficulties may arise when the solids loading rate exceeds approximately 10 kg/m^2·h (2.0 lb/ft^2·h). The increased amount of float created at high solids loading necessitates continuous skimming, often at high skimming speeds.

Primary tank effluent or plant effluent is recommended as the source of air-charged water rather than flotation tank effluent, except when chemical aids are used, because of the possibility of fouling the air-pressure system with solids. The use of polymers as flotation aids is effective in increasing the solids recovery in the floated sludge from 85 to 98 or 99 percent, and in reducing the recycle loads. Polymer dosages for thickening waste-activated sludge are 2 to 5 kg of dry polymer per Mg of dry solids (4 to 10 lb/ton).

Centrifugal Thickening. Centrifuges are used both to thicken and to dewater sludges. As indicated in Table 14–18, their application in thickening is limited normally to waste-activated sludge. Thickening by centrifugation involves the settling of sludge particles under the influence of centrifugal forces. The basic type of centrifuge used for sludge thickening is the solid-bowl centrifuge (see Fig. 14–13).



The solid-bowl centrifuge consists of a long bowl, normally mounted horizontally and tapered at one end. Sludge is introduced into the unit continuously, and the solids concentrate on the periphery. An internal helical scroll, spinning at a slightly different

Table 14-20
Typical solids loadings for dissolved air flotation units[a,b]

Type of sludge or biosolids	Loading, lb/ft²·h		Loading, kg/m²·h	
	Without chemical addition	With chemicals	Without chemical addition	With chemicals
Air-activated sludge:				
Mixed liquor	0.25–0.6	Up to 2.0	1.2–3.0	Up to 10
Settled	0.5–0.8	Up to 2.0	2.4–4.0	Up to 10
High-purity oxygen-activated sludge	0.6–0.8	Up to 2.0	3.0–4.0	Up to 10
Trickling-filter humus sludge	0.6–0.8	Up to 2.0	3.0–4.0	Up to 10
Primary + air-activated sludge	0.6–1.25	Up to 2.0	3.0–6.0	Up to 10
Primary + trickling-filter humus sludge	0.83–1.25	Up to 2.0	4.0–6.0	Up to 10
Primary sludge only	0.83–1.25	Up to 2.5	4.0–6.0	Up to 12.5

Figure 14-13
Schematic diagram of a centrifuge used for sludge thickening.

speed, moves the accumulated sludge toward the tapered end where additional solids concentration occurs and the thickened sludge is discharged.

Under normal conditions, thickening can be accomplished by centrifugal thickening without polymer addition. Maintenance and power costs for the centrifugal thickening process, however, can be substantial. Therefore, the process is usually attractive only at facilities larger than 0.2 m^3/s (5 Mgal/d), where space is limited and skilled operators are available, or for sludges that are difficult to thicken by more conventional means. Many systems are designed with standby polymer systems for use to improve system performance. Polymer dosages for thickening waste-activated sludge range from 0 to 4 kg of dry polymer per Mg of dry solids (0 to 8 lb/ton).

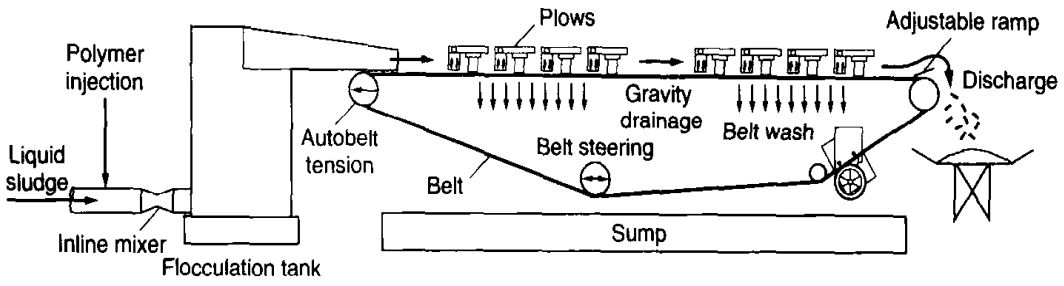
The performance of a centrifuge is often quantified by the concentration achieved in the thickened solids product and the TSS recovery (sometimes termed "capture").

The recovery is calculated as the thickened dry solids as a percentage of the feed solids. Using the commonly measured solids concentrations, the recovery is calculated by the following expression (WEF, 1998):

$$R = \frac{\text{TSS}_P(\text{TSS}_F - \text{TSS}_C)}{\text{TSS}_F(\text{TSS}_P - \text{TSS}_C)} \times 100 \qquad (14\text{–}6)$$

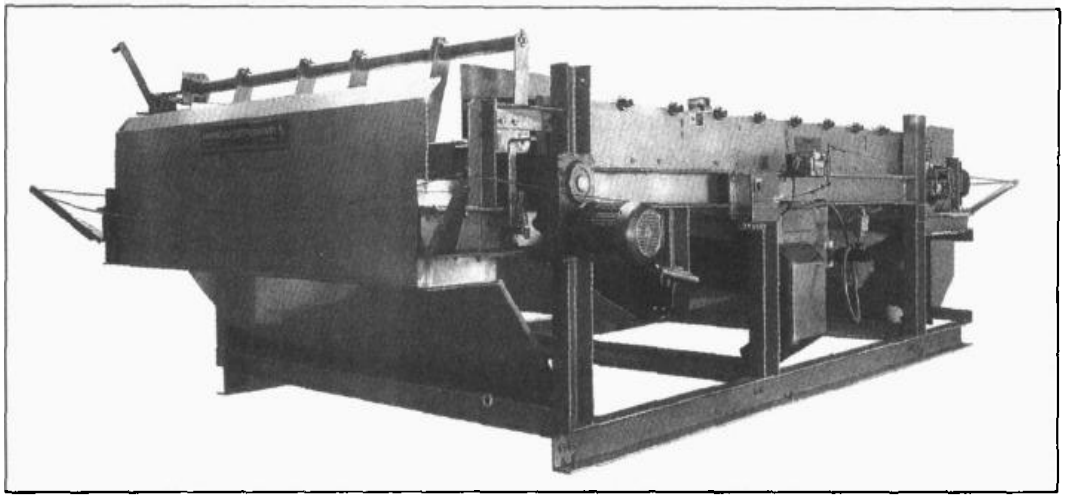
where R = percent recovery
TSS_P = total suspended solids concentration in thickened solids product, percent by weight
TSS_F = total suspended solids concentration in feed, percent by weight
TSS_C = total suspended solids concentration in centrate, percent by weight

For a constant feed concentration, the percent recovery increases as the concentration of solids in the centrate decreases. In concentrating sludge solids, recovery is important because with a higher recovery lesser amounts of biodegradable solids are returned to the treatment process for further treatment. In developing a mass balance for the treatment plant, return flows (also termed sidestream flows) from thickening, stabilization, and dewatering processes must be taken into account (see Sec. 14–16).



The principal operational variables include the following: (1) characteristics of the feed sludge (its water-holding structure and the sludge volume index); (2) rotational speed; (3) hydraulic loading rate; (4) depth of the liquid pool in the bowl; (5) differential speed of the screw conveyor; and (6) the need for polymers to improve the performance. Because the interrelationships of these variables will be different in each location, specific design recommendations are not available; in fact, bench-scale or pilot-plant tests are recommended.

Gravity-Belt Thickening. The development of gravity-belt thickeners stemmed from the application of belt presses for sludge dewatering. In belt-press dewatering, particularly for sludges having solids concentrations less than 2 percent, effective thickening occurred in the gravity drainage section of the press. The equipment developed for thickening consists of a gravity belt that moves over rollers driven by a variable-speed drive unit (see Fig. 14–14). The sludge is conditioned with polymer and fed into a feed/distribution box at one end, where the sludge is distributed evenly across the width of the moving belt. The water drains through the belt as the concentrating sludge is carried toward the discharge end of the thickener. The sludge is ridged and furrowed by a series of plow blades placed along the travel of the belt, allowing the water released from the sludge to pass through the belt. After the thickened sludge is removed, the belt travels through a wash cycle. The gravity-belt thickener has been used for thickening waste-activated sludge, anaerobically and aerobically digested sludge, and some industrial sludges. Polymer addition is required. Testing is recommended to verify that the solids can be thickened at typical polymer dosages.



Typical hydraulic loading rates for gravity-belt thickeners are given in Table 14–21. In lieu of pilot-plant data, a value of 800 L/m·min (200 gal/m·min) is suggested as a design value; the higher the feed rate, the greater the operator attention required to maintain stable operation. Solids loading rates range on the order of 200 to 600 kg/m·h. Systems are often designed for a maximum of 5 to 7 percent thickened solids. Solids capture typically ranges between 90 and 98 percent (WEF, 1998). Polymer dosages for

thickening waste-activated sludge range from 3 to 7 kg of dry polymer per Mg of dry solids (6 to 14 lb/ton).

Rotary-Drum Thickening. Rotary media-covered drums are also used to thicken sludges. A rotary-drum thickening system consists of a conditioning system (including a polymer feed system) and rotating cylindrical screens (see Fig. 14–15). Polymer is mixed with dilute sludge in the mixing and conditioning drum. The conditioned sludge is

Figure 14–15
Rotary-drum thickener. *(Courtesy Parkson Corporation.)*

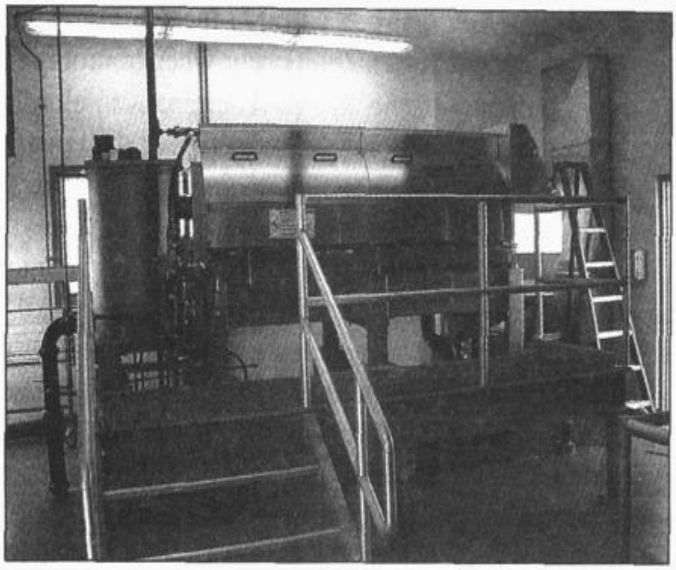

Table 14–22
Typical performance ranges for rotary-drum thickeners[a]

Type of solids or biosolids	Feed, % TS	Water removed, %	Thickened solids, %	Solids recovery, %
Primary	3.0–6.0	40–75	7–9	93–98
Waste activated	0.5–1.0	70–90	4–9	93–99
Primary + waste activated	2.0–4.0	50	5–9	93–98
Aerobically digested	0.8–2.0	70–80	4–6	90–98
Anaerobically digested	2.5–5.0	50	5–9	90–98

[a]WEF (1996).

then passed to rotating-screen drums, which separate the flocculated solids from the water. Thickened sludge rolls out the end of the drums, while separated water decants through the screens. Some designs also allow coupling of the rotary-drum unit to a belt-filter press for combination thickening and dewatering.

Rotary-drum thickeners can be used as a prethickening step before belt-press dewatering and are typically used in small- to medium-sized plants for waste-activated sludge thickening. The addition of large amounts of polymer for conditioning can be of concern because of floc sensitivity and shear potential in the rotating drum (WEF, 1998). Rotary-drum thickeners are available in capacities up to 24 L/s (400 gal/min). Typical performance data for rotary drum thickeners are given in Table 14–22.

14–7 INTRODUCTION TO STABILIZATION

Solids and biosolids are stabilized to (1) reduce pathogens, (2) eliminate offensive odors, and (3) inhibit, reduce, or eliminate the potential for putrefaction. The success in achieving these objectives is related to the effects of the stabilization operation or

process on the volatile or organic fraction of the solids and biosolids. Survival of pathogens, release of odors, and putrefaction occur when microorganisms are allowed to flourish in the organic fraction of the sludge. The means to eliminate these nuisance conditions is mainly related to the biological reduction of the volatile content and the addition of chemicals to the solids or biosolids to render them unsuitable for the survival of microorganisms.

Stabilization is not practiced at all wastewater-treatment plants, but it is used by an overwhelming majority of plants ranging in size from small to very large. In addition to the health and aesthetic reasons cited above, stabilization is used for volume reduction, production of usable gas (methane), and improving the dewaterability of sludge.

The principal methods used for stabilization of sludge are (1) alkaline stabilization, usually with lime; (2) anaerobic digestion; (3) aerobic digestion, including autothermal thermophilic aerobic digestion; and (4) composting. These processes are generally defined in Table 14–23. Each of the processes is discussed in more detail in the following sections, and their ability to mitigate or stabilize the effects related to pathogens, putrefaction, and odors is given in Table 14–24. Heat treatment and the addition of oxidizing chemicals, processes that seldom are used in the United States for stabilization, are not included in this text. For information about these processes, however, Metcalf & Eddy (1991) and WEF (1998) are recommended.

When designing a stabilization process, it is important to consider the sludge quantity to be treated, the integration of the stabilization process with the other treatment units, and the objectives of the stabilization process. The objectives of the stabilization process are often affected by existing or pending regulations. If sludge is to be applied on land, pathogen reduction has to be considered. The effect of regulations on application of biosolids to land is discussed in Sec. 14–17.

14–8 ALKALINE STABILIZATION

A method to eliminate nuisance conditions in sludge is through the use of alkaline material to render the sludge unsuitable for the survival of microorganisms. In the lime stabilization process, lime is added to untreated sludge in sufficient quantity to raise the pH to 12 or higher. The high pH creates an environment that halts or substantially retards the microbial reactions that can otherwise lead to odor production and vector attraction. The sludge will not putrefy, create odors, or pose a health hazard so long as the pH is maintained at this level. The process can also inactivate virus, bacteria, and other microorganisms present.

Chemical Reactions in Lime Stabilization

The lime stabilization process involves a variety of chemical reactions that alter the chemical composition of the sludge. The following simplified equations are illustrative of the types of reactions that may occur (WEF, 1998):

Calcium: $Ca^{2+} + 2HCO_3^- + CaO \rightarrow 2CaCO_3 + H_2O$ (14–7)

Phosphorus: $2PO_4^{3-} + 6H^+ + 3CaO \rightarrow Ca_3(PO_4)_2 + 3H_2O$ (14–8)

Carbon dioxide: $CO_2 + CaO \rightarrow CaCO_3$ (14–9)

Table 14–23
Description of stabilization processes

Process	Description	Comments
Alkaline stabilization	Addition of an alkaline material, usually lime, to maintain a high pH level to effect the destruction of pathogenic organisms	An advantage of alkaline stabilization is that a rich soil-like product results with substantially reduced pathogens. A disadvantage is that the product mass is increased by the addition of the alkaline material. Some alkaline stabilization processes are capable of producing a Class A sludge
Anaerobic digestion	The biological conversion of organic matter by fermentation in a heated reactor to produce methane gas and carbon dioxide. Fermentation occurs in the absence of oxygen	Methane gas can be used beneficially for the generation of heat or electricity. The resulting biosolids may be suitable for land application. The process requires skilled operation as it may be susceptible to upsets and recovery is slow
Aerobic digestion	The biological conversion of organic matter in the presence of air (or oxygen), usually in an open-top tank	Process is much simpler to operate than an anaerobic digester, but no usable gas is produced. The process is energy-intensive because of the power requirements necessary for mixing and oxygen transfer
Autothermal thermophilic digestion	Process is similar to aerobic digestion except higher amounts of oxygen are added to accelerate the conversion of organic matter. Process operates at temperatures of 40 to 80°C, autothermally in an insulated tank	Process is capable of producing a Class A sludge. Skilled operators are required and the process is a high-energy user (to produce air or oxygen)
Composting	The biological conversion of solid organic matter in an enclosed reactor or in windrows or piles	A variety of solids or biosolids can be composted. Composting requires the addition of a bulking agent to provide an environment suitable for biological activity. Volume of compost produced is usually greater than the volume of wastewater solids being composted. Class A or Class B sludge can be produced. Odor control is very important, as process is odorous

Table 14–24
Relative degree of attenuation achieved with various sludge stabilization processes[a]

Process	Degree of attenuation		
	Pathogens	Putrefaction	Odor potential
Alkaline stabilization	Good	Fair	Fair
Anaerobic digestion	Fair	Good	Good
Aerobic digestion	Fair	Good	Good
Autothermal thermophilic digestion (ATAD)	Excellent	Good	Good
Composting	Fair	Good	Poor to fair
Composting (thermophilic)	Excellent	Good	Poor to fair

[a] Adapted, in part, from WEF (1998).

Reactions with organic contaminants:

$$\text{Acids: RCOOH} + \text{CaO} \rightarrow \text{RCOOCaOH} \quad (14\text{–}10)$$

$$\text{Fats: Fat} + \text{Ca(OH)}_2 \rightarrow \text{glycerol} + \text{fatty acids} \quad (14\text{–}11)$$

Other reactions also occur, such as the hydrolysis of polymers, especially polymeric carbohydrates and proteins, and the hydrolysis of ammonia from amino acids.

Initially, lime addition raises the pH of the sludge. Then, reactions occur such as those in the above equations. If insufficient lime is added, the pH decreases as the reactions take place. Therefore, excess lime is required.

Biological activity produces compounds, such as carbon dioxide and organic acids, that react with lime. If biological activity in the sludge being stabilized is not sufficiently inhibited, these compounds will be produced, reducing the pH and resulting in inadequate stabilization. Many odorous, volatile off-gases are also produced, especially ammonia, which require collection and treatment in odor-control systems such as chemical scrubbers or biofilters (see Chap. 15).

Heat Generation

If quicklime, CaO (or any compound high in quicklime), is added to sludge, it initially reacts with water to form hydrated lime. This reaction is exothermic and releases approximately 64 kJ/g·mole (2.75×10^4 Btu/lb·mole) (U.S. EPA, 1982). The reaction between quicklime and carbon dioxide is also exothermic, releasing approximately 180 kJ/g·mole (7.8×10^4 Btu/lb·mole). These reactions can result in substantial temperature rise (see discussion of lime posttreatment).

Application of Alkaline Stabilization Processes

Three methods of alkaline stabilization are commonly used: (1) addition of lime to sludge prior to dewatering, termed "lime pretreatment," (2) the addition of lime to sludge after dewatering, or "lime posttreatment," and (3) advanced alkaline stabilization technologies (WEF 1998). Either hydrated lime, $Ca(OH)_2$, or quicklime is used most commonly for lime stabilization. Fly ash, cement kiln dust, and carbide lime have also been used as a substitute for lime in some cases.

Lime Pretreatment. Pretreatment (before dewatering) of liquid sludge with lime has been used for either (1) the direct application of liquid sludge to land, or (2) combining benefits of sludge conditioning and stabilization prior to dewatering. In the former case, large quantities of liquid sludge have to be transported to land disposal sites, which limits utilization of lime pretreatment of sludge to small treatment plants. When pretreatment is used prior to dewatering, dewatering has been accomplished by a pressure-type filter press. Lime pretreatment is seldom used with centrifuges or belt-filter presses because of abrasive wear and scaling problems.

Lime pretreatment of liquid sludge requires more lime per unit weight of sludge processed than that necessary for dewatering. The higher lime dose is needed to attain the required pH because of the chemical demand of the liquid. In addition, sufficient contact time must be provided before dewatering so as to effect a high level of pathogen kill. The recommended design objective is to maintain the pH above 12 for about 2 h to ensure pathogen destruction (the minimum U.S. EPA criterion for lime stabilization),

Table 14–25
Typical lime dosages for pretreatment sludge stabilization[a]

Type of sludge	Solids concentration, %		Lime dosage[b]			
			lb $Ca(OH)_2$/ton dry solids		g $Ca(OH)_2$/kg dry solids	
	Range	Average	Range	Average	Range	Average
Primary	3–6	4.3	120–340	240	60–170	120
Waste activated	1–1.5	1.3	420–860	600	210–430	300
Anaerobically digested mixed	6–7	5.5	280–500	380	140–250	190
Septage	1–4.5	2.7	180–1020	400	90–510	200

[a] Adapted from WEF (1995a).
[b] Amount of $Ca(OH)_2$ required to maintain a pH of 12 for 30 min.

and to provide enough residual alkalinity so that the pH does not drop below 11 for several days. The lime dosage required varies with the type of sludge and solids concentration. Typical dosages are reported in Table 14–25. Generally, as the percent solids concentration increases, the required lime dose increases. Testing should be performed for specific applications to determine the actual dosage requirements.

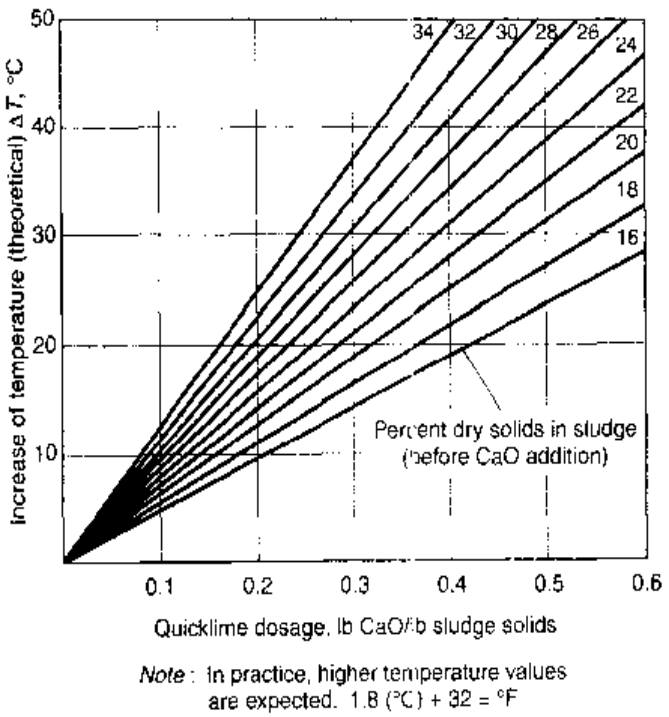
Because lime stabilization does not destroy the organics necessary for bacterial growth, the sludge must be treated with an excess of lime or disposed of before the pH drops significantly. An excess dosage of lime may range up to 1.5 times the amount needed to maintain the initial pH of 12. For additional details about pH decay following lime stabilization, WEF (1995*a*) is recommended.

Lime Posttreatment. In lime posttreatment, hydrated lime or quicklime is mixed with dewatered sludge in a pugmill, paddle mixer, or screw conveyor to raise the pH of the mixture. Quicklime is preferred because the exothermic reaction of quicklime and water can raise the temperature of the mixture above 50°C, sufficient to inactivate worm eggs. The theoretical temperature increase by the addition of quicklime is illustrated on Fig. 14–16.

Lime posttreatment has several significant advantages when compared to lime pretreatment: (1) dry lime can be used; therefore, no additional water is added to the dewatered sludge; (2) there are no special requirements for dewatering; and (3) scaling problems and associated maintenance problems of lime-sludge dewatering equipment are eliminated. Adequate mixing is critical for a posttreatment stabilization system so as to avoid pockets of putrescible material. A lime posttreatment stabilization system consists typically of a dry lime feed system, dewatered sludge cake conveyor, and a lime-sludge mixer (see Fig. 14–17). Good mixing is especially important to ensure contact between lime and small particles of sludge. When the lime and sludge are well mixed, the resulting mixture has a crumbly texture, which allows it to be stored for long periods or easily distributed on land by a conventional manure spreader. A potential disadvantage of

Figure 14–16

Theoretical temperature increase in postlime stabilized sludge using quicklime. *(Roediger, 1987.)*



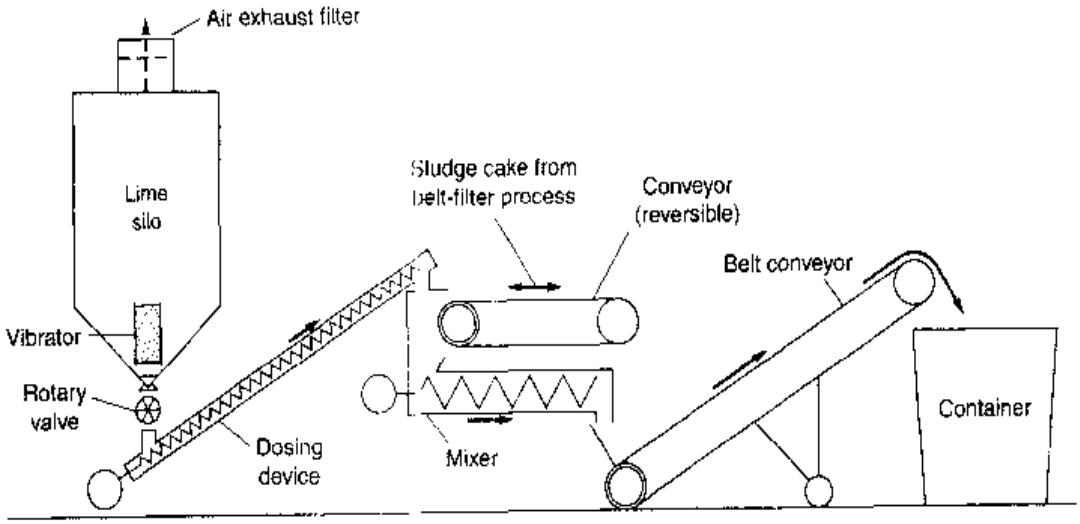


Figure 14–17

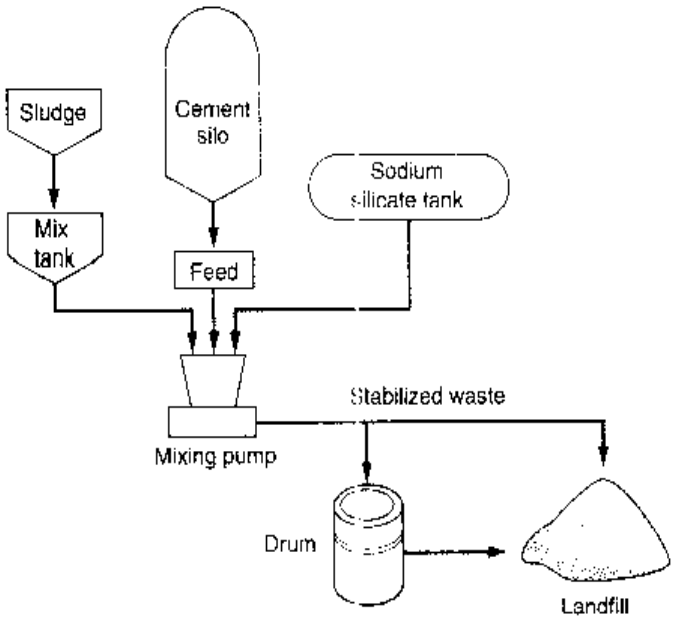
Typical lime posttreatment system. *(From Roediger Pittsburgh.)*



lime posttreatment of anaerobically digested sludge may be the release of odorous gases, specifically trimethyl amine (Novak, 2001).

Advanced Alkaline Stabilization Technologies. Alkaline stabilization using materials other than lime is used by a number of municipalities. Most of the technologies that rely on additives, such as cement kiln dust, lime kiln dust, or fly ash, are modifications of conventional dry lime stabilization. The most common modifications include the addition of other chemicals, a higher chemical dose, and supplemental drying. These processes alter the characteristics of the feed material and, depending on the process, may increase product stability, decrease odor potential, and provide product enhancement. To utilize these technologies, dewatered sludge is required.

Pasteurization may be accomplished by the exothermic reaction of quicklime with water to achieve a process temperature of 70°C and maintain it for more than 30 min.

Figure 14–18

Schematic diagram of a chemical fixation system. *(U.S. EPA, 1989.)*

To meet Class A sludge criteria, the pasteurization reaction must be carried out under carefully controlled and monitored mixing and temperature conditions to ensure uniform treatment and inactivation of pathogens by the heat generated during the reaction. The process produces a soil-like material that is not subject to liquefaction under mechanical stress.

A chemical stabilization/fixation technology typically involves the addition of pozzolanic materials to dewatered sludge cake. Chemical fixation/solidification processes have also been applied for the treatment of industrial sludge and hazardous wastes to immobilize the undesirable constituents. The addition of pozzolanic materials causes cementitious reactions and produces, after drying, a soil-like material of approximately 35 to 50 percent solids content. The principal use of this material is landfill cover. A typical process flow diagram is shown on Fig. 14–18.

Several other process variations of advanced alkaline stabilization are available, some of which are proprietary. Additional information may be found in WEF (1998).

14–9 ANAEROBIC DIGESTION

Anaerobic digestion is among the oldest processes used for the stabilization of solids and biosolids. As described in Chap. 10, anaerobic digestion involves the decomposition of organic matter and inorganic matter (principally sulfate) in the absence of molecular oxygen. The major applications of anaerobic digestion are in the stabilization of concentrated sludges produced from the treatment of municipal and industrial wastewater. Great progress has been made in the fundamental understanding and control of the process, the sizing of tanks, and the design and application of equipment. Because of the emphasis on energy conservation and recovery and the desirability of obtaining beneficial use of wastewater biosolids, anaerobic digestion continues to be the dominant process for stabilizing sludge. Furthermore, anaerobic digestion of municipal wastewater sludge can, in many cases, produce sufficient digester gas to meet most of the energy needs for plant operation.

In this section, a brief review is provided of process fundamentals followed by discussions of mesophilic anaerobic digestion, the most common basic process used; thermophilic digestion; and phased digestion. Phased digestion covers many of the new developments in anaerobic digestion.

Process Fundamentals

As described in Chap. 7, the three types of chemical and biochemical reactions that occur in anaerobic digestion are hydrolysis; fermentation, also called acidogenesis (the formation of soluble organic compounds and short-chain organic acids); and methanogenesis (the bacterial conversion of organic acids into methane and carbon dioxide). Important environmental factors in the anaerobic digestion process are (1) solids retention time, (2) hydraulic retention time, (3) temperature, (4) alkalinity, (5) pH, (6) the presence of inhibitory substances, i.e., toxic materials, and (7) the bioavailability of nutrients and trace metals. The first three factors are important in process selection and are discussed in this section. Alkalinity is a function of feed solids and is important in controlling the digestion process. The effects of pH and inhibitory substances are discussed in Chaps. 7 and 10. The presence of nutrients and trace metals necessary for biological growth is described in Sec. 10–2 in Chap. 10.

Solids and Hydraulic Retention Times. Anaerobic digester sizing is based on providing sufficient residence time in well-mixed reactors to allow significant destruction of volatile suspended solids (VSS) to occur. Sizing criteria that have been used are (1) solids retention time SRT, the average time the solids are held in the digestion process, and (2) the hydraulic retention time τ, the average time the liquid is held in the digestion process. For soluble substrates, the SRT can be determined by dividing the mass of solids in the reactor (M) by the mass of solids removed daily (M/d). The hydraulic retention time τ is equal to the volume of liquid in the reactor (L^3) divided by the quantity of biosolids removed (L^3/d). For digestion systems without recycle, SRT = τ.

The three reactions (hydrolysis, fermentation, and methanogenesis) are directly related to SRT (or τ). An increase or decrease in SRT results in an increase or decrease in the extent of each reaction. There is a minimum SRT for each reaction. If the SRT is less than the minimum SRT, bacteria cannot grow rapidly enough and the digestion process will fail eventually (WEF, 1998).

Temperature. As discussed in Sec. 7–5, temperature not only influences the metabolic activities of the microbial population but also has a profound effect on such factors as gas transfer rates and the settling characteristics of biological solids. In anaerobic digestion, temperature is important in determining the rate of digestion, particularly the rates of hydrolysis and methane formation. The design operating temperature establishes the minimum SRT required to achieve a given amount of VSS destruction. Most anaerobic digestion systems are designed to operate in the mesophilic temperature range, between 30 and 38°C (85 and 100°F). Other systems are designed for operation in the thermophilic temperature range of 50 to 57°C (122 to 135°F). Newly developed systems, as discussed in a latter part of this section, use a combination of mesophilic and thermophilic digestion in separate stages.

While selection of the design operating temperatures is important, maintaining a stable operating temperature is more important because the bacteria, especially the

methane formers, are sensitive to temperature changes. Generally, temperature changes greater than 1°C/d affect process performance, and thus changes less than 0.5°C/d are recommended (WEF, 1998).

Alkalinity. Calcium, magnesium, and ammonium bicarbonates are examples of buffering substances found in a digester. The digestion process produces ammonium bicarbonate from the breakdown of protein in the raw sludge feed: the others are found in the feed sludge. The concentration of alkalinity in a digester is, to a great extent, proportional to the solids feed concentration. A well-established digester has a total alkalinity of 2000 to 5000 mg/L (WEF, 1996).

The principal consumer of alkalinity in a digester is carbon dioxide, and not volatile fatty acids as is commonly believed (Speece, 2001). Carbon dioxide is produced in the fermentation and methanogenesis phases of the digestion process (see Sec. 7–12 in Chap. 7). Due to the partial pressure of gas in a digester, the carbon dioxide solubilizes and forms carbonic acid, which consumes alkalinity. The carbon dioxide concentration in the digester gas is therefore reflective of the alkalinity requirements. Supplemental alkalinity can be supplied by the addition of sodium bicarbonate, lime, or sodium carbonate.

Description of Mesophilic Anaerobic Digestion Processes

The operation and physical facilities for mesophilic anaerobic digestion in single-stage high-rate, two-stage, and separate digesters for primary sludge and waste-activated sludge are described in this section. Standard-rate, sometimes called low-rate, digestion is seldom used for digester design (because of the large tank volume required and the lack of adequate mixing) and is not covered in this text. For information about standard-rate digestion, the reader is referred to the previous edition of this text (Metcalf & Eddy, 1991) and WEF (1998). The processes described below normally operate in the mesophilic range; high-rate digesters also operate in the thermophilic range. Thermophilic digestion is discussed at the end of the section. An aerial view of a large digester installation is shown on Fig. 14–19.

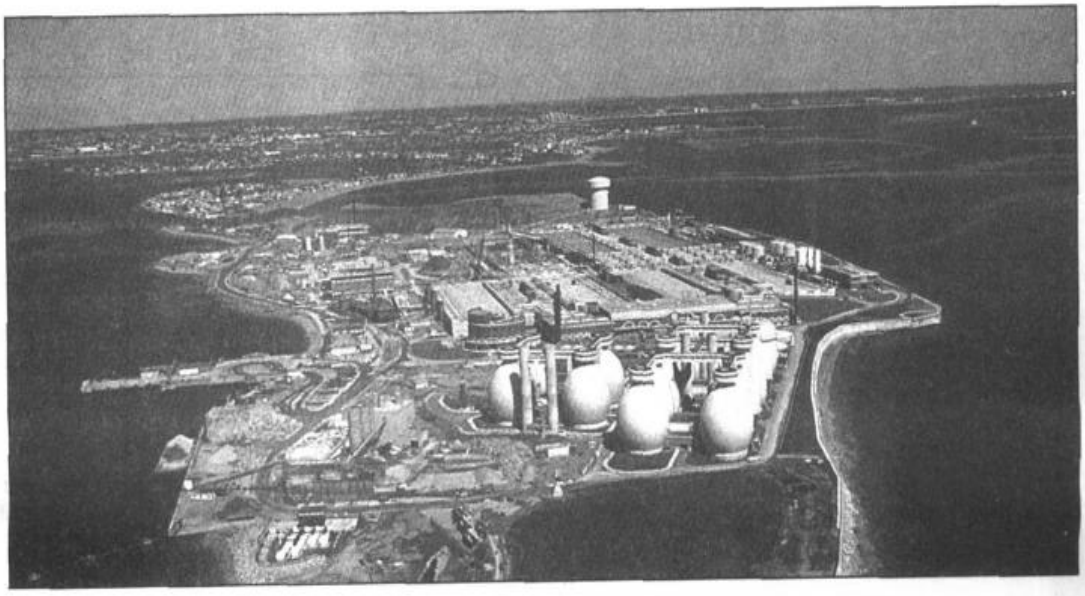


Figure 14–19

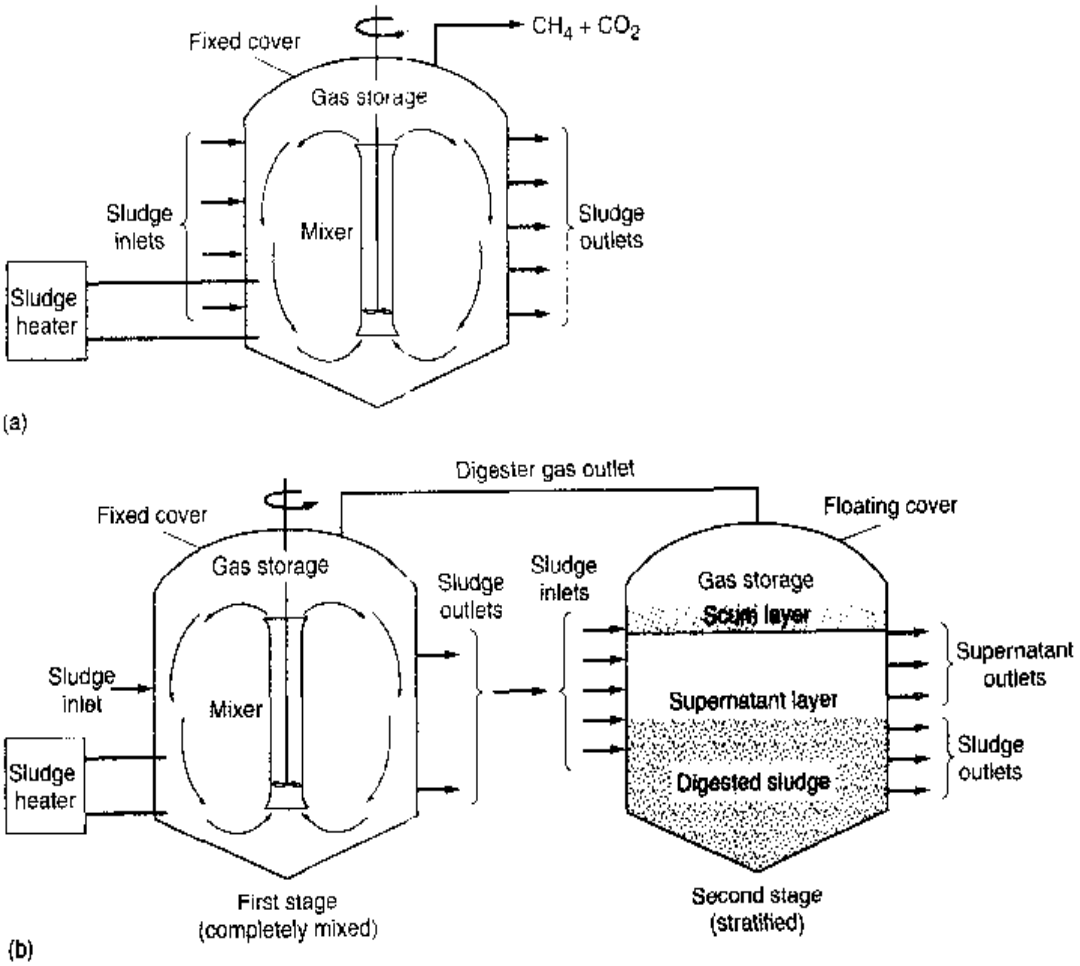

Aerial view of several large anaerobic digesters at Boston, MA. *(Courtesy Massachusetts Water Resources Authority, Kevin Kerwin, photographer, April 22, 1998.)*

Single-Stage High-Rate Digestion. Heating, auxiliary mixing, uniform feeding, and thickening of the feed stream characterize the single-stage high-rate digestion process. The sludge is mixed by gas recirculation, pumping, or draft-tube mixers (separation of scum and supernatant does not take place), and sludge is heated to achieve optimum digestion rates (see Fig. 14–20*a*).

Uniform feeding is very important, and sludge should be pumped to the digester continuously or on a 30-min to 2-h time cycle to help maintain constant conditions in the reactor. In digesters fed on a daily cycle of 8 or 24 h, it is important to withdraw digested sludge from the digester *before* adding the feed sludge, because the pathogen kill is significantly greater when compared to using the feed sludge to displace the waste sludge (Speece, 2001). Because there is no supernatant separation in the high-rate digester, and the total solids are reduced by 45 to 50 percent and given off as gas, the digested sludge is about half as concentrated as the untreated sludge feed. Digestion tanks may have fixed roofs or floating covers. Any or all of the floating covers may be of the gas-holder type, which provides excess gas storage capacity. Alternatively, gas may be stored in a separate low-pressure gas holder or compressed and stored under pressure.

Figure 14–20

Schematic diagram of typical anaerobic digesters: (*a*) single-stage high-rate, and (*b*) two-stage.

Two-Stage Digestion. Two-stage digestion, which was frequently used in the past, is seldom used in modern digester design. In two-stage digestion, a high-rate digester is coupled in series with a second tank (see Fig. 14–20*b*). The first tank is used for digestion and is heated and equipped with mixing facilities. The second tank is usually unheated and used principally for storage. The tanks may be identical, in which case either one may be the primary. Tanks may have fixed roofs or floating covers, the same as single-stage digestion. In other cases, the second tank may be an open tank or a sludge lagoon. Two-stage digestion of the type described above is seldom used, mainly because of the expense of building a large tank that is not fully utilized and because the second tank was of negligible benefit, operationally.

Because anaerobically digested solids may not settle well, the supernatant withdrawn from the second-stage tank may contain high concentrations of suspended solids. Reasons for poor settling characteristics include incomplete digestion in the primary digester (which generates gases in the secondary digester and causes floating solids) and fine-sized solids that have poor settling characteristics. Supernatant returned to the liquid processing system could cause upset conditions and might require separate treatment. Where two-stage digestion is used, return flows from the second tank must be accounted for in the solids mass balance. Less than 10 percent of the gas generated comes from the second stage.

In some installations, the second stage is a heated and mixed reactor to achieve further stabilization prior to dewatering or other subsequent processing. Additional discussion is provided later in this section on two-phase mesophilic digestion that provides more effective utilization of tank capacity.

Separate Sludge Digestion. Most wastewater-treatment plants employing anaerobic digestion use common tanks for the digestion of a mixture of primary and biological sludge. The solid-liquid separation of digested primary sludge, however, is downgraded by even small additions of biological sludge, particularly activated sludge. The rate of reaction under anaerobic conditions is also slowed slightly. In separate sludge digestion, the digestion of primary and biological sludges is accomplished in separate tanks. Reasons cited for separate digestion include (1) the excellent dewatering characteristics of the digested primary sludge are maintained, (2) the digestion process is specifically tailored to the sludge being treated, and (3) optimum process control conditions can be maintained. Design criteria and performance data for the separate anaerobic digestion of biological sludges, however, are very limited. In some cases, especially where biological phosphorus removal is practiced, biological sludge is digested aerobically instead of anaerobically to prevent resolubilization of the phosphorus under anaerobic conditions.

Process Design for Mesophilic Anaerobic Digestion

Ideally, the design of anaerobic sludge digestion processes should be based on an understanding of the fundamental principles of biochemistry and microbiology discussed in Chap. 7 in Sec. 7-12. Because these principles have not been appreciated fully in the past, a number of empirical methods have also been used in the design of digesters. The purpose of the following discussion is to illustrate the various methods that have been used to design single-stage, high-rate digesters in terms of size. These

methods are based on (1) solids retention time, (2) the use of volumetric loading factors, (3) volatile solids destruction, (4) observed volume reduction, and (5) loading factors based on population.

Solids Retention Time. Digester design based on SRT involves application of the principles discussed in Chap. 10. To review briefly, the respiration and oxidation end products of anaerobic digestion are methane gas and carbon dioxide. The quantity of methane gas can be calculated using Eq. (14–12):

$$V_{CH_4} = (0.35)[(S_o - S)(Q)(10^3 g/kg)^{-1} - 1.42\,P_x] \quad (14\text{–}12)$$

where V_{CH_4} = volume of methane produced at standard conditions (0°C and 1 atm), m^3/d
0.35 = theoretical conversion factor for the amount of methane produced, m^3, from the conversion of 1 kg of bCOD at 0°C (conversion factor at 35°C = 0.40, see Example 7–9 in Chap. 7)
Q = flowrate, m^3/d
S_o = bCOD in influent, mg/L
S = bCOD in effluent, mg/L
P_x = net mass of cell tissue produced per day, kg/d

The theoretical conversion factor for the amount of methane produced from the conversion of 1 g of bCOD is derived in Sec. 7–12 in Chap. 7.

For a complete-mix high-rate digester without recycle, the mass of biological solids synthesized daily, P_x, can be estimated using Eq. (14–13).

$$P_x = \frac{YQ(S_o - S) \times (10^3\ g/kg)^{-1}}{1 + k_d\,(SRT)} \quad (14\text{–}13)$$

where Y = yield coefficient, g VSS/g bCOD
k_d = endogenous coefficient, d^{-1} (typical values range from 0.02 to 0.04)
SRT = solids retention time, d
other terms as defined previously

For a complete-mix digester, the SRT is the same as the hydraulic retention time τ.

Typical anaerobic reaction values for Y and k_d are given in Table 10–10 and range from 0.05 to 0.10 and 0.02 to 0.04, respectively. Typical values for SRT at various temperatures are reported in Table 14–26. In practice for high-rate digestion, however, values for SRTs range from 10 to 20 days. Grady, Daigger, and Lim (1999) observed that (1) a lower SRT limit of 10 days at a temperature of 35°C is sufficient to ensure an adequate safey factor against a washout of the menthanogenic population, and (2) incremental changes in volatile solids destruction are relatively small for SRT values above 15 days at 35°C. In selecting the design SRT for anaerobic digestion, peak hydraulic loading must be considered. The peak loading can be estimated by combining poor thickener performance with the maximum sustained plant loading expected during seven continuous days during the design period (U.S. EPA, 1979). The application of Eqs. (14–12) and (14–13) in the process design of a high-rate digester is illustrated in Example 14–5.

Table 14–26 Suggested solids retention times for use in the design of complete-mix anaerobic digesters[a]

Operating temperature, °C	SRT (minimum)	SRT_{des}
18	11	28
24	8	20
30	6	14
35	4	10
40	4	10

[a]McCarty (1964) and (1968).
Note: 1.8 (°C) + 32 = °F.

EXAMPLE 14–5 Estimating Single-Stage, High-Rate Digester Volume and Performance Estimate the size of digester required to treat the sludge from a primary treatment plant designed to treat 38,000 m^3/d (10 Mgal/d) of wastewater. Check the volumetric loading, and estimate the percent stabilization and the amount of gas produced per capita. For the wastewater to be treated, it has been found that the quantity of dry volatile solids and biodegradable COD removed is 0.15 kg/m^3 and 0.14 kg/m^3, respectively. Assume that the sludge contains about 95 percent moisture and has a specific gravity of 1.02. Other pertinent design assumptions are as follows:

1. The hydraulic regime of the reactor is complete-mix.
2. τ = SRT = 10 days at 35°C (see Table 14–26).
3. Efficiency of waste utilization (solids conversion) $E = 0.70$.
4. The sludge contains adequate nitrogen and phosphorus for biological growth.
5. $Y = 0.08$ kg VSS/kg bCOD utilized and $k_d = 0.03\ d^{-1}$.
6. Constants are for a temperature of 35°C.
7. Digester gas is 65 percent methane.

Solution

1. Determine the daily sludge volume using Eq. (14–2).

$$\text{Sludge volume} = \frac{(0.15\ \text{kg/m}^3)(38{,}000\ \text{m}^3/\text{d})}{1.02(10^3\ \text{kg/m}^3)(0.05)} = 111.8\ \text{m}^3/\text{d}$$

2. Determine the bCOD loading.

$$\text{bCOD loading} = (0.14\ \text{kg/m}^3)(38{,}000\ \text{m}^3/\text{d}) = 5320\ \text{kg/d}$$

3. Compute the digester volume.

$$\tau = \frac{V}{Q}$$

$$V = Q\tau = (111.8\ \text{m}^3/\text{d})\ (10\ \text{d}) = 1118\ \text{m}^3$$

4. Compute the volumetric loading.

$$\text{kg bCOD/m}^3\cdot\text{d} = \frac{(5320\ \text{kg/d})}{1118\ \text{m}^3} = 4.76\ \text{kg/m}^3\cdot\text{d}$$

5. Compute the quantity of volatile solids produced per day using Eq. (14–13).

$$P_x = \frac{YQ(S_o - S)(10^3\ \text{g/kg})}{1 + (k_d)\text{SRT}}$$

$$S_o = 5320\ \text{kg/d}$$

$$S = 5320(1 - 0.70) = 1596\ \text{kg/d}$$

$$S_o - S = 5320 - 1596 = 3724\ \text{kg/d}$$

$$P_x = \frac{(0.08)[(5320 - 1596)\ \text{kg/d}]}{1 + (0.03\ \text{d}^{-1})(10\ \text{d})} = 229.2\ \text{kg/d}$$

6. Compute the percent stabilization.

$$\text{Stabilization, \%} = \frac{[3724\ \text{kg/d} - 1.42\ (229.2\ \text{kg/d})]}{(5320\ \text{kg/d})} \times 100 = 63.9\%$$

7. Compute the volume of methane produced per day at 35°C using Eq. (14–12) (conversion factor at 35°C = 0.40).

$$V_{CH_4} = (0.40)[(S_o - S)(Q)/(10^3\ \text{g/kg}) - 1.42\ P_x]$$

$$V_{CH_4} = \{(0.40\ \text{m}^3/\text{kg})[(5320 - 1596)\ \text{kg/d}] - 1.42(229.2\ \text{kg/d})\}$$

$$= 1359\ \text{m}^3/\text{d}$$

8. Estimate the total gas production.

$$\text{Total gas volume} = \frac{1359}{0.65} = 2091\ \text{m}^3/\text{d}$$

Loading Factors. One of the most common methods used to size digesters is to determine the required volume based on a loading factor. Although a number of different factors have been proposed, the two most favored are based on (1) the mass of volatile solids added per day per unit volume of digester capacity, and (2) the mass of volatile solids added to the digester each day per mass of volatile solids in the digester. Of the two, the first method is preferred. Loading criteria are based generally on sustained loading conditions (see Chap. 3), typically peak 2-week or peak month solids production with provisions for avoiding excessive loadings during shorter periods. Typical design criteria for sizing mesophilic high-rate anaerobic digesters are given in Table 14–27. The upper limit of volatile solids loading rates is typically determined by the rate of accumulation of toxic materials, particularly ammonia, or washout of methane formers (WEF, 1998).

Table 14–27
Typical design criteria for sizing mesophilic high-rate complete-mix anaerobic sludge digesters[a]

Parameter	U.S. customary units		SI units	
	Units	Value	Units	Value
Volume criteria:				
Primary sludge	ft³/capita	1.3–2.0	m³/capita	0.03–0.06
Primary sludge + trickling-filter humus sludge	ft³/capita	2.6–3.3	m³/capita	0.07–0.09
Primary sludge + activated sludge	ft³/capita	2.6–4	m³/capita	0.07–0.11
Solids loading rate	lb VSS/10^3 ft³·d	100–300	kg/m³·d	1.6–4.8
Solids retention time	d	15–20	d	15–20

[a] Adapted, in part, from U.S. EPA (1979).

Excessively low volatile solids loading rates can result in designs that are costly to build and are troublesome to operate. In a survey conducted by Speece (1988) of 30 digester installations in the United States, one of the most significant observations was the relatively low solids content in the sludge feed to the digesters. The average TSS in the sludge feed was 4.7±1.6 percent and the average volatile solids content was 70 percent. The average VSS value in the digesters was a dilute 1.6 percent. Dilute sludge results in the following adverse effects in digester operation: (1) reduced τ, (2) reduced VS destruction, (3) reduced methane generation, (4) reduced alkalinity, (5) increased volumes of digested biosolids and supernatant, (6) increased heating requirements, (7) increased dewatering capacity, and (8) increased hauling cost for liquid biosolids. One cautionary measure should be noted, however. A potential problem with ammonia toxicity could occur if the waste-activated sludge is thickened too much. Thus, in planning the design and operation of anaerobic digesters, consideration should be given to optimizing volatile solids loading to effectively utilize digester capacity. The effect of solids concentration and hydraulic detention time on volatile solids loading is reported in Table 14–28.

Estimating Volatile Solids Destruction. The degree of stabilization obtained is often measured by the percent reduction in volatile solids. The reduction in volatile solids can be related either to the SRT or to the detention time based on the untreated sludge feed. The amount of volatile solids destroyed in a high-rate complete-mix digester can be estimated by the following empirical equation (Liptak, 1974):

$$V_d = 13.7 \ln (\mathrm{SRT}_{\mathrm{dcs}}) + 18.9 \qquad (14\text{–}14)$$

where V_d = volatile solids destruction, %
SRT = time of digestion, d (range 15 to 20 d)

Volatile solids destruction estimates can also be made using Table 14–29.

Because the untreated sludge feed can be measured easily, this method is also used commonly. In plant operation, calculation of volatile solids reduction should be made

Table 14–28
Effect of sludge concentration and hydraulic detention time on volatile solids loading factors[a]

Sludge concentration, %	Volatile solids loading factor							
	lb/ft³·d				kg/m³·d			
	10 d[b]	12 d	15 d	20 d	10 d	12 d	15 d	20 d
2	0.09	0.07	0.06	0.04	1.4	1.2	0.95	0.70
3	0.13	0.11	0.09	0.07	2.1	1.8	1.4	1.1
4	0.18	0.15	0.12	0.09	2.9	2.4	1.9	1.4

20	60.0
15	56.0

[a] Adapted from WEF (1998).

routinely as a matter of record whenever sludge is drawn to processing equipment or drying beds. Alkalinity and volatile acids content should also be checked daily as a measure of the stability of the digestion process.

In calculating the volatile solids reduction, the ash content of the sludge is assumed to be conservative; that is, the number of pounds of ash going into the digester is equal to that being removed. A typical calculation of volatile solids reduction is presented in Example 14–6.

EXAMPLE 14–6 Determination of Volatile Solids Reduction From the following analysis of untreated and digested biosolids, determine the total volatile solids reduction achieved during digestion. It is assumed that (1) the weight of fixed solids in the digested biosolids equals the weight of fixed solids in the untreated sludge and (2) the volatile solids are the only constituents of the untreated sludge lost during digestion.

	Volatile solids, %	Fixed solids, %
Untreated sludge	70	30
Digested sludge	50	50

Solution

1. Determine the weight of the digested solids. Because the quantity of fixed solids remains the same, the weight of the digested solids based on 1.0 kg of dry untreated sludge, as computed below, is 0.6 kg.

$$\text{Fixed solids in untreated sludge, } 30\% = \frac{(0.3\text{ kg})100}{0.3\text{ kg} + 0.7\text{ kg}}$$

Let X equal the weight of volatile solids after digestion. Then

$$\text{Fixed solids in untreated sludge, } 50\% = \frac{(0.3\text{ kg})\ 100}{0.3\text{ kg} + X\text{ kg}}$$

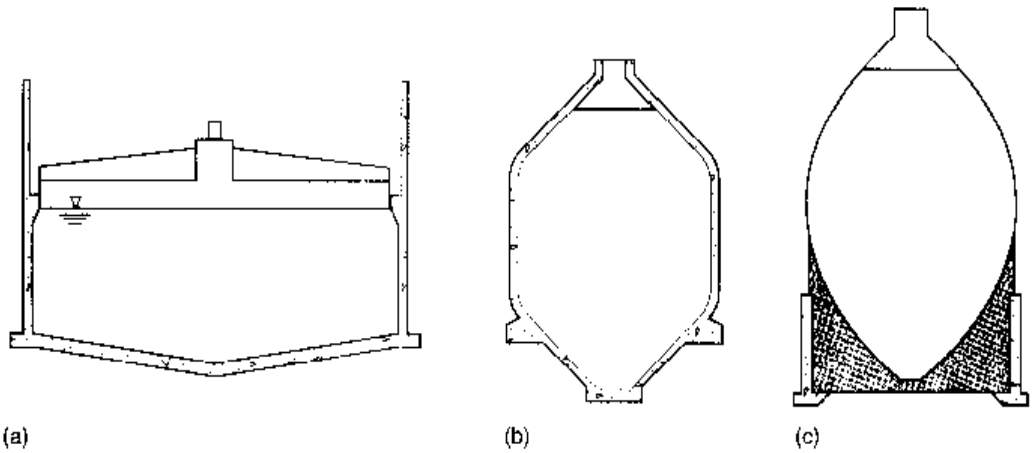
$$X = \frac{(0.3\text{ kg})100}{50} - 0.3\text{ kg} = 0.3\text{ kg to volatile solids}$$

$$\text{Weight of digested solids} = 0.3\text{ kg} + X = 0.6\text{ kg}$$

2. Determine the percent reduction in total and volatile suspended solids.
   a. Percent reduction of total suspended solids

$$R_{TSS} = \frac{(1.0 - 0.6)\text{ kg}}{1.0\text{ kg}} \times 100 = 40\%$$

   b. Percent reduction in volatile suspended solids



$$R_{VSS} = \frac{(0.7 - 0.3)\text{ kg}}{0.7\text{ kg}} \times 100 = 57.1\%$$

Population Basis. Digestion tanks are also designed on a volumetric basis by allowing a certain number of cubic meters per capita (cubic feet per capita). Detention times range from 10 to 20 d for high-rate digesters (U.S. EPA, 1979). These detention times are recommended for design based on total tank volume, plus additional storage volume if sludge is dried on beds and weekly sludge withdrawals are curtailed because of inclement weather.

Typical design criteria for heated anaerobic digesters based on population are shown in Table 14–27. The criteria are applied only where analyses and volumes of sludge to be digested are not available. The capacities shown in Table 14–27 should be increased 60 percent in a municipality where the use of garbage grinders is universal and should be increased on a population-equivalent basis to allow for the effect of industrial wastes.

Figure 14–21

Typical shapes of anaerobic digesters: (*a*) cylindrical with reinforced concrete construction, (*b*) conventional German design with reinforced concrete construction, and (c) egg-shaped with steel shell.

Selection of Tank Design and Mixing System

Most anaerobic digestion tanks are either cylindrical, conventional German design, or egg-shaped (see Fig. 14–21). The most common shape used in the United States is a shallow, vertical cylinder shown on Fig. 14–21*a*. Rectangular tanks were used in the past, but they experienced great difficulty in mixing the tank contents uniformly. German designers have worked on optimizing the shape of digesters and two basic types have emerged: the conventional German digester and the egg-shaped digester. The conventional German digester (see Fig. 14–21*b*) is a deep cylindrical vessel with steeply sloped top and bottom cones (Stukenberg, et al, 1992). The egg-shaped digester, shown on Fig. 14–21*c*, is similar in appearance to an upright egg, and the design is sometimes modified to a sphere-cone shape. Egg-shaped tanks have been used extensively in Europe, especially in Germany, and are growing in popularity in the United States. Essentially all of the modern digester designs in the United States are of either the cylindrical or egg-shaped type. Cylindrical and egg-shaped digesters and the mixing systems used for each type of tank are discussed in the following paragraphs. Advantages and disadvantages of each type of digester are summarized in Table 14–30.

Proper mixing is one of the most important considerations in achieving optimum process performance. Various systems for mixing the contents of the digesters have been used; the most common types involve the use of (1) gas injection, (2) mechanical stirring, and (3) mechanical pumping. Some digester installations use a combination of gas mixing and recirculation by pumping. The advantages and disadvantages of the various mixing systems are summarized in Table 14–31; typical design parameters are shown in Table 14–32.

Cylindrical Tanks. Cylindrical sludge digestion tanks are seldom less than 6 m (20 ft) or more than 38 m (125 ft) in diameter. The water depth should not be less than 7.5 m (25 ft) at the sidewall because of the difficulty in mixing shallow tanks, and the depth may be as much as 15 m (50 ft). The floor of the digester is usually conical with the bottom sloping to the center, with a minimum slope of 1 vertical to 6 horizontal where the sludge is drawn off (see Fig. 14–22). An alternative design uses a "waffle" bottom to minimize grit accumulation and to reduce the need for frequent digester cleaning (see Fig. 14–23).

Table 14–30
Comparison of cylindrical and egg-shaped anaerobic digesters[a]

Type of digester	Advantages	Disadvantages
Cylindrical	Reactor shape allows a relatively large volume for gas storage	Reactor shape results in inefficient mixing and dead spaces
	Reactor can be equipped with gas-holder covers	Poor mixing results in grit and silt accumulation
	Low profile	Large surface area provides space for scum accumulation and foam formation
	Conventional construction techniques can be applied; construction costs can be competitive	Cleaning is required for removal of grit and scum accumulation; digester may be required to be taken out of service
Egg-shaped	Minimum grit accumulation	Very little gas storage volume; external gas storage is required if gas is recovered
	Reduced scum formation	High-profile structures; may be aesthetically objectionable
	Higher mixing efficiency	Difficult access to top-mounted equipment; installation requires a high stair tower or an elevator
	More homogeneous biomass is obtained	Greater foundation design requirements and seismic considerations
	Lower operating and maintenance costs; cleaning frequency significantly reduced	Foaming of gas-mixed digester may be a problem in collecting gas
	Smaller footprint; less land area is required	Higher construction costs
	Foaming is minimized (except for gas mixing)	Construction limited to specialty contractors

[a] Adapted, in part, from Brinkman and Voss (1998).

Gas-injection systems used in cylindrical tanks are classified as unconfined or confined (Fig. 14–24*a* and *b*). Unconfined gas systems collect gas at the top of the digesters, compress the gas, and then discharge the gas through a pattern of bottom diffusers or through a series of radially placed top-mounted lances. Unconfined gas systems mix the digester contents by releasing gas bubbles that rise to the surface, carrying and moving the sludge. These systems are suitable for digesters with fixed, floating, or gas-holder covers. In confined gas systems, gas is collected at the top of the digesters, compressed, and discharged through confined tubes. Two major types of confined systems are the gas lifter and the gas piston. The gas lifter system consists of submerged gas pipes or lances inserted into an eductor tube or gas lifter. Compressed gas is released from the lances or pipes, and the gas bubbles rise, creating an air-lift effect. In the gas piston system, gas bubbles are released intermittently at the bottom of a cylindrical tube or piston. The bubbles rise and act like a piston, pushing the sludge to the surface. These systems are suitable for fixed, floating, or gas-holder covers.

Table 14–31
Summary of advantages and disadvantages of various anaerobic digester mixing systems[a]

Type of mixer	Advantages	Disadvantages
All systems	Increased rate of biosolids stabilization	Corrosion and tear of ferrous-metal piping and supports. Equipment wear by grit. Equipment plugging and operational interference by rags
Gas injection:		
Unconfined		
Cover-mounted lances	Lower maintenance and less hindrance to cleaning than bottom-mounted diffusers. Effective against scum buildup	Corrosion of gas piping and equipment. High maintenance for compressor. Potential gas-seal problem. Compressor problems if foam gets inside. Solids deposition. Plugging of gas lances. Entire tank contents are not mixed
Bottom-mounted diffusers	Better movement of bottom deposits than cover-mounted lances	Corrosion of gas piping and equipment. High compressor maintenance. Potential gas-seal problem. Foaming. Incomplete mixing. Scum formation. Diffuser plugging. Bottom deposits can alter mixing patterns. Requires digester dewatering for maintenance
Confined:		
Gas lifters	Better mixing and gas production and better movement of bottom deposits than cover-mounted lances. Lower power requirements	Corrosion of gas piping and equipment. High maintenance for compressor. Potential gas-seal problem. Corrosion of gas lifter. Lifter interferes with digester cleaning. Scum buildup. Does not provide good top mixing. Requires digester dewatering for maintenance if bottom mounted
Gas pistons	Good mixing efficiency	Corrosion of gas piping and equipment. High maintenance for compressor. Potential gas-seal problem. Equipment internally mounted. Pistons interfere with digester cleaning. Requires digester dewatering for maintenance
Mechanical stirring:		
Low-speed turbines	Good mixing efficiency	Wear of impellers and shafts. Bearing failures. Interference of impellers with rags. Requires oversized gear boxes. Gas leaks at shaft seal. Long overhung loads
Low-speed mixers	Breaks up scum layers	Not designed to mix entire tank contents. Bearing and gear box failures. Impeller wear. Interference of impellers by rags
Mechanical pumping:		
Internal draft tubes	Good top-to-bottom mixing	Sensitive to liquid level. Corrosion and wear of impeller. Bearing and gear box failures. Requires oversized gear box
External draft tubes	Same as internal draft tube. Draft-tube maintenance easier than internal type	Same as internal draft tube
Pumps	Better mixing control. Scum layer and sludge deposits can be recirculated. Pumps easier to maintain than compressors	Impeller wear. Plugging of pumps by rags. Bearing failures

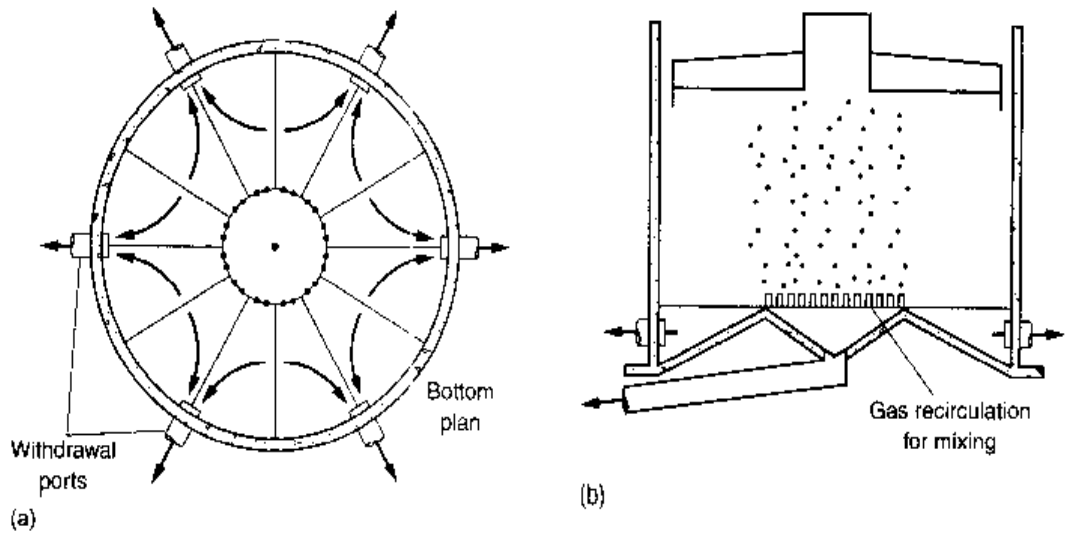
Table 14–32
Typical design parameters for anaerobic digester mixing systems[a]

Parameter	Type of mixing system	Typical values[b] U.S. customary units	Typical values[b] SI units
Unit power	Mechanical systems	0.025–0.04 hp/10^3 gal of digester volume	0.005–0.008 kW/m^3 of digester volume
Unit gas flow[c]	Gas mixing		
	Unconfined	4.5–5 $ft^3/10^3$ ft^3·min	0.0045–0.005 m^3/m^3·min
	Confined	5–7 $ft^3/10^3$ ft^3·min	0.005–0.007 m^3/m^3·min
Velocity gradient G	All	50–80 s^{-1}	50–80 s^{-1}
Turnover time of tank contents	Confined gas mixing and mechanical systems	20–30 min	20–30 min

[a] Adapted from WEF (1987*b*).
[b] Actual design values may differ depending on the type of mixing system, manufacturer, and digestion process or function.
[c] Quantity of gas delivered by the gas-injection system divided by the digester gas volume.

Figure 14–22
Typical cross section through a high-rate, gas-mixed cylindrical digester.



Mechanical stirring systems commonly use low-speed turbines or mixers (see Fig. 14–24*c*). In both systems, the rotating impeller(s) displaces the sludge, mixing the digester contents. Low-speed turbine systems usually have one cover-mounted motor with two turbine impellers located at different sludge depths. A low-speed mixer system usually has one cover-mounted mixer. Mechanical stirring systems are most suitable for digesters with fixed or floating covers.

Most mechanical pumping systems consist of propeller-type pumps mounted in internal or external draft tubes, or axial-flow or centrifugal pumps and piping installed

Figure 14–23

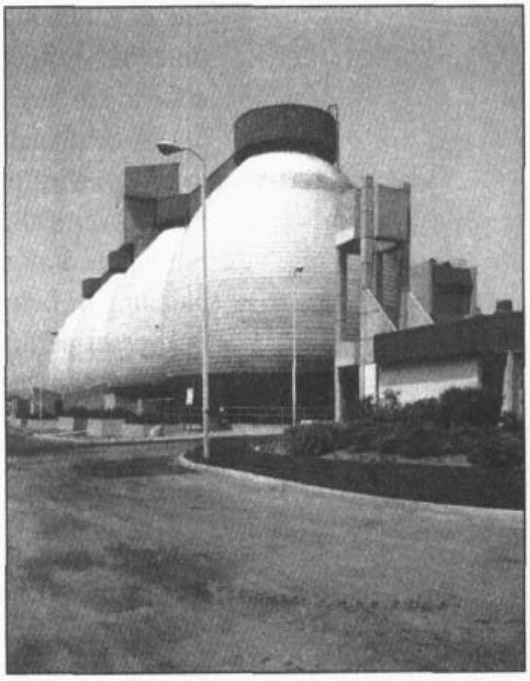
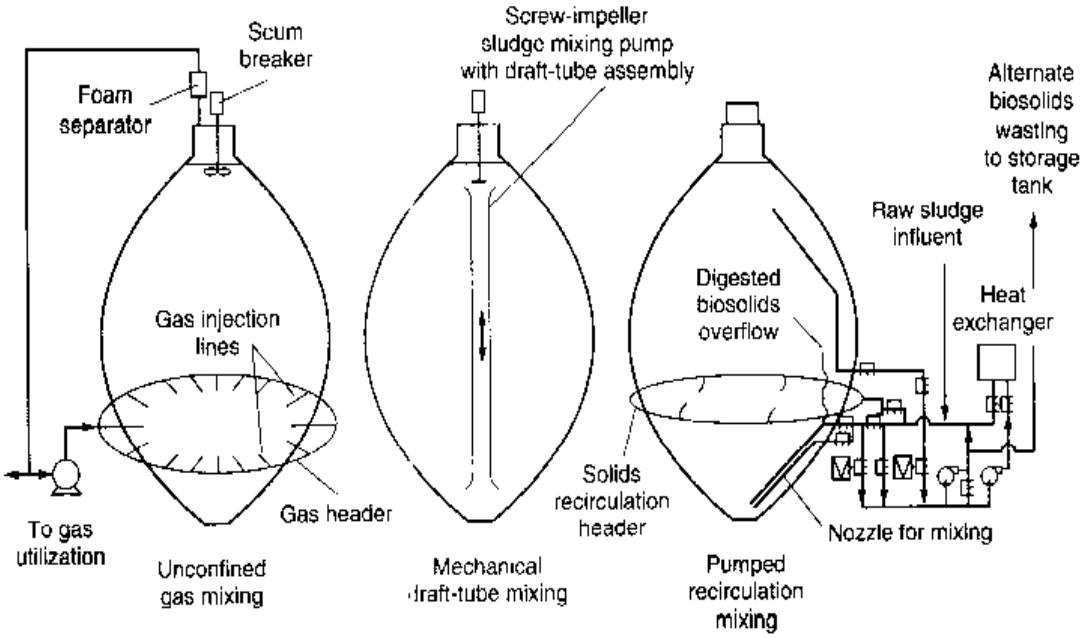
externally (see Fig. 14–24*d*). Mixing is promoted by the circulation of sludge. Mechanical pumping systems are suitable for digesters with fixed covers.

Egg-Shaped Tanks. The purpose of the egg-shaped design is to enhance mixing and to eliminate the need for cleaning. The digester sides form a steep cone at the bottom so that grit accumulation is minimized (see Fig. 14–25*a*). Other advantages cited for the egg-shaped design include better mixing, better control of the scum layer, and smaller land-area requirements. Steel construction is more common for egg-shaped tanks in the United States; reinforced concrete construction requires complex formwork and special construction techniques. The structures are relatively high as compared to other treatment plant structures (see Fig. 14–25*b*), and may require an elevator for access to the top of the structure. In recent designs in Boston, MA (see Fig. 14–19), and Baltimore, MD, the heights of the digesters were over 40 m (130 ft).

Egg-shaped digester mixing systems are similar to those for cylindrical tanks and consist of unconfined gas mixing, mechanical draft-tube mixing, or pumped recirculation mixing (see Fig. 14–26). Gas mixing is considered by some to be relatively ineffective in mixing the digester contents below the level of the injection nozzles. The mechanical draft tube and pumped recirculation mixing systems, however, are considered able to provide sufficient energy to mix even the sludge in the bottom cone of the digester. The mechanical draft-tube mixer, which can be operated in either an up- or





(b)

Figure 14–25

Figure 14-26

Mixing systems for egg-shaped anaerobic digesters. *(From Stukenberg et al., 1992.)*

down-pumping mode, also provides a positive means of mixing at the surface to control scum and foam (Stukenberg et al., 1992).

Recirculation mixing is generally more effective when the sludge is taken from the bottom and discharged near the gas-liquid interface or above the gas-liquid interface to break up scum that may have accumulated. Recirculation mixing is also effective for foam control in gas-mixed digesters.

Any or all of the mixing systems may be used, and all may be operated during any one day, although gas and mechanical draft-tube mixing are seldom used at the same time. Most digesters are fitted with a gas lance or hydraulic jet near the bottom of the cone to stir any accumulated grit.

A combination jet-pump draft-tube mixing system is also used that permits mixing in three zones of the digester. One jet pump is attached to the bottom of the centrally located vertical draft tube, and a second jet pump is attached to the top. In this configuration, the draft tube can function for pumping sludge upward or downward for periodic blending of bottom sludge and scum with the tank contents. A third pump is located at the vessel perimeter to create a swirling action. External recirculation pumps are also provided for sludge heating and additional circulation of the tank contents. The system is designed to circulate the tank volume 10 times per day (Clark and Ruehrwein, 1992).

Methods for Enhancing Solids Loading and Digester Performance

Opportunities for enhancing the performance of anaerobic digesters include thickening the digester feed sludge or thickening a portion of the digesting sludge to increase the SRT. Recirculating a portion of the digested sludge and cothickening with untreated primary and waste sludge was reported originally by Torpey and Melbinger (1967). The solids concentration in the feed sludge improved and the performance of the digester, as measured by volatile solids destruction, increased significantly. The thickening system was installed at wastewater plants in New York City. In a recent study by Maco et al. (1998), the effects of thickening digested solids, either thickened separately or

combined with prethickening of untreated sludge, increased the SRT of the digestion process and the production of biogas and decreased the hydraulic retention time.

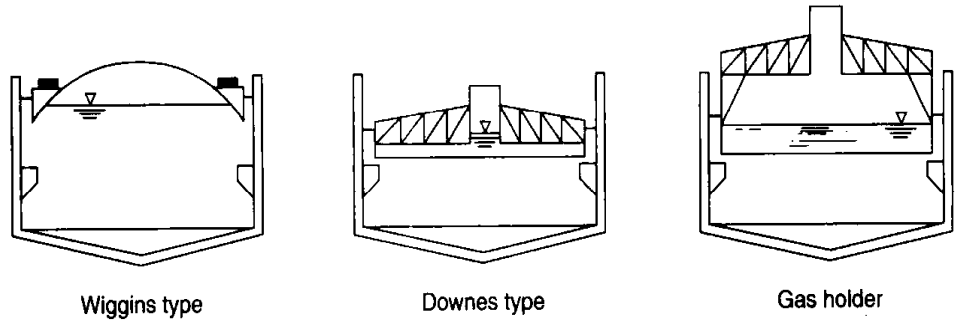
The value of thickening the feed sludge to the digester is indicated by data presented in Table 14–28. For example, for a 15-d hydraulic retention time and an average TSS of 3 percent, the volatile solids loading factor in Table 14–28 is 1.4 kg/m^3·d. By improving the feed solids TSS to 6 percent, the VSS loading can be increased to 2.9 kg/m^3·d, near the middle of the solids loading range given in Table 14–27. In this hypothetical example, a doubling in digester capacity is achieved. In evaluating digested solids recycling to reduce the size and number of digesters or increase the solids processing capacity of existing digesters, sludge rheology and sludge handling equipment require evaluation. While most digesters can accommodate increases in solids concentrations, the limits imposed by pumping and mixing systems require careful evaluation (Maco et al., 1998).

Gas Production, Collection, and Use

Gas from anaerobic digestion contains about 65 to 70 percent CH_4 by volume, 25 to 30 percent CO_2, and small amounts of N_2, H_2, H_2S, water vapor, and other gases. Digester gas has a specific gravity of approximately 0.86 relative to air. Because production of gas is one of the best measures of the progress of digestion and because digester gas can be used as fuel, the designer should be familiar with its production, collection, and use.

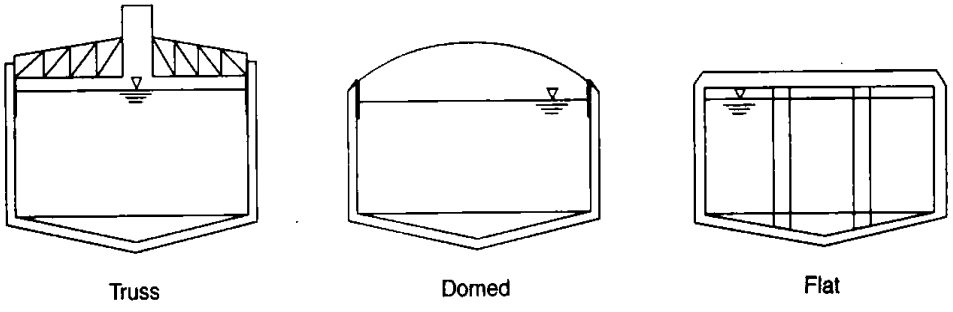
Gas Production. The volume of methane gas produced during the digestion process can be estimated using Eq. (14–12), which has been discussed previously. Total gas production is usually estimated from the percentage of volatile solids reduction. Typical values vary from 0.75 to 1.12 m^3/kg (12 to 18 ft^3/lb) of volatile solids destroyed. Gas production can fluctuate over a wide range, depending on the volatile solids content of the sludge feed and the biological activity in the digester. Excessive gas production rates sometimes occur during startup and may cause foaming and escape of foam and gas from around the edges of floating digester covers. In egg-shaped and shallow cylindrical digesters, foaming can clog the gas outlet unless foam control is provided. If stable operating conditions have been achieved and the foregoing gas production rates are being maintained, a well-digested sludge can be obtained.

Gas production can also be estimated crudely on a per capita basis. The normal yield is 15 to 22 m^3/10^3 persons·d (0.6 to 0.8 ft^3/person·d) in primary plants treating normal domestic wastewater. In secondary treatment plants, the gas production is increased to about 28 m^3/10^3 persons·d (1.0 ft^3/person·d).



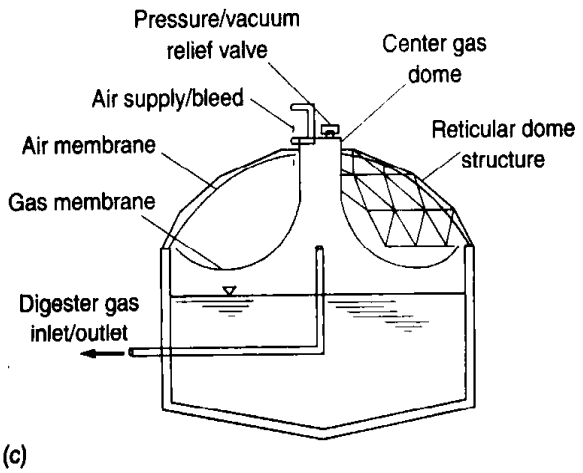
Gas Collection. In cylindrical digesters, gas is collected under the cover of the digester. Three principal types of covers are used: (1) floating, (2) fixed, and (3) membrane. Floating covers fit on the surface of the digester contents and allow the volume of the digester to change without allowing air to enter the digester (see Fig. 14–27*a*). Gas and air must not be allowed to mix, or an explosive mixture may result. Explosions have occurred in wastewater-treatment plants. Gas piping and pressure-relief valves must include adequate flame traps. The covers may also be installed to act as gas holders for a limited storage of gas. High-rate digesters produce about two volumes of gas per volume of digester capacity/d (Speece 2001). Floating covers can be used for single-stage digesters or in the second stage of two-stage digesters.

Fixed covers provide a free space between the roof of the digester and the liquid surface (see Fig. 14–27*b*). Gas storage must be provided so that (1) when the liquid volume is changed, gas, and not air, will be drawn into the digester; otherwise an overflow weir with a U-shaped trap needs to be provided to maintain a liquid seal, and (2) gas will not be lost by displacement. Gas can be stored either at low pressure in external gas holders that use floating covers or at high pressure in pressure vessels if gas compressors are used. Gas not used should be burned in a flare. Gas meters should be installed to measure gas produced and gas used or wasted.

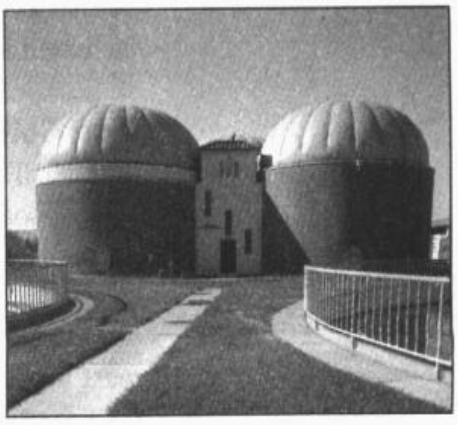


A recent development in gas-holder covers for cylindrical tanks is the membrane cover (see Fig. 14–27*c*). This cover consists of a support structure for a small center gas dome and flexible air and gas membranes. An air-blower system is provided to pressurize the air space between the two membranes and vary the air space volume. Only

Figure 14–27



Types of anaerobic digester covers: (*a*) floating, (*b*) fixed, and (*c*) schematic and view of membrane gas cover.



(a)

(b)

(c)

the gas membrane and the center gas dome are in contact with the digester contents. The gas membrane is made from a flexible polyester fabric (WEF, 1998).

In egg-shaped digesters, the volume available for gas storage is small. For efficient utilization of digester gas, supplemental external storage may be required.

Use of Digester Gas. Methane gas at standard temperature and pressure (20°C and 1 atm) has a lower heating value of 35,800 kJ/m^3 (960 Btu/ft^3). Lower heating value is the heat of combustion less the heat of vaporization of any water vapor present. Because digester gas is only 65 percent methane, the lower heating value of digester gas is approximately 22,400 kJ/m^3 (600 Btu/ft^3). By comparison, natural gas, which is a mixture of methane, propane, and butane, has a heating value of 37,300 kJ/m^3 (1000 Btu/ft^3).

In large plants, digester gas may be used as fuel for boiler and internal-combustion engines which are, in turn, used for pumping wastewater, operating blowers, and generating electricity. Hot water from heating boilers or from engine jackets and exhaust-heat boilers may be used for sludge heating and for building heating, or gas-fired sludge-heating boilers may be used. Energy recovery is more efficient if prime movers are designed to run hot because heat rejected at high temperatures can be put to a greater variety of uses than heat rejected at low temperatures.

Digester gas can be used in cogeneration. Cogeneration is generally defined as a system for generating electricity and producing another form of energy (usually steam or hot water). Digester gas can be used to power an engine-generator to generate electricity, and the jacket water from the internal-combustion engine can then be used for digester or building heating. Surplus power, over and above that required for plant purposes, can sometimes be sold to local electric utilities.

Because digester gas contains hydrogen sulfide, nitrogen, particulates, and water vapor, the gas frequently has to be cleaned in dry or wet scrubbers before it is used in internal-combustion engines. Hydrogen sulfide concentrations in excess of approximately 100 ppm by volume may require the installation of hydrogen sulfide removal equipment (WEF, 1998).

Digester Heating

The heat requirements of digesters consist of the amount needed (1) to raise the incoming sludge to digestion tank temperatures, (2) to compensate for the heat losses through walls, floor, and roof of the digester, and (3) to make up the losses that might occur in the piping between the source of heat and the tank. The sludge in digestion tanks is heated by pumping the sludge and supernatant through external heat exchangers and back to the tank.

Analysis of Heat Requirements. In computing the energy required to heat the incoming sludge to the temperature of the digester, it is assumed that the specific heat of most sludges is essentially the same as that of water. The assumption that the specific heats of sludge and water are essentially the same has proved to be acceptable for engineering computations. The heat loss through the digester sides, top, and bottom is computed using the following expression:

$$q = UA\Delta T \tag{14–15}$$

where q = heat loss, J/s, Btu/h
U = overall coefficient of heat transfer, J/m^2·s·°C (Btu/ft^2·h·°F)
A = cross-sectional area through which the heat loss is occurring, m^2 (ft^2)
ΔT = temperature drop across the surface in question, °C (°F)

In computing the heat losses from a digester using Eq. (14–15), it is common practice to consider the characteristics of the various heat transfer surfaces separately and to develop transfer coefficients for each one. The application of Eq. (14–15) in the computation of digester heating requirements is illustrated in Example 14–7.

Heat-Transfer Coefficients. Typical overall heat-transfer coefficients are reported in Table 14–33. As shown, separate entries are included for the walls, bottom, and top of the digester.

Digestion tank walls may be surrounded by earth embankments that serve as insulation, or they may be of compound construction consisting of approximately 300 mm (12 in) of concrete, insulation, or an insulating air space, plus brick facing or corrugated aluminum facing over rigid insulation. The heat transfer from plain concrete walls

Table 14–33
Typical values of heat transfer coefficients used for computing digester heat losses[a]

Item	U.S. customary, Btu/ft^2·°F·h	SI units, W/m^2·°C
Plain concrete walls (above ground):		
300 mm (12 in) thick, not insulated	0.83–0.90	4.7–5.1
300 mm (12 in) thick with air space plus brick facing	0.32–0.42	1.8–2.4
300 mm (12 in) thick wall with insulation	0.11–0.14	0.6–0.8
Plain concrete walls (below ground):		
Surrounded by dry earth	0.10–0.12	0.57–0.68
Surrounded by moist earth	0.19–0.25	1.1–1.4
Plain concrete floors:		
300 mm (12 in) thick in contact with moist earth	0.5	2.85
300 mm (12 in) thick in contact with dry earth	0.3	1.7
Floating covers:		
With 35-mm (1.5-in) wood deck, built-up roofing, and no insulation	0.32–0.35	1.8–2.0
With 25-mm (1-in) insulating board installed under roofing	0.16–0.18	0.9–1.0
Fixed concrete covers:		
100 mm (4 in) thick and covered with built-up roofing, not insulated	0.70–0.88	4.0–5.0
100 mm (4 in) thick and covered, but insulated with 25-mm (1-in) insulating board	0.21–0.28	1.2–1.6
225 mm (9 in) thick, not insulated	0.53–0.63	3.0–3.6
Fixed steel covers 6 mm (0.25 in) thick	0.70–0.95	4.0–5.4

[a]Adapted, in part, from U.S. EPA (1979).

below ground level and from floors depends on whether they are below the groundwater level. If the groundwater level is not known, it may be assumed that the sides of the tank are surrounded by dry earth and that the bottom is saturated earth. Because the heat losses from the tank warm up the adjacent earth, it is assumed that the earth forms an insulating blanket 1.5 to 3 m (5 to 10 ft) thick before stable ambient earth temperatures are reached. In northern climates, frost may penetrate to a depth of 1.2 m (4 ft). Therefore, the ground temperature can be assumed to be 0°C (32°F) at this depth and to vary uniformly above this depth to the design air temperatures at the surface. Below the frost depth, normal winter ground temperatures can be assumed, which are 5 to 10°C (10 to 20°F) higher at the base of the wall. Alternatively, an average temperature may be assumed for the entire wall below grade.

The loss through the roof depends on the type of construction, the absence or presence of insulation and its thickness, the presence of air space (as with floating covers between the skin plate and the roofing), and whether the underside of the roof is in contact with sludge liquor or gas

Radiation from roofs and aboveground walls also contributes to heat losses. At the temperatures involved, the effect is small and is included in the coefficients normally used, such as those given in the foregoing discussion. For the theory of radiant-heat transmission, the reader is referred to McAdams (1954). Heat requirements for a digester are determined in Example 14–7.

When external heaters are installed, the sludge is pumped at high velocity through the tubes while water circulates at high velocity around the outside of the tubes. The circulation promotes high turbulence on both sides of the heat transfer surface and results in higher heat transfer coefficients and better heat transfer. Another advantage of external heaters is that untreated cold sludge on its way into the digesters can be warmed, intimately blended, and seeded with sludge liquor before entering the tank. Heat exchangers require cleaning periodically to maintain heat transfer efficiency.

Digestion tanks have also been heated using internal heating systems. Some arrangements have included pipes mounted to the interior face of the digester wall and mixing tubes equipped with hot-water jackets. Because of inherent operating and maintenance problems with this type of heating system, internal heating is not recommended. Reported problems include caking of sludge on the heating surface and the inability to inspect or service the equipment unless the tank is dewatered (WEF, 1987*a*).

EXAMPLE 14–7 Estimation of Digester Heating Requirements A digester with a capacity of 45,000 kg/d (100,000 lb/d) of sludge is to be treated by circulation of sludge through an external hot water heat exchanger. Assuming that the following conditions apply, find the heat required to maintain the required digester temperature. If all heat were shut off for 24 h, what would be the average drop in temperature of the tank contents?

1. Concrete digester dimensions:

   Diameter = 18 m

   Side depth = 6 m

   Middepth = 9 m

2. Heat-transfer coefficients:

   Dry earth embanked for entire depth, $U = 0.68$ W/m^2·°C

   Floor of digester in groundwater, $U = 0.85$ W/m^2·°C

   Roof exposed to air, $U = 0.91$ W/m^2·°C

3. Temperatures:

   Air = −5°C

   Earth next to wall = 0°C

   Incoming sludge = 10°C

   Earth below floor = 5°C

   Sludge contents in digester = 32°C

4. Specific heat of sludge = 4200 J/kg·°C

Solution

1. Compute the heat requirement for the sludge.

   $q = (45{,}000 \text{ kg/d})[(32 - 10)°\text{C}](4200 \text{ J/kg}·°\text{C})$

   $= 41.6 \times 10^8$ J/d

2. Compute the area of the walls, roof, and floor.

   Wall area = π (18) (6) = 339.2 m^2

   Floor area = π (9) $(9^2 + 3^2)^{1/2}$ = 268.2 m^2

   Roof area = π (9^2) = 254.5 m^2

3. Compute the heat loss by conduction using Eq. (14–15).

   $q = UADT$

   a. Walls:

      $q = 0.68$ W/m^2·°C (339.3 m^2)(32 − 0°C)(86,400 s/d) = 6.38×10^8 J/d

   b. Floor:

      $q = 0.85$ W/m^2·°C (268.2 m^2) (32 − 5°C)(86,400 s/d) = 5.32×10^8 J/d

   c. Roof:

      $q = 0.91$ W/m^2·°C (254.5 m^2) (32 + 5°C)(86,400 s/d) = 7.40×10^8 J/d

   d. Total losses:

      $q_t = (6.38 + 5.32 + 7.40) \times 10^8$ J/d = 19.1×10^8 J/d

4. Compute the required heat-exchanger capacity.

   Capacity = heat required for sludge and heat required for digester

   $= (41.6 + 19.1) \times 10^8$ J/d = 60.7×10^8 J/d

5. Determine the effect of heat shutoff.

a. Digester volume $= \pi\left(\frac{D^2}{4}\right)h_s + \pi\left(\frac{D^2}{12}\right)h_c$

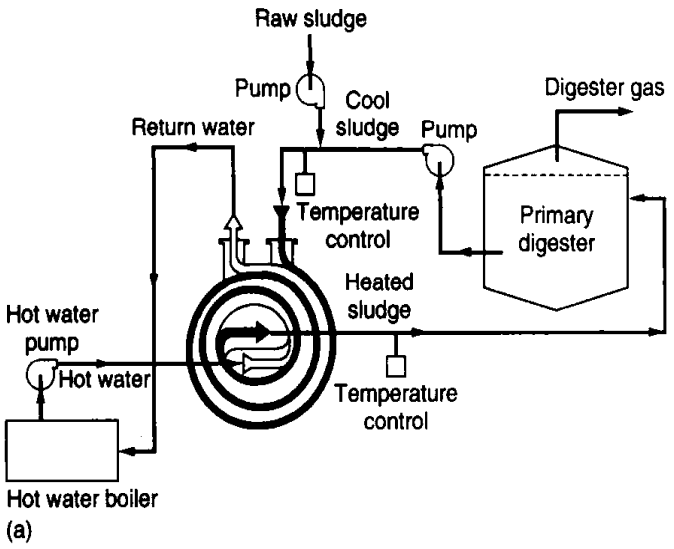
$= \pi\left(\frac{18^2}{4}\right)(6) + \pi\left(\frac{18^2}{12}\right)(3) = 1526.8 + 254.5$

$= 1781.3\ \text{m}^3$

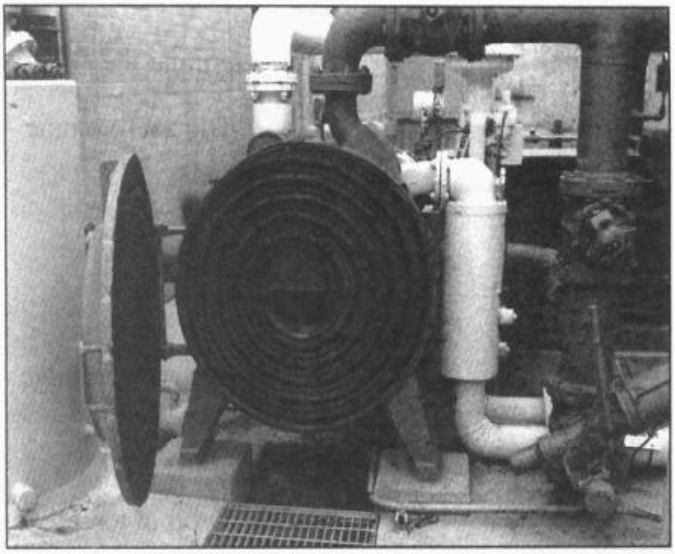
b. Weight of sludge $= (1781.3\ \text{m}^3)(10^3\ \text{kg/m}^3)$

$= 1.78 \times 10^6\ \text{kg}$

c. Drop in temperature $= \dfrac{(60.7 \times 10^8\ \text{J/d})(1.0)}{(1.78 \times 10^6\ \text{kg})(4200\ \text{J/kg}\cdot^\circ\text{C})} = 0.81^\circ\text{C/d}$



Heating Equipment. The contents of the digester can be heated by tube-in-tube, spiral-plate, or water-bath external heat exchangers. The tube-in-tube and spiral-heat exchangers are similar in design. A tube-in-tube exchanger consists of two concentric pipes, one containing the circulating sludge and the other containing hot water. Flow through the pipes is countercurrent. Spiral-plate heat exchangers (see Fig. 14–28*a* and *b*) are composed of two long strips of plate that are wrapped to form a pair of concentric passages. The flow regime is also countercurrent. Water temperatures are kept generally below 68°C (154°F) to prevent caking of the sludge. Heat-transfer coefficients for external heat exchangers range from 0.9 to 1.6 kJ/m^2·°C (WEF 1998).



Operation of a water-bath heat exchanger involves circulation of the sludge through a heated water bath (see Fig. 14–28*c*). The heat transfer rate is increased by pumping hot water in and out of the bath. Recirculation pumps allow the sludge feed to be heated before introduction to the digester.

Boilers and cogeneration systems are used typically to supply heat to the circulating water in the heat exchangers. Boilers can be fueled by digester gas; however, natural gas or fuel oil may be used as auxiliary fuel for times when sufficient digester gas is not available, such as for digester startup. If a cogeneration system is provided that uses digester gas to fuel an internal-combustion engine for generating electricity or powering pumps or blowers, heat from the engine jacket water can be used in the heat exchanger.

Thermophilic Anaerobic Digestion

Thermophilic digestion occurs at temperatures between 50 and 57°C (120 and 135°F), conditions suitable for thermophilic bacteria. Because biochemical reaction rates increase with temperature, doubling with every 10°C (18°F) rise in temperature until a limiting temperature is reached, thermophilic digestion is much faster than mesophilic digestion. Advantages cited for thermophilic digestion include increased solids destruction capability, improved dewatering, and increased bacterial destruction. Disadvantages of thermophilic digestion are higher energy requirements for heating, poorer-quality supernatant containing larger quantities of dissolved solids, odors, and less

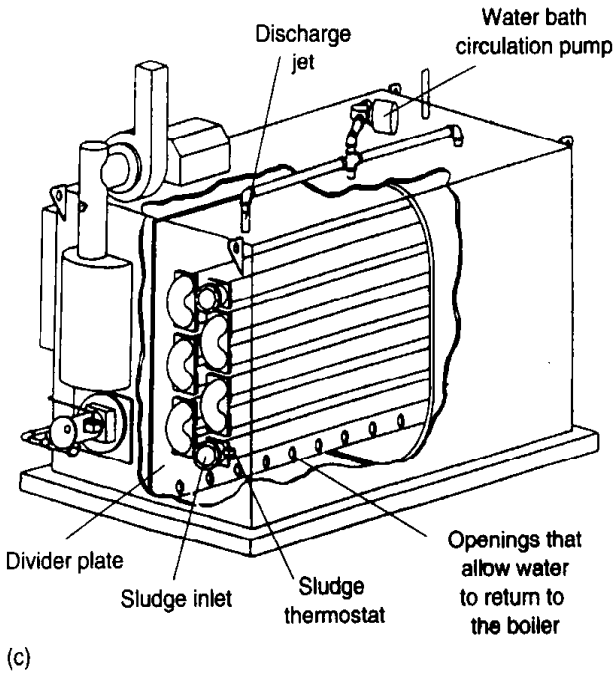


Figure 14–28

Heat exchangers used for heating digesting sludge: (*a*) schematic diagram of a spiral type, (*b*) pictorial view of a spiral type, and (*c*) schematic of a water bath type heat exchanger.

process stability (WEF, 1987*a*). Single-stage thermophilic digesters have been used only in limited applications; for municipal sludge treatment, they have been mainly used as the first stage of a temperature-phased anaerobic digestion process (Moen, 2000).

Although there may be greater reductions in pathogens in thermophilic digestion than in mesophilic digestion, U.S. federal regulations controlling land application of biosolids do not classify thermophilic digestion as a process to significantly reduce pathogens (PSRP). Both mesophilic and thermophilic digestion are classified as processes to further reduce pathogens (PFRP). Therefore, single-stage thermophilic digestion has significant limitations, as cited above.

Two-Phased Anaerobic Digestion

In search for improved anaerobic digestion performance, several options for phasing or staging the digestion process in multiple reactors have been investigated. Four basic phasing methods have been evaluated: (1) staged mesophilic digestion, (2) temperature-phased digestion, (3) acid/gas (A/G) phased digestion, and (4) staged thermophilic digestion (Schafer and Farrell, 2000*a* and 2000*b*). These phasing options are shown on Fig. 14–29 and are discussed below. Typical SRTs are also noted on Fig. 14–29.

Staged Mesophilic Digestion. Although digestion performed in two tanks coupled in series has been done in the past, little information is available about the operation of two-stage heated and mixed high-rate digesters. Researchers Torpey and Garber found that there were few benefits in volatile solids reduction and gas production in two

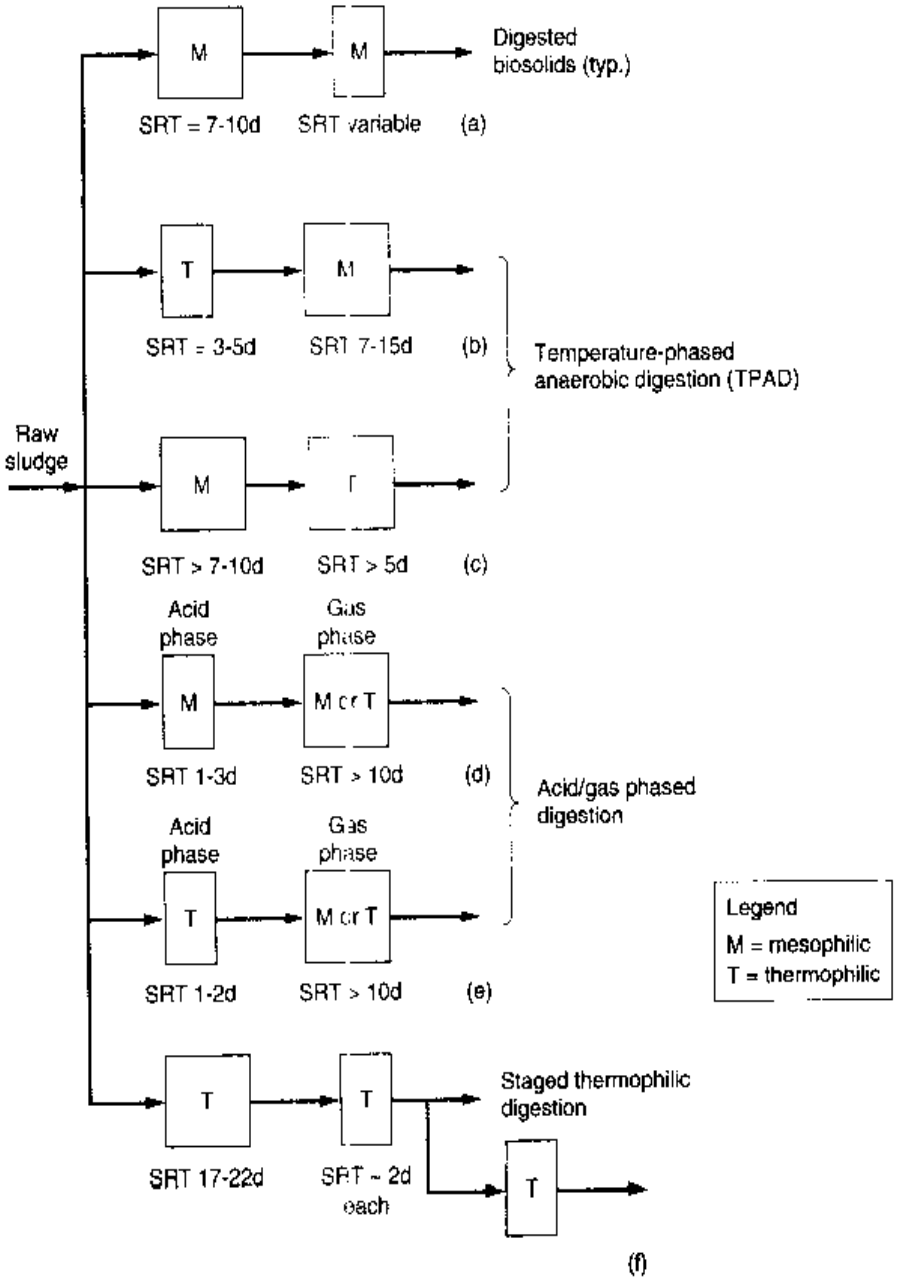

Figure 14–29

Options for staged anaerobic digestion: (*a*) staged mesophilic digestion, (*b*) temperature-phased thermophilic-mesophilic digestion, (*c*) temperature-phased mesophilic-thermophilic digestion, (*d*) acid/gas phased digestion with mesophilic acid-phase, (*e*) acid/gas phased digestion with thermophilic acid/gas phase, and (*f*) staged thermophilic digestion. *(Adapted from Schafer and Farrell (2000a) and Moen (2000).)*

series tanks as compared to a single-stage high-rate process. More recent testing indicates that two-stage mesophilic digestion may produce more stable, less odorous biosolids that are easier to dewater (Schafer and Farrell, 2000*a*). Staged mesophilic digestion is shown on Fig. 14–29*a*.

Temperature-Phased Digestion. Temperature-phased anaerobic digestion (TPAD), shown on Fig. 14–27*b*, was developed in Germany and is an approach that incorporates the advantages of thermophilic digestion and mitigates the disadvantages through the addition of a mesophilic phase that enhances stabilization. The design of the temperature-phased process utilizes the advantage of the greater thermophilic digestion rate, which generally is four times faster than mesophilic digestion. The TPAD process has shown the capability for absorbing shock loadings better, as compared to single-stage mesophilic or thermophilic digestion. The process can operate in either of two modes, thermophilic-mesophilic or mesophilic-thermophilic. In the thermophilic-mesophilic mode (shown on Fig. 14–29*b*), the thermophilic phase is designed to operate at 55°C (130°F) with a 3 to 5 d detention time. The mesophilic phase is designed to operate at 35°C (95°F) with a 10 d or greater detention. The total average detention time of 15 d compares to the typical 10 to 20 d range of the single-stage high-rate mesophilic digestion process. The volatile suspended solids (VSS) destruction efficiencies of the TPAD process are on the order of 15 to 25 percent greater than single-stage mesophilic digestion (Schafer and Farrell, 2000*b*).

Through greater hydrolysis and biological activity in the thermophilic phase, the system tends to have greater VSS destruction and gas production. Foaming is also reduced. The mesophilic phase provides additional VSS destruction and conditions the sludge for further processing. The main advantages of the mesophilic phase are (1) the destruction of odorous compounds (mostly fatty acids) that are common to the thermophilic digestion process and (2) the improved stability of the digestion operation. The process is also reported to be capable of meeting Class A sludge requirements (WEF, 1998).

A second temperature-phased digestion process shown on Fig. 14–29*c* has a mesophilic stage that precedes the thermophilic stage. Limited results from full-scale and pilot testing show that the volatile solids reduction is greater than that from single-stage mesophilic digestion (Schafer and Farrell, 2000*b*).

Design considerations for the temperature-phased anaerobic digestion process include selection of the heating and mixing systems to ensure proper temperature control of each stage, sizing of the gas-handling equipment to meet the greater gas production rates, and control of the pumping systems for digester feed and heating (WEF, 1998).

Acid/Gas Phased Digestion. In the acid/gas digestion process, anaerobic digestion proceeds through the three distinct phases of digestion described earlier—hydrolysis, fermentation (acidogenesis), and methanogenesis. In the first stage, solubilization of particulate matter occurs and volatile acids are formed. The first phase is conducted at a pH of 6 or less and at a short SRT conducive to the production of high concentrations of volatile acids (> 6000 mg/L). The second phase is conducted at a neutral pH and a longer SRT, to suit the environmental conditions for the methane-generating bacteria and maximize gas production. Advantages of this method of digestion are (1) greater volatile solids reduction can be achieved, (2) digester foaming can

be controlled, and (3) either stage can be operated at mesophilic or thermophilic temperatures (see Fig. 14–29*d* and *e*). Three full-scale plants using the acid/gas process are in operation at the time of writing of this text (2001) (Wilson and Dichtl, 2000). Volatile solids reductions range from 50 to 60 percent. At the Belmont Wastewater Plant in Indianapolis, IN, where a thermophilic acid phase and mesophilic gas phase system was pilot tested, it was found that the process was effective in meeting Class A requirements for pathogen reduction (Schafer and Farrell, 2000*a*).

Staged Thermophilic Digestion. A staged thermophilic digestion process (see Fig. 14–29*f*) uses a large reactor followed by one or more smaller reactors to reduce pathogen short circuiting and achieve a Class A sludge. At the Annacis Island Wastewater Treatment Plant in Vancouver, BC, the first stage is followed by three subsequent stages. Volatile solids reductions for the digestion system are reported to be on the order of 63 percent (Schafer and Farrell, 2000*b*).

14–10 AEROBIC DIGESTION

Aerobic digestion may be used to treat (1) waste-activated sludge only, (2) mixtures of waste-activated sludge or trickling-filter sludge and primary sludge, or (3) waste sludge from extended aeration plants. Aerobic digestion has been used primarily in plants of a size less than 0.2 m^3/s (5 Mgal/d), but in recent years the process has been employed in larger wastewater-treatment plants with capacities up to 2 m^3/s (50 Mgal/d) (WEF, 1998). Advantages of aerobic digestion as compared to anaerobic digestion are: (1) volatile solids reduction in a well-operated aerobic digester is approximately equal to that obtained anaerobically; (2) lower BOD concentrations in supernatant liquor; (3) production of an odorless, humuslike, biologically stable end product; (4) recovery of more of the basic fertilizer values in the sludge; (5) operation is relatively easy; (6) lower capital cost; and (7) suitability for digesting nutrient-rich biosolids. In cases where separate sludge digestion is considered, aerobic digestion of biological sludge may be an attractive application. The major disadvantages of the aerobic digestion process are that (1) high power cost is associated with supplying the required oxygen; (2) digested biosolids produced have poorer mechanical dewatering characteristics; and (3) the process is affected significantly by temperature, location, tank geometry, concentration of feed solids, type of mixing/aeration device, and type of tank material. An additional disadvantage is that a useful byproduct such as methane is not recovered.

As discussed in Sec. 14–2 and Table 14–12, aerobic digestion is one of the processes defined to meet PSRP requirements. To meet Class B requirements for pathogen reduction, the regulations state the solids retention times must be at least 40 d at 20°C and 60 d at 15°C. In many instances, plants that have facilities designed for SRTs less than 40 d and wish to meet the Class B requirements for pathogen reduction have had to add additional storage capacity or thickeners. If the design engineer uses aerobic digestion for stabilization and does not meet the above SRTs, it will be necessary to monitor the performance of the process to demonstrate that the pathogen reduction criterion has been met. Monitoring is also required to demonstrate that the volatile solids reduction requirements are met for compliance to the vector attraction criterion (U.S. EPA, 1999).

Process Description

Aerobic digestion is similar to the activated-sludge process. As the supply of available substrate (food) is depleted, the microorganisms begin to consume their own protoplasm to obtain energy for cell maintenance reactions. When energy is obtained from cell tissue the microorganisms are said to be in the endogenous phase. Cell tissue is oxidized aerobically to carbon dioxide, water, and ammonia. In actuality, only about 75 to 80 percent of the cell tissue can be oxidized; the remaining 20 to 25 percent is composed of inert components and organic compounds that are not biodegradable. The ammonia is subsequently oxidized to nitrate as digestion proceeds. Nonbiodegradable volatile suspended solids will remain in final product from aerobic digestion. Considering the biomass wasted to a digester and the formula $C_5H_7NO_2$ is representative for cell mass of a microorganism, the biochemical changes in an aerobic digester can be described by the following equations:

Biomass destruction:

$$C_5H_7NO_2 + 5O_2 \rightarrow 4CO_2 + H_2O + NH_4HCO_3 \quad (14\text{–}16)$$

Nitrification of released ammonia nitrogen:

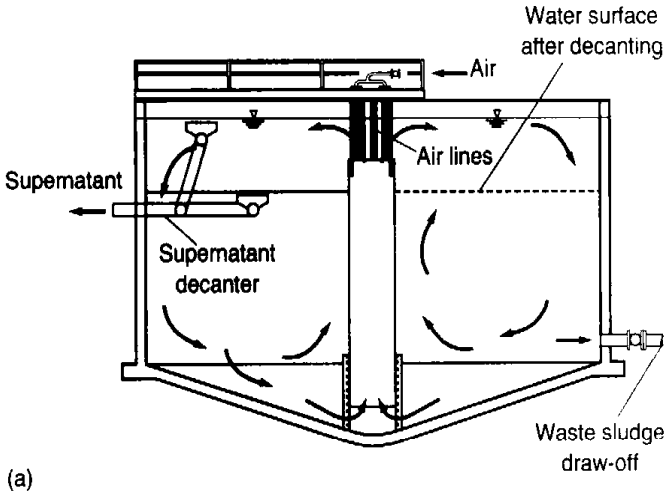
$$NH_4^+ + 2O_2 \rightarrow NO_3^- + 2H^+ + H_2O \quad (14\text{–}17)$$

Overall equation with complete nitrification:

$$C_5H_7NO_2 + 7O_2 \rightarrow 5CO_2 + 3H_2O + HNO_3 \quad (14\text{–}18)$$

Using nitrate nitrogen as electron acceptor (denitrification):

$$C_5H_7NO_2 + 4NO_3^- + H_2O \rightarrow NH_4^+ + 5HCO_3^- + 2NO_2 \quad (14\text{–}19)$$



With complete nitrification/denitrification:

$$2C_5H_7NO_2 + 11.5O_2 \rightarrow 10CO_2 + 7H_2O + 2N_2 \quad (14\text{–}20)$$

As given by Eqs. (14–16) through (14–18), the conversion of organic nitrogen to nitrate results in an increase in the concentration of hydrogen ions and subsequently a decrease in pH if sufficient buffering capacity is not available in the sludge. Approximately 7 kg of alkalinity, expressed as $CaCO_3$, are destroyed per each kg of ammonia oxidized. Theoretically, approximately 50 percent of the alkalinity consumed by nitrification can be recovered by denitrification. If the dissolved oxygen is kept very low (less than 1 mg/L), however, nitrification will not occur. In practice, cycling of the aerobic digester between aeration and mixing has been found to be effective in maximizing denitrification while maintaining pH control. In situations where the buffering capacity is insufficient resulting in pH depressions below 5.5, it may be necessary to install alkalinity feed equipment to maintain the desired pH.

Where activated or trickling-filter sludge is mixed with primary sludge and the combination is to be digested aerobically, direct oxidation of the organic matter in the primary sludge and oxidation of the cell tissue will both occur. Aerobic digesters can be operated as batch or continuous flow reactors (see Fig. 14–30).

Three proven variations of the process are most commonly used: (1) conventional aerobic digestion, (2) high-purity oxygen aerobic digestion, and (3) autothermal aerobic digestion (ATAD). Aerobic digestion accomplished with air is the most commonly used process, so it is considered in greater detail in the following discussion.

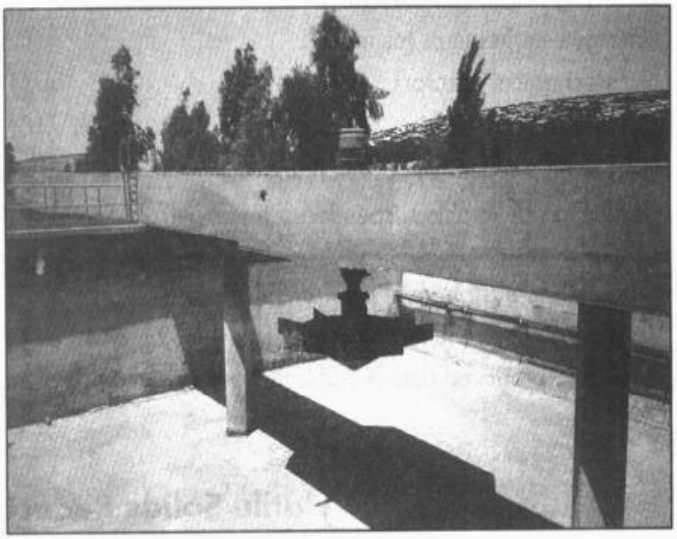


Figure 14-30

Examples of aerobic digesters: (*a*) batch operation type with air addition, (*b*) continuous operation type with air addition, and (*c*) view of empty aerobic digester with mechanical surface aerator.

Conventional Air Aerobic Digestion

Factors that must be considered in designing conventional aerobic digesters include temperature, solids reduction, tank volume, feed solids concentration, oxygen requirements, energy requirements for mixing, and process operation. Typical design criteria for aerobic digestion are presented in Table 14–34.

Temperature. Because the majority of aerobic digesters are open tanks, digester liquid temperatures are dependent on weather conditions and can fluctuate extensively. As with all biological systems, lower temperatures retard the process while higher temperatures accelerate it. In considering the temperature effects, heat losses should be minimized by using concrete instead of steel tanks, placing the tanks below grade instead of above grade or providing insulation for above-grade tanks, and using subsurface instead of surface aeration. In extremely cold climates, consideration should be given to heating the sludge or the air supply, covering the tanks, or both. The design should provide for the necessary degree of sludge stabilization at the lowest expected liquid operating temperature, and should provide the maximum oxygen requirements at the maximum expected liquid operating temperature.

Table 14-34
Design criteria for aerobic digesters[a]

Parameter	U.S. customary units		SI units	
	Units	Value	Units	Value
SRT[b]	d		d	
At 20°C		40		40
At 15°C		60		60
Volatile solids loading	lb/ft^3·d	0.1–0.3	kg/m^3·d	1.6–4.8
Oxygen requirements:				
Cell tissue[c]	lb O_2/lb VSS	~2.3	kg O_2/kg VSS	~2.3
BOD_5 in primary sludge	Destroyed	1.6–1.9	Destroyed	1.6–1.9
Energy requirements for mixing:				
Mechanical aerators	hp/10^3 ft^3	0.75–1.5	kW/10^3 m^3	20–40
Diffused air mixing	ft^3/10^3 ft^3·min	20–40	m^3/m^3·min	0.02–0.040
Dissolved oxygen residual in liquid	mg/L	1–2	mg/L	1–2
Reduction of volatile suspended solids	%	38–50	%	38–50

[a] Adapted, in part, from WEF (1995a); Federal Register (1993).
[b] To meet pathogen reduction requirements (PSRP) of 40 CFR Part 503 regulations.
[c] Ammonia produced during carbonaceous oxidation oxidized to nitrate.

Volatile Solids Reduction. A major objective of aerobic digestion is to reduce the mass of the solids for disposal. This reduction is assumed to take place only with the biodegradable content of the sludge, although there may be some destruction of the nonorganics as well. Volatile solids reductions ranging from 35 to 50 percent are achievable by aerobic digestion. Optional criteria for meeting vector attraction requirements of 40 CFR Part 503 are (1) a minimum of 38 percent reduction in volatile solids during biosolids treatment or (2) less than a specific oxygen uptake rate (SOUR) of (1.5 mg O_2/h)/g of total sludge solids at 20°C (U.S. EPA, 1999).

The change in biodegradable volatile solids in a completely mixed digester can be represented by a first-order biochemical reaction at constant-volume conditions:

$$\frac{dM}{dt} = -k_d M \tag{14-21}$$

where $\frac{dM}{dt}$ = rate of change of biodegradable volatile solids (M) per unit of time (Δ mass/time), MT^{-1}
k_d = reaction rate constant, T^{-1}
M = mass of biodegradable volatile solids remaining at time t in the aerobic digester, M

The time factor in Eq. (14–17) is the solids retention time (SRT) in the aerobic digester. Depending on how the aerobic digester is being operated, time t can be equal

to or considerably greater than the theoretical hydraulic residence time (t). Use of the biodegradable portion of the volatile solids in the equation recognizes that approximately 20 to 35 percent of the waste-activated sludge from wastewater-treatment plants with primary treatment is not biodegradable. The percentage of nonbiodegradable volatile solids in waste-activated sludge from contact stabilization processes (no primary tanks) ranges from 25 to 35 percent (WEF, 1998).

The reaction rate term k_d is a function of the sludge type, temperature, and solids concentration. Representative values for k_d may range from 0.05 d^{-1} at 15°C to 0.14 d^{-1} at 25°C for waste-activated sludge. Because the reaction rate is influenced by several factors, it may be necessary to confirm decay coefficient values by bench-scale or pilot-scale studies.

Solids destruction is primarily a direct function of both basin liquid temperature and the SRT (sometimes referred to as sludge age), as indicated on Fig. 14–31. The data were derived from both pilot- and full-scale studies. The plot on Fig. 14–31 relates volatile solids reduction to degree-days (temperature times sludge age). Initially, as the degree-days increase, the rate of volatile solids reduction increases rapidly. As the degree-days approach 500, the curve begins to flatten. To produce well-stabilized biosolids, at least 550 degree-days are recommended for the aerobic digestion system (Enviroquip, 2000). The use of Fig. 14–31 is demonstrated in Example 14–8, the design of an aerobic digester.

Tank Volume and Detention Time Requirements. The tank volume is governed by the detention time necessary to achieve the desired volatile solids reduction. In the past, SRTs of 10 to 20 d were the norm for the design of aerobic digestion systems (Metcalf & Eddy, 1991). To meet the pathogen reduction requirements of 40 CFR Part 503 regulations, the SRT criteria (see Table 14–34) in conventional aerobic digesters take precedence over the vector attraction criteria of 38 percent solids reduction for sizing the tank volume.

The digester tank volume can be calculated by Eq. (14–22) (WEF, 1998)

$$V = \frac{Q_i(X_i + YS_i)}{X(k_d P_v + 1/\text{SRT})} \tag{14-22}$$

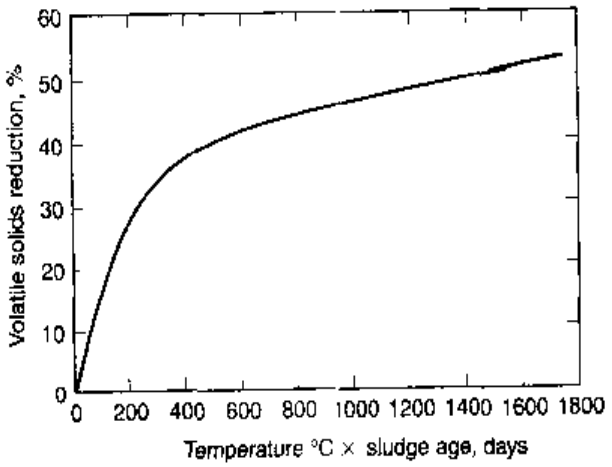

Figure 14–31
Volatile solids reduction in an aerobic digester as a function of digester liquid temperature and digester sludge age. *(From WEF, 1995a.)*

where V = volume of aerobic digester, m^3 (ft^3)
Q_i = influent average flowrate to digester, m^3/d (ft^3/d)
X_i = influent suspended solids, mg/L
Y = fraction of the influent BOD consisting of raw primary solids, (expressed as a decimal)
S_i = influent BOD, mg/L
X = digester suspended solids, mg/L
k_d = reaction rate constant, d^{-1}
P_v = volatile fraction of digester suspended solids (expressed as a decimal)
SRT = solids retention time, d

The term YS_i can be neglected if primary sludge is not included in the sludge load to the aerobic digester.

If the aerobic digestion process is operated in a complete-mix, staged configuration (two or three stages), the total SRT should be divided approximately equally among the stages. For more information on staging aerobic digestion, Enviroquip (2000) should be consulted.

Feed Solids Concentration. The concentration of the feed solids digester is important in the design and operation of the aerobic digester. If thickening precedes aerobic digestion, higher feed solids concentrations will result in higher oxygen input levels per digester volume, longer SRTs, smaller digester volume requirements, easier process control (less decanting in batch-operated systems), and subsequently increased levels of volatile solids destruction (WEF 1998). However, feed solids concentrations greater than 3.5 to 4 percent may affect the ability of the mixing and aeration system in maintaining well-mixed tank contents with adequate dissolved oxygen levels necessary to support the biological process. At feed solids concentrations greater than 4 percent, the aeration equipment must be evaluated carefully to ensure adequate mixing and aeration are achieved.

Oxygen Requirements. The oxygen requirements that must be satisfied during aerobic digestion are those of the cell tissue and, with mixed sludges, the BOD in the primary sludge. The oxygen requirement for the complete oxidation of cell tissue (including nitrification), computed using Eqs. (14–16) and (14–17), is equal to 7 mole/mole of cells, or about 2.3 kg/kg of cells. The oxygen requirement for the complete oxidation of the BOD contained in primary sludge varies from about 1.6 to 1.9 kg/kg destroyed. The oxygen residual should be maintained at 1 mg/L or above under all operating conditions.

Energy Requirements for Mixing. To ensure proper operation, the contents of the aerobic digester should be well mixed. In large tanks, multiple mixing devices should be installed to ensure good distribution of the mixing energy. Typical energy requirements for mixing are given in Table 14–34. In general, because of the large amount of air that must be supplied to meet the oxygen requirement, adequate mixing should be achieved; nevertheless, mixing power requirements should be checked, particularly when feed solids concentrations are greater than 3.5 percent. If polymers are used in the thickening process, especially for centrifuge thickening, a greater amount of unit energy may be required for mixing.

If fine-pore diffused air mixing is used, considerations for selecting the aeration system should include limitations of feed solids concentration on achieving good mixing. Recommendations on feed solids limitations should be obtained from manufacturers of aeration equipment. In addition, the potential for diffuser fouling should be evaluated, especially if the process operation requires decanting.

Process Operation. Depending on the buffering capacity of the system, the pH may drop to a low value of about 5.5 at long hydraulic detention times. The potential drop in pH is due to the increased presence of nitrate ions in solution and the lowering of the buffering capacity due to air stripping. Filamentous growths may also develop at low pH values. The pH should be checked periodically and adjusted if found to be excessively low. Dissolved oxygen levels and respiration rates should also be checked to ensure proper process performance.

Aerobic digesters that do not include prethickening should be equipped with decanting facilities for thickening the digested solids before discharge to subsequent operations. Operator control and visibility of the decanting operation are important design considerations. If the digester is operated so that the incoming sludge is used to displace supernatant and the solids are allowed to build up, the solids retention time will not be equal to the hydraulic retention time.

EXAMPLE 14–8 Aerobic Digester Design Design an aerobic digester to treat the waste sludge produced by the activated-sludge treatment plant. Assume that the following conditions apply:

1. The amount of waste sludge to be digested is 2057 kg TSS/d.
2. The minimum and maximum liquid temperatures are 15°C for winter operation and 25°C for summer operation.
3. The system must achieve 40 percent volatile solids reduction in the winter.
4. The minimum SRT for winter conditions is 60 d.
5. Waste sludge is concentrated to 3 percent, using a gravity-belt thickener.
6. The specific gravity of the waste sludge is 1.03.
7. Sludge concentration in the digester is 70 percent of the incoming thickened sludge concentration.
8. The reaction rate coefficient k_d is 0.06 d^{-1} at 15°C.
9. Volatile fraction of digester TSS is 0.80.
10. No primary solids are included in the influent to the digester.
11. Diffused-air mixing is used.
12. Air temperature in diffused air system = 20°C.

Solution

1. Compute the volatile solids reduction for winter conditions using Fig. 14–31 and compute the percent volatile solids reduction under summer (maximum) conditions.

a. For winter conditions, the degree-days from Fig. 14–31 are 15°C × 60 d = 900 degree-days. From Fig. 14–31, the volatile solids reduction is 45 percent, which exceeds the winter requirements of 40 percent.

In order to meet the pathogen reduction requirements, the SRT must be 60 d; therefore, the required volume is 66.6 $m^3/d \times 60$ d = 3996 m^3.

b. During the summer, the liquid temperature will be 25°C, and the degree-days will be 25 × 60 = 1500. From Fig. 14–31, the volatile solids reduction in the summer will be 50 percent.

2. Compute the winter and summer volatile solids reduction based on a total mass of volatile suspended solids

Total mass of VSS (VSS_M) = (0.8)(2057 kg/d) = 1646 kg/d

a. Winter: 1646 × 0.45 = 741 kg VSS_M reduced/d
b. Summer: 1646 × 0.50 = 823 kg VSS_M reduced/d

3. Determine oxygen requirements (see Table 14–34 for oxygen requirements).
   a. Winter: 741 × 2.3 = 1704 kg O_2/d
   b. Summer: 724 × 2.3 = 1893 kg O_2/d

4. Compute the volume of air required per d at standard conditions. For the density of air, see Appendix B-1.

a. Winter: $V = \dfrac{1704 \text{ kg}}{(1.204 \text{ kg/m}^3)(0.232)} = 6100 \text{ m}^3/\text{d}$

b. Summer: $V = \dfrac{1893 \text{ kg}}{(1.204 \text{ kg/m}^3)(0.232)} = 6777 \text{ m}^3/\text{d}$

Assuming an oxygen transfer efficiency of 10 percent, the air flowrates are

Winter: $q = \dfrac{(6100 \text{ m}^3/\text{d})}{(0.10)(1440 \text{ min/d})} = 42.4 \text{ m}^3/\text{min}$

Summer: $q = \dfrac{(6777 \text{ m}^3/\text{d})}{(0.10)(1440 \text{ min/d})} = 47.1 \text{ m}^3/\text{min}$

5. Compute the volume of sludge to be disposed of per day using Eq. (14–2).

$$V = \frac{2057 \text{ kg}}{(10^3 \text{ kg/m}^3)(1.03)(0.03)} = 66.6 \text{ m}^3/\text{d}$$

6. Determine the volume of the aerobic digester (winter conditions govern) using Eq. (14–22).

$$V = \frac{(66.6 \text{ m}^3/\text{d})(30{,}000 \text{ g/m}^3)}{(30{,}000 \text{ g/m}^3)[(0.7)(0.06/\text{d})(0.80) + (1/60 \text{ d})]}$$

$$= 1318 \text{ m}^3$$

7. Compute the air requirement per m^3 of digester volume.

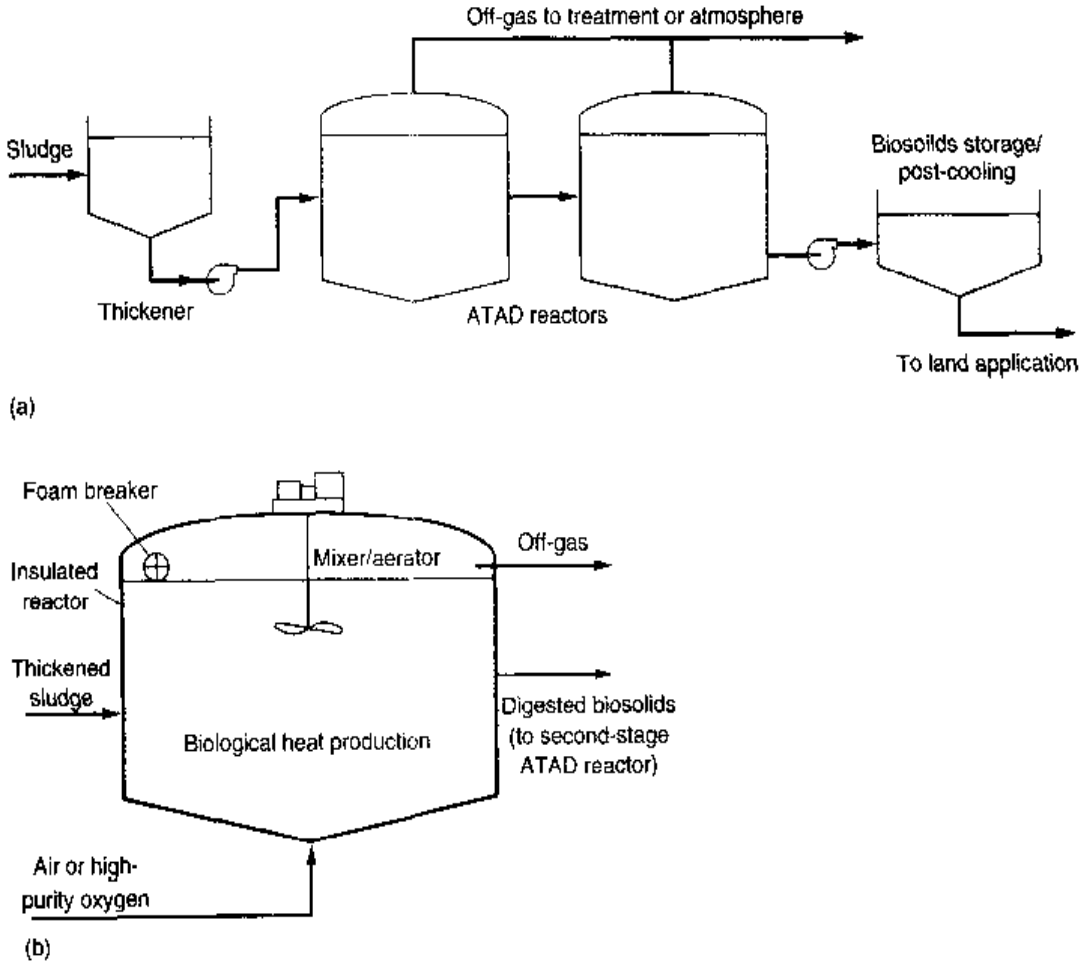
$$q = \frac{(47.1 \text{ m}^3/\text{min})}{1318 \text{ m}^3} = 0.036 \text{ m}^3/\text{min}\cdot\text{m}^3$$

8. Check the mixing requirements. Because the air requirement computed in Step 7 is within the range of values given in Table 14–34, adequate mixing should prevail.

Comment The above example is based on a single-stage aerobic digester. If a two-stage or more digester were used, a significant reduction in tank volume is possible. In a multistage arrangement, the air distribution between tanks would vary based on the expected demand as most of the volatile solids reduction will occur in the first stage where the biomass is most active.

Dual Digestion

Aerobic thermophilic digestion has also been used extensively in Europe as a first stage in the dual digestion process. The second stage is mesophilic anaerobic digestion. Dual digestion has also been tried in the United States using high-purity oxygen in the first stage. Residence times in the aerobic digester range typically from 18 to 24 h, and the reactor temperature ranges from 55 to 65°C. Typical residence time in the anaerobic digester is 10 d. The advantages of using aerobic thermophilic digestion in dual digestion are (1) increased levels of pathogen reduction, (2) improved overall volatile solids reduction, (3) increased methane gas generation in the anaerobic digester, (4) less organic material in and fewer odors produced by the stabilized sludge, and (5) equivalent volatile solids reductions can be achieved in one-third less tankage than a single-stage anaerobic digester. Prior hydrolysis in the aerobic reactor results in increased degradation during subsequent anaerobic digestion and gas production. Approximately 10 to 20 percent of the volatile solids is liquefied in the aerobic digester, while COD reduction is less than 5 percent. Provisions for foam suppression and odor control are required (Roediger and Vivona, 1998).



Autothermal Thermophilic Aerobic Digestion (ATAD)

Autothermal thermophilic aerobic digestion (ATAD), illustrated on Fig. 14–32, represents a variation of both conventional and high-purity oxygen aerobic digestion. In the ATAD process, the feed sludge is generally prethickened and the reactors are insulated to conserve the heat produced from the oxidation of volatile solids during the digestion process. Thermophilic operating temperatures (generally in the range of 55 to 70°C) can be achieved without external heat input by using the heat released by the exothermic microbial oxidation process. Approximately 20,000 kJ of heat is produced per kg of volatile solids destroyed. Because supplemental heat is not provided (other than the heat introduced by aeration and mixing), the process is termed autothermal.

Within the ATAD reactor, sufficient levels of oxygen, volatile solids, and mixing allow aerobic microorganisms to degrade organic matter to carbon dioxide, water, and nitrogen byproducts. The major advantages of ATAD are (1) retention times required to achieve a given suspended solids reduction are decreased significantly (to about 5 to 6 d) to achieve volatile solids reductions of 30 to 50 percent, similar to conventional aerobic digestion; (2) simplicity of operation; (3) greater reduction of bacteria and viruses are achieved as compared to mesophilic anaerobic digestion; and (4) when the reactor is well mixed and maintained at 55°C and above, pathogenic viruses, bacteria,

Figure 14–32

Autothermal thermophilic aerobic digester (ATAD) system: (a) system schematic, and (b) reactor schematic.

viable helminth ova, and other parasites can be reduced to below detectable levels, thus meeting the pathogen reduction requirements of Class A biosolids. Disadvantages cited are (1) objectionable odors are formed, (2) poor dewatering characteristics of ATAD biosolids, and (3) lack of nitrification. Because the ATAD system is capable of producing Class A biosolids, it is growing in popularity. As of June 2000, there are approximately 35 ATAD systems operating in North America (25 in the United States and 10 in Canada). In excess of 40 plants are operating in Europe (Stensel and Coleman, 2000).

Process Theory. The biochemical conditions in thermophilic aerobic digesters differ significantly from conventional aerobic digesters. Because of the high operating temperatures, nitrification is inhibited and aerobic destruction of volatile solids occurs as described by Eq. (14–18) without the subsequent reactions described by Eqs. (14–19) through (14–22). Additionally, most, if not all, ATAD systems may be operating under microaerobic conditions where oxygen demand exceeds oxygen supply (Stensel and Coleman, 2000). Under microaerobic conditions, proteinaceous cellular material will undergo fermentation where protein is represented as peptone as described by Eq. (14–23) (Chu and Mavinic, 1998):

$$4CH_2NH_2COOH + 4H_2O \rightarrow 3CH_3COOH + 2(NH_4)_2CO_3 \qquad (14\text{–}23)$$

Both Eqs. (14–16) and (14–23) result in the production of ammonia that reacts with water and carbon dioxide to form ammonium bicarbonate and ammonium carbonate to increase alkalinity. Because nitrification does not occur, the pH in the ATAD system will typically range from 8 to 9, higher than in conventional aerobic digesters. Ammonia-nitrogen produced will be present in the off-gas and in solution with concentrations of several hundred mg/L in each. Most of the ammonia nitrogen will be returned to the liquid process in sidestreams from the odor-control and dewatering facilities. The acetic acid (or acetate) produced by the fermentation of proteins is one of the volatile fatty acids. Acetic acid will be oxidized subsequently in the presence of sufficient dissolved oxygen as described by Eq. (14-24):

$$CH_3COOH + 2O_2 \rightarrow 2CO_2 + 2H_2O \qquad (14\text{–}24)$$

Anaerobic conditions will occur at times in ATAD systems and will most likely take place in the pre-ATAD sludge holding facilities and in the first-stage ATAD reactors during and immediately after sludge transfers and batch feeding. Under anaerobic conditions, reduced sulfur compounds can be formed that can affect the design and performance of odor-control systems.

Process Design. ATAD systems are designed to have short hydraulic retention times within insulated reactors (see Fig. 14–32*b*). As long as the ATAD system is well mixed and sufficient oxygen is provided, the temperature in the reactor will rise until a balance occurs; i.e., the heat lost equals the heat input from the exothermic reaction and mechanical energy input. The temperature will continue to rise until the process becomes oxygen mass-transfer-limited.

Factors that must be considered in designing an ATAD system include prethickening, number and type of reactors, postcooling/thickening, feed characteristics, detention time, feed cycle, aeration and mixing, temperature and pH, and foam and odor control. Nearly all of the ATAD systems currently installed in the United States utilize two or more reactors operated in series (see Fig. 14–32*a*). Design considerations for ATAD systems are presented in Table 14–35; typical design criteria are summarized in Table 14–36.

ATAD systems must be designed to (1) transfer sufficient oxygen to meet the high demand of the reactors and 2) supply the required oxygen while minimizing the latent heat loss in the exhaust air. It is difficult to define the oxygen transfer rate in an ATAD system while using typical design procedures used for selecting and sizing aeration equipment for wastewater treatment processes. The oxygen transfer coefficient α (alpha) and the oxygen saturation coefficient β (beta) have not been quantified under the environmental conditions present in an ATAD reactor (Stensel and Coleman, 2000). Factors affecting oxygen transfer are the high temperatures (that would reduce α values) and the foam layer and low dissolved oxygen levels (that might increase oxygen transfer). Nearly all ATAD systems utilize a type of aspirating aerator to introduce oxygen into the reactors. The types include hollow-shaft propeller or turbine aerators, pumped venturi aspirators, and jet aspirators. With all air aspirating systems, the equipment provides both mixing and oxygen transfer. Typical energy requirements for mixing and aeration are given in Table 14–36.

Substantial amounts of foam are generated in the ATAD process as cellular proteins, lipids, and oil and grease materials are broken down and released into solution. The foam layer contains high concentrations of biologically active solids that provide

Table 14–35
Typical design considerations for an autothermal aerobic digester (ATAD) system[a]

System component	Design consideration
Prethickening system	Thickening or blending facilities may be required to maintain an influent COD to the ATAD reactor greater than 40 g/L
Reactors	Number of reactors; a minimum of two enclosed insulated reactors in series should be provided and equipped with mixing, aeration, and foam control equipment
Screening	Fine screening, 6- to 12-mm (0.25- to 0.5-in.) clear openings, of raw wastewater or solids feed stream should be provided for the removal of inert materials, plastics, and rags
Feed cycle	Continuous or batch processing is acceptable, except batch processing provides greater assurance in meeting Class A pathogen reduction requirements
Foam control	Foam suppression is required to ensure effective oxygen transfer and enhanced biological activity. Freeboard of 0.5 to 1.0 m (1.65 to 3.3 ft) is recommended
Post-ATAD storage/dewatering	Postprocess cooling is necessary to achieve solids consolidation and to enhance dewaterability. A minimum of 20 d detention may be necessary unless heat exchangers are used for cooling the processed biosolids
Odor control	Because of high temperatures in the ATAD system, relatively high concentrations of ammonia are released. Reduced sulfur compounds also result, which can include hydrogen sulfide, carbonyl sulfide, methyl mercaptan, ethyl mercaptan, dimethyl sulfide, and dimethyl disulfide. Odor-control systems may include wet scrubbers, biofilters, or a combination of both (see Chap. 15)
Sidestreams	Liquid sidestreams from odor-control and dewatering systems, when returned to the liquid processing system, may contain constituents that could affect process performance unless accounted for or treated separately

[a]Adapted in part from WEF (1998) and Stensel and Coleman (2000).

insulation of the reactor and improved oxygen utilization. It is important, therefore, that the foam layer be effectively managed and controlled. Mechanical foam cutters are used most commonly for foam control, but other methods such as spray systems have been employed. A freeboard of 0.5 to 1.0 m is generally recommended for controlling the foam layer (Stensel and Coleman, 2000).

Where ATAD systems are followed by mechanical dewatering, post-ATAD storage is recommended to allow for cooling of the biosolids to improve belt-filter press and centrifuge performance. Post-ATAD storage coupled with long detention times in the final-stage ATAD reactors may further increase the reduction of volatile solids.

Process Control. The provisions of the 40 CFR Part 503 regulations applicable for meeting the Class A biosolids requirements with the ATAD process are complex because several alternative pathogen-reduction requirements are given. The basic

requirement that needs to be demonstrated is (1) fecal coliform densities are less than 1000 MPN/g of total solids (dry weight basis), or (2) *Salmonella* sp. bacteria concentrations are below detection limits of 3 MPN/4 g of total solids (dry weight basis). For compliance with these pathogen regulations for Class A biosolids, the withdrawal and feeding of the sludge to the reactors is performed on a batch basis. (In flow-through systems, it is possible that some pathogens might pass through.) Two or more reactors in a series configuration are used typically to ensure that all particles in the reactor are subjected to the time and temperature requirements and that no insufficiently treated biosolids are released to the environment. The ATAD pumping system is designed to withdraw and feed the daily amount of sludge in 1 h or less. The reactor is then isolated for the remaining 23 h each day at a minimum temperature of 55°C.

High-Purity Oxygen Digestion

High-purity oxygen aerobic digestion is a modification of the aerobic digestion process in which high-purity oxygen is used in lieu of air. The resultant biosolids are similar to biosolids from conventional aerobic digestion. Influent sludge concentrations vary from 2 to 4 percent. Recycle flows are similar to those achieved by conventional aerobic digestion. High-purity oxygen aerobic digestion is particularly applicable in cold weather climates because of its relative insensitivity to changes in ambient air temperatures due to the increased rate of biological activity and the exothermal nature of the process.

While one variation of the high-purity aerobic digestion process uses open tanks, aerobic digestion is usually done in closed tanks similar to those used in the high-purity oxygen activated-sludge process. Using closed tanks for high-purity oxygen aerobic digestion will generally result in higher operating temperatures because of the exothermic nature of the digestion process. Maintenance of these higher temperatures in the digester results in a significant increase in the rate of volatile suspended solids destruction. Where covered tanks are used, a high-purity oxygen atmosphere is maintained above the liquid surface, and oxygen is transferred into the sludge via mechanical aerators. Where an open aeration tank is used, oxygen is introduced to the liquid sludge by a special diffuser that produces minute oxygen bubbles. The bubbles dissolve before reaching the air-liquid interface.

The major disadvantage of high-purity oxygen aerobic digestion is the increased cost associated with oxygen generation. As a result, high-purity oxygen aerobic digestion is cost-effective generally only when used in conjunction with the high-purity oxygen activated-sludge system. Also, neutralization may be required to offset the reduced buffering capacity of the system

14–11 COMPOSTING

Composting is a cost-effective and environmentally sound alternate for the stabilization of wastewater biosolids. Increasingly stringent air pollution regulations and biosolids disposal requirements coupled with the anticipated shortage of available landfills have accelerated the development of composting as a viable sludge-management option.

Composting is a process in which organic material undergoes biological degradation to a stable end product. Sludge that has been composted properly is a nuisance-free, humuslike material. Approximately 20 to 30 percent of the volatile solids are converted to carbon dioxide and water. As the organic material in the sludge decomposes, the compost heats to temperatures in the pasteurization range of 50 to 70°C (120 to 160°F), and enteric pathogenic organisms are destroyed. Properly composted biosolids may be used as soil conditioners in agricultural or horticultural applications, subject to any limitations based on the constituents in the composed biosolids (WEF, 1995*b*).

Although composting may be accomplished under anaerobic or aerobic conditions, essentially all municipal wastewater biosolids composting applications are under mostly aerobic conditions (composting is never completely aerobic). Aerobic composting accelerates material decomposition and results in the higher rise in temperature necessary for pathogen destruction. Aerobic composting also minimizes the potential for nuisance odors.

The anticipated daily production of biosolids from a wastewater-treatment facility will have a pronounced effect on the alternate composting systems available for use, as will the availability of land for the construction of the composting facility. Other factors affecting the type of composting system are the nature of the biosolids produced; stabilization, if any, of the biosolids prior to composting; and the type of dewatering equipment and chemicals used. Biosolids that are stabilized by aerobic or anaerobic digestion prior to composting may result in reducing the size of the composting facilities by up to 40 percent.

Process Microbiology

The composting process involves the complex destruction of organic material coupled with the production of humic acid to produce a stabilized end product. The microorganisms involved fall into three major categories: bacteria, actinomycetes, and fungi. Although the interrelationship of these microbial populations is not fully understood, bacterial activity appears to be responsible for the decomposition of proteins, lipids, and fats at thermophilic temperatures, as well as for much of the heat energy produced. Fungi and actinomycetes are also present at varying levels during the mesophilic and thermophilic stages of composting and appear to be responsible for the destruction of complex organics and the cellulose supplied in the form of amendments or bulking agents.

During the composting process, three separate stages of activity and associated temperatures are observed: mesophilic, thermophilic, and cooling (see Fig. 14–33). In the initial mesophilic stage, the temperature in the compost pile increases from ambient to approximately 40°C (104°F) with the appearance of fungi and acid-producing bacteria. As the temperature in the composting mass increases to the thermophilic range of 40 to 70°C (104 to 160°F), these microorganisms are replaced by thermophilic bacteria, actinomycetes, and thermophilic fungi. It is in the thermophilic temperature range that the maximum degradation and stabilization of organic material occur. The cooling stage is characterized by a reduction in microbial activity, and replacement of the thermophilic organisms with mesophilic bacteria and fungi. During the cooling period, further evaporative release of water from the composted material will occur, as well as stabilization of pH and completion of humic acid formation.

Process Description

Most composting operations consist of the following basic steps (see Fig. 14–34): (1) preprocessing, the mixing of dewatered sludge with an amendment and/or a bulking agent; (2) high-rate decomposition, aerating the compost pile either by the addition of air, by mechanical turning, or by both; (3) recovery of the bulking agent (at the end of either the high-rate decomposition or curing phase, if practicable); (4) further curing and storage, which allows further stabilization and cooling of the compost; (5) postprocessing, screening for the removal of nonbiogradable material such as metals and plastics or grinding for size reduction, and (6) final disposition. A portion of the final product is sometimes recycled to the preprocessing step to aid in conditioning the compost mixture.

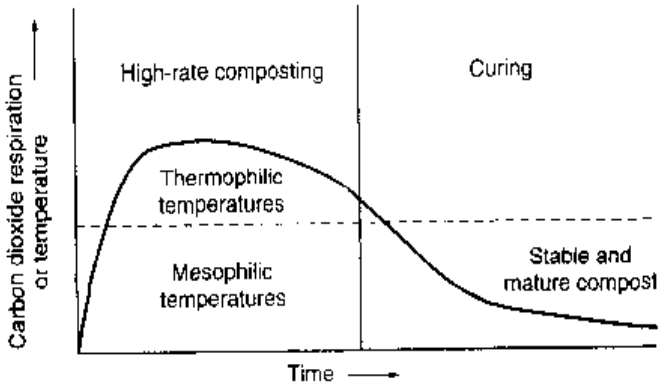

Figure 14–33
Phases during composting as related to carbon dioxide respiration and temperature. *(Epstein, 1997.)*

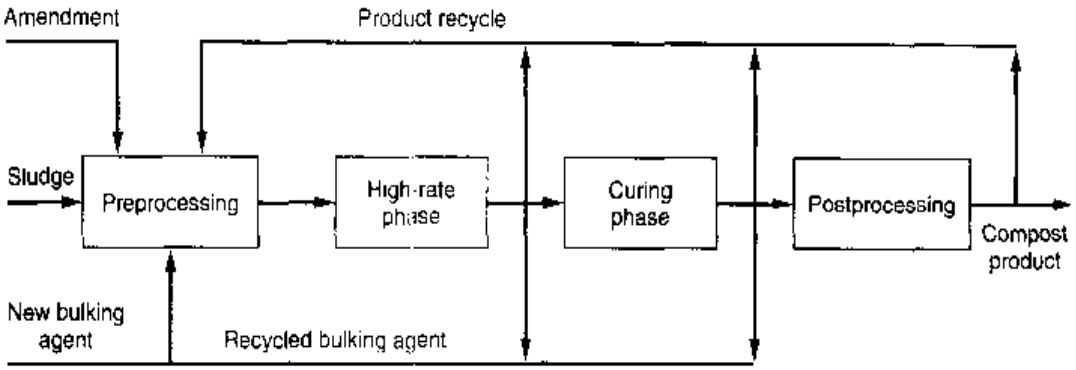

Figure 14–34
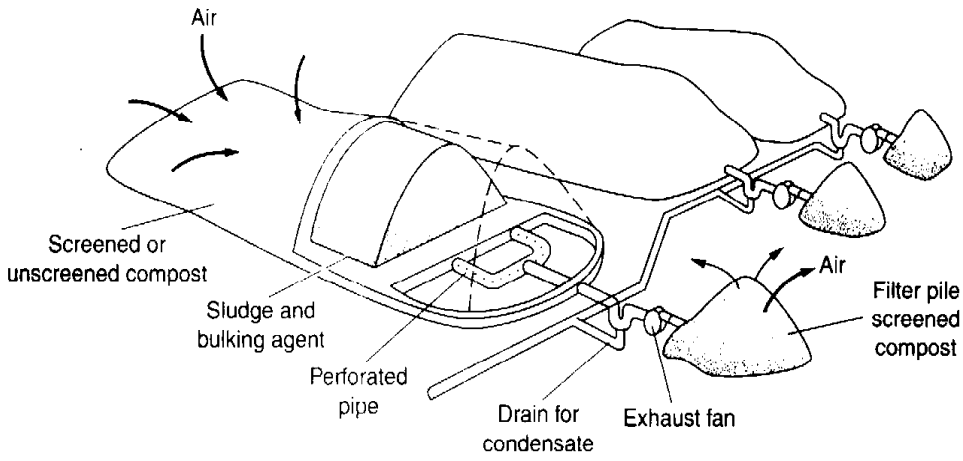
Generalized process diagram for composting showing inputs of sludge (feed substrate), amendments, and bulking agents. *(Haug, 1993.)*

The high-rate decomposition stage of composting has been more engineered and controlled due to the need to reduce odors, supply high aeration rates, and maintain process control. The curing stage is often less engineered, less controlled, and given only small consideration in some designs. The curing stage is an integral part of the system design and operation, and both stages need to be designed and operated properly to produce a mature compost product (Haug, 1993).



The two principal methods of composting now in use in the United States may be classified as *agitated* or *static*. In the agitated method the material to be composted is agitated periodically to introduce oxygen, to control the temperature, and to mix the material to obtain a uniform product. In the static method, the material to be composted remains static and air is blown through the composting material. The most common agitated and static methods of composting are known as the windrow and static pile methods, respectively. Proprietary composting systems in which the composting operation is carried out in a reactor of some type are known as in-vessel composting systems (Tchobanoglous et al., 1993).

An amendment is an organic material added to the feed substrate primarily to reduce the bulk weight, reduce moisture content, and increase the air voids for proper aeration. Amendments can also be used to increase the quantity of degradable organics in the mixture. Commonly used amendments are sawdust, straw, recycled compost, and rice hulls. A bulking agent is an organic or inorganic material that is used to provide structural support and to increase the porosity of the mixture for effective aeration. Wood chips are the most commonly used bulking agents and can be recovered and reused.

Aerated Static Pile. The aerated static pile system consists of a grid of aeration or exhaust piping over which a mixture of dewatered sludge and bulking agent is placed (see Fig. 14–35*a*). In a typical static pile system, the bulking agent consists of wood chips, which are mixed with the dewatered sludge by a pug-mill type or rotating-drum mixer or by movable equipment such as a front-end loader. Material is composted for 21 to 28 days and is typically followed by a curing period of 30 days or longer. Typical pile heights are generally about 2 to 2.5 m (6 to 8 ft). A layer of screened compost is often placed on top of the pile for insulation. Disposable corrugated plastic drainage pipe is commonly used for air supply and each individual pile is recommended to have an individual blower for more effective aeration control. Screening of the cured compost usually is done to reduce the quantity of the end product requiring ultimate dis-

(a)

(b)

(c)

posal and to recover the bulking agent. For improved process and odor control, many facilities cover or enclose all or significant portions of the system.

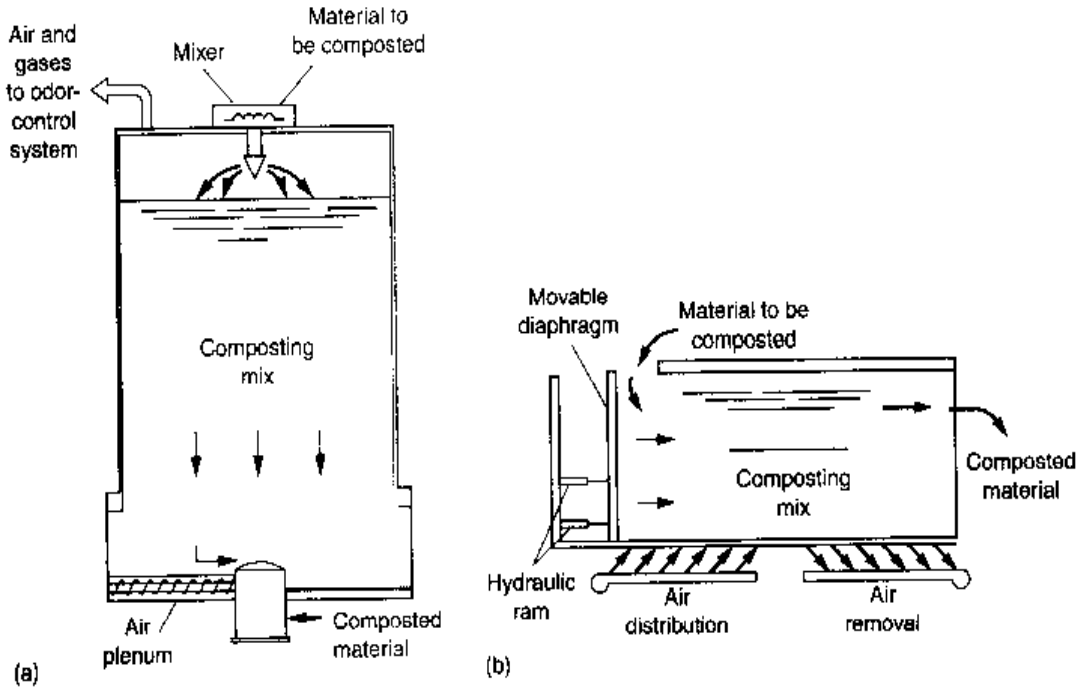
Windrow. In a windrow system, the mixing and screening operations are similar to those for the aerated static pile operation. Windrows are constructed from 1 to 2 m (3 to 6 ft) high and 2 to 4.5 m (6 to 14 ft) at the base (see Fig. 14–35*b*). The rows are turned and mixed periodically during the composting period. Supplemental mechanical aeration is used in some applications. The composting period is about 21 to 28 d. Under typical operating conditions, the windrows are turned a minimum of five times while the temperature is maintained at or above 55°C. In windrow composting, aerobic conditions are difficult to maintain throughout the cross-sectional area of the windrow. Thus, the microbial activity within the pile may be aerobic, facultative, anaerobic, or various combinations thereof, depending on when and how often the pile is turned. Turning of the windrows is often accompanied by the release of offensive odors. The release of odors occurs typically when anaerobic conditions develop within the windrow. Specialized equipment is available to mix the sludge and bulking agent and to turn the composting windrows (see Fig. 14–35*c*). Some windrow operations are covered or enclosed, similar to aerated static piles.

In-Vessel Composting Systems. In-vessel composting is accomplished inside an enclosed container or vessel. Mechanical systems are designed to minimize odors and process time by controlling environmental conditions such as air flow, temperature, and oxygen concentration. The advantages of in-vessel composting systems are better process and odor control, faster throughput, lower labor costs, and smaller area requirements.

In-vessel composting systems can be divided into two major categories: plug flow and dynamic (agitated bed). In plug-flow systems, the relationship between particles in the composting mass stays the same throughout the process, and the system operates on the basis of a first-in, first-out principle. In a dynamic system, the composting material is mechanically mixed during the processing. In-vessel systems can be further categorized based on the geometric shape of the vessels or containers used. Examples of plug-flow reactors are shown on Fig. 14–36 and examples of dynamic-type systems are illustrated on Fig. 14–37.

Design Considerations

Many factors must be considered in the design of a composting system (see Table 14–37). Each of the factors has to be considered carefully to meet the special requirements of each system. A design approach using a materials balance is particularly important because the amount of each component (sludge or biosolids, bulking agent, and amendment) used during each phase of the process is determined. In a materials balance, the following parameters must be measured or calculated for each component: (1) total volume, (2) total wet weight, (3) total solids content (dry weight), (4) volatile solids content (dry weight), (5) water content (weight), (6) bulk density (wet weight/unit volume), (7) percent water content, and (8) percent volatile solids of the compost mix. An important output of the materials balance is to determine the composition of the compost mix. The compost mix should be about 40 percent dry solids to ensure ade-



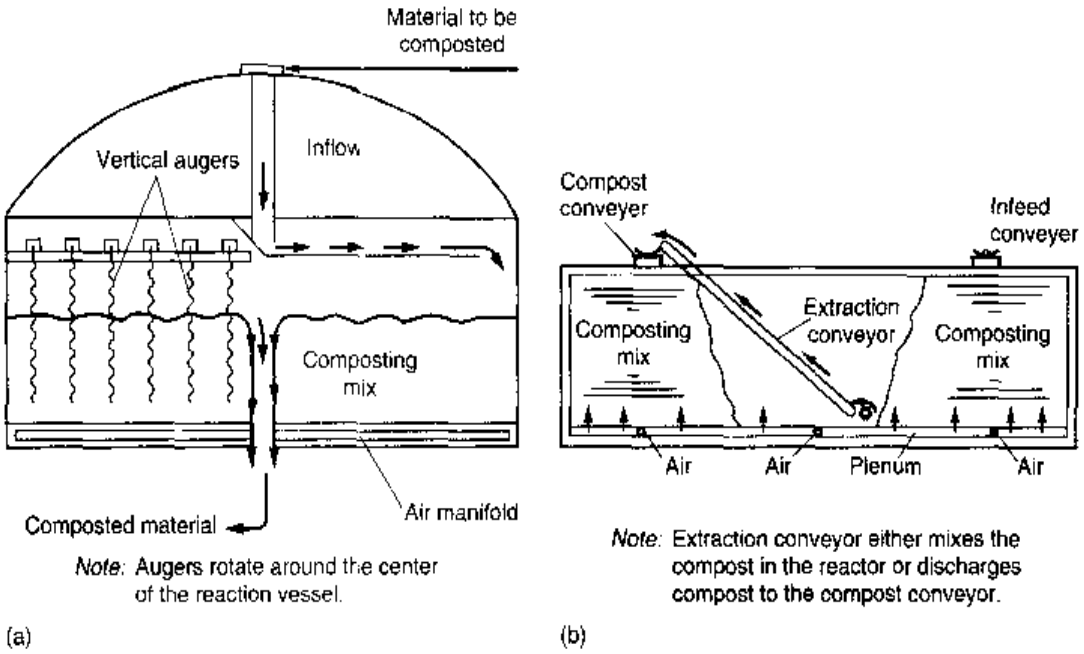


Figure 14–36
Plug-flow in-vessel composting reactors: (*a*) unmixed horizontal plug-flow reactor and (*b*) unmixed tunnel (horizontal plug-flow) reactor.

Figure 14–37

Dynamic (mixed) in-vessel composting units: (*a*) vertical reactor and (*b*) horizontal reactor.

quate composting in windrow and static-pile composting. In-vessel systems require similar solids requirements, but slightly lower values may be used, depending on the aeration system. Starting the compost process with solids higher than 40 percent soon results in a "dry mix." A dry mix is dusty, and sufficient biological activity and temperature levels are difficult to maintain. The addition of water will likely be required for the duration of the process; thus, provisions for a water supply should be made.

The effect of moisture content in the dewatered sludge on the compost mix is illustrated on Fig. 14–38. The moisture content of the sludge affects the wet weight of the mixture and the amount of amendment that has to be used. Using Fig. 14–38*a*, for example, if the sludge cake contains 24 percent solids, the wet weight of the mix is about 6.7 Mg (tonne) per dry Mg of sludge. If the sludge solids content decreases to 16 percent, the wet weight increases to about 11 Mg per dry Mg of sludge. The additional moisture content would require larger materials-handling systems and larger reactors. The amendment requirements, as indicated on Fig. 14–38*b*, would triple over the same range of sludge solids. In compost-system design, the types of sludge-dewatering system and the consistency of resulting product have to be evaluated carefully.

Postprocessing is often used to prepare the finished compost for marketing. Preparation includes conveying the finished compost from the active composting area to the curing, screening, and preparation areas. Trommel screens and belt shredders are used frequently; shredding can precede or follow curing. In some cases, double screening is preferable, especially for the horticultural market to meet product quality requirements. Particle size of the finished product for general use ranges typically from 6 to 25 mm (1/4 to 1 in).

Cocomposting with Municipal Solid Wastes

Cocomposting of sludge and municipal solid wastes is a possible alternative where integrated waste-disposal facilities are considered. Mixing the sludge with the organic fraction of municipal solid waste or source separated yard wastes is beneficial because

Table 14–37
Design considerations for aerobic sludge composting processes[a]

Item	Comment
Type of sludge	Both untreated sludge and digested biosolids can be composted successfully. Untreated sludge has a greater potential for odors, particularly for windrow systems. Untreated sludge has more energy available, will degrade more readily, and has higher oxygen demand
Amendments and bulking agents	Amendment and bulking agent characteristics (i.e., moisture content, particle size, and available carbon) affect the process and quality of product. Bulking agents should be readily available. For characteristics of typical bulking agents, see Table 14–38
Carbon-nitrogen ratio	The initial C/N ratio should be in the range of 20:1 to 35:1 by weight. At lower ratios, ammonia is given off. Carbon should be checked to ensure it is readily biodegradable
Volatile solids	The volatile solids of the composting mix should be greater than 30 percent of the total solids content. Dewatered sludge will usually require an amendment or bulking agent to adjust the solids content
Air requirements	Air with at least 50 percent of the oxygen remaining should reach all parts of the composting material for optimum results, especially in mechanical systems
Moisture content	Moisture content of the composting mixture should be not greater than 60 percent for static pile and windrow composting and not greater than 65 percent for in-vessel composting
pH control	pH of the composting mixture should generally be in the range of 6 to 9. To achieve optimum aerobic decomposition, pH should remain in the 7 to 7.5 range
Temperature	For best results, temperature should be maintained between 50 and 55°C for the first few days and between 55 and 60°C for the remainder of the active composting period. If the temperature is allowed to increase beyond 65°C for a significant period of time, biological activity will be reduced
Control of pathogens	If properly conducted, it is possible to kill all pathogens, weeds, and seeds during the composting process. To achieve this level of control, the temperature must be maintained between 60 and 70°C for 24 h. For temperatures and times of exposure required for the destruction of common pathogens, see Table 14–39
Mixing and turning	To prevent drying, caking, and air channeling, material in the process of being composted should be mixed or turned on a regular schedule or as required. Frequency of mixing or turning will depend on the type of composting operation
Heavy metals and trace organics	Heavy metals and trace organics in the sludge and finished compost should be monitored to ensure that the concentrations do not exceed the applicable regulations for end use of the product
Site constraints	Factors to be considered in selecting a site include available area, access, proximity to treatment plant and other land uses, climatic conditions, and availability of buffer zone

[a]Adapted in part from U.S. EPA (1985); Tchobanoglous et al. (1993).

(1) sludge dewatering may not be required, and (2) the overall metals content of the composted material will be less than that of the composted sludge alone. Liquid treatment plant sludges typically have a solids content ranging from 3 to 8 percent. A 2 to 1 mixture of compostable municipal solid or yard wastes to sludge is recommended as a minimum. Both static and agitated compost systems have been tried (Tchobanoglous et al., 1993).

Table 14–38
Characteristics of compost bulking agents used in the aerobic composting of sludge from wastewater treatment[a]

Bulking agent	Comments
Wood chips	May have to be purchased
	High recovery rate by screening
	Provides supplemental carbon source
Chipped brush	Possibly available as a waste material
	Low recovery rate by screening
	Provides supplemental carbon source
	Longer curing time of compost
Leaves and yard waste	Must be shredded
	Wide range of moisture content
	Readily available source of carbon
	Relatively low porosity
	Nonrecoverable
Shredded tires	Often mixed with other bulking agents
	Supplemental carbon is not available
	Nearly 100 percent recoverable
	May contain metals
Ground waste lumber	Possibly available as waste material
	Often a poor source of supplemental carbon

[a]Adapted, in part, from WEF (1998).

Table 14–39
Temperature and time of exposure required for destruction of some common pathogens and parasites[a]

Organism	Observations
Salmonella typhosa	No growth beyond 46°C; death within 30 min at 55–60°C and within 20 min at 60°C; destroyed in a short time in compost environment
Salmonella sp.	Death within 1 h at 55°C and within 15–20 min at 60°C
Shigella sp.	Death within 1 h at 55°C
Escherichia coli	Most die within 1 h at 55°C and within 15–20 min at 60°C
Entamoeba histolytica cysts	Death within a few minutes at 45°C and within a few seconds at 55°C
Taenia saginata	Death within a few minutes at 55°C
Trichinella spiralis larvae	Quickly killed at 55°C; instantly killed at 60°C
Brucella abortus or *Br. suis*	Death within 3 min at 62–63°C and within 1 h at 55°C
Micrococcus pyogenes var. *aureus*	Death within 10 min at 50°C
Streptococcus pyogenes	Death within 10 min at 54°C
Mycobacterium tuberculosis var. *hominis*	Death within 15–20 min at 66°C or after momentary heating at 67°C
Corynebacterium diphtheria	Death within 45 min at 55°C
Necator americanus	Death within 50 min at 45°C
Ascaris lumbricoides eggs	Death in less than 1 h at temperatures over 50°C

Public Health and Environmental Issues

The principal public health and environmental issues concerning compost operations relate to exposure to pathogens and bioaerosols. Exposure to pathogens can occur during the composting process or through the use of the product if the composting process is not executed properly and the resulting product is not disinfected. The potential modes of infection for workers are (1) inhalation of aerosols containing airborne microorganisms, (2) dermal contact, or (3) oral through inadvertent contact of dust or contaminated food or through hand-to-mouth contact such as cigarette smoking. Ingestion of contaminated product or contamination by the product to cigarettes or food is the greatest potential source of pathogen invasion by workers or users (Epstein, 1997).

Compost bioaerosols are organisms or biological agents that can be dispersed through the air and affect human health. Bioaerosols can contain living organisms including bacteria, fungi, actinomycetes, arthropods, and protozoa and microbial products such as endotoxin and microbial enzymes. During composting, bioaerosols are not only present in waste materials but also can be generated during the process. The level and type of bioaerosols are a function of feedstock. The two bioaerosols of greatest interest to worker health and the environment surrounding composting facilities are *Aspergillus fumigatus* and endotoxin. *A. fumigatus*, a common fungus, is of concern to both worker health and populations surrounding composting facilities, as it can cause lung disease. Endotoxin, part of the cell wall of gram-negative bacteria that is released to the environment during the composting process, is of primary concern to workers in composting, recycling, and other solid-waste processing facilities. There is little evidence that exposure to airborne endotoxin causes toxic conditions. Most of the data, however, concerning worker illness is associated with composting municipal solid waste, principally in Europe. Proper ventilation, dust control, and use of dust masks reduce worker exposure to bioaerosols (Epstein, 1997).

14–12 CONDITIONING

Sludge and biosolids are chemically conditioned expressly to improve their dewatering characteristics. Other conditioning methods, heat treatment and freeze-thaw, have also been used to a limited extent or experimentally and are discussed briefly in this section.

Chemical Conditioning

The use of chemicals to condition sludge and biosolids for dewatering is economical because of the increased yields and greater flexibility obtained. Chemical conditioning can reduce the 90 to 99 percent incoming moisture content to 65 to 85 percent, depending on the nature of the solids to be treated. Chemical conditioning results in coagulation of the solids and release of the absorbed water. Conditioning is used in advance of mechanical dewatering systems such as centrifugation, belt-filter presses, and pressure-filter presses. Chemicals used include ferric chloride, lime, alum, and organic polymers.

Adding conditioning chemicals to sludges and biosolids may increase the dry solids. Polymers do not increase the dry solids while iron salts and lime can increase the dry solids by 20 to 30 percent.

Chemicals are most easily applied and metered in the liquid form. Dissolving tanks are needed if the chemicals are received as dry powder. In most plants, these tanks should be large enough for at least one day's supply of chemicals and should be furnished in duplicate. In large plants, tankage sufficient for one shift is usually adequate. The tanks must be fabricated or lined with corrosion-resistant material. Polyvinyl chloride, polyethylene, and rubber are suitable materials for tank and pipe linings for acid solutions. Metering pumps must be corrosion-resistant. These pumps are generally of the positive-displacement type with variable-speed or variable-stroke drives to control the flowrate.

Factors Affecting Chemical Conditioning. Factors that affect the selection of the type and dosage of the conditioning agents are the properties of the solids and the type of mixing and dewatering devices to be used. Important solids properties include source, solids concentration, age, pH, and alkalinity. Sources such as primary sludge, waste-activated sludge, and digested biosolids are good indicators of the range of probable conditioner doses required. Solids concentrations will affect the dosage and the dispersal of the conditioning agent. The pH and alkalinity may affect the performance of the conditioning agents, in particular the inorganic conditioners. When lime is used to maintain a high pH for dewatering, strong ammonia odor and lime scaling problems may occur. The method of dewatering may also affect the selection of the conditioning chemical because of the differences in mixing equipment used by various vendors and the characteristics of particular methods of dewatering. For example, polymers are used commonly in centrifuge and belt-press dewatering but are used less frequently for pressure filtration. Laboratory- or pilot-scale testing is recommended to determine the types of chemical conditioning agents required, particularly for solids and biosolids that may be difficult to dewater.

Dosage. The chemical dosage required for any sludge is determined in the laboratory. Tests used for selecting chemical dosage include the Buchner funnel test for the determination of specific resistance of sludge, capillary suction time test (CST), and the standard jar test. The Buchner funnel test is a method of testing sludge drainability or dewatering characteristics using various conditioning agents. The capillary suction test relies on gravity and the capillary suction of a piece of thick filter paper to draw out water from a small sample of conditioned sludge. The standard jar test, the easiest method to use, consists of testing standard volumes of sludge samples (usually 1 L)

with different conditioner concentrations, followed by rapid mixing, flocculation, and settling using standard jar test apparatus. Detailed descriptions of testing procedures are provided in WEF (1988).

In general, it has been observed that the type of sludge has the greatest impact on the quantity of chemical required. Difficult-to-dewater sludges that require larger doses of chemicals, generally do not yield as dry a cake, and have poorer quality of filtrate or centrate. Sludge types, listed in the approximate order of increasing conditioning chemical requirements, are as follows:

1. Untreated (raw) primary sludge
2. Untreated mixed primary and trickling-filter sludge
3. Untreated mixed primary and waste-activated sludge
4. Anaerobically digested primary sludge
5. Anaerobically digested mixed primary and waste-activated sludge
6. Untreated waste-activated sludge
7. Aerobically digested sludge

Typical levels of polymer addition for various types of sludge using belt-filter press and centrifuge dewatering are shown in Table 14–40. Actual dosages in any given case may vary considerably from the indicated values. Polymer dosages will also vary greatly depending on the molecular weight, ionic strength, and activity levels of the polymers used. Manufacturers should be consulted for applicability and dosage information. Dosages of ferric chloride and lime also vary widely.

Mixing. Intimate admixing of sludge and coagulant is essential for proper conditioning. The mixing must not break the floc after it has formed, and the detention should

Table 14–40
Typical levels of polymer addition for belt-filter press and solid-bowl centrifuge sludge dewatering[a]

[a] Adapted from WEF (1983); WEF (1988).

be kept to a minimum so that sludge reaches the dewatering unit as soon after conditioning as possible. Mixing requirements vary depending on the dewatering method used. A separate mixing and flocculation tank is usually provided ahead of pressure filters; a separate flocculation tank may be provided for a belt-filter press or the conditioner may be added directly to the sludge feed line of the belt-press unit; and in-line mixers are usually used with a centrifuge. It is generally desirable in design to provide at least two locations for the addition of conditioning chemicals.

Other Conditioning Methods

Other conditioning methods that have been used or evaluated include heat-treatment, sludge preheating, and freeze-thaw conditioning.

Heat Treatment. Heat treatment is a process that has been used for the conditioning and stabilization of sludge, but it is seldom used in new installations. Heat treatment involves heating the sludge for short periods of time under pressure. The treatment coagulates the solids, breaks down the gel structure, and reduces the water affinity of sludge solids. As a result, the sludge is sterilized and is dewatered readily. Supernatant from the heat-treatment unit is high in BOD and may require special sidestream treatment before it is introduced into the mainstream wastewater treatment process.

Advantages cited for heat treatment are (1) the solids content of the dewatered sludge can range from 30 to 50 percent, depending on the degree of oxidation achieved, (2) the processed sludge does not normally require chemical conditioning, (3) the process stabilizes sludge and will destroy most pathogenic organisms, (4) the processed sludge will have a heating value of 28 to 30 kJ/g (12,000 to 13,000 Btu/lb) of volatile solids, and (5) the process is relatively insensitive to changes in sludge composition.

The major disadvantages associated with heat treatment are (1) high capital cost due to its mechanical complexity and the use of corrosion-resistant materials; (2) close supervision, skilled operators, and a strong preventive maintenance program are required; (3) the process produces sidestreams with high concentrations of organics, ammonia nitrogen, and color; (4) significant odorous gases are produced that require extensive containment, treatment, and/or destruction; and (5) scale formation in the heat exchangers, pipes, and reactor requires acid washing or high-pressure water jets. Because of these disadvantages, interest in heat treatment has declined significantly and few new facilities have been constructed.

Sludge Preheating. In pilot testing of centrifuges used in tandem with heat dryers it has been shown that as much as six percentage points incremental increase in cake solids concentration can be achieved by conditioning the sludge with heat to 60°C. The downside of preheating is the increase in soluble BOD in the centrate that could lead to an increase in treatment of the recycle loads (Garelli et al., 1992). Additional factors in evaluating preheating are the source of the heat and the cost of producing the heat. If heat is obtained from a source that otherwise would be wasted, sludge preheating may be an effective and economical method of conditioning to improve dewatering performance.

Freeze-Thaw Conditioning. It is a well-known fact that natural freezing of water and wastewater-treatment plant residuals in cold climates enhances their dewatering

characteristics. Freezing and thawing convert the jellylike consistency of the residuals to a granular-type material that drains readily. Similar results have been achieved by the use of mechanical freeze/thaw equipment.

Residuals can be described as being composed of several types of water: free water, interstitial water, surface water, and bound water. Free water refers to water that surrounds the sludge floc but does not move with the solids. Interstitial water is defined as the water that "is trapped within the floc structure and travels with the floc or is held by capillary forces between the particles." Surface water is held on the surface of the floc and cannot be removed by mechanical means. Finally, bound water is that which is "bound to the particles and can only be released by thermochemical destruction of the particles" (Vesilind and Martel, 1990).

When sludge freezes, the free water begins to freeze first. As the free water binds by crystallization, it seeks more free water to bind and grow with while pushing the floc particles to the ice front. Once free water is frozen, the interstitial water is extracted by diffusion and added to the growing crystalline structure.

The initial concentration of solids in the sludge, the rate of freezing, and the duration of freezing conditions (curing time) are cited as important variables to consider in optimizing the freeze/thaw process (Parker et al., 2000). The concentration of sludge solids in the residual matter is important in sizing the freezing equipment; thickening before freezing can decrease the size of the conditioning facility and reduce energy consumption. Freeze rate and curing time are closely related. Curing time is defined as the time at which the ice block is kept at subfreezing temperatures. Because of the design of the freezing vessel, areas close to the freezing surface will freeze before the more remote areas. Curing time allows extra freezing time to ensure the portion of the ice that was frozen last had enough time to completely dehydrate.

Pilot- and demonstration-scale testing has proved that the mechanical freeze-thaw system technology works on difficult-to-dewater water and wastewater sludges. The core temperature of the frozen sludge is critical to achieving separation of the bound water. To be effective, sludge has to be frozen for at least 30 min at temperatures of minus 10 to 20°C. The time to reach freezing temperature varies depending upon the size of the ice block and solids concentration. After thawing and dewatering, dewatered sludge cake can range from 25 to 40 percent solids with a filtrate that is very low in TSS (EPRI, 1998). Natural freeze-thaw dewatering using sludge-drying beds is discussed in the following section.

14–13 DEWATERING

Dewatering is a physical unit operation used to reduce the moisture content of sludge and biosolids for one or more of the following reasons:

1. The costs for trucking sludge and biosolids to the ultimate disposal site become substantially lower when the volume is reduced by dewatering.
2. Dewatered sludge and biosolids are generally easier to handle than thickened or liquid sludge. In most cases, dewatered sludge may be shoveled, moved about with tractors fitted with buckets and blades, and transported by belt conveyors.

3. Dewatering is required normally prior to the incineration of the sludge to increase the calorific value by removal of excess moisture.
4. Dewatering is required before composting to reduce the requirements for supplemental bulking agents or amendments.
5. In some cases, removal of the excess moisture may be required to render biosolids odorless and nonputrescible.
6. Dewatering is required prior to landfilling sludge and biosolids in monofills to reduce leachate production at the landfill site.

Several techniques are used in dewatering devices for removing moisture. Some of these techniques rely on natural evaporation and percolation to dewater the solids. In mechanical dewatering devices, mechanically assisted physical means are used to dewater the sludge more quickly. The physical means include filtration, squeezing, capillary action, and centrifugal separation and compaction. In the past, vacuum filtration was used to a significant extent for municipal sludge dewatering, but it has largely been replaced by alternative mechanical dewatering equipment. Vacuum filters may sometimes be used in industrial applications. Imperforate basket centrifuges have also been used for dewatering; the most notable application was at the County Sanitation Districts of Los Angeles. Because of the improved design and performance of solid-bowl centrifuges, imperforate basket centrifuges are seldom used in new dewatering installations. Vacuum filters and imperforate basket centrifuges are not discussed in this text; information for vacuum filters and imperforate basket centrifuges may be found in the preceding edition of this text (Metcalf & Eddy, 1991) or WEF (1998).

The selection of the dewatering device is determined by the type of sludge to be dewatered, characteristics of the dewatered product, and the space available. For smaller plants where land availability is not a problem, drying beds or lagoons are generally used. Conversely, for facilities situated on constricted sites, mechanical dewatering devices are often chosen. Odor control is an important design consideration as the level of odor release varies based on the type of sludge and the mechanical equipment selected. High shear dewatering and conveyance equipment can increase odor release, especially from anaerobically digested sludge (Murthy, 2001; Novak, 2001) (see also Sec. 15–3 in Chap. 15).

Some sludges, particularly those that are aerobically digested, are not readily amenable to mechanical dewatering. These sludges can be dewatered on sand beds with good results. When a particular sludge must be dewatered mechanically, it is often difficult or impossible to select the optimum dewatering device without conducting bench-scale or pilot studies. Trailer-mounted, full-size equipment is available from several manufacturers for field-testing purposes.

The dewatering processes that are commonly used include centrifuges, belt-filter presses, recessed-plate filter presses, drying beds, and lagoons. The advantages and disadvantages of the various methods of sludge dewatering are summarized in Table 14–41.

Centrifugation

For separating liquids of different density, thickening slurries, or removing solids, the centrifugation process is widely used in industry. The process is applicable to the dewatering

Table 14–41
Comparison of alternative methods for dewatering various types of sludge and biosolids[a]

Dewatering method	Advantages	Disadvantages
Solid-bowl centrifuge	Clean appearance, good odor containment, fast startup and shutdown capabilities	Scroll wear potentially a high maintenance problem
	Produces a relatively dry sludge cake	Requires grit removal and possibly a sludge grinder in the feed stream
	Low capital cost-to-capacity ratio	Skilled maintenance personnel required
	High installed capacity to building area ratio	Moderately high suspended solids content in centrate
Belt-filter press	Low energy requirements	High odor potential
	Relatively low capital and operating costs	Requires sludge grinder in feed stream
	Less complex mechanically and is easier to maintain	Very sensitive to incoming sludge feed characteristics
	High-pressure machines are capable of producing very dry cake	Automatic operation generally not advised
	Minimal effort required for system shutdown	
Recessed-plate filter press	Highest cake solids concentration	Batch operation
	Low suspended solids in filtrate	High equipment cost
		High labor cost
		Special support structure requirements
		Large floor area required for equipment
		Skilled maintenance personnel required
		Additional solids due to large chemical addition require disposal
Sludge drying beds	Lowest capital cost method where land is readily available	Requires large area of land
	Small amount of operator attention and skill required	Requires stabilized sludge
	Low energy consumption	Design requires consideration of climatic effects
	Low to no chemical consumption	Sludge removal is labor-intensive
	Less sensitive to sludge variability	
	Higher solids content than mechanical methods	
Sludge lagoons	Low energy consumption	Potential for odor and vector problems
	No chemical consumption	Potential for groundwater pollution
	Organic matter is further stabilized	More land-intensive than mechanical methods
	Low capital cost where land is available	Appearance may be unsightly
	Least amount of skill required for operation	Design requires consideration of climatic effects

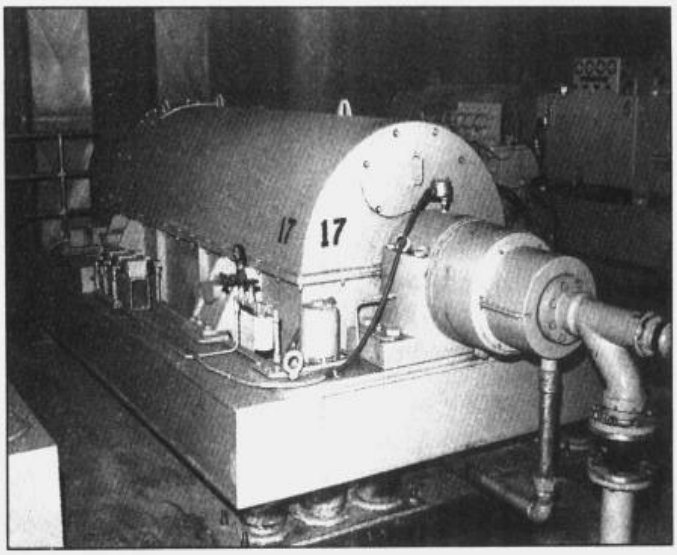

Figure 14–39
Typical solid-bowl centrifuge dewatering installation (see also Fig. 14–40.

of wastewater sludges and has been widely used in both the United States and Europe. Solid-bowl centrifugal devices used for thickening sludge (see Sec. 14–6) may also be used for sludge and biosolids dewatering. In this section, standard solid-bowl and "high-solids" centrifuges are discussed. The high-solids centrifuge is a modification of the standard centrifuge.

Solid-Bowl Centrifuge. In the solid-bowl machine (see Figs. 14–39 and 14–40), sludge is fed at a constant flowrate into the rotating bowl, where it separates into a dense cake containing the solids and a dilute stream called "centrate." The centrate contains fine, low-density solids and is returned to the wastewater treatment system. The sludge cake, which contains approximately 70 to 80 percent moisture, is discharged from the bowl by a screw feeder into a hopper or onto a conveyor belt. Depending on the type of sludge, solids concentration in the cake varies generally from 10 to 30 percent range. Sludge-cake concentrations above 25 percent are desirable for disposal by incineration or by hauling to a sanitary landfill.

Solid-bowl centrifuges are suitable generally for a variety of dewatering applications. The units can be used to dewater sludge and biosolids with no prior chemical conditioning, but the solids capture and centrate quality are improved considerably when solids are conditioned with polymers. Chemicals for conditioning are added to the sludge feed line or to the sludge within the bowl of the centrifuge. Dosage rates for conditioning with polymers vary from 1.0 to 7.5 kg/10^3 kg (2 to 15 lb/ton) of sludge (dry solids basis). Typical performance data for solid-bowl centrifuges are reported in Table 14–42.

High-Solids Centrifuge. High-solids (also called "high-torque") centrifuges are modified solid-bowl centrifuges that are designed to produce a dryer solids cake. These units have a slightly longer bowl length to accommodate a longer "beach" section, a lower differential bowl speed to increase residence time, and a modified scroll to provide a pressing action within the beach end of the unit. The high-solids units are capable of achieving solids contents in excess of 30 percent in dewatering municipal wastewater sludges, although a higher polymer usage may be required.

Table 14–42
Typical dewatering performance data for solid-bowl centrifuges for various types of sludge and biosolids[a]

Type of sludge	Cake solids, %	Solids capture, %	
		Without chemicals	With chemicals
Untreated:			
Primary	25–35	75–90	95+
Primary and trickling filter	20–25	60–80	95+
Primary and air activated	12–20	55–65	92+
Waste sludge:			
Trickling filter	10–20	60–80	92+
Air activated	5–15	60–80	92+
Oxygen activated	10–20	60–80	92+
Anaerobically digested:			
Primary	25–35	65–80	92+
Primary and trickling filter	18–25	60–75	90+
Primary and air activated	15–20	50–65	90+
Aerobically digested:			
Waste activated	8–10	60–75	90+

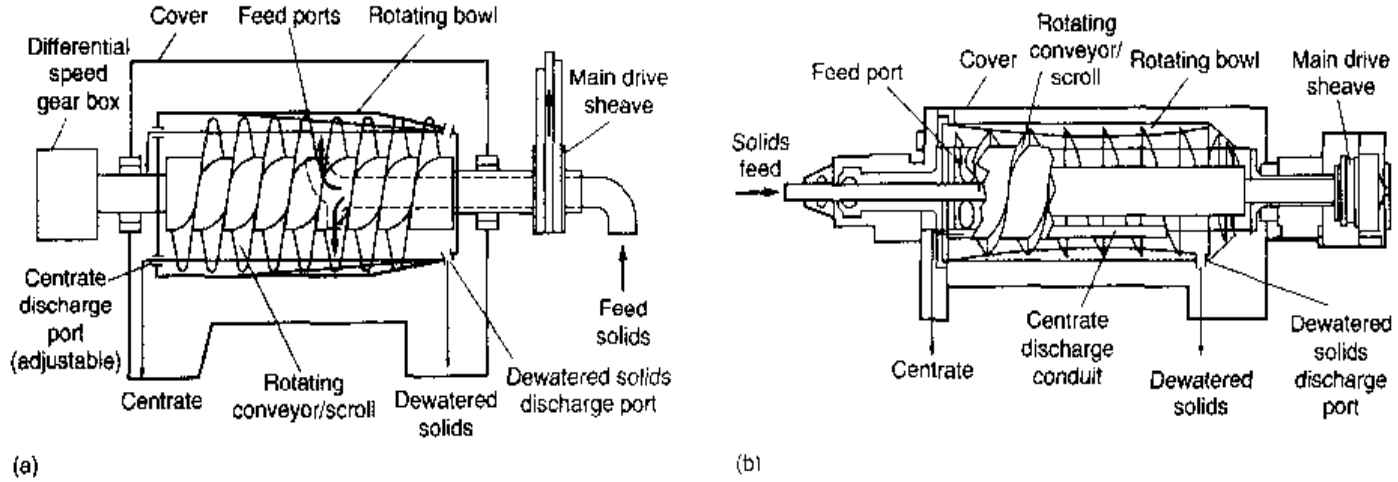

Figure 14–40
Schematic diagrams of two solid-bowl centrifuge configurations for dewatering sludge: (*a*) countercurrent and (*b*) cocurrent.

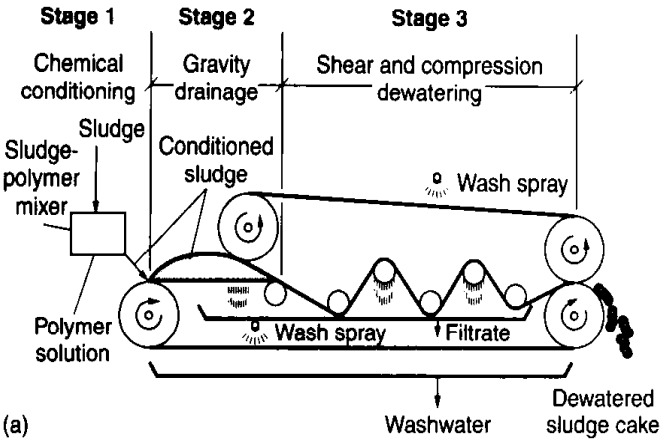
Design Considerations. Two basic designs of centrifuges are used: countercurrent flow and cocurrent flow (see Fig. 14–40*a* and *b*). The main difference in the designs is the location of the sludge feed ports, removal of centrate, and internal flow patterns of the liquid and solid phases. In the countercurrent design, the feed slurry enters at the junction of the cylindrical conical section; solids travel to the conical end

while the liquid phase moves in the opposite direction. In the cocurrent design, the solid phase travels the full length of the bowl as does the liquid phase (WEF, 1998).

Process variables affecting centrifuge performance, as measured by the sludge cake solids and TSS recovery, include feed flowrate, rotational speed, differential speed of the scroll, depth of the settling zone, chemical use, and the physicochemical properties of the suspended solids and suspending liquid. Important properties are particle size and shape, particle density, temperature, and liquid viscosity.

The major difficulty encountered in the operation of centrifuges has been the disposal of the centrate, which can be relatively high in suspended, nonsettling solids. The return of centrate to the wastewater treatment units has resulted in the passage of fine solids through the treatment system, thereby reducing effluent quality. Two methods can be used to control the fine solids discharge and to increase the capture—increased residence time or chemical conditioning. Longer residence of the liquid stream is accomplished by reducing the feed rate or by using a centrifuge with a larger bowl volume. Particle size can be increased by coagulating the sludge prior to centrifugation. Solids capture (measured in percent of influent solids) may be increased from a range of 50 to 80 percent to a range of 80 to 95 percent by longer residence time and chemical conditioning.

The addition of lime will also aid in the control of odors that may develop when centrifuging untreated sludge. Untreated primary sludge can usually be dewatered to a lower moisture content than digested sludge, because it has not been subjected to the liquefying action of the digestion process, which reduces particle size. Chemical conditioning is usually desirable when dewatering combined primary and waste-activated sludge, regardless of whether it has been digested.



Selection of units for plant design is dependent on manufacturer's rating and performance data. Several manufacturers have portable pilot-plant units, which can be used for field testing if sludge is available. Wastewater sludges from supposedly similar treatment processes but in different localities may differ markedly from each other. For this reason, pilot-plant tests should be run whenever possible before final design decisions are made.

The area required for a centrifuge installation is less than that required for other dewatering devices of equal capacity, and the initial cost is lower. Higher power costs will partially offset the lower initial cost. Special consideration must also be given in providing sturdy foundations and soundproofing because of the vibration and noise that result from centrifuge operation. An adequate electric power source is required because large motors may be used.

Because centrifuges are enclosed, odor generation may be better contained as compared to other types of dewatering systems. Ventilation of the centrifuge facility to control potential odors and moisture accumulation should be provided, however.

Belt-Filter Press

Belt-filter presses are continuous-feed dewatering devices that use the principles of chemical conditioning, gravity drainage, and mechanically applied pressure to dewater sludge (see Fig. 14–41). The belt-filter press was introduced in the United States in the early 1970s and has become one of the predominant sludge-dewatering devices. It has proved to be effective for almost all types of municipal wastewater sludge and biosolids.

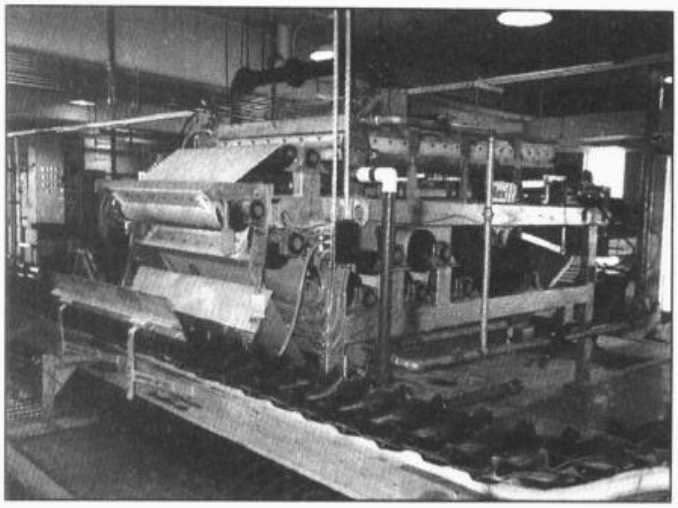


Figure 14–41

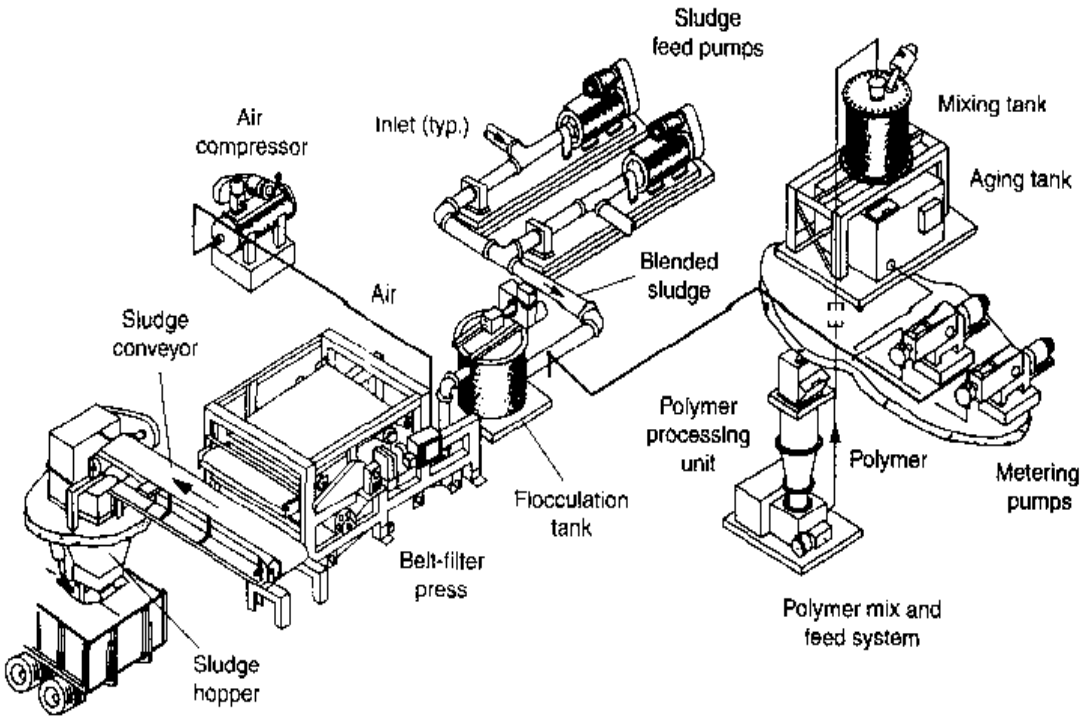
Belt-press dewatering: (*a*) three basic stages of belt-press dewatering, (*b*) pictorial view of a typical installation.



Description. In most types of belt-filter presses, conditioned sludge is first introduced on a gravity drainage section where it is allowed to thicken. In this section, a majority of the free water is removed from the sludge by gravity. On some units, this section is provided with vacuum assistance, which enhances drainage and may help to reduce odors. Following gravity drainage, pressure is applied in a low-pressure section, where the sludge is squeezed between opposing porous cloth belts. On some units, the low-pressure section is followed by a high-pressure section where the sludge is subjected to shearing forces as the belts pass through a series of rollers. The squeezing and shearing forces thus induce release of additional quantities of water from the sludge. The final dewatered sludge cake is removed from the belts by scraper blades.

System Operation and Performance. A typical belt-filter press system consists of sludge feed pumps, polymer feed equipment, sludge-conditioning tank (flocculator), belt-filter press, sludge cake conveyor, and support systems (sludge feed pumps, washwater pumps, and compressed air). Some units do not use a sludge-conditioning tank. A schematic diagram of a typical belt-filter press installation is shown on Fig. 14–42.

Many variables affect the performance of the belt-filter press: sludge characteristics, method and type of chemical conditioning, pressures developed, machine configuration (including gravity drainage), belt porosity, belt speed, and belt width. The belt-filter press is sensitive to wide variations in sludge characteristics, resulting in improper conditioning and reduced dewatering efficiency. Sludge blending facilities should be included in the system design where the sludge characteristics are likely to vary widely. Based on actual operating experience, it has been found that the solids throughput is greater and the cake dryness is improved with higher solids concentrations in the feed sludge. Typical belt-filter press performance data for various types of sludge are reported in Table 14–43.

Figure 14–42

Schematic diagram of a belt-press dewatering system. *(Metcalf & Eddy, 1984b.)*

Design Considerations. Belt-filter presses are available in metric sizes from 0.5 to 3.5 m in belt width. The most common size used for municipal sludge applications is 2.0 m. Sludge loading rates vary from 90 to 680 kg/m·h (200 to 1500 lb/m·h) depending on the sludge type and feed concentrations. Hydraulic throughput based on belt width ranges from 1.6 to 6.3 L/m·s (25 to 100 gal/m·min). Design of a belt-filter press is illustrated in Example 14–9.

Safety considerations in design should include adequate ventilation to remove hydrogen sulfide or other gases, and equipment guards to prevent loose clothing from being caught between the rollers.

Filter Presses

In a filter press, dewatering is achieved by forcing the water from the sludge under high pressure. Advantages cited for the filter press include high concentrations of cake solids achieved, good filtrate clarity, and high solids capture. Disadvantages include mechanical complexity, high chemical costs, high labor costs, and limitations on filter cloth life.

Various types of filter presses have been used to dewater sludge. The two types used most commonly are the fixed-volume and variable-volume recessed-plate filter presses.

Fixed-Volume, Recessed-Plate Filter Press. The fixed-volume, recessed-plate filter press consists of a series of rectangular plates, recessed on both sides, that are supported face to face in a vertical position on a frame with a fixed and movable head (see Fig. 14–43). A filter cloth is hung or fitted over each plate. The plates are held together with sufficient force to seal them to withstand the pressure applied during the filtration process. Hydraulic rams or powered screws are used to hold the plates together.

Table 14-43
Typical dewatering performance data for belt-filter presses for various types of sludge and biosolids[a]

Type of sludge	Dry feed solids, %	Loading per meter of belt length		Dry polymer,[b] g/kg dry solids	Cake solids, %	
		L/s	kg/h		Typical	Range
Raw primary	3–7	1.8–3.2	360–550	1–4	28	26–32
Waste-activated (WAS)	1–4	0.7–2.5	45–180	3–10	15	12–20
Primary + WAS (50:50)[c]	3–6	1.3–3.2	180–320	2–8	23	20–28
Primary + WAS (40:60)[c]	3–6	1.3–3.2	180–320	2–10	20	18–25
Primary + trickling filter	3–6	1.3–3.2	180–320	2–8	25	23–30
Anaerobically digested:						
Primary	3–7	1.3–3.2	360–550	2–5	28	24–30
WAS	3–4	0.7–2.5	45–135	4–10	15	12–20
Primary + WAS	3–6	1.3–3.2	180–320	3–8	22	20–25
Aerobically digested:

[c] Ratio is based on dry solids or the primary and WAS.

EXAMPLE 14–9 Belt-Filter Press Design A wastewater treatment plant produces 72,000 L/d of thickened biosolids containing 3 percent solids. A belt-filter press installation is to be designed based on a normal operation of 8 h/d and 5 d/wk, a belt-filter press loading rate of 275 kg/m·h, and the following data. Compute the number and size of belt-filter presses required and the expected solids capture, in percent. Determine the daily hours of operation required if a sustained 3-d peak solids load occurs.

1. Total solids in dewatered sludge = 25 percent.
2. Total suspended solids concentration in filtrate = 900 mg/L = 0.09 percent.
3. Washwater flowrate = 90 L/min per m of belt width.
4. Specific gravities of sludge feed, dewatered cake, and filtrate are 1.02, 1.07, and 1.01, respectively.

Solution

1. Compute average weekly sludge production rate.

   Wet biosolids = (72,000 L/d)(7 d/wk)(10^3 g/L)(1 kg/10^3 g)(1.02)

   = 514,080 kg/wk

   Dry solids = 514,080 × 0.03 = 15,422 kg/wk

2. Compute daily and hourly dry solids-processing requirements.

   Daily rate = 15,442 kg/wk/5 operating d/wk

   = 3084 kg/d

   Hourly rate = 3084/8 = 385.5 kg/h (per 8 h operating d)

3. Compute belt-filter press size

   $$\text{Belt width} = \frac{(385.5 \text{ kg/h})}{(275 \text{ kg/m·h})} = 1.40 \text{ m}$$

   Use one 1.5-m belt-filter press and provide one identical size for standby.

4. Compute filtrate flowrate by developing solids balance and flow balance equations.

   a. Develop daily solids balance equation.

      Solids in sludge feed = solids in sludge cake + solids in filtrate

      3084 = (S L/d)(1.07)(0.25) + (F L/d)(1.01) × (0.0009)

      3084 = 0.2675S + 0.00091F

      where S = sludge cake flowrate, L/d
      F = filtrate flowrate, L/d

   b. Develop flowrate equation.

      Sludge flowrate + washwater flowrate = filtrate flowrate + cake flowrate

      Daily sludge flowrate = (72,000 L/d)(7/5) = 100,800 L/d

      Washwater flowrate = (90 L/min·m)(1.5 m)(60 min/h)(8 h/d)

      = 64,800 L/d

      100,800 + 64,800 = 165,600 = F + S

   c. Solve the mass balance and flowrate equations simultaneously.

      F = 154,600 L/d

5. Determine solids capture.

$$\text{Solids capture} = \frac{\text{solids in feed} - \text{solids in filtrate}}{\text{solids in feed}} \times 100\%$$

$$= \frac{(3084\ \text{kg/d}) - \left[(154{,}600\ \text{L/d})(1.01)(0.0009)(10^3\ \text{g/L})(1\ \text{kg}/10^3\ \text{g})\right]}{(3084\ \text{kg/d})} \times 100\%$$

$$= 95.4\ \text{percent}$$

6. Determine operating requirements for sustained peak biosolids load.
   a. Determine peak 3-d load.
      From Fig. 3–9*b*, the ratio of peak to average mass loading for 3 consecutive days is 2. The peak load is 72,000 (2) = 144,000 L/d.
   b. Determine daily operating time requirements, neglecting sludge in storage.

$$\text{Dry solids/d} = 144{,}000/\text{d}\ (1.02)\ (0.03)$$

$$= 4406\ \text{kg/d}$$

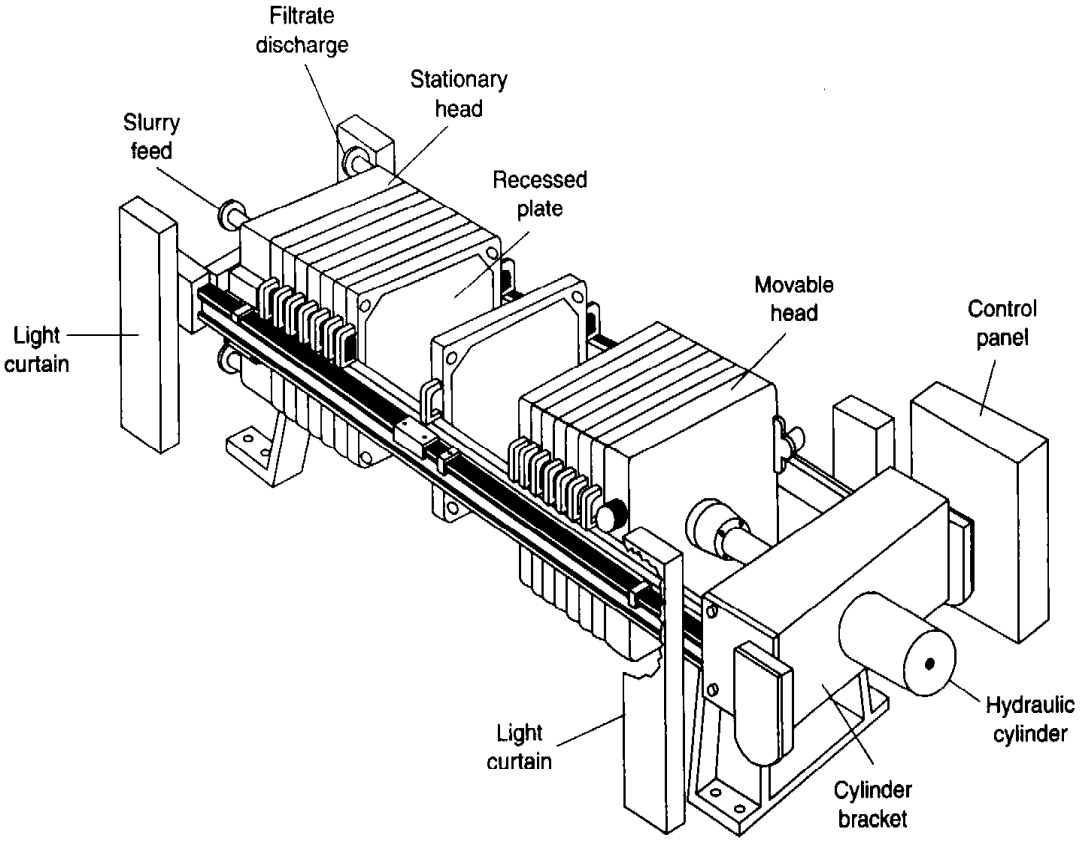
$$\text{Operating time} = \frac{(4406\ \text{kg/d})}{(275\ \text{kg/m·h})(1.5\ \text{m})} = 10.7\ \text{h}$$

The operating time can be accomplished by running the standby belt-filter press in addition to the duty press, or operating the duty press for an extended shift.

Comment The value of sludge storage is important in dewatering applications because of the ability to schedule operations to suit labor availability most efficiently. Scheduling sludge dewatering operations during the day shift is also desirable if sludge has to be hauled off-site.

In operation, chemically conditioned sludge is pumped into the space between the plates, and pressure of 690 to 1550 kN/m^2 (100 to 225 lb$_f$/in^2) is applied and maintained for 1 to 3 h, forcing the liquid through the filter cloth and plate outlet ports. The plates are then separated and the sludge is removed. The filtrate normally is returned to the influent of the treatment plant. The sludge cake thickness varies from about 25 to 38 mm (1 to 1.5 in), and the moisture content varies from 48 to 70 percent. The filtration cycle time varies from 2 to 5 h and includes the time required to (1) fill the press, (2) maintain the press under pressure, (3) open the press, (4) wash and discharge the cake, and (5) close the press. Depending on the degree of automation incorporated into the machine, operator attention must be devoted to the filter press during feed, discharge, and wash intervals.

Variable-Volume, Recessed-Plate Filter Press. Another type of filter press used for wastewater sludge dewatering is the variable-volume recessed-plate filter press, commonly called the "diaphragm press." This type of filter press is similar to the fixed-volume press except that a rubber diaphragm is placed behind the filter media, as shown on Fig. 14–44. The rubber diaphragm expands to achieve the final squeeze pres-



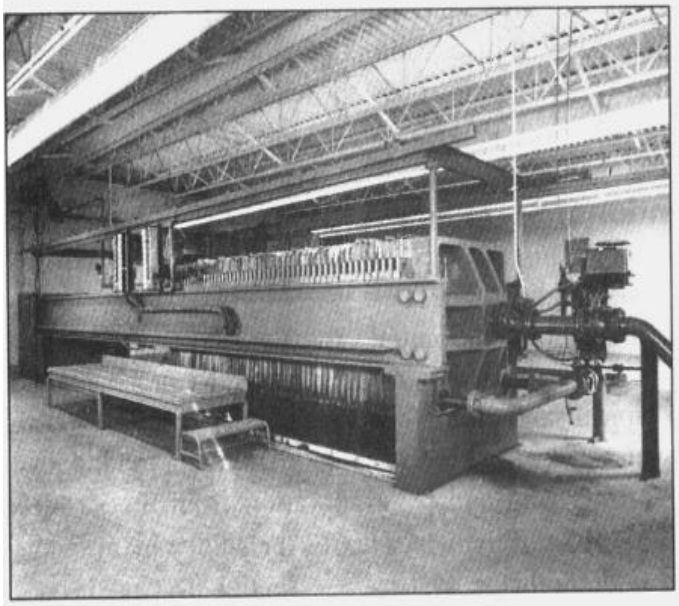


Figure 14–43

Typical fixed-volume, recessed-plate filter press used for dewatering sludge: (*a*) schematic, (*b*) pictorial view of a typical installation.

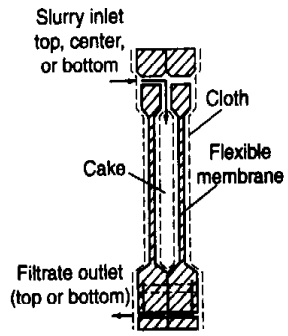

Figure 14–44

Cross section of a variable-volume recessed-plate filter press.

sure, thus reducing the cake volume during the compression step. Generally about 10 to 20 min are required to fill the press and 15 to 30 min of constant pressure are required to dewater the cake to the desired solids content. Variable-volume presses are generally designed for 690 to 860 kN/m^2 (100 to 125 lb$_f$/in^2) for the initial stage of dewatering followed by 1380 to 2070 kN/m^2 (200 to 300 lb$_f$/in^2) for final compression. Variable-volume presses can handle a wide variety of sludges with good performance results but require considerable maintenance (Metcalf & Eddy, 1984*c*).

Design Considerations. Several operating and maintenance problems have been identified for recessed-plate filter presses ranging from difficulties in the chemical feed and sludge-conditioning system to excessive downtime for equipment maintenance. Features that should be considered in the design of a filter press installation include (1) adequate ventilation in the dewatering room (6 to 12 air changes per hour are recommended depending on the ambient temperature), (2) high-pressure washing systems, (3) an acid wash circulation system to remove calcium scale when lime is used, (4) a sludge grinder ahead of the conditioning tank, (5) cake breakers or shredders following the filter press (particularly if the dewatered sludge is incinerated), and (6) equipment to facilitate removal and maintenance of the plates (Metcalf & Eddy, 1984*c*).

Sludge Drying Beds

Drying beds are the most widely used method of sludge dewatering in the United States. Sludge drying beds are typically used to dewater digested biosolids and settled sludge from plants using the extended aeration activated-sludge treatment process without prethickening. After drying, the solids are removed and either disposed of in a landfill or used as a soil conditioner. The principal advantages of drying beds are low cost, infrequent attention required, and high-solids content in the dried product. The principal disadvantages are the large space required, effects of climatic changes on drying characteristics, labor-intensive sludge removal, insects, and potential odors. Five types of drying beds are used: (1) conventional sand, (2) paved, (3) artificial media, (4) vacuum-assisted, and (5) solar. Because conventional sand and paved drying beds are used most extensively, more detailed discussion is provided for these types. For additional information on the other types of drying beds, the reader is referred to U.S. EPA (1979) and U.S. EPA (1987*c*).

Conventional Sand Drying Beds. Conventional sand drying beds are generally used for small- and medium-sized communities. For cities with populations over 20,000, consideration should be given to alternative means of sludge dewatering. In larger municipalities, the initial cost, the cost of removing the sludge and replacing sand, and the large area requirements generally preclude the use of sand drying beds.

In a typical sand drying bed, sludge is placed on the bed in a 200 to 300 mm (8 to 12 in) layer and allowed to dry. Sludge dewaters by drainage through the sludge mass and supporting sand and by evaporation from the surface exposed to the air (see Fig. 14–45). Most of the water leaves the sludge by drainage; thus the provision of an adequate underdrainage system is essential. Drying beds are equipped with lateral drainage lines (perforated plastic pipe or vitrified clay pipe laid with open joints), sloped at a minimum of 1 percent and spaced 2.5 to 6 m (8 to 20 ft) apart. The drainage lines should be adequately supported and covered with coarse gravel or crushed stone. The sand layer should be from 230 to 300 mm (9 to 12 in) deep with an allowance for some loss from cleaning operations. Deeper sand layers generally retard the draining process. Sand should have a uniformity coefficient of not over 4.0 and an effective size of 0.3 to 0.75 mm.

The drying area is partitioned into individual beds 6 m wide by 6 to 30 m long (approximately 20 ft wide by 20 to 100 ft long), or a convenient size so that one or two beds will be filled in a normal loading cycle. The interior partitions commonly consist

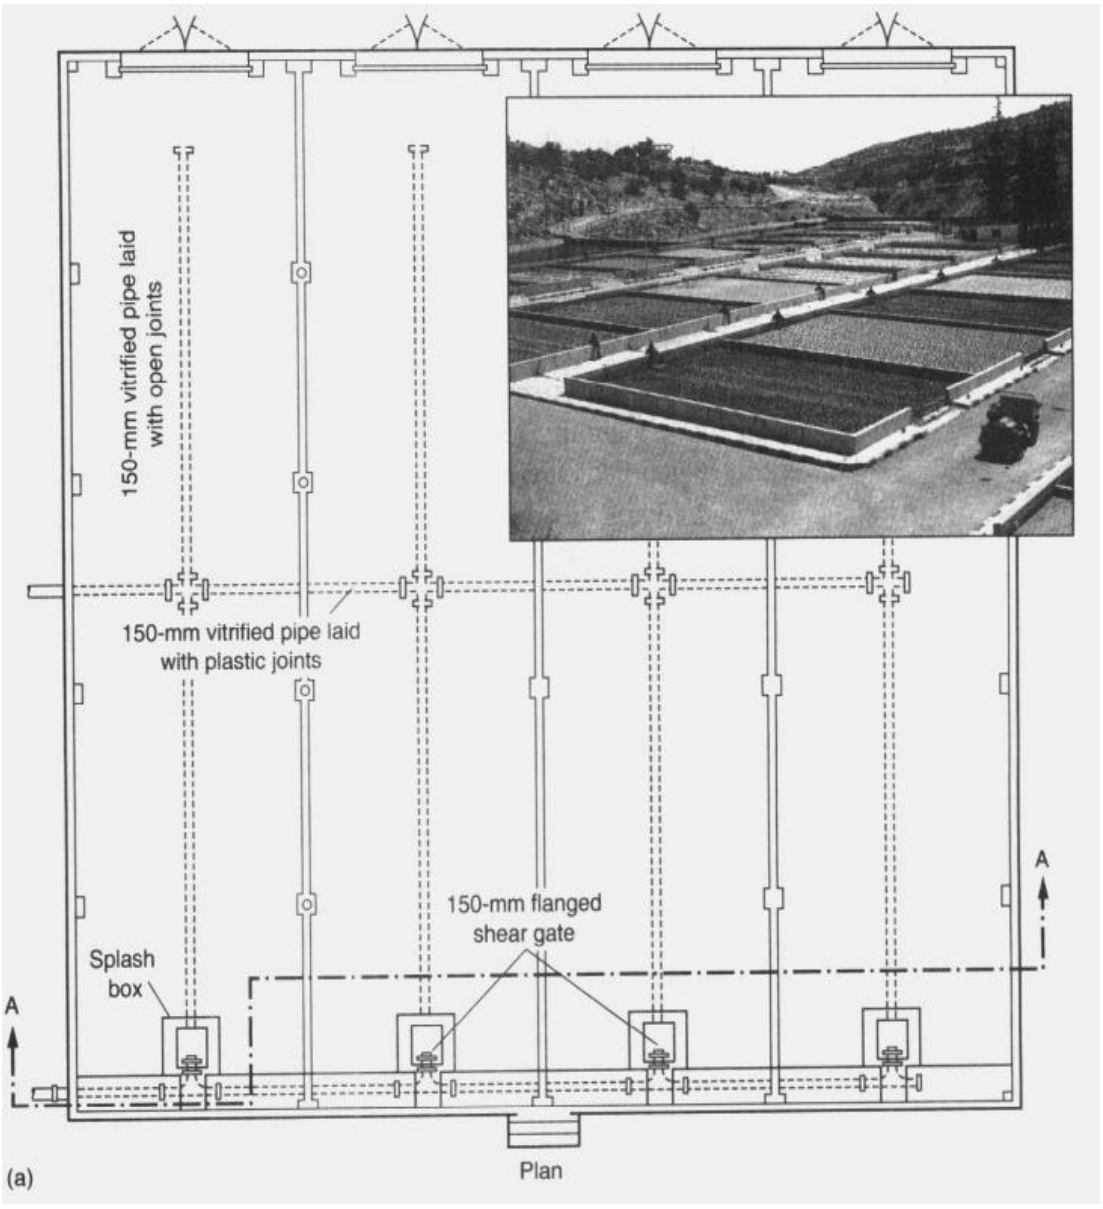

Figure 14–45

Typical conventional sand drying bed: (*a*) plan and pictorial views and (*b*) cross-sectional view. Insert—view of sludge drying beds with sludge in various stages of dryness.

of two or three planks, one on top of the other, to a height of 380 to 460 mm (15 to 18 in), stretching between slots in precast-concrete posts. The outer boundaries may be of similar construction or may be earthen embankments for open drying beds. Concrete foundation walls are required if the beds are to be covered.

Piping to the sludge beds should be designed for a velocity of at least 0.75 m/s (2.5 ft/s) and preferably should drain to the beds. Cast iron or plastic pipe is commonly

used. Provisions should be included to flush the lines, if necessary, and to prevent their freezing in cold climates. Distribution boxes are required to divert the sludge flow into the bed selected. Splash plates are placed in front of the sludge outlets to spread the sludge over the bed and to prevent erosion of the sand.

Sludge can be removed from the drying bed after it has drained and dried sufficiently. Dried sludge has a coarse, cracked surface and is black or dark brown. The moisture content is approximately 60 percent after 10 to 15 d under favorable conditions. Sludge removal is accomplished by manual shoveling into wheelbarrows or trucks, or by a scraper, front-end loader, or special mechanical sludge removal equipment. Provisions should be made for driving a truck onto or alongside of the bed to facilitate loading.

Open beds are used where adequate area is available and sufficiently isolated to avoid complaints caused by occasional odors. Open sludge beds should be located at least 100 m (about 300 ft) from dwellings to avoid odor nuisance. Covered beds with greenhouse types of enclosures are used where it is necessary to dewater sludge continuously throughout the year regardless of the weather, and where sufficient isolation does not exist for the installation of open beds (see Solar Drying Beds).

Sludge bed loadings are computed on a per capita basis or on a unit loading of pounds of dry solids per square foot per year (kilograms of dry solids per square meter per year). Typical data for various types of biosolids are shown in Table 14–44. With covered drying beds, more biosolids can be applied per year because of the protection from rain and snow.

As discussed previously, the effects of freezing and thawing in cold climates have been observed to improve the dewatering characteristics of sludge. After freezing, solids concentrations exceeding 20 percent may occur when the material thaws and may increase to over 50 percent with additional drying time. An 75-mm (3-in) layer of sludge has been found to be practical for most locations in moderately cold climates that experience alternating freeze-thaw periods. In colder climates, greater depths [up to 225 mm (9 in)] may be feasible. The type of facility used for natural freeze-thaw

Table 14–44
Typical area requirements for open sludge drying beds for various types of biosolids[a]

Type of biosolids	Area[a]		Sludge loading rate	
	ft^2/person	m^2/person	lb dry solids/$ft^2 \cdot yr$	kg dry solids/$m^2 \cdot yr$
Primary digested	1.0–1.5	0.1	25–30	120–150
Primary and trickling-filter humus digested	1.25–1.75	0.12–0.16	18–25	90–120
Primary and waste-activated digested	1.75–2.5	0.16–0.23	12–20	60–100
Primary and chemically precipitated digested	2.0–2.5	0.19–0.23	20–33	100–160

[a]Corresponding area requirements for covered beds vary from about 70 to 75 percent of those for the open beds.

dewatering is similar to conventional sand drying beds, or deep lined and underdrained trenches can be used. Dewatered biosolids are recommended to be removed once each year; biosolids stored in deep trenches should be removed before the onset of warm weather (Reed et al., 1995).

Paved Drying Beds. Two types of paved drying beds have been used as an alternate to sand drying beds: a drainage type and a decanting type. The drainage type functions similarly to a conventional bed in that underdrainage is collected, but sludge removal is improved by using a front-end loader. Sludge drying may also be improved by frequent agitation with mobile equipment. With this design, the beds are normally rectangular in shape and are 6 to 15 m (20 to 50 ft) wide by 20 to 45 m (~70 to 150 ft) long with vertical sidewalls. Concrete or bituminous concrete linings are used, overlaying a 200 to 300 mm (8 to 12 in) sand or gravel base. The lining should have a minimum 1.5 percent slope to a center unpaved drainage area. For a given amount of sludge, this type of paved drying bed requires more area than conventional sand beds.

The decanting type of paved drying bed is advantageous for warm, arid, and semi-arid climates. This type of drying bed uses low-cost impermeable paved beds that depend on decanting of the supernatant and mixing of the drying sludge for enhanced evaporation. Features of this design include (1) a soil-cement mixture paving material, (2) drawoff pipes for decanting the supernatant, and (3) a sludge feed pipe at the center of the bed (see Fig. 14–46). Decanting may remove about 20 to 30 percent of the water with a good settling sludge. Solids concentration may range from 40 to 50 percent for a 30 to 40 d drying time in an arid climate for a 300 mm (12 in) sludge layer.

The water losses and bottom area of the drying bed may be determined by the following equations (U.S. EPA, 1987*a*, 1987*b*):

The water content in the applied sludge can be determined by

$$W_o = 1.04(S)\left[\frac{1 - s_o}{s_o}\right] \qquad (14\text{–}25)$$

where W_o = total water content in the applied sludge, kg/yr
1.04 = assumed specific gravity of biosolids
S = annual sludge production, dry solids, kg/yr
s_o = percent dry solids in applied sludge, as a decimal

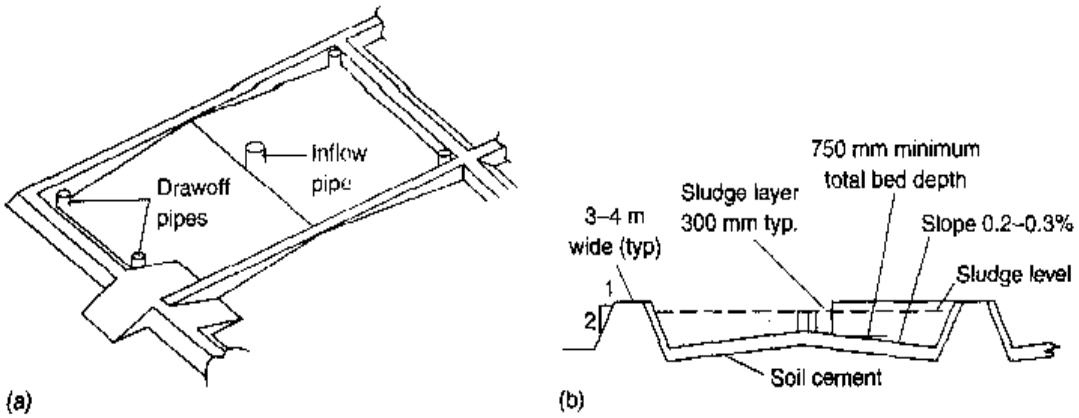

Figure 14–46
Paved sludge drying bed for decantation and evaporation: (*a*) isometric view, (*b*) cross section.

The water content after decanting can be determined by

$$W_d = 1.04(S)\left[\frac{1 - s_d}{s_d}\right] \tag{14-26}$$

where W_d = total water content after decanting, kg/yr
s_d = percent dry solids in decanted sludge, as a decimal

The water content to be removed by evaporation is given by

$$W_e = W_d - 1.04(S)\left[\frac{1 - s_e}{s_e}\right] + (P)(A)(10^3 \text{ kg/m}^3) \tag{14-27}$$

where W_e = water to be evaporated after decanting, kg/yr
s_e = percent dry solids required after evaporation, as a decimal
P = annual precipitation, m/yr
A = bottom area of paved bed, m^2 (ft^2)

The evaporation rate for a given location is given by

$$R_e = (10)(k_e)(E_p) \tag{14-28}$$

where R_e = annual evaporation rate, $kg/m^2 \cdot yr$
10 = factor used for converting cm/yr to $kg/m^2 \cdot yr$
k_e = reduction factor for evaporation from sludge versus a free water surface. Use 0.6 for preliminary estimate; pilot test to determine factor for final design
E_p = free water pan evaporation rate, cm/yr

The area required can be estimated by combining Eqs. (14–27) and (14–28), which yields

$$A = \frac{1.04\,S\left[(1 - s_d)/s_d - (1 - s_e)/s_e\right] + (10^3 \text{ kg/m}^3)(P)(A)}{(10)(k_e)(E_p)} \tag{14-29}$$

Application of the equations is shown in Example 14–10.

EXAMPLE 14–10 Paved Drying Bed Design Design a paved drying bed for a wastewater treatment plant that produces 180,000 kg/yr of dry solids. Assume the following conditions:

1. Percent of dry solids in applied biosolids (before decanting) = 6 percent
2. Percent of dry solids in biosolids after decanting = 8 percent
3. Percent dry solids required for final disposal = 30 percent
4. Free water pan evaporation rate = 120 cm/yr
5. $k_e = 0.6$.

Solution

Determine evaporation rate by Eq. (14–28).

$$R_e = (10)(0.6)(120) = 720 \text{ kg/m}^2 \cdot \text{yr}$$

Determine bed area by Eq. (14–29).

$$A = \frac{(1.04)(180{,}000)[(1 - 0.08)/0.08 - (1 - 0.35)/0.35] + (0.6)(A)(10^3)}{720}$$

A = 14,741 m^2 (1.47 ha or 3.63 ac)

Divide area into beds of approximately 0.25 ha each for operating flexibility. The number of beds required is 6.

Comment A detailed month-by month analysis of weather records and sludge production rates should be made when sizing the bed area. Testing should also be done to determine the solids concentrations reasonably achievable after settling and decanting the biosolids.

Artificial-Media Drying Beds. Artificial-media can be used such as stainless-steel wedgewire or high-density polyurethane formed into panels. In a wedgewire drying bed, liquid sludge is introduced onto a horizontal, relatively open drainage medium (see Fig. 14–47). The medium consists of small stainless-steel wedge-shaped bars with the flat part of the wedge on top. The slotted openings between the bars are 0.25 mm (0.01 in) wide. The wedgewire is formed into panels and installed in a false floor. An outlet valve is used to control the drainage. Advantages cited for this method of dewatering are (1) no clogging of the wedgewire, (2) drainage is constant and rapid, (3) throughput is higher than sand beds, (4) aerobically digested sludges can be dried, and (5) beds are relatively easy to maintain. The principal disadvantage is that the capital costs are higher than for conventional drying beds. Typical solids loading rates are 2 to 5 kg/m^2·cycle. The number of operating cycles varies depending on local climatic conditions. Typically the biosolids will dry to 8 to 12 percent solids after 24 h of drying.

In the high-density polyurethane media system, special 300 mm- (12 in-) square interlocking panels are formed for installation on a sloped slab or in prefabricated steel self-dumping trays. Each panel has an 8 percent open area for dewatering and contains

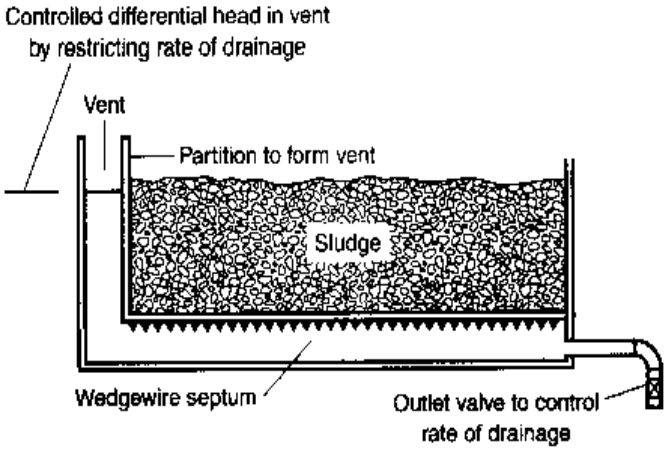

Figure 14–47
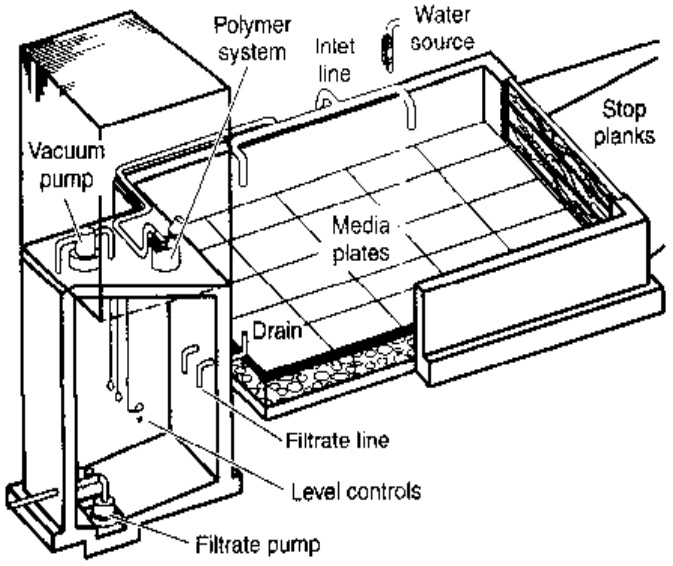
Cross section of a wedgewire sludge drying bed.

a built-in underdrain system. The system can be designed for installation in open or covered beds. Advantages of this method of dewatering are (1) dilute sludges can be dewatered including aerobically digested waste-activated sludge, (2) filtrate contains low suspended solids, and (3) fixed units can be cleaned easily with a front-end loader. Drying rates are comparable to those of wedgewire media.

Vacuum-Assisted Drying Beds. A method used to accelerate dewatering and drying is the vacuum-assisted sludge drying bed (see Fig. 14–48). Dewatering and drying are assisted by the application of a vacuum to the underside of porous filter plates. Operation of this method consists usually of the following steps: (1) preconditioning the biosolids with a polymer, (2) filling the beds with biosolids, (3) dewatering the biosolids initially by gravity drainage followed by applying a vacuum, (4) allowing the biosolids to air-dry for approximately 24 to 48 h, (5) removal of the dewatered biosolids by a front-end loader, and (6) washing of the surface of the porous plates with a high-pressure hose to remove the remaining biosolids residue. Typical solids concentrations produced by vacuum-assisted drying beds are reported in Table 14–45 (WEF, 1998). The principal advantages cited for this method are the reduced cycle time required for biosolids dewatering, thereby reducing the effects of weather on biosolids drying, and the smaller area required as compared to other types of drying beds. The principal disadvantage is that adequate polymer conditioning must be used for successful operation or further processing may be required for additional moisture reduction (U.S. EPA 1987*a*).

Solar Drying Beds. A method used to enhance the dewatering and drying of liquid, thickened, or dewatered biosolids is solar drying in covered drying beds. The solar drying system, which is a sophisticated "greenhouse," consists of a rectangular base structure, translucent chamber, sensors to measure atmospheric drying conditions, air louvers, ventilation fans, a mobile electromechanical device (called a "mole") that agitates and moves the drying biosolids, and a microprocessor that controls the drying environment (see Fig. 14–49). The system's main source of drying energy is solar radiation.

Figure 14–48
Isometric view of a vacuum-assisted sludge drying bed.



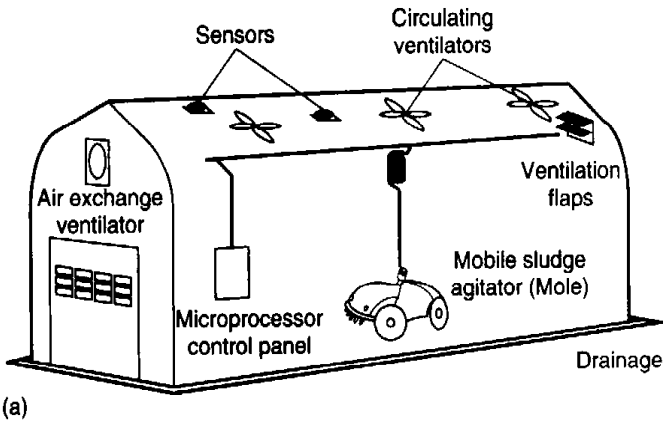


Table 14-45
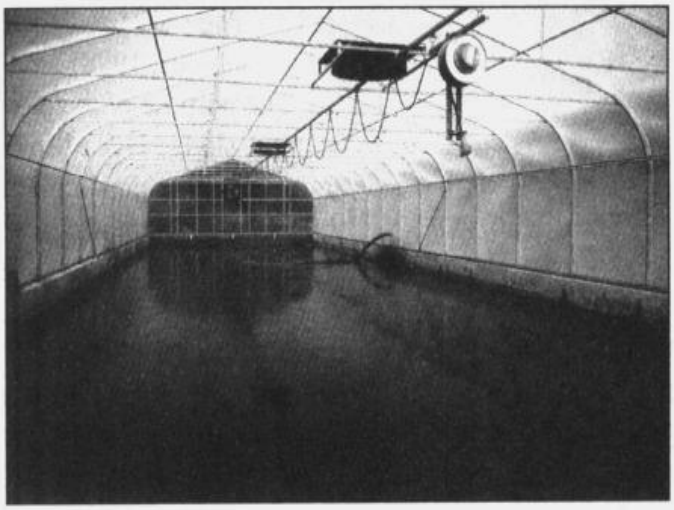
Typical performance data for vacuum-assisted sludge drying beds for various types of biosolids[a]

Type of biosolids	Dry feed solids %	Dry solids loading lb/ft²	Dry solids loading kg/m²	Cycle time h	Polymer dose lb/ton	Polymer dose g/kg	Cake solids range %
Anaerobically digested:							
Primary	1–7	2–4	10–20	8–24	4–40	2–20	12–26
Primary + WAS	1–4	1–4	5–20	18–24	30–40	15–20	15–20
Primary + TF	3–10	3–6	15–30	18–24	40–52	20–26	20–26
Aerobically digested:							
Conventional WAS	1–4	1–3	5–15	8–24	2–34	1–17	10–23
Oxidation ditch	1–2	1–2	5–10	8–24	4–14	2–7	10–20

[a] Adapted from WEF (1998).
WAS = waste-activated sludge.
TF = trickling-filter humus sludge.

(a)



(b)

Figure 14-49
Solar sludge drying bed system employing mobile sludge agitator: (*a*) schematic and (*b*) interior view of a typical installation. *(Courtesy Parkson, Corp.)*

The microprocessor evaluates the number of climatic variables and then initiates one or more operations that optimize the moisture-absorbing potential of the ambient air. Ventilating fans provide circulating air movement to exhaust the moisture-laden air. The mole tills the sludge bed, bringing moist biosolids to the surface to accelerate drying. Ultimately, a dry pelletized material is produced with a solids content as high as 90 percent.

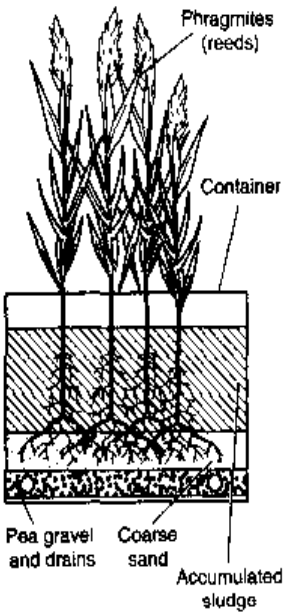


Figure 14–50
Cross section of a reed bed for dewatering and storage of biosolids.

Reed Beds

Reed beds can be used for biosolids dewatering at treatment plants with capacities up to 0.2 m^3/s (5 Mgal/d). Reed beds are similar in appearance to subsurface flow constructed wetlands, which consist of channels or trenches filled with sand or rock to support emergent vegetation. The difference between reed beds used for biosolids application and subsurface flow wetlands is that the liquid biosolids are applied to the surface of the beds (as compared to subsurface application) and the filtrate flows through the gravel to underdrains. A typical reed bed for biosolids dewatering, treatment, and storage is shown on Fig. 14–50.

Typically, reed beds are constructed of washed river-run gravel in the following layers: (1) a 250 mm (10 in) deep drainage layer composed of 20 mm (0.8 in) washed gravel, (2) a 250 mm (10 in) deep layer composed of 4 to 6 mm (0.16 to 0.24 in) washed gravel, and (3) a 100 to 150 mm (4 to 6 in) layer of sand (0.4 to 0.6 mm). Sometimes an even coarser bottom layer is used. At least 1 m (3 ft) of freeboard above the sand layer is provided for a 10-year accumulation of sludge. Phragmites (reeds) are planted on 300 mm (12 in) centers in the gravel layer just below the sand. Other wetland vegetation can be used, although reeds are the most popular. The first sludge application is made after the reeds are well established. Harvesting of the reeds is practiced typically in the winter by cutting the tops back to a level above the sludge blanket. Harvesting is necessary whenever the plant growth becomes too thick and restricts the even flow of sludge. The harvested material can be composted, burned, or landfilled (Crites and Tchobanoglous, 1998).

The purpose of the plants is to provide a pathway for continuous drainage of water from the sludge layer. Movement and growth of the plants create pathways for water to drain from the biosolids into the underdrains. The plants also absorb water from the sludge. Oxygen transfer to the plant roots assists in the biological stabilization and mineralization of the sludge. The reed bed system is a form of passive composting. The design loading rates for reed beds range from 30 to 60 $kg/m^2 \cdot yr$ (6 to 12 $lb/ft^2 \cdot yr$). Loading rates as high as 100 $kg/m^2 \cdot yr$ (20 $lb/ft^2 \cdot yr$) have been used, depending on the nature of the sludge and climatic conditions. The liquid sludge is applied intermittently, as in sand drying beds. The typical sludge depth applied is 75 to 100 mm (3 to 4 in) every week to 10 d (Crites and Tchobanoglous, 1998; Cooper et al., 1996).

Lagoons

Drying lagoons may be used as a substitute for drying beds for the dewatering of digested sludge. Lagoons are not suitable for dewatering untreated sludges, limed sludges, or sludges with a high-strength supernatant because of their odor and nuisance potential. The performance of lagoons, like that of drying beds, is affected by climate; precipitation and low temperatures inhibit dewatering. Lagoons are most applicable in areas with high evaporation rates. Dewatering by subsurface drainage and percolation is limited by increasingly stringent environmental and groundwater regulations. If a groundwater aquifer used for a potable water supply underlies the lagoon site, it may be necessary to line the lagoon or otherwise restrict significant percolation.

Unconditioned digested biosolids are discharged to the lagoon in a manner suitable to accomplish an even distribution. Biosolids depths usually range from 0.75 to 1.25 m (2.5 to 4 ft). Evaporation is the prime mechanism for dewatering. Facilities for decant-

ing of supernatant are usually provided, and the liquid is recycled to the treatment facility. Biosolids are removed mechanically, usually at a solids content of 25 to 30 percent. The cycle time for lagoons varies from several months to several years. Typically, biosolids are pumped to the lagoon for 18 months, and then the lagoon is rested for 6 months. Solids loading criteria range from 36 to 39 kg/m^3·yr (2.2 to 2.4 lb/ft^3·yr) of lagoon capacity (U.S. EPA, 1987*c*). A minimum of two cells is essential, even in very small plants, to ensure availability of storage space during cleaning, maintenance, or emergency conditions.

14-14 HEAT DRYING

Heat drying involves the application of heat to evaporate water and to reduce the moisture content of biosolids below that achievable by conventional dewatering methods. The advantages of heat drying include reduced product transportation costs, further pathogen reduction, improved storage capability, and marketability (WEF, 1998).

Heat-Transfer Methods

The classification of dryers is based on the predominant method of transferring heat to wet solids. These methods are convection, conduction, radiation, or a combination of both. Dryers using infrared radiation are relatively new and have been used mostly for demonstration testing.

Convection. In convection (direct drying) systems the wet sludge directly contacts the heat-transfer mechanism, usually hot gases. Under equilibrium conditions of constant rate drying, mass transfer is proportional to (1) the area of wetted surface exposed, (2) the difference between water content of the drying air and saturation humidity at the wet-bulb temperature of the sludge-air interface, and (3) other factors, such as velocity and turbulence of drying air expressed as a mass transfer coefficient. The heat-transfer rate for evaporation is determined by the following equation (U.S. EPA, 1979; WEF, 1998):

$$q_{conv} = h_c A(T_g - T_s) \qquad (14\text{-}30)$$

where q_{conv} = convective heat-transfer rate, kJ/h (Btu/h)
h_c = convection heat-transfer coefficient, kJ/m^2·h·°C (Btu/ft^2·h·°F)
A = area of the heated surface, m^2 (ft^2)
T_g = gas temperature, °C (°F)
T_s = temperature at sludge/gas interface, °C (°F)

The convection heat-transfer coefficient can be obtained from dryer manufacturers or from pilot studies.

Conduction. In conduction (indirect) drying systems, a solid retaining wall separates the wet sludge from the heat-transfer medium, usually steam or another hot fluid. Heat transfer for conduction is determined by the following equation (U.S. EPA, 1979; WEF, 1998):

$$q_{cond} = h_{cond} A(T_m - T_s) \qquad (14\text{-}31)$$

where q_{cond} = conductive heat-transfer rate, kJ/h (Btu/h)
h_{cond} = conductive heat-transfer coefficient, kJ/m²·h·°C (Btu/ft²·h·°F)
A = area of wetted surface exposed to gas, m² (ft²)
T_m = temperature of heating medium, °C (°F)
T_s = temperature sludge at drying surface, °C (°F)

The conductive heat-transfer coefficient, a composite term, includes the effects of the heat-transfer surface films of the sludge and the medium. The conduction heat-transfer coefficient can be obtained from dryer manufacturers or from pilot studies.

Radiation. In radiation (infrared) drying systems, infrared lamps, electric resistance elements, or gas-fired incandescent refractories supply radiant energy that transfers to the wet sludge and evaporates moisture. Radiation heat transfer is expressed as follows (U.S. EPA, 1979; WEF, 1998):

$$q_{rad} = C_s A\sigma(T_r^4 - T_s^4) \qquad (14\text{–}32)$$

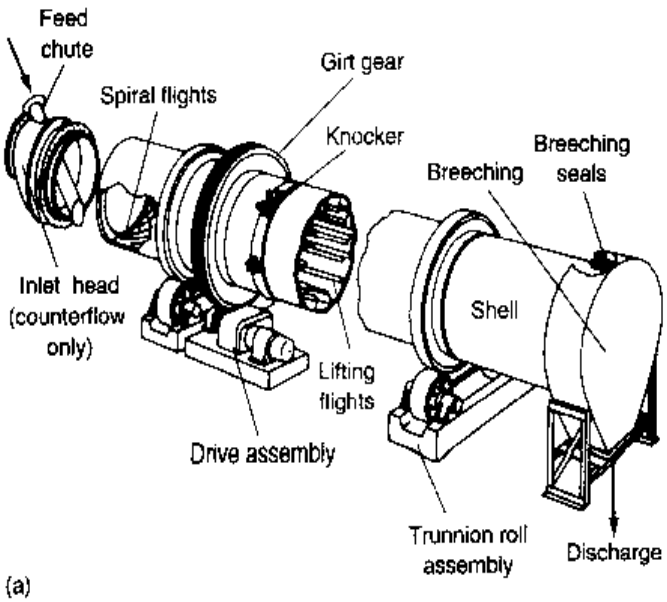
where q_{rad} = radiation heat-transfer rate, kJ/h (Btu/h)
C_s = emissivity of the drying surface, dimensionless
A = sludge surface area exposed to radiant source, m² (ft²)
σ = Stefan-Boltzmann constant, 20.41×10^{-8} kJ/m²·h·K⁴ (1.713×10^{-9} Btu/ft²·h·°R⁴)
T_r = absolute temperature of radiant source, K (°R)
T_s = absolute temperature of the sludge drying surface, K (°R)

Process Description

Heat dryers are classified as follows: direct, indirect, combined direct-indirect, and infrared. Direct and indirect dryers are described below as they are the types most commonly used for municipal biosolids drying. Coal, oil, gas, infrared radiation, or dried sludge may be used as the means of supplying the energy for heat drying.

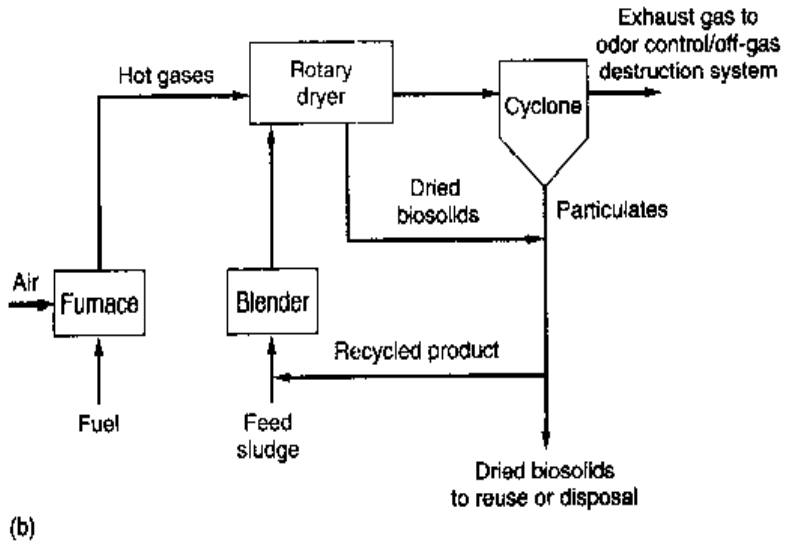
Direct Dryers. Direct (convection) dryers that have been used for drying municipal wastewater sludge are the flash dryer, rotary dryer, and fluidized-bed dryer. Although approximately 50 municipal flash dryers have been installed in the United States since 1940, only five or six currently remain in operation (WEF, 1998). Rotary dryers are used for a variety of industrial applications, and to a lesser extent for municipal wastewater sludge. Fluidized-bed drying of wastewater sludge is a relatively new application in the United States.

Flash Dryer Flash drying involves pulverizing the sludge in a cage mill or by an atomized suspension technique in the presence of hot gases. The equipment is designed so that the particles remain in contact with the turbulent hot gases long enough to accomplish mass transfer of moisture from sludge to the gases.



One operation involves a cage mill that receives a mixture of wet sludge or sludge cake and recycled dried sludge. The mixture contains approximately 40 to 50 percent moisture. The hot gases and sludge are forced up a duct in which most of the drying takes place and to a cyclone, which separates the vapor and solids. It is possible to

achieve a moisture content of 8 to 10 percent in this operation. The dried sludge may be used or sold as soil conditioner or it may be incinerated in a furnace in any proportion up to 100 percent of production. Flash-dried cake is extremely dusty, which creates the potential for fires and explosions (see following discussion on fire and explosion hazards).



Rotary Dryer Rotary dryers have been used for the drying of raw primary sludge, waste-activated sludge, and digested primary biosolids. A rotary dryer consists of a cylindrical steel shell that is rotated on bearings and usually is mounted with its axis at a slight slope from the horizontal (see Fig. 14–51*a*). The feed sludge is mixed with previously dried sludge cake in a blender located ahead of the dryer (see Fig. 14–51*b*). The blended feed sludge has a moisture content of approximately 65 percent that improves its ability to move through the dryer without sticking. The mixture and hot gases are conveyed to the discharge end of the dryer. During conveyance, axial flights along the

Figure 14–51

Rotary sludge dryer: (*a*) isometric view, (*b*) system schematic.

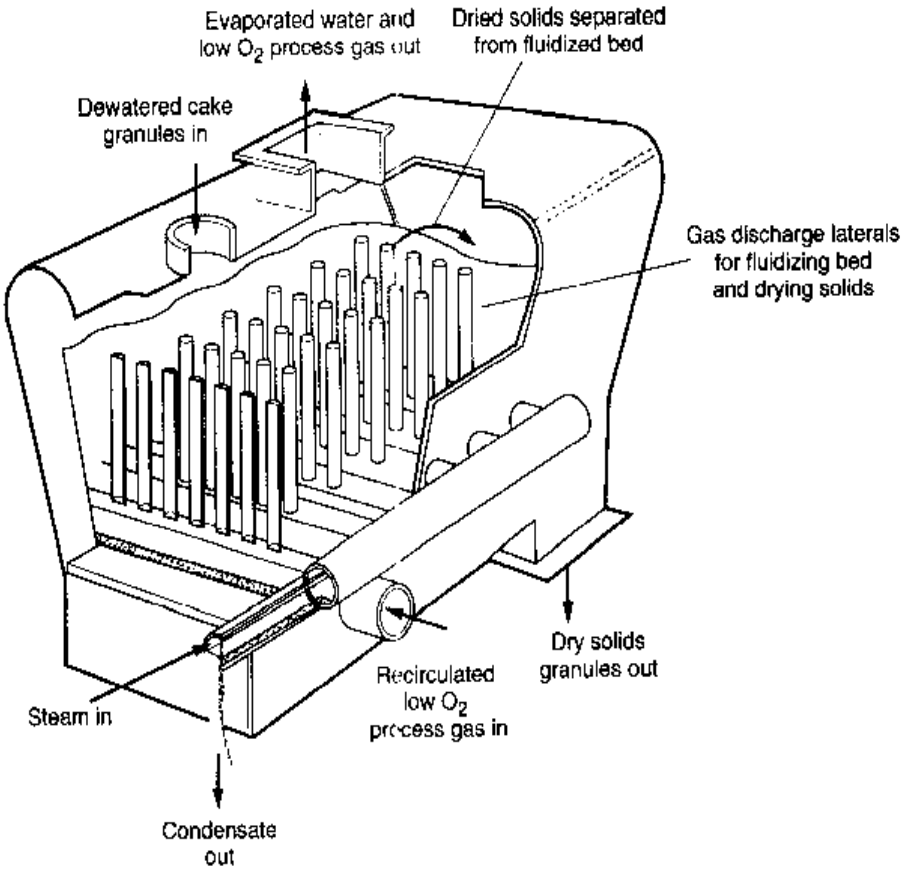
(a)

(b)

rotating interior wall pick up and cascade the sludge through the dryer. The product, which has a dry solids content of 90 to 95 percent, is screened and the oversize material passes through a crusher and then is transported to a recycle bin. The dried product is amenable to handling, storage, and marketing as a fertilizer or soil conditioner. Recently, a large rotary dryer facility for drying dewatered bisolids was installed in the Boston area for the Massachusetts Water Resources Authority.

Fluidized-Bed Dryer A new type of fluidized-bed dryer, developed in Europe, has been introduced recently into the United States (see Fig. 14–52). The dryer has the capability of producing a pellet product, similar to that obtained from rotary drying systems (Holcomb et al., 2000). The dryer system has certain components that are similar to rotary dryers: product classification and cooling of the product before storage and loading. The main differences are that a steam boiler and fluid-bed reactor are used in lieu of a hot gas furnace and rotary drum. The heat required for evaporation is supplied by steam via an in-bed heat exchanger. A uniform temperature of ~120°C (~230°F) is maintained in the bed through intimate contact between the sand granules and the fluidizing air.

Advantages cited for the dryer are (1) the product has a granular consistency suitable for use as a fuel or in soil blending to augment landfill cover, (2) the product has a low odor, (3) the system can be equipped for automatic operation, and (4) it has a smaller footprint than a rotary dryer. Disadvantages are that there is only one unit in



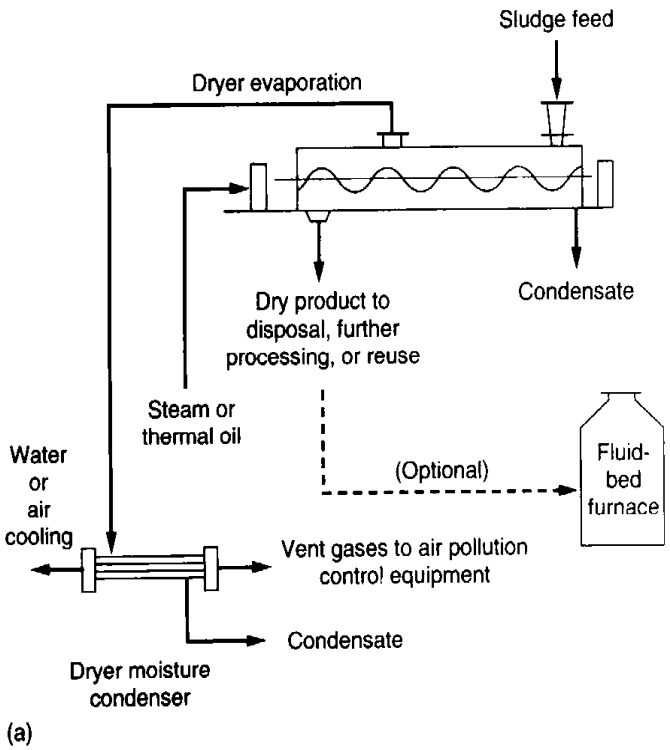


Figure 14–52
View of a fluidized-bed reactor. *(From Andritz.)*

operation in the United States (although several are in operation in Europe), and it uses a larger amount of electric power than a rotary-drum dryer because it requires a large induced-draft fan (Holcomb et al, 2000).

Indirect Dryers. Indirect dryers are designed in either a horizontal or vertical configuration. Horizontal dryers employ paddles, hollow flights, or disks mounted on one or more rotating shafts to convey biosolids through the dryer (see Fig. 14–53*a*). A heated medium, usually steam or oil, is circulated through the jacketed shell of the dryer and the hollow core of the rotating assembly. Dewatered biosolids are fed perpendicular to the dryer shaft and pass horizontally in a helical pattern through the dryer. The dryer performs the dual function of heat transfer and solids conveying. Drying occurs as the biosolids particles are broken up through agitation and come into contact with the heated metal surfaces in the dryer. The granular particles are both hot and abrasive. Moving parts, as in most dryers, will become abraded, and corrosion will accelerate the deterioration of the metal. The design of the agitator has to allow for efficient heat transfer, mixing of the sludge mass, and minimum fouling of the agitator. A weir at the discharge end ensures complete submergence of the heat-transfer surface in the biosolids being dried. The water vapor derived from the drying operation may be drawn off under a slightly negative pressure by an induced-draft fan located in the off-gas duct.

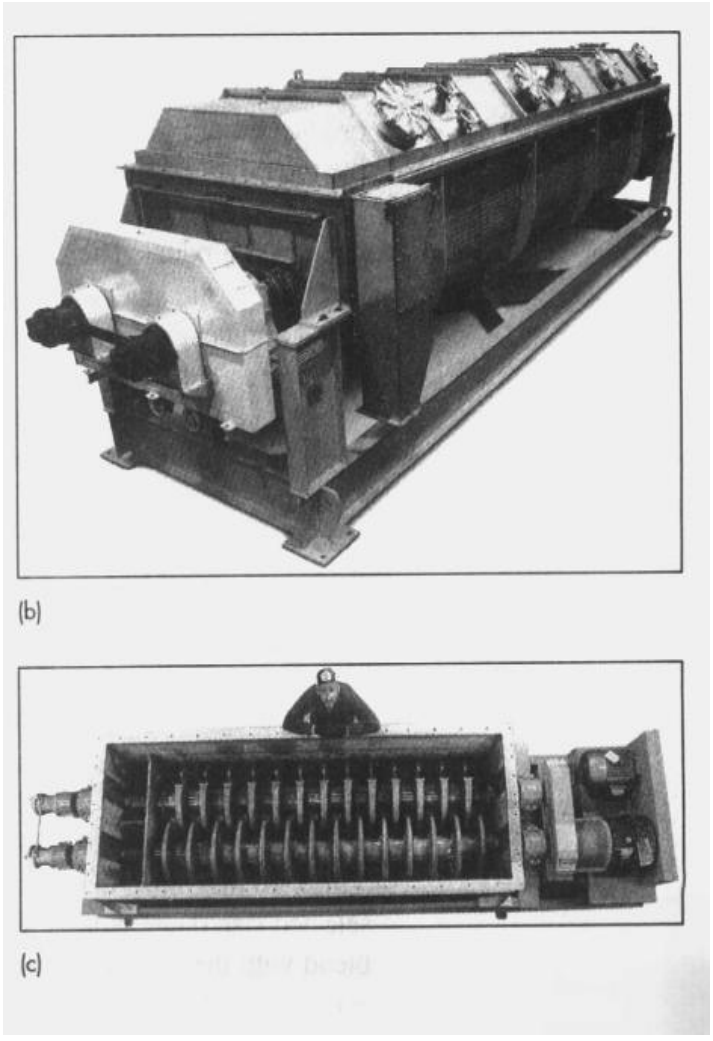

Figure 14–53

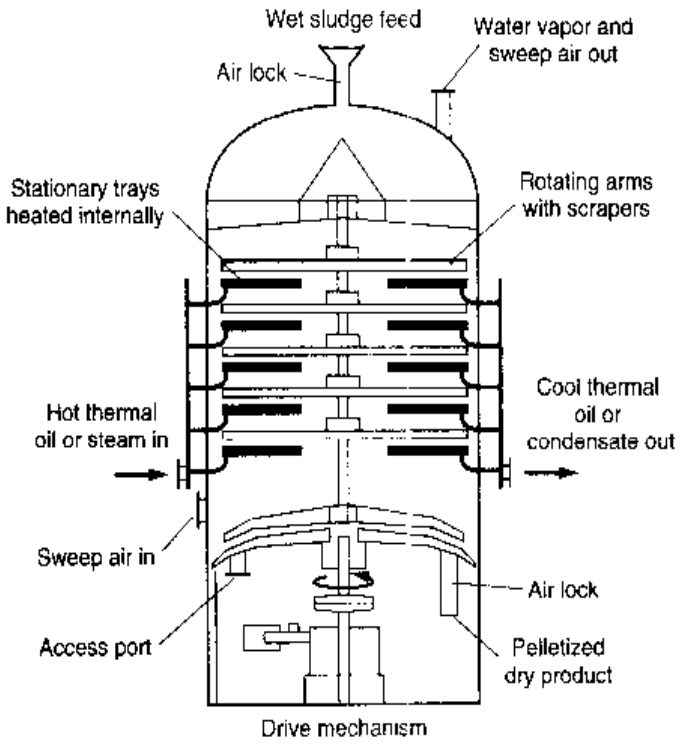

Figure 14–54

Cross section of a vertical indirect dryer. *(From Pelletech.)*

In vertical indirect dryers, sludge contacts a metal surface heated by a medium, such as steam or oil, and the heat is conductively transferred to the sludge (see Fig. 14–54). The sludge does not come in contact with the heating medium. Dewatered product (approximately 20 percent solids) mixed with recycled product is fed through the top inlet of a multistage dryer. Rotating arms move the sludge from the heated stationary tray to another in a rotating zigzag motion until it exits at the bottom as a dried, pelletized product. The rotating arms are equipped with adjustable scrapers that move and tumble the sludge in thin layers (20 to 30 mm) over the heated stationary trays. Dried product exits the dryer at a moisture content ranging from 5 to 8 percent and at a size of 2 to 4 mm (O'Brien and Schweizer, 1990).

In indirect dryers, sludge is dried to a specific level of dryness and discharged to a product conveyor for transfer to storage. Solids concentrations in the dryer product can range from 65 to over 95 percent depending on the ultimate use or disposal of the product.

Product Characteristics

The characteristics of the finished biosolids product depend on the type of sludge, the type of preprocessing, and the physical configuration of the drying surfaces. Raw primary sludge produces a fibrous, dusty material that is difficult to manage. Digested sludge can produce an amorphous particle that can be handled and transported. Particles will vary in size from 6 to 8 mm. The best size range for marketing may be from 3 to 5 mm. To maximize marketing potential, screening for sizes smaller and larger than the selected size range will be required. The fines and oversize particles can be returned to blend with the incoming sludge (see Fig. 14–51*b*), hence increasing the solids content entering the dryer but not changing the amount of moisture that must be evaporated.

In the range of 45 to 65 percent dry solids, the sludge mass passes through a very plastic and sticky phase that can impede the rotation of drying paddles or disks, particularly in horizontal dryers. Care should be taken in selecting equipment that is capable of being restarted if the dryer should be stopped while the sludge mass is in this phase.

Product Transport and Storage

Although the granular product from heat drying is reasonably durable, long conveyors that create an abrasive action such as screw conveyors and drag conveyors should be avoided. Even the use of pneumatic and dense-phase pneumatic conveyors may be too abrasive and cause crumbling and dust formation. Open or folded belt conveyors may be the preferred choices.

Upon exiting the dryer, the hot biosolids should be cooled to below 50°C (120°F) before placing in silos or storage vessels. The combination of initial heat plus heat that could be introduced by biological activity in the silo can cause smoldering or an open flame. This condition can occur where the drying operation is expected to pass through frequent start-and-stop cycles and drying may not be complete. In general, the product entering storage should be from 92 to 98 percent dry solids.

Fire and Explosion Hazards

With the fine particles and high levels of dryness in heat-dried sludge, hazards due to fire and explosion may exist when dried sludge is conveyed or stored. An organic dust suspended in air can rapidly combust if exposed to an ignition source. The heat of combustion can rapidly increase the volume and/or pressure of hot combustion products. If the pressure exceeds the rupture strength of the containing vessel, an explosion occurs. The phenomenon is called "deflageration," and deflageration explosions are the most serious concern when handling dried biosolids (Haug et al., 1993). Design considerations that are recommended for preventing dust explosions are given in Table 14–46.

Air Pollution and Odor Control

Two important control measures associated with heat drying of sludge are fly ash collection and odor control. Cyclone separators having efficiencies of 75 to 80 percent are suitable for vent gas temperatures up to 340 or 370°C (650 or 700°F). Wet scrubbers have higher efficiencies and will condense some of the organic matter in the vent gas but may carry over water droplets.

Sludge drying occurs in direct dryers at temperatures of approximately 370°C (700°F), whereas temperatures ranging from 650 to 760°C (1200 to 1400°F) are required for complete incineration. To achieve destruction of odors, the exhaust gases must reach approximately 730°C (1350°F). Thus, if the gases evolved in the drying process are reheated in an incinerator to a minimum of 730°C, odors will be diminished greatly. At lower temperatures, partial oxidation of odor-producing compounds may occur, resulting in an increase in the intensity or disagreeable character of odor produced. In the absence of an incinerator, thermal oxidizers have proved most effective in odor destruction. Thermally treated sludge vapors, aldehydes, and various species of sulfides and disulfides (methyl, dimethyl, and carbonyl) are difficult to remove without the use of a thermal oxidizer.

Table 14–46
Prevention measures to avoid dust hazards in the heat drying of sludge and biosolids[a]

Item	Prevention measure
Venting system (for processing, conveyance, and storage components)	Provide explosion relief vents Size explosion vents for "worst case" explosion in an air atmosphere
Nitrogen padding	Provide a nitrogen inerting atmosphere for all dried biosolids conveyance and processing facilities. Maintain oxygen levels below 5 percent by volume to reduce potential for self-heating and ignition of hot biosolids
Electrical equipment	Design in accordance with appropriate National Fire Protection Association criteria. If dust is present, all equipment must be dusttight and electronic cabinets nitrogen purged. Motor control centers that contain sparking devices, such as starters and relays, must be located outside classified areas
Ducts and vessels	Electrically bond and ground all conductive elements of the system that contact dried biosolids
Maintenance	Keep areas clean to prevent accumulation of dust. Any vessel containing powder must have powder removed before opening or the powder must be cooled to ambient temperatures before safe entry clearance is given
Miscellaneous	Eliminate or move outside all heat sources from classified areas. Equip electric motors located in a Class II, Division 2 area with Class F insulation to reduce "skin" temperatures

[a] Adapted from Haug et al. (1993)

14–15 INCINERATION

Incineration of sludge involves the total conversion of organic solids to oxidized end products, primarily carbon dioxide, water, and ash. The major advantages of incineration are (1) maximum volume reduction thereby lessening disposal requirements, (2) destruction of pathogens and toxic compounds, and (3) energy recovery potential (U.S. EPA, 1985*a*). Disadvantages include (1) high capital and operating cost, (2) highly skilled operating and maintenance staffs are required, (3) the residuals produced (air emissions and ash) may have adverse environmental effects, and (4) disposal of residuals, which may be classified as hazardous wastes, if they exceed prescribed maximum pollutant concentrations. Incineration is used most commonly by medium- to large-sized plants with limited disposal options.

Sludges processed by incineration are usually dewatered, untreated sludges. It is normally unnecessary to stabilize sludge before incineration. In fact, such practice may be detrimental because stabilization, specifically aerobic and anaerobic digestion, decreases the volatile content of the sludge and consequently increases the requirement for an auxiliary fuel. Sludges may be incinerated separately or in combination with municipal solid wastes.

The incineration processes considered in the following discussion include multiple-hearth incineration, fluidized-bed incineration, and coincineration with municipal solid

waste. Before discussing these processes, it will be helpful to review some fundamental aspects of complete combustion.

Fundamental Aspects of Complete Combustion

Combustion is the rapid exothermic oxidation of combustible elements in fuel. Incineration is complete combustion. The predominant elements in the carbohydrates, fats, and proteins composing the volatile matter of sludge are carbon, oxygen, hydrogen, and nitrogen (C-O-H-N). The approximate percentages of these may be determined in the laboratory by a technique known as *ultimate analysis*.

Oxygen requirements for complete combustion of a material may be determined from a knowledge of its constituents, assuming that carbon and hydrogen are oxidized to the ultimate end products CO_2 and H_2O. The formula becomes

$$C_aO_bH_cN_d + (a + 0.25c - 0.5b)O_2 \rightarrow aCO_2 + 0.5cH_2O + 0.5dN_2 \qquad (14\text{-}33)$$

The theoretical quantity of air required will be 4.35 times the calculated quantity of oxygen, because air is composed of 23 percent oxygen on a mass basis. To ensure complete combustion, excess air amounting to about 50 percent of the theoretical amount will be required. A materials balance must be made to include the above compounds and the inorganic substances in the sludge, such as the inert material and moisture, and the moisture in the air. The specific heat of each of these substances and of the products of combustion must be taken into account in determining the heat required for the incineration process.

Heat requirements will include the sensible heat Q_s in the ash, plus the sensible heat required to raise the temperature of the flue gases to 760°C (1400°F) or whatever higher temperature of operation is selected for complete oxidation and elimination of odors, less the heat recovered in preheaters or recuperators. Latent heat Q_e must also be furnished to evaporate all of the moisture in the sludge. The total heat required may be expressed as

$$Q = \Sigma Q_s + Q_e = \Sigma C_p W_s (T_2 - T_1) + W_w \lambda \qquad (14\text{-}34)$$

where Q = total heat, kJ (Btu)
Q_s = sensible heat in the ash, kJ (Btu)
Q_e = latent heat, kJ (Btu)
C_p = specific heat for each category of substance in ash and flue gases, kJ/kg·°C (Btu/lb·°F)
W_s = mass of each substance, kg (lb)
W_w = mass of water, kg (lb)
T_1, T_2 = initial and final temperatures
λ = latent heat of evaporation, kJ/kg (Btu/lb)

Reduction of moisture content of the sludge is the principal way to lower heat requirements, and the moisture content may determine whether additional fuel will be needed to support combustion.

The heating value of a sludge may be determined by (U.S. EPA, 1979; WEF, 1998):

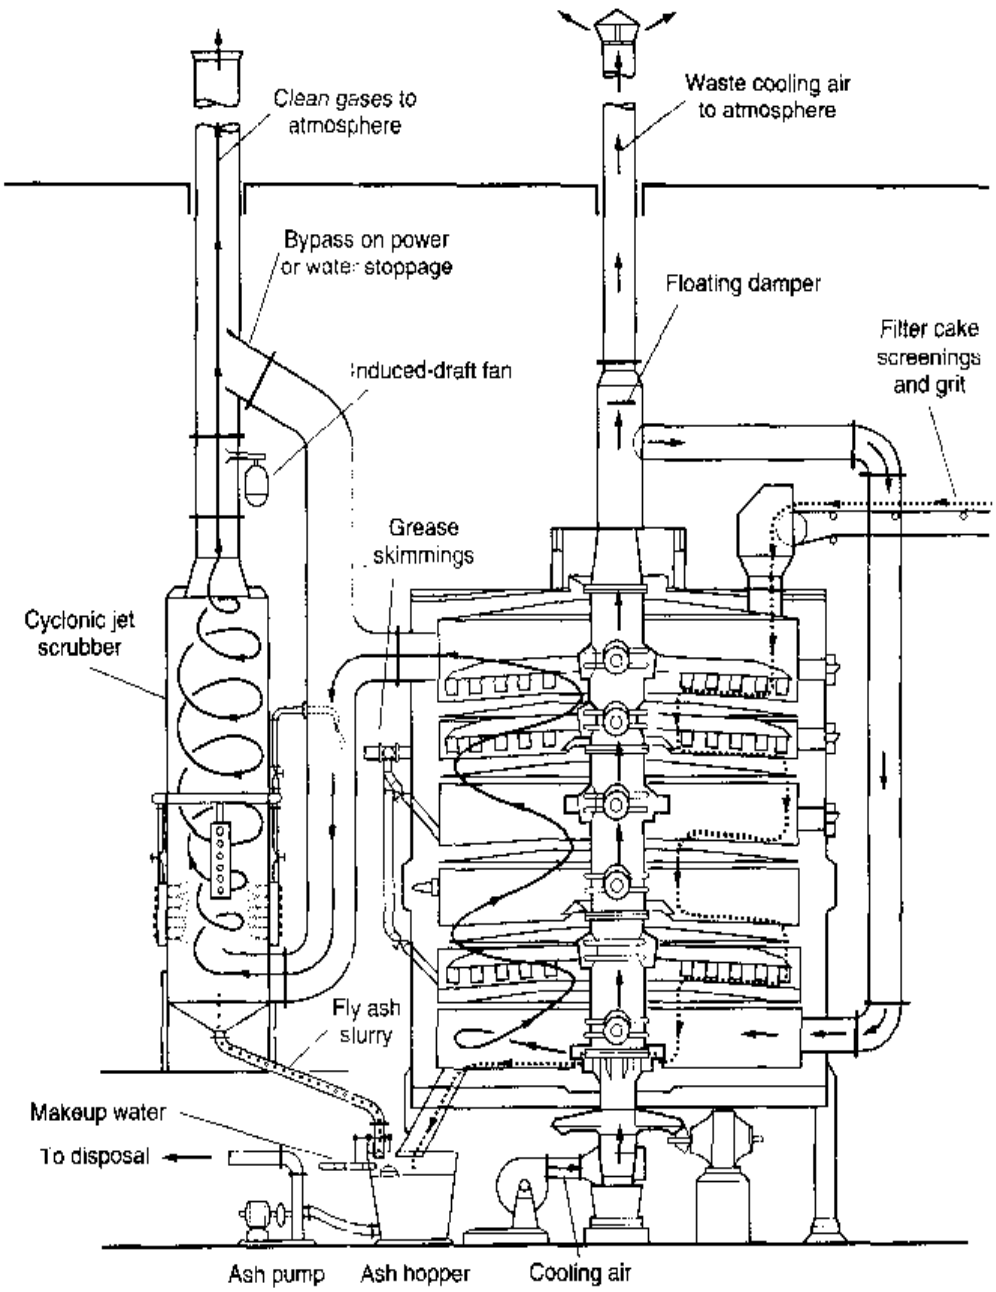
$$Q = 14{,}544C + 62{,}208(H - O/8) + 4050S \qquad (14\text{-}35)$$

where Q = total value, kJ/kg dry solids (Btu/lb = kJ/kg × 0.43)
C = carbon, percent
H = hydrogen, percent
O = oxygen, percent
S = sulfur, percent

The fuel value of sludge ranges widely depending on the type of sludge and the volatile solids content. The fuel value of untreated primary sludge is the highest, especially if it contains appreciable amounts of grease and skimmings. Where kitchen food grinders are used, the volatile and thermal content of the sludge will also be high. Digested biosolids have significantly lower heating values than raw sludge. Typical heating values for various types of sludge are reported in Table 14–47. The heating value for sludge is equivalent to that of some of the lower grades of coal.

To design an incinerator for solids volume reduction, a detailed heat balance must be prepared. Such a balance must include heat losses through the walls and pertinent equipment of the incinerator, as well as losses in the stack gases and ash. Approximately 4.0 to 5 MJ (4000 to 5500 Btu) are required to evaporate each kg (2.2 lb) of water in the sludge. Heat is obtained from the combustion of the volatile matter in the sludge and from the burning of auxiliary fuels. For untreated primary sludge incineration, the auxiliary fuel is needed only for warming up the incinerator and maintaining the desired temperature when the volatile content of the sludge is low. The design should include provisions for auxiliary heat for startup and for assuring complete oxidation at the desired temperature under all conditions. Fuels such as oil, natural gas, or excess digester gas are suitable.

Multiple-Hearth Incineration



Multiple-hearth incineration is used to convert dewatered sludge cake to an inert ash. Because the process is complex and requires specially trained operators, multiple-hearth furnaces are normally used only in large plants. Multiple-hearth incinerators have been

Table 14–47
Typical heating values for various types of sludge and biosolids[a]

Type of sludge/biosolids	Btu/lb of total solids[b]		kJ/kg of total solids[b]	
	Range	Typical	Range	Typical
Raw primary	10,000–12,500	11,000	23,000–29,000	25,000
Activated	8,500–10,000	9,000	20,000–23,000	21,000
Anaerobically digested primary	4,000–6,000	5,000	9,000–14,000	12,000
Raw chemically precipitated primary	6,000–8,000	7,000	14,000–18,000	16,000
Biological filter	7,000–10,000	8,500	16,000–23,000	20,000

[a]Adapted, in part, from WEF (1988).
[b]Lower value applies to plants with long solids retention times.

Figure 14–55
Typical multiple-hearth incinerator.

used at smaller facilities where land for the disposal of sludge is limited and at chemical treatment plants for the recalcining of lime sludges.

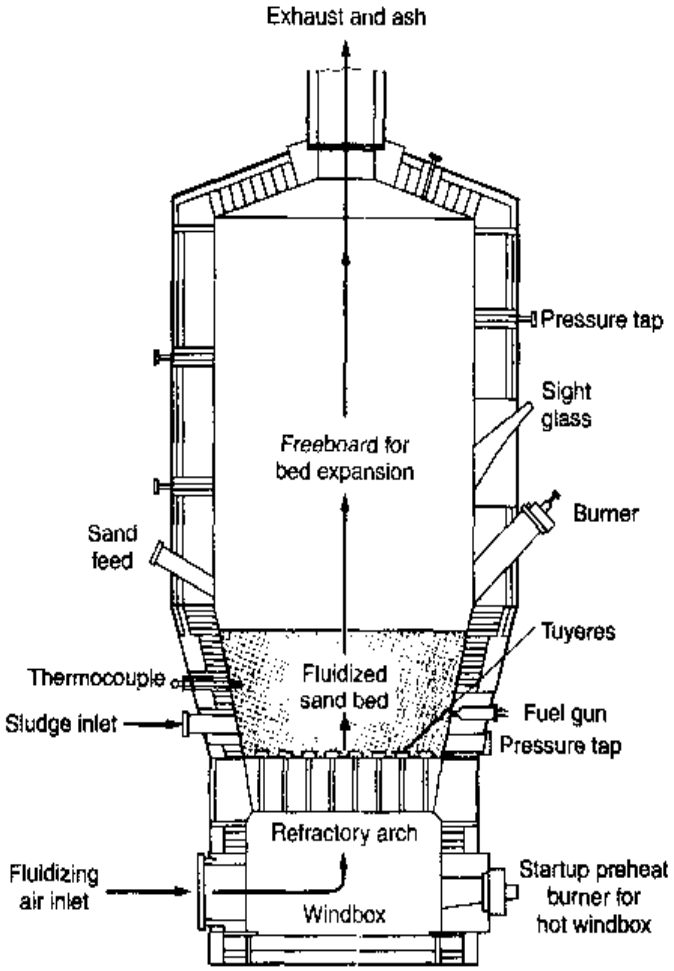
As shown on Fig. 14–55, sludge cake is fed onto the top hearth and is slowly raked to the center. From the center, sludge cake drops to the second hearth, where the rakes move it to the periphery. The sludge cake then drops to the third hearth and is again raked to the center. The hottest temperatures are on the middle hearths, where the sludge burns and where auxiliary fuel is also burned as necessary to warm up the furnace and to sustain combustion. Preheated air is admitted to the lowest hearth and is further heated by the sludge as the air rises past the middle hearths where combustion is occurring. The air then cools as it gives up its heat to dry the incoming sludge on the top hearths.

The highest moisture content of the flue gas is found on the top hearths where sludge with the highest moisture content is heated and some water is vaporized. Cooling

air is initially blown into the central column and hollow rabble arms to keep them from overheating. A large portion of this air, after passing out of the central column at the top, is recirculated to the lowest hearth as preheated combustion air.

A multiple-hearth furnace may also be designed as a dryer only. In this case, a furnace is needed to provide hot gases, and the sludge and gases both proceed downward through the furnace in parallel flow. Parallel flow of product and hot gases is frequently used in drying operations to prevent burning or scorching heat-sensitive materials.

Feed sludge must contain more than 15 percent solids because of limitations on the maximum evaporating capacity of the furnace. Auxiliary fuel is required usually when the feed sludge contains between 15 and 30 percent solids. Feed sludge containing more than 50 percent solids may create temperatures in excess of the refractory and metallurgical limits of standard furnaces. Average loading rates of wet cake are approximately 40 $kg/m^2 \cdot h$ (8 $lb/ft^2 \cdot h$) of effective hearth area but may range from 25 to 75 $kg/m^2 \cdot h$ (5 to 15 $lb/ft^2 \cdot h$).



In addition to dewatering, required ancillary processes include ash handling systems and some type of wet or dry scrubber to meet air pollution requirements. In wet scrubbers, scrubber water comes in contact with and removes most of the particulate matter in the exhaust gases. The recycle BOD and COD is nil, and the total suspended solids content is a function of the particulates captured in the scrubber. Under proper operating conditions, particulate discharges to the air from wet scrubbers are less than 0.65 $kg/10^3$ kg (1.3 lb/ton) of dry sludge input.

Ash handling may be either wet or dry. In the wet system, the ash falls into an ash hopper located beneath the furnace, where it is slurried with water from the exhaust gas scrubber. After agitation, the ash slurry is pumped to a lagoon or is dewatered mechanically. In the dry system, the ash is conveyed mechanically to a storage hopper for discharge into a truck for eventual disposal as fill material. The ash is usually conditioned with water. Ash density is about 5.6 kg/m^3 (0.35 lb/ft^3) dry and 880 kg/m^3 (55 lb/ft^3) wet.

Fluidized-Bed Incineration

The fluidized-bed incinerator used commonly for sludge incineration is a vertical, cylindrically shaped, refractory-lined steel shell that contains a sand bed (media) and fluidizing air orifices to produce and sustain combustion (see Fig. 14–56). The fluidized-bed incinerator ranges in size from 2.7 to 7.6 m (9 to 25 ft) in diameter. The sand bed, when quiescent, is approximately 0.8 m (2.5 ft) thick, and rests on a brick dome or refractory-lined grid. The sand bed support area contains orifices, called "tuyeres," through which air is injected into the incinerator at a pressure of 20 to 35 kN/m^2 (3 to 5 lb_f/in^2) to fluidize the bed. At low velocities, combustion gas "bubbles" appear within the fluidized bed. The main bed of suspended particles remains at a certain elevation in the combustion chamber and "boils" in place. Units that function in this manner are called "bubbling-bed" incinerators. The mass of suspended solids and gas, when active and at operating temperature, expands to about double the at-rest volume. Sludge is mixed quickly within the fluidized bed by the turbulent action of the bed. The minimum temperature needed in the sand bed prior to injection of sludge is approximately 700°C (1300°F). The temperature of the sand bed is controlled between 760 and 820°C (1400 and 1500°F). Evaporation of the water and combustion of the sludge solids takes place rapidly. Combustion gases and ash leave the bed and are transported through the freeboard area to the gas outlet through the top of the incinerator. No ash exits from the bed

Figure 14-56
Typical fluidized-bed incinerator.

at the bottom of the incinerator. Combustion gases and entrained ash are scrubbed, normally with a venturi scrubber.

Recycle flows consist of scrubber water produced at a rate of approximately 25 to 40 L/kg (3 to 5 gal/lb) of dry solids feed to the fluidized bed. Most of the ash (99 percent) is captured in the scrubber water, and the total suspended solids content is approximately 20 to 30 percent of the dry solids feed. The recycle flow is normally directed to an ash lagoon. BOD and COD are nil. Particulates and other air emissions are comparable to those from the multiple-hearth incinerator.

The combustion process is controlled by varying the sludge feed rate and the air flow to the reactor to oxidize completely all the organic material. If the process is operated continuously or with shutdowns of short duration, there is no need for auxiliary fuel after startup.

A modification of the fluidized-bed incineration technology is the "circulating-bed" incinerator. In the circulating-bed unit, the reactor gas passes through the combustion chamber at much higher velocities, ranging from 3 to 8 m/s (10 to 25 ft/s). At these velocities, the bubbles in the fluidized bed disappear and streamers of solids and gas prevail. The entire mass of entrained particles flow up the reactor shaft to a particle separator, are deposited in storage momentarily, and are recirculated back to the primary combustion zone in the bottom of the reactor. Ash is removed continuously from the bottom of the bed. On turndown, the circulating bed becomes a bubbling bed.

Like the multiple hearth, the fluidized bed, though reliable, is complex and requires the use of trained personnel. Because fluidized-bed incinerators are complex, they are normally used in medium to large plants, but may be used in plants with lower flow ranges where land for the disposal of sludge is limited.

Coincineration with Municipal Solid Waste

Coincineration is the process of incinerating wastewater sludges with municipal solid wastes. The major objective is to reduce the combined costs of incinerating sludge and solid wastes. Coincineration is not practiced widely. The process has the advantages of producing the heat energy necessary to evaporate water from sludges, supporting combustion of solid wastes and sludge, and providing an excess of heat for steam generation, if desired, without the use of auxiliary fossil fuels. In properly designed systems, the hot gases from the process can be used to remove moisture from sludges to a content of 10 to 15 percent. Direct feeding of sludge cake containing 70 to 80 percent moisture over solid wastes on traveling or reciprocating grates has been found to be ineffective.

For systems operating without heat recovery, a disposal ratio of 1 kg (2.2 lb) of dry wastewater solids to 4.6 kg (11 lb) of solid wastes is fired in normal operation. In the case of the water-walled boiler with heat recovery, the ratio is approximately 1 kg of dry (industrial plant) solids to 7 kg (17 lb) of solid wastes.

Based on past experience in municipal solid-waste disposal, the application of coincineration will likely continue to proceed very slowly, despite the advantages to the community in combining the two waste-disposal functions.

Air-Pollution Control

Incineration methods for wastewater sludge have the potential to be significant contributors to air pollution. Air contaminants associated with incineration can be divided into two categories: (1) odors and (2) combustion emissions. Odors are particularly offensive to the human senses and special attention is required to minimize nuisance odor emissions. Combustion emissions vary depending upon the type of thermal reduction technology employed and the nature of the sludge and auxiliary fuel used in the combustion process. Combustion emissions of particular concern are particulates, oxides of nitrogen, acid gases, and specific constituents such as hydrocarbons and heavy metals (mercury, beryllium, etc.). Regulations promulgated by the U.S. EPA concerning incinerator emissions are discussed in Sec. 14–2.

14–16 SOLIDS MASS BALANCES

Solids-processing facilities, such as thickening, digestion, and dewatering, produce waste streams that must be recycled to the treatment process or to treatment facilities designed specifically for the purpose. The recycled flows impose an incremental solids, hydraulic, and organic and nutrient load on the wastewater-treatment facilities that must be considered in the plant design. When the flows are recycled to the treatment process, they should be directed to the head of the plant and blended with the plant flow following preliminary treatment. Equalization facilities can be provided for the recycled flows so that their reintroduction into the plant flow will not cause a shock loading on the subsequent treatment processes. To predict the incremental loads imposed by the recycled flows, it is necessary to perform a materials mass balance for the treatment system.

Preparation of Solids Mass Balances

Typically, a materials mass balance is computed on the basis of average flow and average BOD and total suspended solids concentrations. To size certain facilities properly, such as sludge storage tanks and plant piping, it is also important to perform a materials mass balance for the maximum expected concentration of BOD and TSS in the untreated wastewater. However, the maximum concentrations will not usually result in a proportional increase in the recycled BOD and TSS. The principal reason is that the storage capacity in the wastewater and sludge-handling facilities tends to dampen peak solids loads. For example, for a maximum TSS load equal to twice the average value, the resulting peak solids loading to a dewatering unit may be only 1.5 times the average loading. Further, it has been shown that periods of maximum hydraulic loading typically do not correlate with periods of maximum BOD and TSS. Therefore, coincident maximum hydraulic loadings should not be used in the preparation of a materials mass balance for maximum organic loadings (see Chap. 5). The preparation of a mass balance is illustrated in Example 14–11.

Performance Data for Solids-Processing Facilities

To prepare a materials mass balance, it is necessary to have information on the operational performance and efficiency of the various unit operations and processes that are used for the processing of waste solids. Representative data on the solids capture and expected solids concentrations for the most commonly used operations are reported in Tables 14–48 and 14–49. These data were derived from an analysis of the records from

Table 14–48
Typical solids concentrations and capture values for various solids-processing methods

Operation	Solids concentration, %		Solids capture, %	
	Range	Typical	Range	Typical
Gravity thickeners:				
Primary sludge only	4–10	6	85–92	90
Primary and waste-activated	2–6	4	80–90	85
Flotation thickeners:				
With chemicals	4–6	5	90–98	95
Without chemicals	3–5	4	80–95	90

a number of installations throughout the United States. The wide variation that can occur in the reported values is apparent; thus, the values in Tables 14–48 and 14–49 should be used *only* if no other information is available. Wherever possible, local conditions and data should be used in performing the mass balance.

Impact of Return Flows and Loads

In addition to performance data for expected solids capture and constituent concentrations for the various process components, data for the expected concentrations of BOD and TSS in the return flows must also be included in preparing of mass balances. If the quantities and characteristics of recycled flows and loads are not accounted for properly, the facilities that receive them may be underdesigned significantly. The major impacts of return flows and measures that can mitigate these impacts are summarized in Table 14–50.

Table 14–50
Major impacts and potential mitigation measures for return flows from sludge and biosolids-processing facilities[a]

Source of return flow	Impact	Process impacted	Mitigation measure
Sludge thickening	Effluent degradation by colloidal SS	Sedimentation	Add flocculent aid ahead of sedimentation tank
			Separately thicken primary and biological sludges
			Optimize gravity thickener dilution water
	Floating sludge	Sedimentation	Minimize gravity thickener detention time
			Remove sludge continuously and uniformly
	Odor release and septicity	Recycle point	Reduce gravity thickener detention time
			Return flows ahead of aerated grit chamber
			Provide odor containment, ventilation, and treatment (scrubber or biofilter)
		Biological	Return odorous flows to aeration tank
			Remove sludge continuously and uniformly
			Provide separate return flow treatment (with other recycle streams)
	Solids buildup	Sedimentation	Increase dewatering unit operation time
		Biological	Remove sludge continuously and uniformly
			Include recycle loads in mass balance analysis
Sludge dewatering	Effluent degradation by colloidal suspended solids	Sedimentation	Optimize dewatering unit solids capture by improved sludge conditioning
			Add flocculent aid ahead of sedimentation tank
			Return centrate/filtrate to thickener
			Provide separate return flow treatment (with other recycle streams)
	Solids buildup	Sedimentation	Increase dewatering unit operation time
		Biological	Remove sludge continuously and uniformly
			Reduce trickling-filter recycle rate
			Include recycle loads in mass balance analysis
Sludge stabilization	Effluent degradation by excessive BOD load	Biological	Optimize supernant/decant removal, i.e., remove smaller amounts over a longer period of time, or reschedule removal to off-peak periods
			Provide separate return flow treatment
			Increase RBC speed
			Increase MLVSS in activated-sludge system (decrease F:M ratio)
			Increase dissolved oxygen level in activated-sludge process
	Effluent degradation by nutrients	Biological	Regulate digester supernatant/decant removal
			Thicken sludge before stabilization
			Provide separate return flow treatment

(continued)

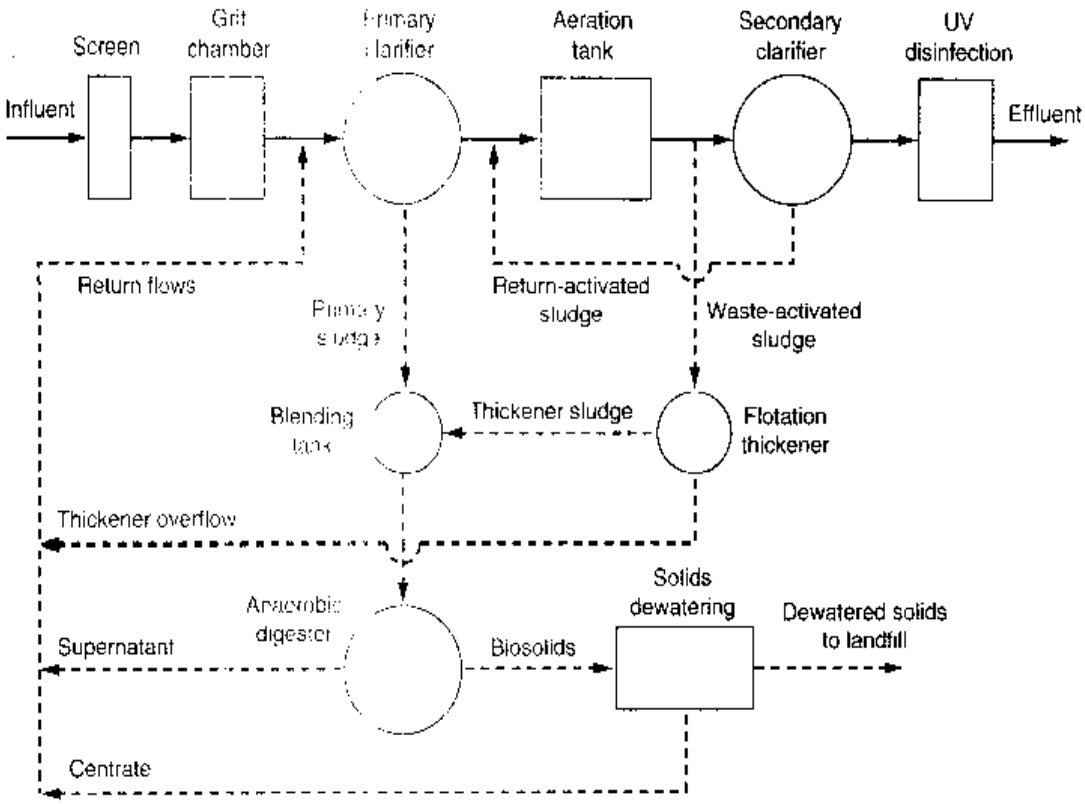

Table 14–50 (*Continued*)

Source of return flow	Impact	Process impacted	Mitigation measure
Washwater from depth filters	Hydraulic surges	Sedimentation	Provide backwash storage for flow equalization Schedule filter backwashing for off-peak periods

[a] Adapted, in part, from U.S. EPA (1987b).

EXAMPLE 14–11 Preparation of Solids Mass Balance for a Secondary Treatment Facility Prepare a solids balance for the treatment flow diagram shown in the following figure, using an iterative computational procedure.

1. Definition of terms
   BOD_C = biochemical oxygen demand expressed as a concentration, g/m^3
   BOD_M = biochemical oxygen demand expressed as a mass, kg/d
   TSS_C = total suspended solids expressed as a concentration, g/m^3
   TSS_M = total suspended solids expressed as a mass, kg/d
   Assume for the purpose of this example that the following data apply:
2. Wastewater flowrates
   a. Average dry weather flow = 21,600 m^3/d
   b. Peak dry weather flow = 2.5(21,600 m^3/d) = 53,900 m^3/d
3. Influent characteristics
   a. BOD_C = 375 g/m^3
   b. TSS_C = 400 g/m^3
   c. TSS_C after grit removal = 360 g/m^3
4. Solids characteristics
   a. Concentration of primary solids = 6%
   b. Concentration of thickened waste-activated sludge = 4%
   c. Total suspended solids in digested sludge = 5%
   d. For the purposes of this example, assume that the specific gravity of the solids from the primary sedimentation tank and the flotation thickener is equal to 1.0
   e. Fraction of the biological solids that are biodegradable = 65%
   f. The value of BOD_C can be obtained by multiplying the value of UBOD by a factor of 0.68 (corresponds to a k value of 0.23 d^{-1} in the BOD equation, see Chap. 2)
5. Effluent characteristics
   a. BOD_C = 20 g/m^3
   b. TSS_C = 22 g/m^3

Solution

1. Convert the given constituent quantities to daily mass values.
   a. BOD_M in influent:

   $$BOD_M = (21{,}600\ m^3/d)(375\ g/m^3)/(10^3\ g/kg)$$
   $$= 8100\ kg/d$$

   b. TSS_M in influent:

   $$TSS_M = (21{,}600\ m^3/d)(400\ g/m^3)/(10^3\ g/kg)$$
   $$= 8640\ kg/d$$

   c. TSS_M after grit removal (influent to primary settling tanks):

   $$TSS_M = (21{,}600\ m^3/d)(360\ g/m^3)/(10^3\ g/kg)$$
   $$= 7776\ kg/d$$

2. Estimate the concentration of soluble BOD_C in the effluent using the following relationship:

   Effluent BOD_C = influent soluble BOD_C escaping treatment + BOD_C of effluent TSS_C

   a. Determine the BOD_C of the effluent TSS_C.
      i. Biodegradable portion of effluent TSS_C is 0.65 (22 g/m^3) = 14.3 g/m^3

ii. UBOD of the biodegradable effluent TSS_C is [0.65(22 g/m^3)](1.42 g/g) = 20.3 g/m^3

iii. BOD_C of effluent suspended solids = 20.3 g/m^3 (0.68) = 13.8 g/m^3

b. Solve for the influent soluble BOD_C escaping treatment.

$20 \text{ g/m}^3 = S + 13.8 \text{ g/m}^3$

$S = 6.2 \text{ g/m}^3$

3. Prepare the first iteration of the solids balance. (In the first iteration, the effluent wastewater TOTAL suspended solids and the biological solids generated in the process are distributed among the unit operations and processes that make up the treatment system.)

a. Primary setting

i. Operating parameters:

BOD_C removed = 33%

TSS_C removed = 70% (see also Fig. 5–46)

ii. BOD_M removed = 0.33(8100 kg/d) = 2700 kg/d

iii. BOD_M to secondary = (8100 − 2700) kg/d = 5400 kg/d

iv. TSS_M removed = 0.7(7776 kg/d) = 5443 kg/d

v. TSS_M to secondary = (7776 − 5443) kg/d = 2333 kg/d

b. Determine the volatile fraction of primary sludge.

i. Operating parameters:

Volatile fraction of TSS_C in influent = 67%
Volatile fraction of grit = 10%
Volatile fraction of incoming TSS_C discharged to the secondary process = 85%

ii. Volatile suspended solids (VSS_M) in influent prior to grit removal = 0.67 (8640 kg/d) = 5789 kg/d

iii. VSS_M removed in grit chamber = 0.10(8640 − 7776) kg/d = 86 kg/d

iv. VSS_M in secondary influent, kg/d = 0.85(2333 kg/d) = 1983 kg/d

v. VSS_M in primary sludge, kg/d = (5789 − 86 − 1983) kg/d = 3710 kg/d

vi. Volatile fraction in primary sludge = [(3710 kg/d)/(5443 kg/d)](100%) = 68.2%

c. Secondary process

i. Operating parameters:

Mixed-liquor TSS_C = 4375 g/m^3

Volatile fraction of mixed-liquor suspended solids = 0.80 TSS_C

Y_{obs} = 0.3125

ii. Determine the effluent mass quantities.

$BOD_M = (21{,}600 \text{ m}^3/\text{d})(20 \text{ g/m}^3)/(10^3 \text{ g/kg}) = 432 \text{ kg/d}$

$TSS_M = (21{,}600 \text{ m}^3/\text{d})(22 \text{ g/m}^3)/(10^3 \text{ g/kg}) = 475 \text{ kg/d}$

iii. Estimate the mass of volatile solids produced in the activated-sludge process that must be wasted. [The required value is computed using Eq. (8–14)].

$$P_{x,\text{VSS}} = Y_{\text{obs}}\, Q(S_o - S)/(10^3\ \text{g/kg})$$

$$= \frac{0.3125(21{,}600\ \text{m}^3/\text{d})[(250 - 6.2)\ \text{g/m}^3]}{(10^3\ \text{g/kg})} = 1646\ \text{kg/d}$$

Note: The actual flowrate will be the primary influent less the flowrate of the primary underflow. However, the primary underflow is normally small and can be neglected. If the underflow is significant, the actual flowrate should be used to determine the volatile solids production.

iv. Estimate the TSS_M that must be wasted assuming the volatile fraction represents 0.80 of the total solids.

$$\text{TSS}_M = 1646/0.80 = 2057\ \text{kg/d}$$

Note: If it is assumed that the fixed solids portion of the influent suspended solids equals 0.15, the mass of fixed solids in the input from the primary settling facilities is equal to $0.15 \times 2333 = 350$ kg/d. This value can then be compared with the fixed solids determined in the above computations, which is equal to $2057 - 1646 = 411$ kg/d. The ratio of these values is 1.18[(411 kg/d)/(350 kg/d)]. Values that have been observed for this ratio vary from about 1.0 to 1.3; a value of 1.15 is considered to be the most representative.

v. Estimate the waste quantities discharged to the thickener. (It is assumed in this example that wasting is from the biological reactor.)

$$\text{TSS}_M = (2057 - 475)\ \text{kg/d} = 1582\ \text{kg/d}$$

$$\text{Flowrate} = \frac{(1582\ \text{kg/d})(10^3\ \text{g/kg})}{(4375\ \text{g/m}^3)} = 362\ \text{m}^3/\text{d}$$

The assumed concentration value of MLSS of 4375 g/m^3 in the aeration tank will increase when the recycled BOD_C and TSS_C are taken into consideration in the second and subsequent iterations of the mass balance.

d. Flotation thickeners

i. Operating parameters:

Concentration of thickened sludge = 4%

Assumed solids recovery = 90%

Assumed specific gravity of feed and thickened sludge = 1.0

ii. Determine the flowrate of the thickened sludge.

$$\text{Flowrate} = \frac{(1582\ \text{kg/d})(0.9)}{(10^3\ \text{kg/m}^3)(0.04)} = 35.6\ \text{m}^3/\text{d}$$

iii. Determine the flowrate recycled to the plant influent.

Recycled flowrate = (362 − 35.6) m^3/d = 326.4 m^3/d

iv. Determine the TSS_M to the digester.

TSS_M = (1582 kg/d)(0.9) = 1424 kg/d

v. Determine the TSS_M recycled to the plant influent.

TSS_M = (1582 − 1424) kg/d = 158 kg/d

vi. Determine the BOD_C of the TSS_C in the recycled flow.

$$TSS_C \text{ in recycled flow} = \frac{(158 \text{ kg/d})(10^3 \text{ g/kg})}{(326 \text{ m}^3/\text{d})} = 485 \text{ g/m}^3$$

BOD_C of the TSS_C = (485 g/m^3)(0.65)(1.42)(0.68)
= 304.6 g/m^3

BOD_M = (304.6 g/m^3)(326 m^3/d)/(10^3 g/kg) = 99 kg/d

e. Sludge digestion

i. Operating parameters:

SRT = 10 d

VSS destruction during digestion = 50%

Gas production = 1.12 m^3/kg of VSS destroyed

BOD_C in digester supernatant = 1000 g/m^3 (0.1%)

TSS_C in digester supernatant = 5000 g/m^3 (0.5%)

TSS_C in digested sludge = 5%

ii. Determine the total solids fed to the digester and the corresponding flowrate.

TSS_M = solids from primary settling plus waste solids from thickener

TSS_M = 5443 kg/d + 1424 kg/d = 6867 kg/d

$$\text{Total flowrate} = \frac{(5443 \text{ kg/d})}{0.06(10^3 \text{ kg/m}^3)} + \frac{(1424 \text{ kg/d})}{0.04(10^3 \text{ kg/m}^3)}$$

= (90.7 + 35.6) m^3/d = 126.3 m^3/d

iii. Determine the VSS_M fed to the digester.

VSS_M = 0.682(5443 kg/d) + 0.80(1424 kg/d)
= (3712 + 1139) kg/d = 4851 kg/d

$$\text{Percent VSS}_M \text{ in mixture fed to digester} = \frac{(4851 \text{ kg/d})}{(6867 \text{ kg/d})}(100)$$
$$= 70.6\%$$

iv. Determine the VSS_M destroyed.

$VSS_M = 0.5(4851 \text{ kg/d}) = 2426 \text{ kg/d}$

v. Determine the mass flow to the digester.
Primary sludge at 6% solids:

$$\text{Mass flow} = \frac{(5443 \text{ kg/d})}{0.06} = 90{,}717 \text{ kg/d}$$

Thickened waste-activated sludge at 4% solids:

$$\text{Mass flow} = \frac{(1424 \text{ kg/d})}{0.04} = 35{,}600 \text{ kg/d}$$

Total mass flow = (90,717 + 35,600) kg/d = 126,317 kg/d

Note: The total mass flow can also be computed by multiplying the total flowrate to the digester by the density of the combined primary sludge and the thickened biosolids, if known.

vi. Determine the mass quantities of gas and sludge after digestion. Assume that the total mass of fixed solids does not change during digestion and that 50% of the volatile solids is destroyed.

Fixed solids = $TSS_M - VSS_M$ = (6867 − 4851) kg/d = 2016 kg/d

TSS_M in digested sludge = 2016 kg/d + 0.5(4851 kg/d) = 4441 kg/d

Gas production assuming that the density of digester gas is equal to 0.86 times that of air (1.204 kg/m^3, see Appendix B):

Gas = (1.12 m^3/kg)(0.5)(4851 kg/d)(0.86)(1.204 kg/m^3) = 2813 kg/d

Mass balance of digester output:

Mass input = 126,317 kg/d

Less gas = −2813 kg/d

Mass output = 123,504 kg/d (solids and liquid)

vii. Determine the flowrate distribution between the supernatant at 5000 mg/L and digested sludge at 5% solids. Let S = kg/d of supernatant suspended solids.

$$\frac{S}{0.005} + \frac{4441 - S}{0.05} = 123{,}504 \text{ kg/d}$$

$$S + 444.1 - 0.1S = 617.5 \text{ kg/d}$$

$$0.9S = 173$$

S = 192 kg/d

Digested solids = (4441 − 192) kg/d = 4249 kg/d

$$\text{Supernatant flowrate} = \frac{(192\ \text{kg/d})}{0.005(10^3\ \text{kg/m}^3)} = 38.4\ \text{m}^3/\text{d}$$

$$\text{Digested sludge flowrate} = \frac{(4249\ \text{kg/d})}{0.05(10^3\ \text{kg/m}^3)} = 85\ \text{m}^3/\text{d}$$

viii. Establish the characteristics of the recycled flow.

Flowrate = 38.4 m^3/d

BOD_C = (38.4 m^3/d)(1000 g/m^3)/(10^3 g/kg) = 38 kg/d

TSS_M = (38.4 m^3/d)(5000 g/m^3)/(10^3 g/kg) = 192 kg/d

f. Sludge dewatering. (*Note:* In the analysis that follows, the weight of the polymer or other sludge-conditioning chemicals that may be added was not considered. In some cases, their contribution can be significant and must be considered.)

i. Operating parameters for centrifuge:

Sludge cake = 22% solids

Specific gravity of sludge = 1.06

Solids capture = 93%

Centrate BOD_t = 2000 mg/L

ii. Determine the sludge-cake characteristics.

Solids = (4249 kg/d)(0.93) = 3952 kg/d

$$\text{Volume} = \frac{(3952\ \text{kg/d})}{1.06(0.22)(10^3\ \text{kg/m}^3)} = 16.9\ \text{m}^3/\text{d}$$

iii. Determine the centrate characteristics.

Flow = (85 − 16.9) m^3/d = 68.1 m^3/d

BOD_M (at 2000 g/m^3) = (2000 g/m^3)(68.1 g/m^3)/(10^3 g/kg)

= 136 kg/d

TSS_M = (4249 kg/d)(0.07) = 297 kg/d

g. Prepare a summary table of the recycle flows and waste characteristics for the first iteration.

Operation	Flow, m^3/d	BOD_M, kg/d	TSS_M, kg/d
Flotation thickener	326.0	99	158
Digester supernatant	38.4	38	192
Centrate	68.1	136	297
Totals	432.5	273	647[a]

[a]The volatile fraction of the returned suspended solids will typically vary from 50 to 75 percent. A value of 60 percent will be used for the computation in the second iteration.

4. Prepare the second iteration of the solids balance.
   a. Primary settling
      i. Operating parameters = same as those in the first iteration
      ii. TSS_M and BOD_M entering the primary tanks

$$TSS_M = \text{influent } TSS_M + \text{recycled } TSS_M$$
$$= 7776 \text{ kg/d} + 647 \text{ kg/d} = 8423 \text{ kg/d}$$
$$\text{Total } BOD_M = \text{influent } BOD_M + \text{recycled } BOD_M$$
$$= 8100 \text{ kg/d} + 273 \text{ kg/d} = 8373 \text{ kg/d}$$

      iii. BOD_M removed = 0.33(8373 kg/d) = 2763 kg/d
      iv. BOD_M to secondary = (8,373 − 2763) kg/d = 5610 kg/d
      v. TSS_M removed = 0.7(8423 kg/d) = 5896 kg/d
      vi. TSS_M to secondary = (8423 − 5896) kg/d = 2527 kg/d
   b. Determine the volatile fraction of the primary sludge and effluent suspended solids.
      i. Operating parameters:

         Incoming wastewater = same as those for the first iteration

         Volatile fraction of solids in recycle returned to headworks = 60%

      ii. Although the computations are not shown, the computed change in the volatile fractions determined in the first iteration is slight and, therefore, the values determined previously are used for the second iteration. If the volatile fraction of the return is less than about 50%, the volatile fractions should be recomputed.
   c. Secondary process
      i. Operating parameters = same as those for the first iteration and as follows:

         Aeration tank volume = 4700 m^3

         SRT = 10 d

         Y = 0.50 kg/kg

         k_d = 0.06 d^{-1}

ii. Determine the BOD_c in the influent to the aeration tank.

Flowrate to aeration tank = influent flowrate + recycled flowrate

$= (21{,}600 + 432.5)\ m^3/d = 22{,}033\ m^3/d$

$$BOD_c = \frac{(5610\ kg/d)(10^3\ g/kg)}{(22{,}032.5\ m^3/d)} = 225\ g/m^3$$

iii. Determine the new concentration of mixed liquor VSS.

$$X_{VSS} = \frac{(Q)(Y)(S_o - S)SRT}{(SRT)(Q)(Y)(S_o - S)](1 + (k_d)SRT]}$$

$$X_{VSS} = \frac{(22{,}032.5\ m^3/d)(0.5)(255 - 6.2)\ g/m^3](10\ d)}{4500\ m^3/[1 + (0.06\ d^{-1})(10\ d)]} = 3648\ g/m^3$$

iv. Determine the mixed liquor suspended solids.

$$X_{SS} = \frac{X_{VSS}}{0.8}$$

$$X_{SS} = 3648/0.8 = 4560\ g/m^3$$

v. Determine the cell growth.

$$P_{x,VSS} = Y_{obs}(S_o - S)(10^3\ g/kg)$$

$$= \frac{0.3125(22{,}032.5\ m^3/d)[(255 - 6.2)\ g/m^3]}{(10^3\ g/kg)} = 1714\ kg/d$$

$$P_{x,TSS} = 1714/0.8 = 2143\ kg/d$$

vi. Determine the waste quantities discharged to the thickener.

Effluent $TSS_{ff} = 432$ kg/d (specified in the first iteration)

Total TSS_{ff} to be wasted to the thickener = (2143 − 432) kg/d

= 1711 kg/d

$$\text{Flowrate} = \frac{(1711\ kg/d)(10^3\ g/kg)}{(4560\ g/m^3)} = 375\ m^3/d$$

d. Flotation thickeners

i. Operating parameters:

Concentration of thickened sludge = 4%

Assumed solids recovery = 90%

Assumed specific gravity of feed and thickened sludge = 1.0

ii. Determine the flowrate of the thickened sludge.

$$\text{Flowrate} = \frac{(1711 \text{ kg/d})(0.9)}{(10^3 \text{ kg/m}^3)(0.04)} = 38.5 \text{ m}^3/\text{d}$$

iii. Determine the flowrate recycled to the plant influent.

$$\text{Recycled flowrate} = (375 - 38.5) \text{ m}^3/\text{d} = 336.5 \text{ m}^3/\text{d}$$

iv. Determine the TSS_M to the digester.

$$TSS_M = (1711 \text{ kg/d})(0.9) = 1540 \text{ kg/d}$$

v. Determine the TSS_M recycled to the plant influent.

$$TSS_M = (1711 - 1540) \text{ kg/d} = 171 \text{ kg/d}$$

vi. Determine the BOD_C of the TSS_C in the recycled flow.

$$TSS_C \text{ in recycled flow} = \frac{(171 \text{ kg/d})(10^3 \text{ g/kg})}{(336.5 \text{ m}^3/\text{d})} = 508 \text{ g/m}^3$$

$$BOD_C \text{ of } TSS_C = (508 \text{ g/m}^3)(0.65)(1.42)(0.68) = 319 \text{ g/m}^3$$

$$BOD_M = (319 \text{ g/m}^3)(336.5 \text{ m}^3/\text{d})(10^3 \text{ g/kg})^{-1} = 107 \text{ kg/d}$$

e. Sludge digestion

i. Operating parameters = same as those in the first iteration

ii. Determine the total solids fed to the digester and the corresponding flowrate.

TSS_M = TSS_M from primary settling plus waste TSS_M from thickener

$$TSS_M = 5443 \text{ kg/d} + 1540 \text{ kg/d} = 6983 \text{ kg/d}$$

$$\text{Total flowrate} = \frac{(5443 \text{ kg/d})}{0.06(10^3 \text{ kg/m}^3)} + \frac{(1540 \text{ kg/d})}{0.04(10^3 \text{ kg/m}^3)}$$

$$= (90.7 + 38.5) \text{ m}^3/\text{d} = 129.2 \text{ m}^3/\text{d}$$

iii. Determine the total VSS_M fed to the digester.

$$VSS_M = 0.682(5443 \text{ kg/d}) + 0.80(1540 \text{ kg/d})$$

$$= (3712 + 1232) \text{ kg/d} = 4944 \text{ kg/d}$$

$$\text{Percent VSS in mixture fed to digester} = \frac{(4944 \text{ kg/d})}{(6983 \text{ kg/d})}(100)$$

$$= 71.3\%$$

iv. Determine the VSS destroyed.

VSS destroyed = 0.5(4944 kg/d) = 2472 kg/d

v. Determine the mass flow to the digester.

Primary sludge at 6% solids:

$$\text{Mass flow} = \frac{(5443 \text{ kg/d})}{0.06} = 90{,}717 \text{ kg/d}$$

Thickened waste-activated sludge at 4% solids:

$$\text{Mass flow} = \frac{(1540 \text{ kg/d})}{0.04} = 38{,}500 \text{ kg/d}$$

Total mass flow = (90,717 + 38,500) kg/d = 129,217 kg/d

vi. Determine the mass quantities of gas and sludge after digestion. Assume that the total mass of fixed solids does not change during digestion and that 50% of the volatile solids is destroyed.

Fixed solids = $TSS_M - VSS_M$ = (6983 − 4944) kg/d = 2039 kg/d

TSS in digested sludge = 2039 kg/d + 0.5(4944) kg/d = 4511 kg/d

Gas production assuming that the density of digester gas is equal to 0.86 times that of air (1.204 kg/m^3):

Gas = (1.12 m^3/kg)(0.5)(4944 kg/d)(0.86)(1.204 kg/m^3) = 2867 kg/d

Mass balance of digester output:

Mass input = 129,217 kg/d

Less gas − − 2867 kg/d

Mass output = 126,350 kg/d (solids and liquid)

vii. Determine the flowrate distribution between the supernatant at 5000 mg/L and digested sludge at 5 percent solids. Let S = kg/d of supernatant suspended solids.

$$\frac{S}{0.005} + \frac{4511 - S}{0.05} = 126{,}350 \text{ kg/d}$$

$$S + 451.1 - 0.1S = 631.8 \text{ kg/d}$$

$$0.9S = 180.7$$

$$S = 201 \text{ kg/d}$$

Digested TSS_M = (4511 − 201) kg/d = 4310 kg/d

$$\text{Supernatant flowrate} = \frac{(201\ \text{kg/d})}{0.005(10^3\ \text{kg/m}^3)} = 40.2\ \text{m}^3/\text{d}$$

$$\text{Digested sludge flowrate} = \frac{(4310\ \text{kg/d})}{0.05(10^3\ \text{kg/m}^3)} = 86.2\ \text{m}^3/\text{d}$$

viii. Establish the characteristics of the recycled flow.

Flowrate = 40.2 m^3/d

BOD_M = (40.2 m^3/d)(1000 g/m^3)/(10^3 g/kg) = 40 kg/d

TBB_M = (40.2 m^3/d)(5000 g/m^3)/(10^3 g/kg) = 201 kg/d

f. Sludge dewatering

i. Operating parameters for centrifuge = same as those in the first iteration

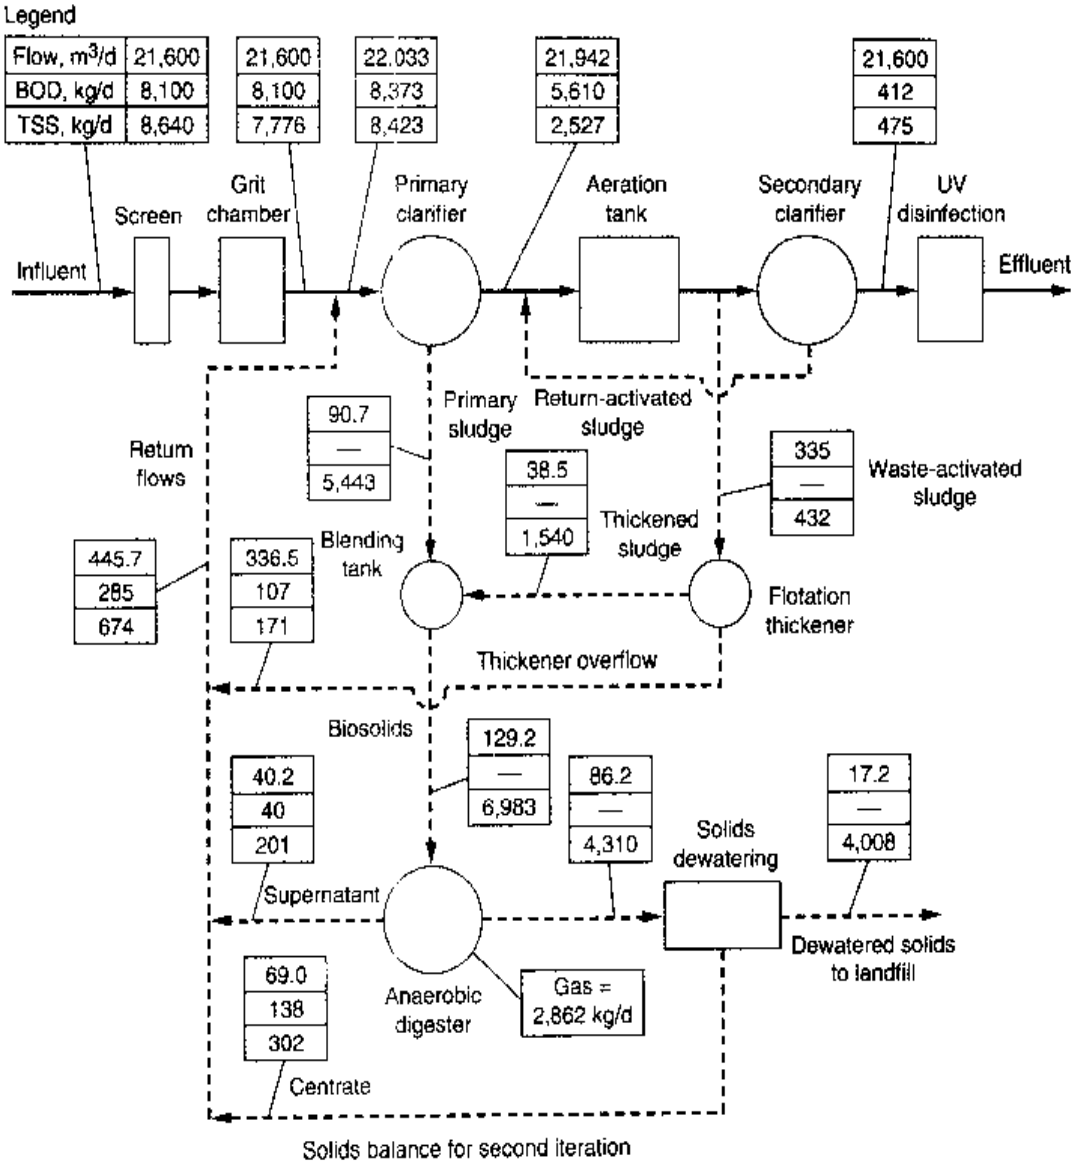
ii. Determine the sludge-cake characteristics.

TSS_M = (4310 kg/d)(0.93) = 4008 kg/d

$$\text{Volume} = \frac{(4008\ \text{kg/d})}{1.06(0.22)(10^3\ \text{kg/m}^3)} = 17.2\ \text{m}^3/\text{d}$$

iii. Determine the centrate characteristics.

Flow = (86.2 − 17.2) m^3/d = 69 m^3/d



BOD_M (at 2000 g/m^3) = (2000 g/m^3)(69 g/m^3)/(10^3 g/kg) = 138 kg/d

TSS_M = (4310 kg/d)(0.07) = 302 kg/d

g. Prepare a summary table of the recycle flows and waste characteristics for the second iteration.

				Incremental change from previous iteration		
Operation/process	**Flow, m^3/d**	**BOD_M, kg/d**	**TSS_M, kg/d**	**Flow, m^3/d**	**BOD_M, kg/d**	**TSS_M, kg/d**
Flotation thickener	336.5	107	171	10.5	8	13
Digester supernatant	40.2	40	201	1.8	2	9
Belt-press filtrate	69.0	138	302	0.9	2	5
Totals	445.7	285	674	13.2	12	27

5. Because the incremental change in the return quantities is less than 5 percent, the values summarized in the above table are acceptable for design. Given that the above computations would be done on a spreadsheet program, additional iterations could be made to obtain an incremental change of less than 1 percent. The flow, TSS_M, and BOD_M values for the various processes from the second iteration are presented in following figure.

Solids balance for second iteration

Comment In this example, an iterative approach was used to illustrate the computational steps in preparing a solids mass balance. Solids balances can be prepared using a specially designed spreadsheet or a proprietary solids balance software program. In general, if the iterative computational procedure is used, similar to the method used in this example, it should be carried out until the incremental change in all of the return quantities from the previous iteration is equal to or less than 5 percent.

14-17 APPLICATION OF BIOSOLIDS TO LAND

Land application of biosolids is defined as the spreading of biosolids on or just below the soil surface. Biosolids may be applied to (1) agricultural land, (2) forest land, (3) disturbed land, and (4) dedicated land disposal sites. In all four cases, the land application is designed with the objective of providing further biosolids treatment. Sunlight, soil microorganisms, and desiccation combine to destroy pathogens and many toxic

organic substances. Trace metals are trapped in the soil matrix and nutrients are taken up by plants and converted to useful biomass. In some cases, a geomembrane liner is installed below a dedicated land disposal area.

To qualify for application to agricultural and nonagricultural land, biosolids or material derived from biosolids must meet at least the pollutant ceiling concentrations, Class B requirements for pathogens, and vector attraction requirements. Bulk biosolids applied to lawns and home gardens and biosolids that are sold or given away in bags or containers must meet the Class A criteria and one of several available vector-attraction reduction processes.

The application of biosolids to land for agricultural purposes is beneficial because organic matter improves soil structure, tilth, water holding capacity, water infiltration, and soil aeration; and macronutrients (nitrogen, phosphorus, potassium) and micronutrients (iron, manganese, copper, chromium, selenium, and zinc) aid plant growth. Organic matter also contributes to the cation-exchange capacity (CEC) of the soil which allows the soil to retain potassium, calcium, and magnesium. The presence of organic matter improves the biological diversity in soil and improves the availability of nutrients to the plants (Wegner, 1992). Nutrients in the biosolids also serve as a partial replacement for expensive chemical fertilizers.

Land application can also be of great value in silviculture and site reclamation. Forest utilization has been practiced extensively in the northwest, and biosolids application has been recognized as being beneficial to forest growth (WEF, 1998). Reclamation of disturbed land such as superfund sites has also been successful (Henry and Brown, 1997).

Site Evaluation and Selection

A critical step in land application of biosolids is finding a suitable site. The characteristics of the site will determine the actual design and will influence the overall effectiveness of the land-application concept. The sites considered potentially suitable will depend on the land-application option or options being considered, such as application to agricultural lands, forest lands, etc. The site-selection process should include an initial screening on the basis of the factors and criteria described in the following discussion. For screening purposes, it is necessary to have at least a rough estimate of land-area requirements for each feasible option.

Ideal sites for land application of biosolids have deep silty loam to sandy loam soils, groundwater deeper than 3 m (10 ft), slopes at 0 to 3 percent, no wells, wetlands, or streams, and few neighbors. Site characteristics of importance are topography, soil characteristics, soil depth to groundwater, and accessibility and proximity to critical areas.

Topography. Topography is important as it affects the potential for erosion and runoff. Suitability of site topographies also depends on the type of biosolids and the method of application. As shown in Table 14–51, liquid biosolids can be spread, sprayed, or injected onto sites with rolling terrain up to 15 percent in slope. Dewatered sludge is usually spread on agricultural land that requires a tractor and spreader. Forested sites can accommodate slopes up to 30 percent if adequate setbacks from streams are provided.

Soil Characteristics. In general, desirable soil characteristics include (1) loamy soil, (2) slow to moderate permeability, (3) soil depth of 0.6 m (2 ft) or more, (4) alkaline

Table 14–51 Typical slope limitations for land application of biosolids

Slope, %	Comment
0–3	Ideal; no concern for runoff or erosion of liquid or dewatered biosolids
3–6	Acceptable; slight risk of erosion; surface application of liquid or dewatered biosolids is acceptable
6–12	Injection of liquid biosolids required for general cases, except in closed drainage basin and/or when extensive runoff control is provided; surface application of dewatered biosolids is generally acceptable
12–15	No application of liquid biosolids should be made without extensive runoff control; surface application of dewatered biosolids is acceptable, but immediate incorporation into the soil is recommended
Over 15	Slopes greater than 15 percent are suitable only for sites with good permeability where the length of slope is short and where the area with steep slope is a minor part of the total application area

or neutral soil pH (pH > 6.5), and (5) well drained to moderately well drained. Practically any soil can be adapted to a well-designed and well-operated system.

Soil Depth to Groundwater. A basic philosophy inherent in federal and state regulations is to design biosolids application systems that are based on sound agronomic principles, so that biosolids pose no greater threat to groundwater than current agricultural practices. Because the groundwater fluctuates on a seasonal basis in many soils, difficulties are encountered in establishing an acceptable minimum depth to groundwater. The quality of the underlying groundwater and the biosolids application option have to be considered carefully, especially where groundwater nondegradation restrictions apply. Generally, the greater the depth to the water table, the more desirable a site is for biosolids application. At least 1 m (3 ft) to groundwater is preferred for land-application sites. Seasonal water-table fluctuations to within 0.5 m (1.5 ft) of the surface can be tolerated. If the shallow groundwater is excluded as a drinking-water aquifer, the groundwater depth can be as shallow as 0.5 m before problems with trafficability of the soil arise. The presence of faults, solution channels, and other similar connections between soil and groundwater is undesirable unless the depth of overlying soil is adequate. When a specific site or sites are being considered for biosolids application, a detailed field investigation may be necessary to obtain the required groundwater information.

Accessibility and Proximity to Critical Areas. Buffer zones or setbacks are needed to separate the active application area from sensitive areas such as residences, wells, roads, surface waters, and property boundaries. Local and state regulations often include minimum distances for setbacks depending on the method of application; example minimum setback distances used in California are listed in Table 14–52.

U.S. EPA Regulations for Beneficial Use and Disposal of Biosolids

As discussed in Sec. 14–2, the U.S. EPA published regulations for biosolids (sewage sludge is the term used in the regulations) use and disposal under the code of Federal

Table 14–52
Typical setback distances for land application of biosolids[a]

Setback from	Minimum distance ft	Minimum distance m
Property boundaries	10	3
Domestic water supply wells	500	150
Nondomestic water supply wells	100	30
Public roads and onsite occupied residences	50	15
Surface waters (wetlands, creeks, ponds, lakes, underground aqueducts, and marshes)	100	30
Primary agricultural drainageways	33	10
Occupied nonagricultural buildings and offsite residences	500	150
Domestic water supply reservoir	400	120
Primary tributary to a domestic water supply	200	60
Domestic surface water supply intake	2500	750

Management practices	See Table 14–54
Pathogen-reduction alternatives	See Table 14–9
Vector attraction reduction	See Table 14–10
Site restrictions for Class B biosolids	See Table 14–55
Metal limits and loading rates	See Table 14–57

[a]Other than bag labeling (similar to fertilizer).

Regulations (CFR), 40 CFR Part 503. For land application, the regulations provide numerical limits on 10 metals, management practice guidance, and requirements for monitoring, record keeping, and reporting. The regulations are summarized in Table 14–53 and discussed in the following paragraphs.

Management Practices. Management practices that must be followed when biosolids are applied on land are specified in the Part 503 rule (see Table 14–54). The practices vary depending on whether the material that is applied is hauled in bulk or in individual bags.

Pathogen-Reduction Alternatives. As discussed in Chap. 1 and in Sec. 14–2, the Part 503 pathogen-reduction requirements for biosolids are divided into Class A and Class B categories (see Table 14–9). The goal of the Class A requirements is to reduce the pathogens in the biosolids (including *Salmonella* sp. bacteria, enteric viruses, and

Table 14–54
Land-application management practices under U.S. EPA Part 503 rule[a]

For bulk biosolids[b]

Bulk biosolids cannot be applied to flooded, frozen, or snow-covered agricultural land, forests, public contact sites, or reclamation sites in such a way that the biosolids enter a wetland or other waters of the United States (as defined in 40 CFR Part 122.2), except as provided in a permit issued pursuant to Section 402 (NPDES permit) or Section 404 (Dredge and Fill Permit) of the Clean Water Act, as amended

Bulk biosolids cannot be applied to agricultural land, forests, or reclamation sites that are 10 m or less from U.S. waters, unless otherwise specified by the permitting authority

If applied to agricultural lands, forests, or public contact sites, bulk biosolids must be applied at a rate that is equal to or less than the agronomic rate for the site. Biosolids applied to reclamation sites may exceed the agronomic rate if allowed by the permitting authority

Bulk biosolids must not harm or contribute to the harm of a threatened or endangered species or result in the destruction or adverse modification of the species' critical habitat when applied to the land. Threatened or endangered species and their critical habitats are listed in Section 4 of the Endangered Species Act. Critical habitat is defined as any place where a threatened or endangered species lives and grows during any stage of its life cycle. Any direct or indirect action (or the result of any direct or indirect action) in a critical habitat that diminishes the likelihood of survival and recovery of a listed species is considered destruction or adverse modification of a critical habitat

For biosolids sold or given away in a bag or other container for application to the land

A label must be affixed to the bag or other container, or an information sheet must be provided to the person who receives this type of biosolids in another container. At a minimum, the label or information sheet must contain the following information:

- The name and address of the person who prepared the biosolids for sale or giveaway in a bag or other container
- A statement that prohibits application of the biosolids to the land except in accordance with the instructions on the label or information sheet
- An AWSAR (annual whole sludge application rate) for the biosolids that does not cause the annual pollutant loading rate limits to be exceeded

[a] Adapted from U.S. EPA (1995).

[b] These management practices do not apply if the biosolids are of "exceptional quality."

viable helminth ova) to below detectable levels. When this goal is achieved, Class A biosolids can be land applied without any pathogen-related restrictions on the site (U.S. EPA, 1995).

The goal of the Class B requirements is to ensure that pathogens have been reduced to levels that are unlikely to pose a threat to public health and the environment under specific use conditions. Site restrictions on land application of Class B biosolids minimize the potential for human and animal contact with the biosolids until environmental factors have reduced pathogens to below detectable levels.

Vector Attraction Reduction. There are 10 potential vector attraction reduction measures that can be combined with pathogen-reduction alternatives for an acceptable

Table 14–55
Site restrictions for Class B biosolids[a]

Restrictions for the harvesting of crops and turf

1. Food crops with harvested parts that touch the biosolids/soil mixture and are totally above ground shall not be harvested for 14 months after application of biosolids
2. Food crops with harvested parts below the land surface where biosolids remains on the land surface for 4 months or longer prior to incorporation into the soil shall not be harvested for 20 months after biosolids application
3. Food crops with harvested parts below the land surface where biosolids remains on the land surface for less than 4 months prior to incorporation shall not be harvested for 38 months after biosolids application
4. Food crops, feed crops, and fiber crops whose edible parts do not touch the surface of the soil shall not be harvested for 30 d after biosolids application
5. Turf grown on land where biosolids are applied shall not be harvested for 1 year after application of the biosolids when the harvested turf is placed on either land with a high potential for public exposure or a lawn, unless otherwise specified by the permitting authority

Restriction for the grazing of animals

1. Animals shall not be grazed on land for 30 d after application of biosolids to the land

Restrictions for public contact

1. Access to land with a high potential for public exposure, such as a park or ball field, is restricted for 1 year after biosolids application. Examples of restricted access include posting with no trespassing signs or fencing
2. Access to land with a low potential for public exposure (e.g., private farmland) is restricted for 30 d after biosolids application. An example of restricted access is remoteness

[a] From U.S. EPA (1995).

land-application project using Class B biosolids (see Table 14–10). The list in Table 14–10 also includes some stabilization processes that reduce pathogens.

Site Restrictions for Class B Biosolids. Site restrictions, listed in Table 14–55, depend on the crops to be used and the contact control for animals and the public. Food crops and turf grass are given the longest time restrictions because of the potential for public exposure (U.S. EPA, 1995).

Exceptional Quality Biosolids. The category of "exceptional quality" biosolids has been defined as those biosolids that meet metal standards, Class A pathogen reduction standards, and vector reduction standards as defined in the Part 503 regulations.

Design Loading Rates

Design loading rates for land application of biosolids can be limited by pollutants (heavy metals) or by nitrogen. The long-term loadings of heavy metals are based on U.S. EPA 503 regulations. The annual loading rate is usually limited by the nitrogen loading rate.

Nitrogen Loading Rates. Nitrogen loading rates are set typically to match the available nitrogen provided by commercial fertilizers (Chang et al., 1995). Because municipal biosolids represent a slow-release organic fertilizer, a combination of ammonia and organic nitrogen must be made according to Eq. (14–36).

$$L_N = [(NO_3) + k_v(NH_4) + f_n(N_o)]F \tag{14–36}$$

where L_N = plant available nitrogen in the application year, g N/kg (lb N/ton)
NO_3 = percent nitrate nitrogen in biosolids, decimal
k_v = volatilization factor for ammonia loss
= 0.5 for surface-applied liquid sludge
= 0.75 for surface-applied dewatered sludge
= 1.0 for injected liquid or dewatered sludge
NH_4 = percent ammonia nitrogen in sludge, decimal
f_n = mineralization factor for organic nitrogen
= 0.5 for warm climates and digested sludge
= 0.4 for cool climates and digested sludge
= 0.3 for cold climates or composted sludge
N_o = percent organic nitrogen in sludge, decimal
F = conversion factor, 1000 g/kg of dry solids (lb/ton)

To use Eq. (14–36) requires knowledge of the method of application, the nitrogen content of the biosolids (nitrate, ammonia, and organic), the type of stabilization, and the type of climate. The use of the mineralization factors simplifies the previously used method of calculating the amount of organic nitrogen mineralized each year and adding up the total for an annual equivalent. The use of Eq. (14–36) is also appropriate if biosolids are applied to a single site once every 2 to 3 years.

The loading rate based on nitrogen loadings is then calculated from Eq. (14–37).

$$L_{SN} = U/N_p \tag{14–37}$$

where L_{SN} = biosolids loading rate based on N, Mg/ha·yr (tons/ac·yr)
U = crop uptake of nitrogen, kg/ha (lb/ac) (see Table 14–56)
N_p = plant available nitrogen in sludge, g/kg (lb/ton)

Loading Rates Based on Pollutant Loading. The pollutants of concern are those listed in Table 14–57. To calculate the biosolids loading rate based on pollutant loading use Eq. (14–38).

$$L_S = \frac{L_C}{CF} \tag{14–38}$$

where L_S = maximum amount of biosolids that can be applied per year, Mg/ha·yr (tons/ac·yr)
L_C = maximum amount of constituent that can be applied per year, kg/ha·yr (lb/ac·yr)
C = pollutant concentration in biosolids, decimal (mg/kg)
F = conversion factor, 0.001 kg/Mg (2000 lb/ton)

Table 14–56
Typical nitrogen uptake values for selected crops[a]

Crop	Nitrogen uptake lb/ac·yr	Nitrogen uptake kg/ha·yr
Forage crops		
Alfalfa	200–600	220–670
Brome grass	115–200	130–220
Coastal Bermuda grass	350–600	390–670
Kentucky bluegrass	175–240	195–270
Quack grass	210–250	235–280
Orchard grass	220–310	250–350

Western forest:		
Hybrid poplar	270	300
Douglas fir	200	225

[a] Adapted from U.S. EPA (1981).
[b] Legume crops can fix nitrogen from the air but will take up most of their nitrogen from applied wastewater.

Land Requirements. Once the minimum biosolids loading rate is determined [by comparing the values from Eqs. (14–37) and (14–38)], the field area can be calculated using Eq. (14–39).

$$A = \frac{B}{L_s} \tag{14-39}$$

where A = application area required, ha
B = biosolids production, Mg of dry solids/yr
L_s = design loading rate, Mg of dry solids/ha·yr

Table 14–57
Metals concentrations and loading rates for land application of biosolids[a]

Pollutant	Ceiling concentration[b]		Cumulative pollutant loading rate[c]		Pollutant concentration for exceptional quality[d]		Annual pollutant loading rate[e]	
	lb/ton	mg/kg	lb/ac	kg/ha	lb/ton	mg/kg	lb/ac	kg/ha
Arsenic	0.15	75	37	41	0.08	41	1.78	2.0
Cadmium	0.17	85	35	39	0.08	39	1.70	1.9
Chromium[f]	—	—	—	—	—	—	—	—
Copper	8.60	4300	1338	1500	3.00	1500	66.91	75

[e] Table 4 from 503 regulations.
[f] A Feb. 25, 1994, Federal Register notice deleted chromium; deleted the molybdenum values for Tables 2, 3, and 4; and raised the selenium value in Table 3 from 36 to 100.

EXAMPLE 14–12 Metals Loadings in Land Application A community has stockpiled biosolids in a storage lagoon. The lagoon needs to be cleaned and the biosolids disposed of to make room for a plant expansion. The metals concentrations (mg/kg) in the lagoon are as follows:

As = 40	Hg = 15
Cd = 56	Ni = 510
Cu = 2500	Se = 10
Pb = 750	Zn = 3400

Determine if the biosolids are acceptable for land application.

Solution

1. Compare the concentrations for the above metals to the ceiling concentration (column 2) and the pollutant concentration for exceptional quality (column 4) in Table 14–57.

a. All metals concentrations are under the ceiling limits in column 2. The biosolids are suitable for land application.
b. Cadmium, copper, lead, nickel, and zinc exceed the values for exceptional quality. Calculations of annual loadings are necessary.

2. Calculate the allowable annual biosolids loading rates, using Eq. (14–38), for the four metals using the annual pollutant loading rates in Table 14–57.
   a. Cadmium-based loading rate.

$$L_S = \frac{L_{Cd}}{C_{Cd}(0.001)} = \frac{(1.9 \text{ kg/ha·yr})}{[(56 \text{ mg/kg})(0.001 \text{ kg/Mg})/(\text{mg/kg})]}$$
$$= 33.9 \text{ Mg/ha·yr}$$

   b. Copper-based loading rate.

$$L_S = \frac{75}{2500(0.001)} = 30 \text{ Mg/ha·yr}$$

   c. Lead-based loading rate.

$$L_S = \frac{15}{750(0.001)} = 20 \text{ Mg/ha·yr}$$

   d. Zinc-based loading rate.

$$L_S = \frac{140}{3400(0.001)} = 41.1 \text{ Mg/ha·yr}$$

3. Compare the whole biosolids loading rates to determine the limiting rate. The 20 Mg/ha·yr biosolids loading based on lead is limiting.

Comment Nitrogen loadings typically are more limiting than metals loadings. If the nitrogen loading rate exceeds 20 Mg/ha·yr, then the lead loading rate will determine the whole biosolids loading rate.

Application Methods

Application methods for biosolids range from direct injection of liquid biosolids to surface spreading of dewatered biosolids. The method of application selected will depend on the physical characteristics of the biosolids (liquid or dewatered), site topography, and the type of vegetation present (annual field crops, existing forage crops, trees, or preplanted land).

Liquid Biosolids Application. Application of biosolids in the liquid state is attractive because of its simplicity. Dewatering processes are not required, and the liquid biosolids can be transferred by pumping. Typical solids concentrations of liquid biosolids applied to land range from 1 to 10 percent. Liquid biosolids may be applied to land by vehicular application or by irrigation methods similar to those used for wastewater distribution.

Vehicular application may be by surface distribution or by subsurface injection or incorporation. Limitations to vehicular application include limited tractability on wet soil and potential reduction in crop yields due to soil compaction from truck traffic. Use of high-flotation tires can minimize these problems.

Surface distribution may be accomplished by tank truck or tank wagon equipped with rear-mounted spreading manifolds or by tank trucks mounted with high-capacity spray nozzles or guns. Specially designed, all-terrain biosolids application vehicles with spray guns are ideally suited for biosolids application on forest. Vehicular surface application is the most common method used for field and forage croplands. The procedure used commonly for annual crops is to (1) spread biosolids prior to planting, (2) allow the biosolids to dry partially, and (3) incorporate the biosolids by disking or plowing. The process is repeated then after harvest.

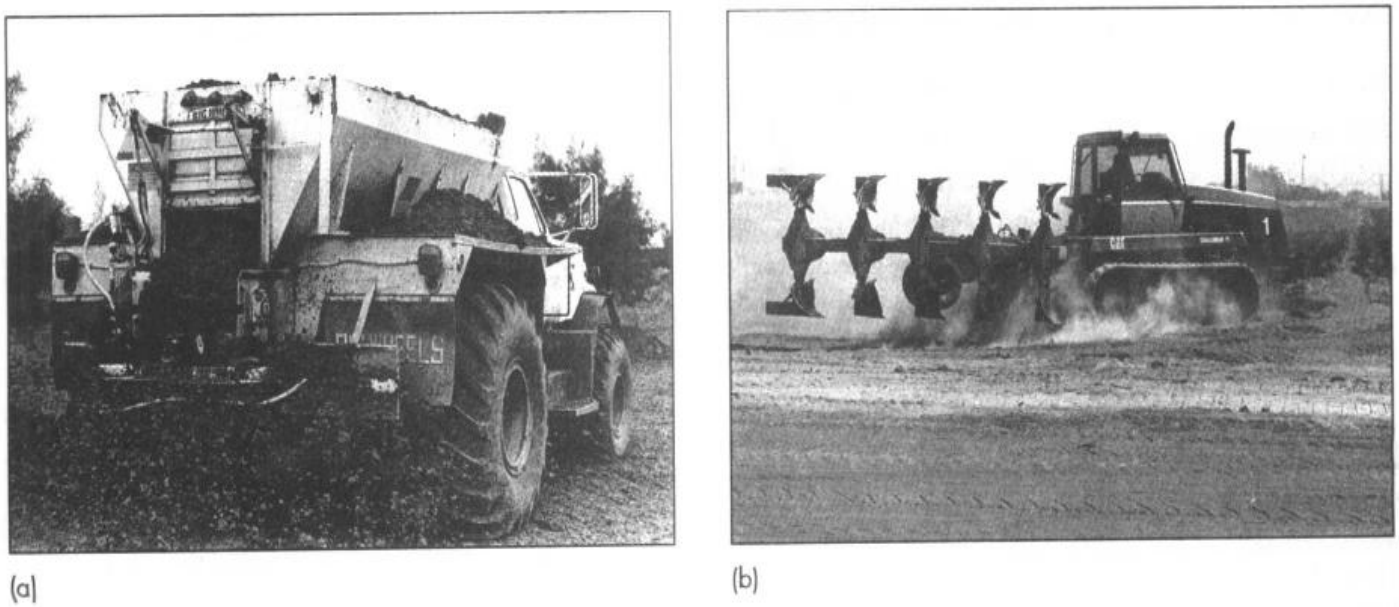
Liquid biosolids can be injected below the soil surface by using tank wagon or tank trucks with injection shanks or incorporated immediately after surface application by using plows or disks equipped with biosolids distribution manifolds and covering spoons (see Fig. 14–57). Advantages of injection or immediate incorporation methods include minimization of potential odors and vector attraction, minimization of ammonia loss due to volatilization, elimination of surface runoff, and minimum visibility leading to better public acceptance. Injection shanks and plows are very disruptive to perennial forage crops or pastures. To minimize such effects, special grassland biosolids injectors have been developed (Crites and Tchobanoglous, 1998).

Irrigation methods include sprinkling and furrow irrigation. Typically, large-diameter, high-capacity sprinkler guns are used to avoid clogging problems. Sprinkling has been used mainly for application to forested lands and occasionally for application

(a) (b)

Figure 14–57

Land application of liquid sludge: (*a*) self-contained vehicle used to haul and to inject the liquid sludge into the ground. Self-contained vehicles of the type shown are used for relatively small amounts of liquid sludge and (*b*) tractor equipped with subsurface liquid sludge injection tines. The liquid sludge to be injected is supplied by a hose connected to the injection device. The tethered sludge supply hose is dragged along by the tractor. The injected liquid sludge is disked in the ground using the tractor and disk such as shown in Fig. 14–58*b*.



to dedicated disposal sites that are relatively isolated from public view and access. Sprinklers can operate satisfactorily on land too rough or wet for tank trucks or injection equipment and can be used throughout the growing season. Disadvantages to sprinkling include power costs of high-pressure pumps, contact of biosolids with all parts of the crop, possible foliage damage to sensitive crops, potential odors and vector attraction problems, and potentially high visibility to the public.

Furrow irrigation can be used to apply biosolids to row crops during the growing season. Disadvantages associated with furrow irrigation are localized settling of solids and the potential for ponding of biosolids in the furrows, both of which can result in odor problems.

Dewatered Biosolids Application. Application of dewatered biosolids to the land is similar to an application of semisolid animal manure. The use of conventional manure spreaders is an important advantage because farmers can apply biosolids on their lands with their own equipment. Typical solids concentrations of dewatered biosolids applied to land range from 15 to 20 percent. Dewatered biosolids are spread most commonly using tractor-mounted box spreaders or manure spreaders followed by plowing or disking into the soil (see Fig. 14–58). For high application rates bulldozers, loaders, or graders may be used. For forest application, a side-slinging vehicle has been tested that can apply dewatered biosolids up to 60 m (200 ft) (Leonard et al., 1992).

Application to Dedicated Lands

Disturbed land reclamation and dedicated land disposal are two types of high-rate land application. Disturbed land reclamation consists of a one-time application of 110 to 220 Mg/ha (50 to 100 dry tons/ac) to correct adverse soil conditions. Lack of soil fertility and poor physical properties can be corrected by biosolids application to allow revegetation programs to proceed. For disturbed land reclamation to be the sole avenue

(a) (b)

Figure 14–58

Land application of dewatered sludge: (a) typical example of vehicle used to apply dewatered sludge on the surface of the soil and (b) typical tractor and rotating two-way disk used to disk dewatered and liquid sludge into the ground.

for biosolids reuse, a large area of disturbed land must be available on an ongoing basis. Dedicated land disposal requires a site where high rates of biosolids application are acceptable environmentally on a continuing basis. Biosolids for a dedicated land disposal (DLD) operation should meet at least Class B requirements.

Site Selection. Siting criteria for a dedicated land disposal site are presented in Table 14–58. Major issues in DLD siting are nitrogen control and the avoidance of groundwater contamination. Groundwater contamination can be avoided by (1) locating sites remote from useful aquifers, (2) intercepting of leachate, and (3) constructing an impervious geological barrier. Low percolation rates and deep aquifers will substantially reduce or eliminate potential contamination effects.

Where groundwater nondegradation restrictions apply, it has been found that for most DLD sites it is less costly to excavate the site entirely, install a geomembrane liner, and replace the excavated material, than to dispose of the sludge by some other means (e.g., dewatering and landfilling). The limited amount, if any, of leachate collected from the liner is returned to the treatment plant for processing.

Loading Rates. Annual biosolids loading rates have ranged from 12 to 2250 Mg/ha (5 to 1000 tons/ac). The higher rates have been associated with sites that:

- Receive dewatered biosolids
- Mechanically incorporate the biosolids into the soil
- Have relatively low precipitation
- Have no leachate problems because of site conditions or project design

Table 14–58
Criteria for dedicated land disposal (DLD) sites for biosolids[a]

Parameter	Unacceptable condition	Ideal condition
Slope	Deep gullies, slope >12%	<3%
Soil permeability	$>1 \times 10^{5}$ cm/s[b]	$\leq 10^{-7}$ cm/s[c]
Soil depth	<0.6 m (2 ft)	>3 m (10 ft)
Distance to surface water	<90 m (300 ft) to any pond or lake used for recreational or livestock purposes, or any surface water body officially classified under state law	>300 m (1000 ft) from any surface water
Depth to groundwater	<3m (10 ft) to groundwater table (wells tapping shallow aquifers)[d]	>15 m (50 ft)
Supply wells	Within 300 m (1000 ft) radius	No wells within 600 m (2000 ft)

[a]Adapted from U.S. EPA (1983).
[b]Permeable soil can be used for DLD if appropriate engineering design preventing DLD leachate from reaching the groundwater is feasible.
[c]When low-permeability soils are at or too close to the surface, liquid disposal operations can be hindered due to water ponding.
[d]If an exempted aquifer underlies the site, poor-quality leachate may be permitted to enter groundwater.

Design loading rates for DLD can be estimated using Eq. (14–40).

$$L_S = \frac{E(TS)F}{100} - TS \tag{14–40}$$

where L_S = annual biosolids loading rate, Mg/ha (tons/ac)
E = net evaporation rate from soil, mm/yr (in/yr)
TS = total solids content, percent by weight
F = conversion factor, 10 Mg/mm (113.3 tons/in)

The net soil evaporation can be estimated from Eq. (14–41).

$$E = (f)E_L - P \tag{14–41}$$

where E = net evaporation rate from soil, mm/yr (in/yr)
f = 0.7
E_L = pan evaporation rate, mm/yr (in/yr)
P = annual precipitation, mm/yr (in/yr)

It should be noted that infiltration into the soil is not considered in Eq. (14–41). If infiltration is allowed, the term E should be increased by the annual infiltration rate in mm/yr.

Once the annual loading rate is calculated, the field area can be determined using Eq. (14–39) (dividing the biosolids production by the loading rate). Other area requirements include buffer zones, surface runoff control, roads, and supporting facilities.

Landfilling

Landfilling of biosolids in a monofill is covered under 40 CFR Part 503. Landfilling of biosolids in a sanitary landfill with municipal solid waste is regulated by the U.S. EPA under 40 CFR 258. If an acceptable site is convenient, landfilling can be used for disposal of biosolids, grit, screenings, and other solids. Stabilization may be required depending on state or local regulations. Dewatering of biosolids is usually required to reduce the volume to be transported and to control the generation of leachate from the landfill. In many cases, solids concentration is an important factor in determining the acceptability of biosolids in landfills. The sanitary landfill method is most suitable if it is also used for disposal of the other types of solid wastes. In a true sanitary landfill, the wastes are deposited in a designated area, compacted in place with a tractor or roller, and covered with a 350 mm (14 in) layer of clean soil. With daily coverage of the newly deposited wastes, nuisance conditions, such as odors and flies, are minimized.

14–18 BIOSOLIDS CONVEYANCE AND STORAGE

The solids removed as biosolids from preliminary and biological treatment processes are concentrated and stabilized by biological and thermal means and are reduced in volume in preparation for final disposal. Because the methods of conveyance and final disposal often determine the type of stabilization required and the amount of volume reduction that is needed, they are considered briefly in the following discussion.

Conveyance Methods

Biosolids may be transported long distances by (1) pipeline, (2) truck, (3) barge, (4) rail, or any combination of these four modes. To minimize the danger of spills, odors, and dissemination of pathogens to the air, liquid biosolids should be transported in closed vessels, such as tank trucks, railroad tank cars, or covered or tank barges. Stabilized, dewatered biosolids can be transferred in open vessels, such as dump trucks, or in railroad gondolas. If biosolids are hauled long distances, the vessels should be covered.

The method of transportation chosen and its costs are dependent on a number of factors, including (1) the nature, consistency, and quantity of biosolids to be transported; (2) the distance from origin to destination; (3) the availability and proximity of the transit modes to both origin and destination; (4) the degree of flexibility required in the transportation method chosen; and (5) the estimated useful life of the ultimate disposal facility.

Each transportation method contributes a minor air pollutant load, either directly or indirectly. A certain amount of air pollution is produced from the facility that generates electricity necessary for sludge pumping. The engines that move trucks, barges, and railroad cars also produce some air pollutants. On a mass (tonnage) basis, the transportation mode that contributes the lowest pollutant load is piping. Next, in sequence, are barging and unit train rail transportation. The highest pollutant load is from trucking. Other factors of environmental concern include traffic, noise, and construction disturbance.

Storage

It is often necessary to store biosolids that have been digested anaerobically before they are disposed of or used beneficially. Storage of liquid biosolids can be accomplished in storage basins, and storage of dewatered biosolids can be done on storage pads.

Storage Basins and Lagoons. Biosolids stored in basins become more concentrated and are further stabilized by continued anaerobic biological activity. Long-term storage is effective in pathogen destruction.

Depth of the biosolids storage basins may vary from 3 to 5 m (10 to 16 ft). Solids loading rates vary from about 0.1 to 0.25 kg VSS/m^2·d (20 to 50 lb VSS/10^3 ft^2·d) of surface area. If the basins are not loaded too heavily ($\leq$0.1 kg VSS/m^2·d), it is possible to maintain an aerobic surface layer through the growth of algae and by atmospheric reaeration. Alternatively, surface aerators can be used to maintain aerobic conditions in the upper layers.

The number of basins to be used should be sufficient to allow each basin to be out of service for a period of about 6 months. Stabilized and thickened biosolids can be removed from the basins using a mud pump mounted on a floating platform or by mobile crane using a drag line. Biosolids concentrations as high as 35 percent solids have been achieved in the bottom layers of these basins.

Long-term storage of solids in lagoons is simple and economical if the treatment plant is in a remote location. A lagoon is an earthen basin into which untreated solids or digested biosolids are deposited. In lagoons with untreated solids, the organic matter is stabilized by anaerobic and aerobic decomposition, which may give rise to objectionable odors. The stabilized solids settle to the bottom of the lagoon and accumulate, and excess liquid from the lagoon, if there is any, is returned to the plant for treatment. Lagoons should be located away from highways and dwellings to minimize possible

nuisance conditions and should be fenced to keep out unauthorized persons. Lagoons should be relatively shallow, 1.25 to 1.5 m (4 to 5 ft), if they are to be cleaned by scraping. If the lagoon is used only for digested biosolids, the nuisances mentioned should not be a problem. If subsurface drainage and percolation are potential problems, the lagoon should be lined. Solids may be stored indefinitely in a lagoon and may be removed periodically after draining and drying. The accumulation of solids can be estimated using the procedure illustrated in Example 8–15 in Chap. 8.

Storage Pads. Where dewatered biosolids have to be stored prior to land application, sufficient storage area should be provided based on the number of consecutive days that biosolids hauling could occur without applying biosolids to land. Allowances also have to be made for paved access and for area to maneuver the biosolids hauling trucks, loaders, and application vehicles. The storage pads should be constructed of concrete or bituminous concrete and designed to withstand the truck loadings and biosolids piles. Provisions for leachate and stormwater collection and disposal also have to be included in the design of sludge storage pads.

PROBLEMS AND DISCUSSION TOPICS

14–1 The water content of a solids slurry is reduced from 98 to 95 percent. What is the percent reduction in volume by the approximate method and by the more exact method, assuming that the solids contain 70 percent organic matter of specific gravity 1.00 and 30 percent mineral matter of specific gravity 2.00? What is the specific gravity of the 98 and the 95 percent slurry?

14–2 Consider an activated-sludge treatment plant with a capacity of 40,000 m^3/d. The untreated wastewater contains 200 mg/L suspended solids. The plant provides 60 percent removal of the suspended solids in the primary settling tank. If the primary sludge alone is pumped, it will contain 5 percent solids. Assume that 400 m^3/d of waste-activated sludge containing 0.5 percent solids is to be wasted to the digester. If the waste-activated sludge is thickened in the primary settling tank, the resulting mixture will contain 3.5 percent solids. Calculate the reduction in daily volume of biosolids pumped to the digester that can be achieved by thickening the waste-activated sludge in the primary settling tank as compared with discharging the primary and waste-activated sludge directly to the digester. Assume complete capture of the waste-activated sludge in the primary settling tank.

14–3 For Example 14–4 for gravity thickening, calculate the amount of dilution water required at average design flow using the data provided to maintain a hydraulic loading rate of 12 $m^3/m^2 \cdot d$ for the thickener size computed in the example.

14–4 Determine the required digester volume for the treatment of the sludge quantities specified in Example 14–4 using the (a) volatile solids loading factor, and (b) volumetric per capita allowance methods. Set up a comparison table to display the results obtained using the three different procedures for sizing digesters (two in this problem and one in Example 14–4). Assume the following data apply:

1. Volatile solids loading method
   a. Solids concentration = 5%
   b. Detention time = 10 d
   c. Loading factor = 3.8 kg $VSS/m^3 \cdot d$

2. Volumetric loading method
   a. Per capita contribution = 0.72 g/capita·d
   b. Volume required = 50 $m^3/10^3$ capita·d

14–5 A wastewater-treatment plant is planning to provide for separate anaerobic sludge digestion for its primary sludge. The plant receives an influent wastewater with the following characteristics:

Average flow = 8000 m^3/d

Suspended solids removed by primary sedimentation = 200 mg/L

Volatile matter in settled solids = 75%

Water in untreated sludge = 96%

Specific gravity of mineral solids = 2.60

Specific gravity of organic solids = 1.30

(*a*) Determine the required digester volume using an SRT of 12 d.

(*b*) Determine the minimum digester capacity using the recommended loading parameters of kilograms of volatile matter per cubic meter per day and cubic meters per 1000 persons.

(*c*) Assuming 90 percent moisture in the digested sludge and a 60 percent reduction in volatile matter during digestion at 32°C, determine the minimum theoretical digester capacity for this plant based on parabolic reduction in sludge volume during digestion and a digestion period of 25 d.

14–6 Consider an industrial waste consisting mainly of carbohydrates in solution. Pilot-plant experiments using a continuous-flow stirred-tank anaerobic digester without recycle yielded the following data:

Run	COD influent kg/d	X_T reactor, kg	P_x effluent kg/d
1	1000	428	85.7
2	500	115	46

Assuming a waste-utilization efficiency of 80 percent, estimate the percentage of added COD that can be stabilized when treating a waste load of 5000 kg/d. Assume that the design solids retention time (SRT) is 10 d.

14–7 A digester is loaded at a rate of 300 kg COD/d. Using a waste-utilization efficiency of 75 percent, what is the volume of gas produced when SRT = 40 d? $Y = 0.10$ and $k_d = 0.02\ d^{-1}$.

14–8 Volatile acid concentration, pH, or alkalinity should not be used alone to control a digester. How should they be correlated to predict most effectively how close to failure a digester is at any time?

14–9 A digester is to be heated by circulation of sludge through an external hot water heat exchanger. Using the following data, find the heat required to maintain the required digester temperature:

(*a*) U_x = overall heat-transfer coefficient, $W/m^2 \cdot K$

(*b*) $U_{air} = 0.85$, $U_{ground} = 1.2$, $U_{cover} = 1.0$

(*c*) Digester is a concrete tank with floating steel cover; diameter = 11 m and sidewall depth = 8 m, 4 m of which is above the ground surface. The tank walls and floor are 300 mm thick.

(*d*) Sludge fed to digester = 15 m^3/d at 14°C
(*e*) Outside temperature = −15°C
(*f*) Average ground temperature = 5°C
(*g*) Sludge in tank is to be maintained at 35°C
(*h*) Assume a specific heat of the sludge = 1.0
(*i*) Sludge contains 4% solids
(*j*) Assume a cone-shaped cover with center 0.6 m above digester top, and a cone-shaped bottom with center 1.2 m below bottom edge.

14–10 The ultimate elemental analysis of a dried sludge yields the following data:

Element	Percent
Carbon	52.1
Oxygen	38.3
Hydrogen	2.7
Nitrogen	6.9
Total	100.0

How many kg of air will be required per kg of sludge for its complete oxidation?

14–11 Compute the fuel value of the sludge from a primary settling tank (a) if no chemicals are added and (b) if the coagulating solids amount to 10 percent by weight of the dry sludge. The amount of volatile solids is 75 percent.

14–12 A community of 25,000 persons has asked you to serve as a consultant on their sludge disposal problems. Specifically, you have been asked to determine if it is feasible to compost the sludge from the primary clarifier with the community's solid waste. If this plan is not feasible, you have been asked to recommend a feasible solution. Currently the waste solids from the community's biological process are thickened in the primary clarifier. Assume the following data are applicable:

Solid waste data:

Waste production = 2 kg/person·d

Compostable fraction = 55%

Moisture content of compostable fraction = 22%

Sludge production:

Net sludge production = 0.12 kg/person·d

Concentration of sludge in underflow from primary clarifier = 5%

Specific gravity of underflow solids = 1.08

Compost:

Final moisture content of composted biosolids/solid waste mixture = 55%

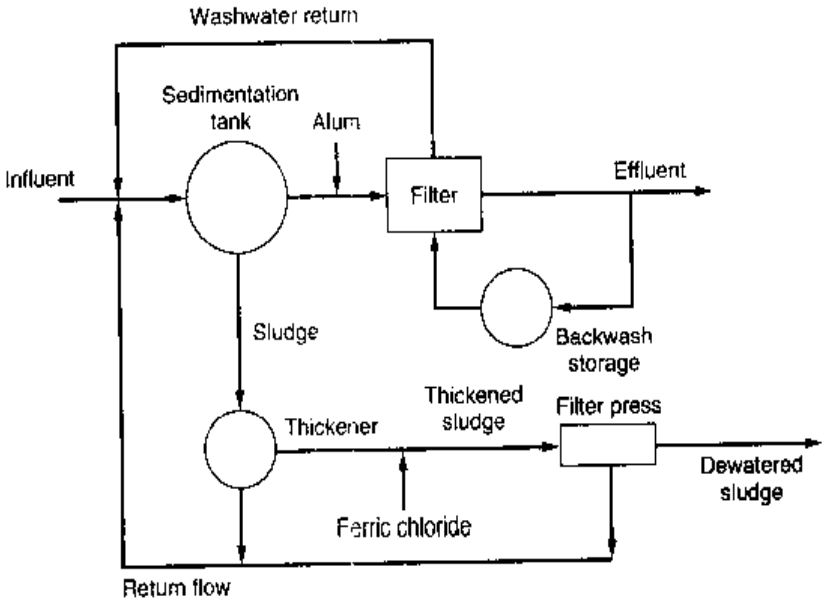
14–13 Prepare a solids balance for the peak loading condition for the treatment plant used in Example 14–9 for one of the parameter series as selected by the instructor. Enter your final values on the solids balance figure in Example 14–9.

	Parameter series			
	A	B	C	D
Peak flow rate, m^3/d	54000	60000	50000	54000
Average BOD at peak flow, mg/L	340	300	350	300
Average SS at peak flow, mg/L	350	320	330	320
SS after grit removal, mg/L	325	300	310	300

Use data given in Example 14–9 for other parameters.

14–14 Discuss the advantages and disadvantages of dissolved air flotation, centrifugation, and gravity belt thickeners for thickening waste-activated sludge.

14–15 Using the Internet and a reference buyer's guide from the Water Environment Federation or similar organization to select candidate equipment manufacturers, obtain descriptive information for egg-shaped digesters and autothermal aerobic digestion (ATAD) processes from at least one manufacturer of each process. Compare the advantages and disadvantages of each process and submit the material obtained from the Internet web sites.



14–16 Prepare a solids balance, using the iterative technique delineated in Example 14–9, for the following flow diagram and one of the following parameter series as selected by the instructor. Also determine the effluent flowrate and suspended solids concentration.

	Parameter series			
	A	B	C	D
Influent characteristics				
Flowrate, m^3/d	4000	10,000	20,000	40,000
Suspended solids, mg/L	1000	350	400	300
Sedimentation tank				
SS removal efficiency, %	75	60	65	60
Underflow SS concentration, %	7	6.5	6	5.5
Specific gravity of sludge	1.1	1.1	1.1	1.1
Alum addition				
Dosage, mg/L	10	10	20	15
Chemical solution, kg alum/L of solution	0 5	0.5	0.5	0.5
Filters				
SS removal efficiency, %	90	90	95	92
Washwater solids concentration, %	6	6	6.8	6.5
Specific gravity of backwash	1 08	1.08	1.089	1.085
Thickener				
Supernatant SS, mg/L	400	300	200	250
Concentration of solids in underflow, %	12	8	9	8

(continued)

(*Continued*)

	Parameter series			
	A	B	C	D
Chemical addition				
Dosage, % of underflow solids from thickener	0.8	1.0	1.0	1.0
Chemical solution, kg/L of solution	2.0	2.0	2.0	2.0
Filter press				
SS concentration in filtrate, mg/L	200	300	250	200
Concentration of dewatered solids, %	40	38	42	42
Specific gravity of sludge cake	1.6	1.5	1.65	1.65

In preparing the solids balance assume that all of the unit operations respond linearly such that the removal efficiency for recycled solids is the same as that for the solids in the influent wastewater. Also assume that the distribution of the chemicals added to improve the performance of the filter and filter press is proportional to the total solids in the return flows and the effluent solids.

14–17 A municipality with a population of 200,000 has hired you as a consultant to investigate alternative mechanical sludge dewatering options. The three alternatives to be investigated are belt-press dewatering, centrifugation, and pressure filter-press dewatering. The biosolids to be dewatered are stabilized by anaerobic digestion, are a mixture of primary sludge and waste-activated sludge, and have a solids concentration of 5 percent. Ultimate disposal is by landfilling at a site located 50 kilometers from the treatment plant. Compare the various dewatering alternatives and recommend one. State the reasons for your recommendation.

14–18 Determine the dry sludge application rate for Reed canary grass on the basis of satisfying crop nitrogen uptake. Assume that a biosolids containing 3 percent nitrogen by weight is applied to a soil that has an initial nitrogen content of zero. Use a decay rate of 30 percent for the first year, 15 percent for the second year, and 5 percent for the third and subsequent years.

14–19 Biosolids containing 50 mg/L of cadmium on a dry basis are to be applied to land. If the limiting mass loading to the soil is set at 10 kg/ha, what would be the safe loading rate for 50 yr of application?

14–20 Compare the advantages and disadvantages of land application of liquid biosolids to dewatered biosolids. Assume the land application site is located 15 kilometers from the treatment plant in primarily an agricultural area and the biosolids are transported by truck. The biosolids are stabilized by anaerobic digestion and the liquid biosolids concentration is 6 percent and the dewatered solids concentration is 25 percent.

14–21 In problem 14–20, what would be the advantages and limitations of conveying the liquid biosolids by pipeline to the land application site? What types of facilities, i.e., structures, equipment, and vehicles, would be required and what are the operating and maintenance considerations?

PROBLEMS AND DISCUSSION TOPICS 1723
REFERENCES 1726

In the previous chapters of this book, special attention has been devoted to the unit operations and chemical and biological unit processes used for the treatment of wastewater. While the importance of these subjects cannot be overstated, a number of other issues related to treatment-plant performance are of equal, if not of greater, importance in the planning and design of wastewater management facilities. The two most important issues are the need to treat a broader range of constituents and the fact that discharge permit limits are becoming more stringent. In response to these issues, the following topics are addressed in this chapter: (1) the need for upgrading treatment-plant performance, (2) treatment process reliability and the selection of design values, (3) odor management, (4) process control strategies, (5) upgrading wastewater treatment plants, (6) energy efficiency in wastewater treatment, and (7) considerations in the design of new wastewater treatment plants.

15–1 NEED FOR UPGRADING TREATMENT-PLANT PERFORMANCE

To meet both current and future wastewater discharge permit requirements and to meet more stringent requirements for discharge and reuse, most wastewater treatment facilities will need to undergo significant modifications and improvements.

Meeting Current and Future Needs

In the 20th century the primary focus of wastewater treatment was on the removal and treatment of settleable and floatable solids, organic matter expressed as biochemical oxygen demand (BOD), total suspended solids (TSS), and pathogenic microorganisms (see Chap. 1). Late in the century, nutrient removal and odors also became an issue. In the 21st century, wastewater treatment will still include the aforementioned constituents, but will also include a wide variety of human and veterinary antibiotics, human prescription and nonprescription drugs, industrial and household wastewater products, and sex and steroidal hormones (see Table 2–20 in Chap. 2). To treat many of these compounds, it will be necessary to optimize and upgrade existing treatment facilities and operations. In some cases, additional treatment beyond secondary treatment, such as the advanced treatment processes described in Chap. 11, will be required. For example, a considerable amount of upgrading will be required to meet new odor requirements at existing wastewater treatment plants. In some situations, new facilities will have to be designed and built.

Meeting More Stringent Discharge Requirements

Based on past events, it is clear that the discharge requirements specified in NPDES permits will become more stringent in the 21st century. For example, the following constituent values were specified in a recently issued (2001) NPDES permit in California to be complied with by the year 2006.

Constituent	Unit	Limit		Type of sample
		Type	Value	
BOD	mg/L	Monthly average	7	Daily composite
	mg/L	Weekly average	8.5	Daily composite
	mg/L	Daily maximum	10	Daily composite
TSS	mg/L	Monthly average	10	Daily composite
	mg/L	Weekly average	15	Daily composite
Trihalomethanes (THMs)				
Bromodichloromethane	μg/L	Daily maximum	1.14	Monthly grab
	μg/L	Monthly average	0.56	Monthly grab
Chloroform	μg/L	Daily average	9.3	Monthly grab
	μg/L	Monthly average	5.7	Monthly grab
Dibromochloromethane	μg/L	Daily average	0.92	Monthly grab
	μg/L	Monthly average	0.41	Monthly grab

Comparing the BOD and TSS values given above and the secondary standards given in Table 1–3 in Chap. 1, it is clear that treatment processes will have to be designed and operated differently to meet these standards. The total daily average for the three THMs is astounding, given that the current (2001) limit for total THMs in drinking water is 100 μg/L. Further, the constituent values given above are specified as *not-to-exceed* values, subject to fines and legal action for any exceedances. The State of California has enacted legislation (AB 307) by which fines can be levied for an individual exceedance, depending on the constituents and circumstances, and a mandatory fine is levied if more than four exceedances occur during any six-month period.

Discharge Limits for Wastewater Treatment Plants

Because not-to-exceed values are impossible to achieve with current wastewater treatment-plant facilities without massive expenditures, it is appropriate to define what is an acceptable level of performance. For example, 6 and 3 exceedances per year correspond to a 98.3 and 99.2 percent level of compliance, respectively. The U.S. EPA recommends an average frequency for excursions of both acute and chronic criteria not to exceed once in 3 years or 99.9 percent (U.S. EPA, 1994). It is interesting to note that not-to-exceed standards have been applied in England and Europe for the past 10 years; however, the not-to-exceed limit is usually set at the 95 percent level. For values that exceed 95 percent, fines can be levied. With nondegradation groundwater requirements that are

making their way into new NPDES permits, even 99.9 percent compliance may not be acceptable.

To meet permit limits, such as those given above, at the 98.3, 99.2, or 99.9 percent compliance level, it will be necessary to consider (1) the variability of the influent wastewater characteristics, (2) the inherent variability of biological treatment processes, and (3) the reliability of the mechanical treatment-plant components. Even with effective design and operation, it may not be possible to meet very stringent discharge requirements at the 99.9 percent compliance level for a number of constituents without the use of additional treatment processes. Management of the additional residuals that would result from enhanced treatment is another issue that must be addressed. The need for process optimization, additional treatment processes, or even the implementation of new treatment technologies will have to be addressed on a case-by-case basis, depending on the constituent or constituents that must be removed and the levels to which those constituents must be removed. The question of what NPDES permit limits are set and whether these limits are appropriate is left to the courts and to another book.

15–2 TREATMENT PROCESS RELIABILITY AND SELECTION OF DESIGN VALUES

Reliability of a treatment plant or a treatment process may be defined as the probability of adequate performance for a specified period of time under specified conditions or, in terms of treatment-plant performance, the percent of the time that effluent concentrations meet specified permit requirements. For example, a treatment process with a reliability of 99 percent is expected to meet the performance requirements 99 percent of the time. For 1 percent of the time, or three to four times per year, the not-to-exceed daily permit limits would be expected to be exceeded. Such a level of performance may, or may not, be acceptable depending on the permit requirements. For each specific case where the reliability concept is to be employed, the levels of reliability must be evaluated including the cost of the facilities required to achieve the specified levels of reliability and the associated operating and maintenance costs. Thus, the purpose of this section is to examine how treatment process variability is assessed and how the performance of combined processes can be evaluated. The specific topics to be discussed are (1) variability in wastewater treatment, (2) selection of process design parameters, (3) the performance of combined processes, and (4) the development of input-output relationships.

Variability in Wastewater Treatment

Three categories of variability that can affect the design, performance, and reliability of a wastewater treatment plant are (1) variability of the influent wastewater flowrate and characteristics, (2) inherent variability in wastewater treatment processes, and (3) variability caused by mechanical breakdown, design deficiencies, and operational failures. Each of these categories of variability is considered in the following discussion. Following the discussion of these topics, an approach to the selection of design values in which the observed variability can be taken into account is introduced and illustrated subsequently in Example 15–1.

Variability of Influent Wastewater Flowrate and Characteristics. Because of the way modern human life is organized, there is variability in the influent wastewater flowrates and characteristics observed at wastewater treatment plants (see Chap. 3). A typical example of the variability that can be observed in influent wastewater flowrates and characteristics is illustrated on Fig. 15–1. As shown on Fig. 15–1*a*, the summer flowrates are very stable and follow a log-normal distribution, whereas the entire daily set of flowrate data is influenced significantly by the high winter flowrates and is therefore extremely variable. In fact, the complete daily flowrate data set cannot be modeled with either an arithmetic or a log-normal distribution. As will be discussed subsequently, such variability, which is not uncommon, is of concern where stringent discharge requirements must be met. In some cases, it will be necessary to reduce the amount of infiltration/inflow in the collection system and/or install equalization facilities to improve treatment process performance. The use of equalization facilities has the added benefit of reducing the size of the individual treatment units that may be needed. In general, as the capacity of the treatment facility increases, the observed variability in flowrates will tend to decrease.

Inherent Variability in Wastewater Treatment Processes. Because of the variability of the influent wastewater flowrate and characteristics, the variability of all treatment processes due to design limitations, the inherent variability of biological

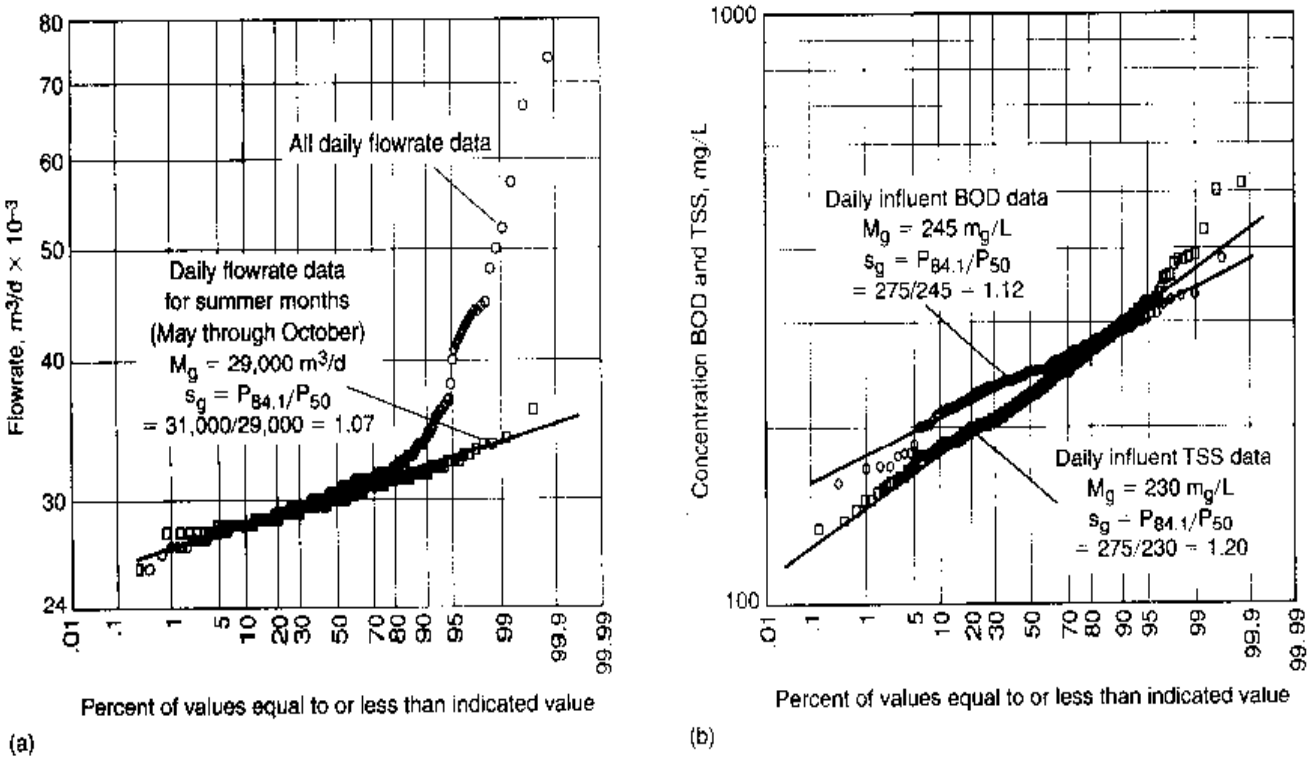

Figure 15–1

Probability distributions for daily influent wastewater characteristics collected over one year: (*a*) flowrate and (*b*) biochemical oxygen demand (BOD) and total suspended solids (TSS).

treatment processes due to the presence of living microorganisms and the laws of chance, all physical, chemical, and biological treatment processes exhibit some measure of variability with respect to the performance that can be achieved. Based on an analysis of effluent performance data from a number of wastewater treatment processes, it has been observed that the performance of most processes for most constituents can be modeled with a log-normal distribution. In some cases, when dealing with advanced wastewater treatment processes, many of the effluent constituent values will be reported as nondetect (ND), method detection limit (MDL), or level of quantification (LOQ) (see Sec. 2–1 in Chap. 2). When such values occur in a data set, the data set is said to be *censored* in a statistical sense. Methods that can be used to estimate summary statistics for censored data sets are discussed in Helsel and Cohn (1998) and Helsel (1990). Typical performance summaries for various processes for a variety of constituents that have been presented in previous chapters of this textbook are summarized in Table 15–1. The variability in these distributions, measured in terms of the geometric standard deviation, s_g, is also presented in Table 15-1 for the purpose of discussion and comparison. The greater the numerical value of s_g, the greater the observed range in the measured values.

Table 15–1
Variability observed in selected treatment processes taken from various figures presented in previous chapters

Constituent	Figure	Unit	Statistic[a]		
			$M_g = P_{50}$	$P_{84.1}$	s_g[b]
Flowrate	3–11	m^3/d	8000	9100	1.14
Primary influent BOD	3–11	mg/L	175	220	1.26
Primary influent TSS	3–11	mg/L	150	195	1.27
Effluent turbidity from granular-medium filtration following biological treatment	1 –19	NTU	1.4	1.8	1.29
Effluent TSS from granular-medium filtration following biological treatment	1 –19	mg/L	1.95	2.8	1.44
Effluent turbidity from disk filter following biological treatment	1 .–31*a*	NTU	0.65	0.85	1.31
Effluent TSS from disk filter following biological treatment	11–31*a*	mg/L	0.58	0.90	1.55
Primary influent coliphage	13–16	pfu/100 mL	2.1×10^4	3.5×10^4	1.67
Secondary effluent coliphage following activated-sludge treatment	13–16	pfu/100 mL	300	500	1.67
Filter effluent coliphage following secondary sedimentation	13–16	pfu/100 mL	140	450	3.21
Coliphage following disinfection with chlorine	13–16	pfu/100 mL	2	5	2.50
TDS in reverse osmosis effluent following microfiltration	13–17*a*	mg/L	16	21	1.31
Seeded coliphage removal with reverse osmosis	13–17*b*	log removal	5.9	6.8	1.15

[a] All of the reported distributions are log-normal.
[b] $s_g = P_{84.1}/P_{50}$.

In general, it has been found that the performance of conventional biological treatment processes for wastewater constituents that can be modified by treatment, such as BOD, TOC, etc., can be described most frequently with a log-normal distribution. For constituents that are not modified significantly such as inorganic TDS, both arithmetic and log-normal distributions can be used to model process performance. Where the variability in performance is not great, both the arithmetic and log-normal distributions can be used to model the observed performance. The Weibull distribution (Kokoska and Zwillinger, 2000) has also proven to be useful in the analysis of the performance of advanced wastewater treatment processes (WCPH, 1996, 1997). It should also be noted that censored effluent data sets are encountered often in assessing the performance of advanced wastewater treatment processes (see above).

Mechanical Process Reliability. In addition to the variability in the influent wastewater flowrate and characteristics and the inherent variability in the response of wastewater treatment processes, the variability associated with the mechanical equipment used at wastewater treatment facilities must also be considered in analyzing what design values and how much standby equipment must be available to meet stringent standards at some specified reliability value (e.g., 99 or 99.9 percent). Several approaches are available for analyzing mechanical reliability of a treatment plant including the following (WCPH, 1996).

1. Critical component analysis (CCA)
2. Failure modes and effects analysis
3. Event tree analysis
4. Fault tree analysis

All four of these approaches are cited frequently in the literature and are used by a variety of industries. The critical component analysis (CCA) approach was developed by the U.S. EPA to determine the in-service reliability, maintainability, and operational availability of selected critical wastewater treatment components (U.S. EPA, 1982). The objective of the CCA is to determine which mechanical components in the wastewater treatment plant will have the most immediate impact on effluent quality should failure occur (WCPH, 1996, 1997). The statistical parameters used most commonly in applying the CCA method, as defined in Table 15–2, are *mean time before failure* (MTBF),

Table 15–2
Statistical measures used to assess equipment reliability[a]

Statistical measure	Description
Mean time before failure (MTBF)	A measure of the mechanical reliability of equipment, determined by the number of failures. The usual approach is to divide the operating hours by the number of failures
Expected time before failure (ETBF)	Similar to the MTBF, but the actual elapsed time is used as the total time in service
Inherent availability (AVI)	Fraction of calendar time that the component or unit was operating
Operating availability (AVO)	Fraction of time the component or unit can be expected to be operational excluding preventive maintenance

[a]Adapted from U.S. EPA (1982). WCPH (1996, 1997).

Table 15–3

expected time before failure (ETBF), *inherent availability* (AVI), *and operating availability* (AVO).

In a study of the San Pasqual Aqua III treatment system in San Diego, CA, a complete process reliability analysis was performed (WCPH, 1996, 1997). The Aqua III treatment system was designed to produce 3800 m^3/d (1.0 Mgal/d) of reclaimed water. The treatment facility includes preliminary treatment (coarse screening and grit removal), primary treatment (rotary drum and disk screens), secondary treatment (water hyacinth ponds), and tertiary treatment (a package plant consisting of coagulation, softening, sedimentation, and filtration). Advanced wastewater treatment consists of ultraviolet disinfection, reverse osmosis, air stripping, and granular activated carbon adsorption. Sodium hypochlorite is used for plant effluent disinfection, with the required contact time taking place within the distribution system. The results of the process reliability analysis are presented in Table 15–3. As shown, the preliminary treatment process has the lowest MTBF. Typical problems experienced with the preliminary treatment facilities included tripped breaker, packing leak, and gearbox failure. With the exception of three treatment processes, the AVO for the remaining processes was greater than 0.99. The AVI was greater than 0.99 for all of the treatment process (WCPH, 1996, 1997). Information such as that presented in Table 15–3 is used to determine maintenance schedules and the requirements for standby parts and backup components.

Selection of Process Design Parameters to Meet Discharge Permit Limits

Because of the variations in effluent quality, treatment plants must now be designed to produce an average effluent concentration below the permit requirements. The question

is: What mean value should be used for process design to be assured that constituent concentrations in the effluent will be equal to or less than a specified limit with a specified degree of reliability? Two approaches can be used to estimate the design mean value needed to meet prescribed standards: (1) a statistical approach involving the coefficient of reliability and (2) a graphical approach. Both of these approaches are described and illustrated in the following discussion. Whether the mean value arrived at can be designed for is a question that is addressed subsequently.

Statistical Approach to Selection of Mean Design Value. One approach that can be used to determine the mean design value involves the use of the coefficient of reliability (COR) approach developed by Niku et al. (1979, 1981). In the COR method, the mean constituent values (design values) are related to the standards that must be achieved on a probability basis. The mean value, m_d, may be obtained by the relationship

$$m_d = (\text{COR})X_s \tag{15–1}$$

where m_d = mean constituent design value (e.g., g/m^3, mg/L)
X_s = a fixed standard that must be met at a specified reliability level (e.g., g/m^3, mg/L)
COR = coefficient of reliability, unitless

The coefficient of reliability is determined using the following expression.

$$\text{COR} = [(V_x^2 + 1)^{1/2}] \exp\{-Z_{1-\alpha}[\ln (V_x^2 + 1)]^{1/2}\} \tag{15–2}$$

where V_x = coefficient of variation of the ratio of the existing distribution = σ_x/m_x (see also Table 3–10 in chap. 3)
σ_x = standard deviation of performance values (i.e., daily, weekly, or monthly) from an existing treatment process
m_x = mean of performance values (i.e., daily, weekly,or monthly) from an existing treatment process
$Z_{1-\alpha}$ = number of standard deviations away from mean of a normal distribution
$1 - \alpha$ = cumulative probability of occurrence (reliability level)

Values of $Z_{1-\alpha}$ for various cumulative probability levels, $1 - \alpha$, are given in Table 15–4. Values of COR for determining effluent concentrations for different coefficients of variation at different levels of reliability are reported in Table 15–5. Selection of an appropriate value of V_x must be based on data from operating facilities. The use of the reliability concept is illustrated in Example 15–1, following the discussion of the graphical approach to the selection of process design values.

Graphical Approach to Selection of Mean Design Value. Another method of determining appropriate mean design values to meet the specified effluent standards is the graphical probability method. If it is assumed that the geometric standard deviation can be used as a measure of reliability and that the value remains approximately constant at other design values, then the required effluent value can be set at the specified reliability level (e.g., 10 mg/L at 99 percent) and a line is passed through the value with the same geometric standard deviation as the measured data. The value at a probability value of 50 percent is the new mean design value.

Table 15–4 Values of standardized normal distribution[a]

Cumulative probability $1 - \alpha$	Percentile $Z_{1-\alpha}$
99.9	3.090
99	2.326
98	2.054
95	1.645
92	1.405
90	1.282
80	0.842
70	0.525
60	0.253
50	0

[a]From Niku et al. (1979).

The graphical approach is illustrated on Fig. 15–2. The plotted data correspond to the monthly total copper concentration values in the effluent from a wastewater treatment plant. If the permit limit is to be 10 μg/L at the 99.9 percent reliability value, that value is plotted and a line with the same geometric standard deviation is drawn through the point. The value at a probability of 50 percent on the line drawn through permit limit corresponds to the required mean design value, in this case 2.1 μg/L. For many constituents, it will be found that the required mean design value cannot be met with an existing process. Where the required mean value cannot be met with a single process,

Figure 15–2

Probability distributions: (a) monthly effluent total copper (Cu) concentration values collected over a period of 2 years and (b) corresponding distribution to achieve 99.9 percent compliance with a copper permit limit of 10 μg/L, drawn with the same geometric standard deviation as the original distribution.

it may be necessary to use two or more treatment processes in series. The typical geometric standard deviation values given in Table 15–1 can also be used for the design of new treatment plants if the discharge permit limits are known.

EXAMPLE 15–1 Estimating Effluent Design BOD and TSS Concentrations Based on Reliability Considerations An existing activated sludge plant is required to be expanded and upgraded to meet new permit requirements. The new effluent requirements are as given below. Determine the mean design effluent BOD and TSS concentrations required to meet the 99 percent reliability level for the monthly standard and the 99.9 percent reliability level for the weekly standard using the COR method and the log-probability graphical method. Average monthly effluent BOD and TSS data for the existing facility for a period of 1 year are also given below.

Effluent requirements

Constituent	Monthly mean	Weekly mean
BOD, mg/L	15	20
TSS, mg/L	15	20

Monthly performance data

Month	BOD, mg/L	TSS, mg/L
Jan	34.0	15.0

Median	23.55	20.80
RMS	24.33	21.46
Std deviation	4.65	3.64
Variance	21.67	13.22
Std error	1.34	1.05
Skewness	0.61	0.21
Kurtosis	0.05	−0.53

2. Determine the coefficient of reliability using Eq. (15–2) at a cumulative probability of 99%.

$$\text{COR} = [(V_x^2 + 1)^{1/2}] \exp\{-Z_{1-\alpha}[\ln (V_x^2 + 1)]^{1/2}\}$$

a. Determine the value of V_x using the results of the statistical analysis.
   i. For BOD

$$V_x = \frac{\sigma_x}{m_x} = \frac{4.65}{23.92} = 0.194$$

   ii. For TSS

$$V_x = \frac{\sigma_x}{m_x} = \frac{3.64}{21.18} = 0.172$$

b. The value of $Z_{1-\alpha}$ for a cumulative probability of 99% from Table 15–4 is 2.326.
c. Determine the coefficient of reliability.
   i. For BOD

$$\text{COR} = [(0.194^2 + 1)^2]\exp\{-2.326[\ln(0.194^2 + 1)]^{1/2}\} = 0.69$$

   ii. For TSS

$$\text{COR} = [(0.172^2 + 1)^2]\exp\{-2.326[\ln(0.172^2 + 1)]^{1/2}\} = 0.71$$

3. Determine the coefficient of reliability using Eq. (15–2) at a cumulative probability of 99.9%.
   a. Determine the value of V_x from Step 2a.
      i. For BOD

$$V_x = 0.194$$

      ii. For TSS

$$V_x = 0.172$$

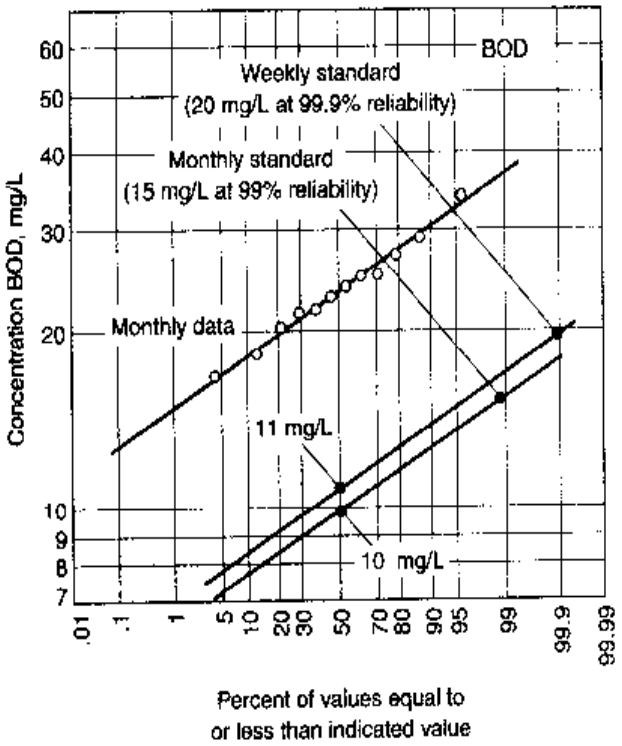
   b. The value of $Z_{1-\alpha}$ for a cumulative probability of 99.9% from Table 15–4 is 3.090.
   c. Determine the coefficient of reliability.
      i. For BOD

$$\text{COR} = [(0.194^2 + 1)^2]\exp\{-3.090[\ln(0.194^2 + 1)]^{1/2}\} = 0.59$$

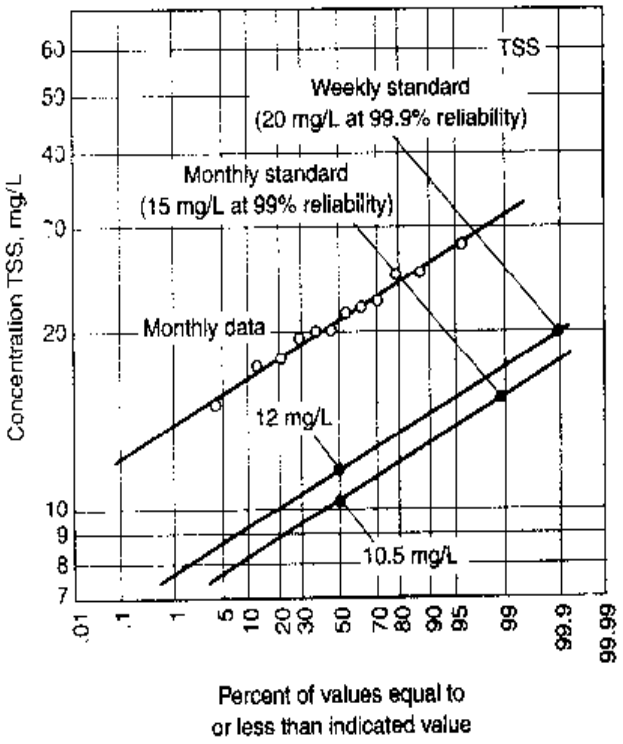
      ii. For TSS

$$\text{COR} = [(0.172^2 + 1)^2]\exp\{-3.090[\ln(0.172^2 + 1)]^{1/2}\} = 0.63$$

4. Determine the design effluent concentrations for 99% reliability for the monthly standard.
   a. Mean design BOD = (COR) X_s
   $= 0.69 \times 15$ mg/L $= 10.4$ mg/L
   b. Mean design TSS $= 0.71 \times 15$ mg/L $= 10.7$ mg/L
5. Determine the design effluent concentrations for 99.9% reliability for the weekly standard.
   a. Mean design BOD = (COR) X_s
   $= 0.59 \times 20$ mg/L $= 11.8$ mg/L
   b. Mean design TSS $= 0.63 \times 20$ mg/L $= 12.6$ mg/L



6. Use the most conservative values for design.



$BOD_{design} = 10.4$ mg/L

$TSS_{design} = 10.7$ mg/L

Solution Part 2 Log-Probability Graphical Method

1. Plot the monthly data for BOD and TSS on log-probability paper. The required plots for BOD and TSS are shown below.

2. Estimate the design effluent concentrations for BOD and TSS for (a) 99% reliability for the monthly standard and (b) 99.9% reliability for the weekly standard.
   a. Determine the design effluent concentrations for BOD. The BOD concentrations are determined by passing lines with the same slope as the measured data through the points at 15 mg/L and 99% and 20 mg/L and 99.9% and noting the corresponding values at 50%. The values so determined are:

      BOD_{design} at 15 mg/L and 99% = 10.0 mg/L

      BOD_{design} at 20 mg/L and 99.9% = 11.0 mg/L

   b. Determine the design effluent concentrations for TSS. The TSS concentrations are determined by passing lines with the same slope as the measured data through the points at 15 mg/L and 99% and 20 mg/L and 99.9% and noting the corresponding values at 50%. The values so determined are:

TSS_{design} at 15 mg/L and 99% = 10.5 mg/L

TSS_{design} at 20 mg/L and 99.9% = 11 mg/L

It is interesting to note that the values determined graphically are essentially the same as those determined analytically using the COR method.

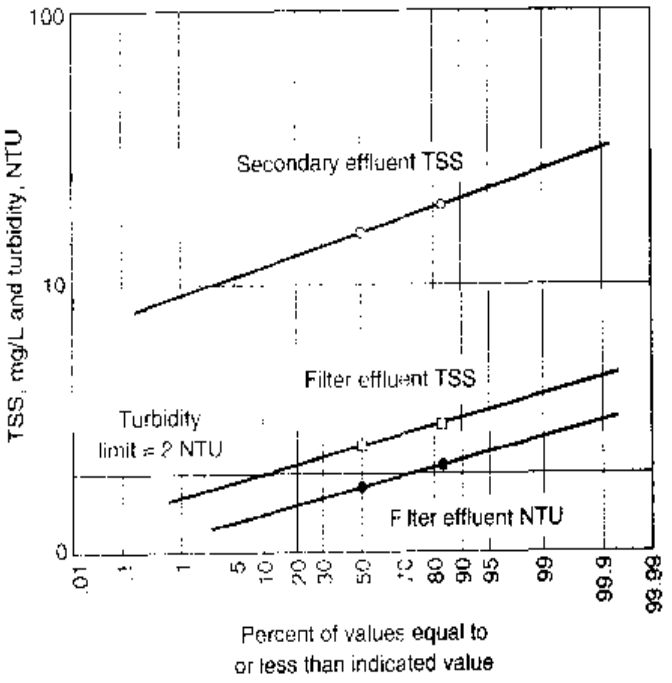
Comment When the concept of reliability is used, the mean effluent values selected for design will typically be significantly lower than permit requirements. Loge et al. (2001) demonstrated how the coefficient of variation was reduced (i.e. process variability) when processes are used in series with respect to the disinfection of treated effluent with UV radiation. Based on numerous past designs in England and Europe, it has been found that to achieve the prescribed limit at the 95 percent level the average design value should be about 50 percent of the prescribed limit.

Performance of Combined Processes

Applying the statistical and graphical procedures as illustrated in Example 15–1, it will often be found that the resulting mean design value for a given process is well below the range where any factual knowledge exists on how to design the process. For example, assume that to meet NPDES permit requirements, an activated sludge process must be designed to meet an average effluent suspended solids concentration of 4 mg/L. Realistically, it is now not possible to design a secondary clarifier to meet a specific design value. What is typically assumed is that with good design and effective operation of the secondary process, an average TSS value of 4 or 5 mg/L can be achieved. Unfortunately, such assumptions are not acceptable when not-to-exceed permit limits must be met. In such a situation, it will usually be necessary to add an additional process, such as depth or surface filtration, to meet the permit requirements consistently. In the following example the basis for determining the performance of the combined treatment processes is addressed.

EXAMPLE 15–2 Estimating the Performance of Combined Treatment Processes Based on Reliability Considerations Estimate the combined performance at the 98.3, 99.2, and 99.9 percent levels for an activated sludge process followed by a granular-medium depth filter with respect to the removal of TSS and turbidity. Assume the following data apply to the activated sludge process. Also, assume that no chemicals are to be used with the depth filter.

1. Distribution for effluent TSS is log-normal
2. Geometric mean for effluent TSS, M_g = 15 mg/L
3. Geometric standard deviation for TSS, s_g = 1.25
4. Also $s_g = P_{84.1}/P_{50}$ (see Table 3–10 in Chap. 3)



Solution

1. From Fig. 11–18, develop a relationship between influent turbidity for a typical granular-medium depth filter. From Fig. 11–18, find, for a best fit line by eye, that

when the effluent turbidity is 2 NTU, the influent turbidity is 7.5 NTU, and the intercept of the line of best fit passes through 0.5 NTU. For these conditions the corresponding relationship is:

Filter effluent turbidity, NTU = 0.5 NTU + 0.2(filter influent turbidity, NTU)

2. To determine the TSS values after filtration, use the following two relationships given previously in Chap. 11.
   a. Secondary effluent TSS, mg/L = (2.3 mg/L/NTU) (effluent turbidity, NTU) [Eq. (11–32)]
   b. Filter effluent TSS = (1.4 mg/L/NTU) (filter effluent turbidity, NTU) [Eq. (11–33)]
3. Using the above relationships, determine the values corresponding to 50% and 84.1% (one standard deviation) after filtration
   a. At 50%
      i. Secondary effluent turbidity = (15 mg/L)/[(2.3 mg/L)/NTU] = 6.52 NTU
      ii. Filter effluent turbidity = 0.5 NTU + 0.2(6.52 NTU) = 1.8 NTU
      iii. Filter effluent TSS = [(1.4 mg/L)/NTU] (1.8 NTU) = 2.52 mg/L
   b. At 84.1% [use Eq. (3-9) from Chap. 3]
      i. $P_{84.1} = P_{50} \times s_g$ = 15 mg/L × 1.25 = 18.75 mg/L
      ii. Secondary effluent turbidity = (18.75 mg/L)/[(2.3 mg/L)/NTU]
      = 8.15 NTU
      iii. Filter effluent turbidity = 0.5 NTU + 0.2(8.15 NTU) = 2.13 NTU
      iv. Filter effluent TSS = [(1.4 mg/L)/NTU] (2.13 NTU) = 2.98 mg/L
4. Plot the secondary effluent TSS and the filter effluent turbidity and TSS and prepare a summary compliance table.
   a. Log-probability plot

b. Summary table

Item	Unit	Value at indicated probability		
		98.3%	99.2%	99.9%
TSS	mg/L	2.6	2.9	4.2
Turbidity	NTU	2.5	2.8	3.0

Comment As shown in the summary table, 6 TSS exceedances per year (98.3 percent probability) would be equal to or greater than 2.6 mg/L, 3 TSS exceedances per year (99.2 percent probability) would be equal to or greater than 2.9 mg/L, and 1 TSS exceedance in 3 years (99.9 percent probability) would be equal to or greater than 4.2 mg/L. If a turbidity level of 2 NTU had to be met for reuse applications, the 2 NTU limit would be exceeded 25 percent of the time, without the use of additional treatment.

Development of Input-Output Data

To predict the performance of different combined processes, input-output relationships such as presented in Example 15–2 will have to be developed. In general, input-output relationships are needed for processes with short treatment retention times such as granular and surface filtration, microfiltration, ultrafiltration, and reverse osmosis. Input-output relationships for processes where the treatment process performance is decoupled from the hydraulic retention time, such as the activated sludge process, are not very useful because of the buffering provided by the process. Further, as illustrated in Sec. 7–5 in Chap. 7, the value of the effluent substrate concentration for the activated sludge process is independent of the influent concentration. The variability observed in the effluent BOD, TSS, and other constituent values from activated sludge processes reflects (1) the inherent variability of the biological process (notwithstanding conclusions reached from the theoretical equations); (2) the diurnal, daily, monthly, and seasonal variation in the influent flowrates and wastewater characteristics; (3) the impact of process adjustments made by operators; and (4) the configuration of the physical facilities. For most processes with short retention times, the output values will be affected by the influent concentrations. It is interesting to note that the performance of the cloth media disk filter, as illustrated on Fig. 11–31*b* in Chap. 11, is essentially independent of the influent turbidity for turbidity values up to 30 NTU.

A further and very important consideration in the development of input-output relationships for processes following the activated sludge process is the solids retention time (SRT) at which the process is operated. As illustrated on Fig. 12–48 in Chap. 12, the number of particles with one or more associated coliform organisms will vary with the SRT. It has also been observed that the performance of downstream processes employing some form of filtration will also vary with the SRT value. Thus, the SRT value must be taken into account when developing input-output relationships for downstream processes. In general, it will not be possible to use input-output relationships developed for processes following activated sludge processes with long SRT values

(> 10 d) to predict the combined performance of downstream processes following activated sludge processes with short SRT values (1 to 2 d).

15–3 ODOR MANAGEMENT

The potential release of odors is a major concern of the public relative to modifying existing wastewater treatment facilities and constructing new facilities. Thus, the control of odors has become a major consideration in the design and operation of wastewater collection, treatment, and disposal facilities, especially with respect to the public acceptance of these facilities. In many instances, projects have been rejected because of the fear of potential odors. In several states, wastewater management agencies are now subject to fines and other legal action over odor violations. In view of the importance of odors in the field of wastewater management, the following discussion will deal with (1) the types of odors encountered, (2) the sources of odors, (3) the movement of odorous gases, (4) strategies for odor control, (5) odor control methods, and (6) the design of odor-control facilities.

Types of Odors

For humans, the importance of odors at low concentrations is related primarily to the psychological stress the odors cause, rather than to the harm they do to the body. The principal types of odors encountered in wastewater management facilities are reported in Table 15–6. With few exceptions, odorous compounds typically contain either sulfur or nitrogen. The characteristic odor of organic compounds containing sulfur is that of decayed organic material. Of the odorous compounds reported in Table 15–6, the rotten egg smell of hydrogen sulfide is the odor encountered most commonly in wastewater management facilities. As noted in Chap. 2, gas chromatography has been used successfully for the identification of specific compounds responsible for odors. Unfortunately, this technique has not proved as successful in the detection and quantification of odors derived from wastewater collection, treatment, and disposal facilities, because of the many compounds that may be involved. It should be noted that at higher concentrations, many of the odorous gases (e.g., hydrogen sulfide) can, depending on exposure, be lethal.

Sources of Odors

The principal sources of odors in wastewater management facilities and the relative potential for release of odor are presented in Table 15–7. Minimization of odors from these sources is the concern of odor management.

Wastewater Collection Systems. The potential for odor release from collection systems is high. The principal sources of odorous compounds in collection systems are from (1) the biological conversion, under anaerobic conditions, of organic matter containing nitrogen and sulfur, and (2) the discharge of industrial wastewater that may contain odorous compounds or compounds that may react with compounds in the wastewater to produce odorous compounds. Odorous gases released to the sewer atmosphere can accumulate and be released at air release valves, cleanouts, access ports (i.e., manholes), and house vents.

Table 15–6
Odor thresholds of odorous compounds and their characteristics associated with wastewater management[a]

Odorous compound	Chemical formula	Molecular weight	Odor threshold, ppm_v[b]	Characteristic odor
Ammonia	NH_3	17.0	46.8	Pungent, irritating
Chlorine	Cl_2	71.0	0.314	Pungent, suffocating
Chlorophenol	ClC_6H_4OH		0.00018	Medicinal odor
Crotyl mercaptan	$CH_3—CH=CH—CH_2—SH$	90.19	0.000029	Skunklike
Dimethyl sulfide	$CH_3—S—CH_3$	62	0.0001	Decayed cabbage
Diphenyl sulfide	$(C_6H_5)_2S$	186	0.0047	Unpleasant
Ethyl mercaptan	$CH_3CH_2—SH$	62	0.00019	Decayed cabbage
Ethyl sulfide	$(C_2H_5)_2SH$		0.000025	Nauseating odor
Hydrogen sulfide	H_2S	34	0.00047	Rotten eggs
Indole	C_8H_6NH	117	0.0001	Fecal, nauseating
Methyl amine	CH_3NH_2	31	21.0	Putrid, fishy
Methyl mercaptan	CH_3SH	48	0.0021	Decayed cabbage
Skatole	C_9H_9N	131	0.019	Fecal odor, nauseating
Sulfur dioxide	SO_2	64.07	0.009	Pungent, irritating
Thiocresol	$CH_3—C_6H_4—SH$	124	0.000062	Skunklike, rancid
Trimethyl amine	$(CH_3)_3N$	59	0.0004	Pungent, fishy

[a] Adapted in part from Patterson et al. (1984), U.S. EPA (1985), and WEF (1998).
[b] Parts per million by volume.

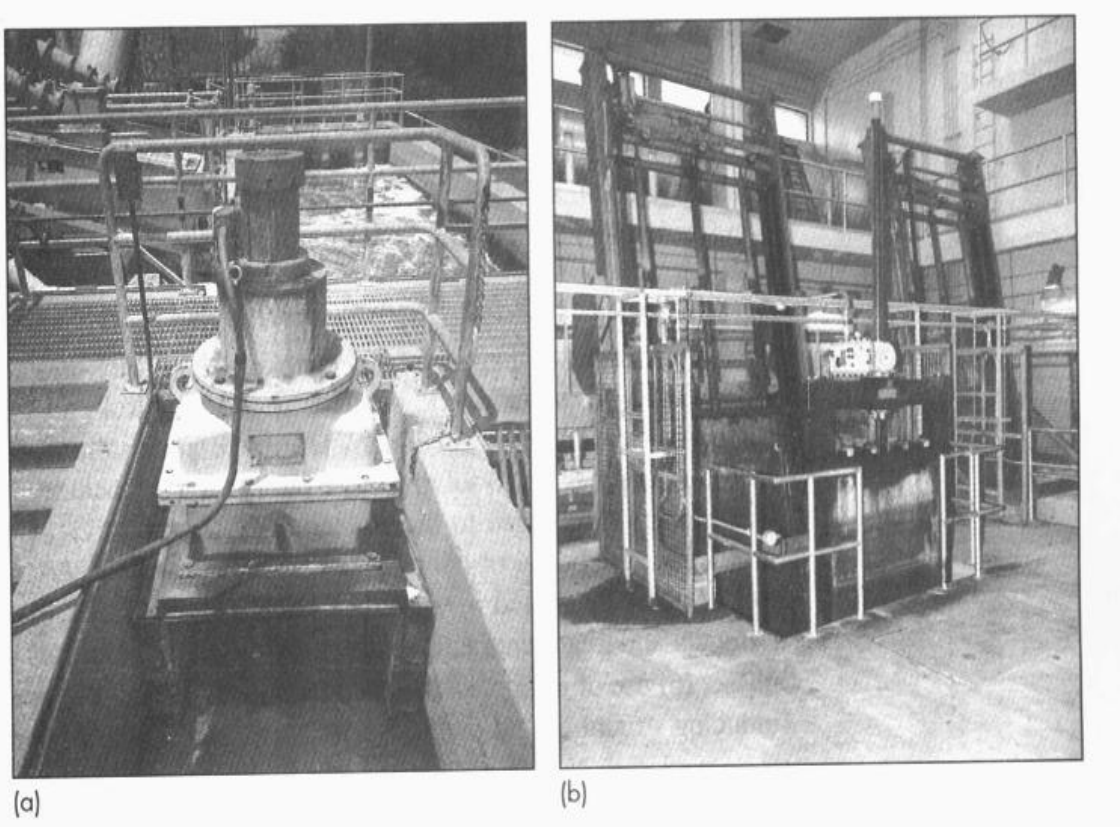
Wastewater Treatment Facilities. In considering the potential for the generation and release of odors from treatment plants, it is common practice to consider the liquid and solids processing facilities separately. The headworks and preliminary treatment operations have the highest potential for release of odor, especially for treatment plants that have long collection systems where anaerobic conditions can be created (see Fig. 15–3). Sidestream discharges including return flows from filter backwashing and from sludge and biosolids processing facilities are often a major source of odors, especially where these flows are allowed to discharge freely into a control structure or mixing chamber.

Sludge and Biosolids Handling Facilities. Typically, the most significant sources of odors at wastewater treatment plants are sludge-thickening facilities, anaerobic digesters, and sludge-loadout facilities. The highest potential for odor release occurs when unstabilized sludge is handled (e.g., turned, spread, or stored).

One of the major contributors to odor in solids processing and an important item to consider in treatment plant design is shear. Shear is the cutting or tearing of solids by shear stress. When solids undergo mixing by either high shear dewatering or conveyance equipment, particle size reduction occurs and odor production increases.

Table 15–7
Sources of odor in wastewater management systems[a]

Location	Source/cause	Odor potential
Wastewater-collection system		
Air release valves	Accumulation of odorous gases released from wastewater	High
Cleanouts	Accumulation of odorous gases released from wastewater	High
Access ports (manholes)	Accumulation of odorous gases released from wastewater	High
Industrial wastewater discharges	Odorous compounds may be discharged to wastewater collection system	Variable
Raw wastewater pumping station	Wetwell/septic raw wastewater, solids, and scum deposits	High
Wastewater treatment facilities		
Headworks	Release odorous gases generated in the wastewater collection system due to turbulence in hydraulic channels and transfer points	High
Screening facilities	Putrescible matter removed by screening	High
Preaeration	Release of odorous compounds generated in wastewater collection system	High
Grit removal	Organic matter removed with grit	High
Flow-equalization basins	Basin surfaces/septic conditions due to accumulation of scum and solids deposits	High
Septage receiving and handling facilities	Odorous compounds can be released at septage receiving stations, especially when septage is being transferred	High
Sidestream returns[b]	Return flows from biosolids processing facilities	High
Primary clarifiers	Effluent weirs and troughs/turbulence that releases odorous gases. Scum—either floating or accumulated on weirs and baffles/putrescible matter. Floating sludge/septic conditions	High/moderate
Fixed-film processes (trickling filters or RBCs)	Biological film/septicity due to insufficient oxygen, high organic loading, or plugging of trickling filter medium; turbulence causing release of odorous material	Moderate/high
Aeration basins	Mixed liquor/septic return sludge, odorous sidestream flows, high organic loading, poor mixing, inadequate DO, solids deposits	Low/moderate
Secondary clarifiers	Floating solids/excessive solids retention	Low/moderate
Sludge and biosolids facilities		
Thickeners, solids holding tanks	Floating solids; weirs and troughs/scum and solids septicity due to long holding periods, solids deposits, and temperature increases; odor release by turbulence	High/moderate
Aerobic digestion	Incomplete mixing in reactor	Low/moderate
Anaerobic digestion	Leaking hydrogen sulfide gas/upset conditions, high sulfate content in solids	Moderate/high
Sludge storage basins	Lack of mixing, formation of scum layer	Moderate/high
Mechanical dewatering by belt-filter press, recessed plate-filter press, or centrifuge	Cake solids/putrescible matter; chemical addition, ammonia release	Moderate/high



(continued)

Table 15–7 (*Continued*)

Location	Source/cause	Odor potential
Sludge and biosolids facilities (*continued*)		
Sludge loadout facilities	Release of odors during the transfer of biosolids from storage to transfer facilities	High
Composting facilities	Composting solids/insufficient aeration, inadequate ventilation	High
Alkaline stabilization	Stabilized solids/ammonia generation resulting from reaction with lime	Moderate
Incineration	Air emissions/combustion temperature is not high enough to destroy all organic substances	Low
Sludge drying beds	Drying solids/excess putrescible matter due to insufficient stabilization	Moderate/high

[a] Adapted in part from WEF (1995).

[b] Sidestreams could include digester decant, dewatering return flows, or backwash water.

(a) (b)

Figure 15–3

Typical examples of headworks facilities: (*a*) uncovered influent channel leading to in-line comminutor and (*b*) coarse bar screens housed in an enclosed building with odor-control facilities.

Solids that exit a dewatering facility can be sheared enough to release odors. The major mechanism appears to be the release of proteinaceous biopolymer. Once released, these proteins are degraded, liberating a number of odorous compounds, but mostly mercaptans. The increase in solution protein also makes dewatering poorer. The solution proteins can be "coagulated" by addition of polymer, but the synthetic polymers are degraded and the protein becomes degradable. The synthetic polymer can also generate methylamines when degraded (Novak, 2001; Murthy, 2001).

Trimethylamine (TMA) is present in the liquid phase in many anaerobically digested sludges. Trimethylamine is like ammonia in that it is soluble below pH 9, but above this pH level it is a gas and can be released into the air. Adding lime to digested sludge for odor control may, in fact, liberate odor by converting TMA to a gas (Novak, 2001; Murthy, 2001). Some plants may be unable to land apply dewatered sludge because of the increased odor production. Thus, in evaluating processing and disposal options, the ramifications of odor generation and control have to be evaluated carefully.

Movement of Odors from Wastewater Treatment Facilities

Under quiescent meteorological conditions, odorous gases that develop at treatment facilities tend to hover over the point of generation (e.g., sludge thickening facilities, sludge storage lagoons), because the odorous gases are more dense than air. Depending on the local meteorological conditions, it has been observed that odors may be measured at undiluted concentrations at great distances from the point of generation. The following events appear to happen: (1) in the evening or early morning hours, under quiescent meteorological conditions, a cloud of odors will develop over the wastewater treatment unit prone to the release of odors; and (2) the concentrated cloud of odors can then be transported (i.e., pushed along), without breaking up, over great distances by the weak evening or early morning breezes, as they develop. In some cases, odors have been detected at distances of up to 25 km from their source. This transport phenomenon has been termed the *puff movement* of odors (Tchobanoglous and Schroeder, 1985). The *puff movement* of odors was first described by Wilson (1975). The most common method used to mitigate the effects of the odor puff is to install barriers to induce turbulence, thus breaking up and dispersing the cloud of concentrated odors, and/or to use wind generators to maintain a minimum velocity across the source.

Strategies for Odor Management

Strategies for the management and control of odors are presented and discussed below. An overview of some of the methods used to control and treat odorous gases is presented in the following section. Where there are chronic odor problems at treatment facilities, approaches to solving these problems may include (1) control of odor-causing wastewaters discharged to the collection system and treatment plant that creates odor problems, (2) control of odors generated in the wastewater-collection system, (3) control of odors generated in wastewater treatment facilities, (4) installation of odor containment and treatment facilities, (5) application of chemicals to the liquid (wastewater) phase, (6) use of odor masking and neutralizing agents, (7) use of gas-phase turbulence-inducing structures and facilities, and (8) establishment of buffer zones.

Control of Discharges to Wastewater-Collection System. The elimination and/or control of wastewater discharges containing odorous compounds to the collection system can be accomplished by (1) the adoption of more stringent waste discharge ordinances and enforcement of their requirements, (2) requiring pretreatment of industrial wastewater, and (3) providing flow equalization at the source to eliminate slug discharges of wastewater.

Odor Control in Wastewater-Collection Systems. The release of odors from the liquid phase in wastewater-collection systems can be limited by (1) maintain-

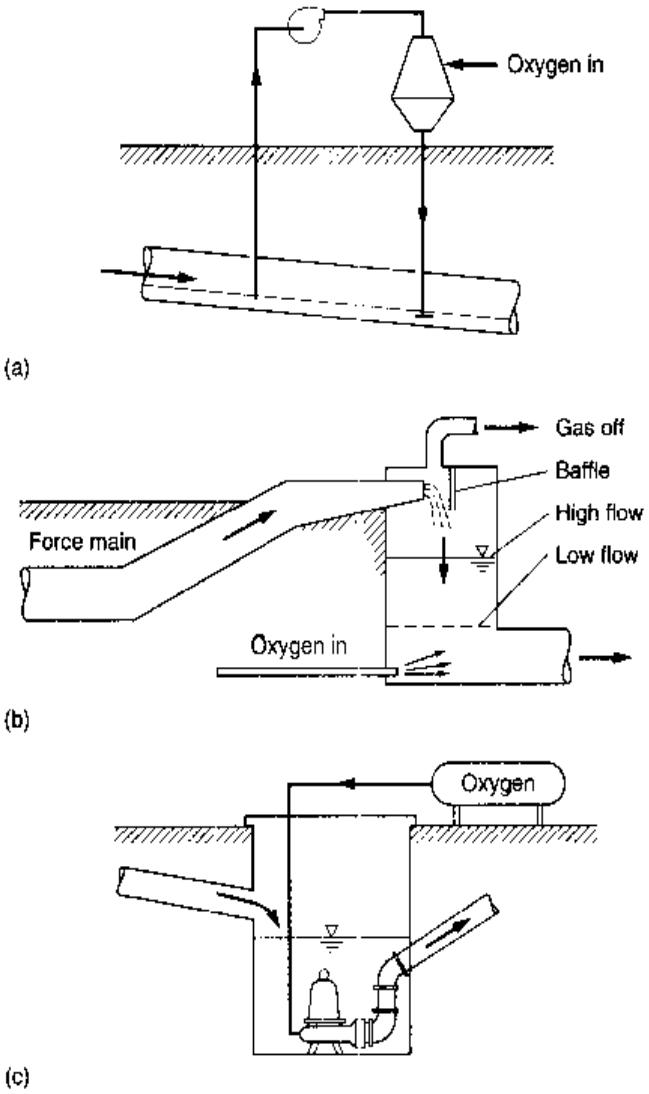


Figure 15–4

Typical uses of commercial oxygen in wastewater-collection systems for odor control: (a) sidestream oxygenation and reinjection of wastewater into a gravity sewer, (b) injection of oxygen into a hydraulic fall, and (c) injection of oxygen into two-phase flow in force main. *(From Speece et al., 1990.)*

ing aerobic conditions through the addition of hydrogen peroxide, pure oxygen, or air at critical locations in the collection system and to long force mains (see Fig. 15–4), (2) controlling anaerobic microbial growth by disinfection or pH control, (3) oxidizing or precipitating odorous compounds by chemical addition, (4) design of the wastewater collection system to minimize the release of odors due to turbulence, and (5) off-gas treatment at selected locations.

Odor Control in Wastewater Treatment Facilities. With the proper attention to design details, such as the use of submerged inlets and weirs, the elimination of hydraulic jumps in influent piping and channels, the elimination of physical conditions leading to the formation of turbulence, proper process loadings, containment of odor sources, off-gas treatment, and good housekeeping, the routine release of odors at treatment plants can be minimized. It must also be recognized, however, that odors will develop occasionally. When they do, it is important that immediate steps be taken to control them. Often, this will involve operational changes or the addition of chemicals, such as chlorine, hydrogen peroxide, lime, or ozone.

Design and operational changes that can be instituted can include (1) minimization of free-fall turbulence by controlling water levels, (2) reduction of overloading of plant

processes, (3) increasing the aeration rate in biological treatment processes, (4) increasing the plant treatment capacity by operating standby process units, (5) reducing solids inventory and sludge backlog, (6) increasing the frequency of pumping of sludge and scum, (7) adding chlorinated dilution water to sludge thickeners, (8) controlling the release of aerosols, (9) increasing the frequency of disposal of grit and screenings, (10) cleaning odorous accumulations more frequently, and (11) containment, ventilation, and treatment of odorous gases.

Odor Containment and Treatment. Odor containment includes the installation of covers, collection hoods, and air handling equipment for containing and directing odorous gases to disposal or treatment systems. In cases where the treatment facilities are close to developed areas, it has become common practice to cover treatment units such as the headworks (see Fig. 15–3*b*), primary clarifiers (see Figs. 15–5*a* and *b*), trickling filters (see Fig. 15–5*c* and *d*), sludge thickeners (see Fig. 15–5*e*), sludge-processing facilities, and sludge-loadout facilities (see Fig. 15–5*f*). Where covers are used, the trapped gases must be collected and treated. The specific method of treatment will depend on the characteristics of the odorous compounds. Typical containment alternatives for the control of odor emissions from wastewater management facilities are reported in Table 15–8. Methods used to treat odorous gases are summarized in Table 15–9.

Chemical Additions to Wastewater for Odor Control. Odors can be eliminated in the liquid phase through the addition of a variety of chemicals to achieve (1) chemical oxidation, (2) chemical precipitation, and (3) pH control. The most common oxidizing chemicals that can be added to wastewater include oxygen, air, chlorine, sodium hypochlorite, potassium permanganate, hydrogen peroxide, and ozone. While all of these compounds will oxidize hydrogen sulfide (H_2S) and other odorous compounds, their use is complicated by the chemical matrix in which the odorous gases exist. The only way to establish the required chemical dosages for the removal of chemical compounds is through bench- or pilot-scale testing. Odorous compounds can also be reduced by precipitation. For example, ferrous chloride and ferrous sulfate can be used for the control of H_2S odors by precipitation of the sulfide ion as ferrous sulfide. As with the oxidation reactions, the required chemical dosage can be determined only through bench- or pilot-scale testing. The release of H_2S can also be controlled by increasing the pH value of the wastewater. Increasing the pH of the wastewater results in reduced bacterial activity and also shifts the equilibrium so that the sulfide ion is present as HS^-. With most of the odor-control methods involving the addition of chemicals to wastewater, some residual product is formed that must ultimately be dealt with. Shock treatment involving the addition of sodium hydroxide (NaOH) can be used to reduce microbial slimes in sewers. The high pH also reduces sulfide (S^{2-}) formation. Additional details on chemical addition may be found in Rafson (1998).

Use of Odor Masking and Neutralization. On occasion, chemicals have been added to wastewater or offgases to mask an offensive odor with a less offensive odor. Masking chemicals are based on essential oils with the most common aromas being vanilla, citrus, pine, or floral (Williams, 1996). Typically, enough masking chem-

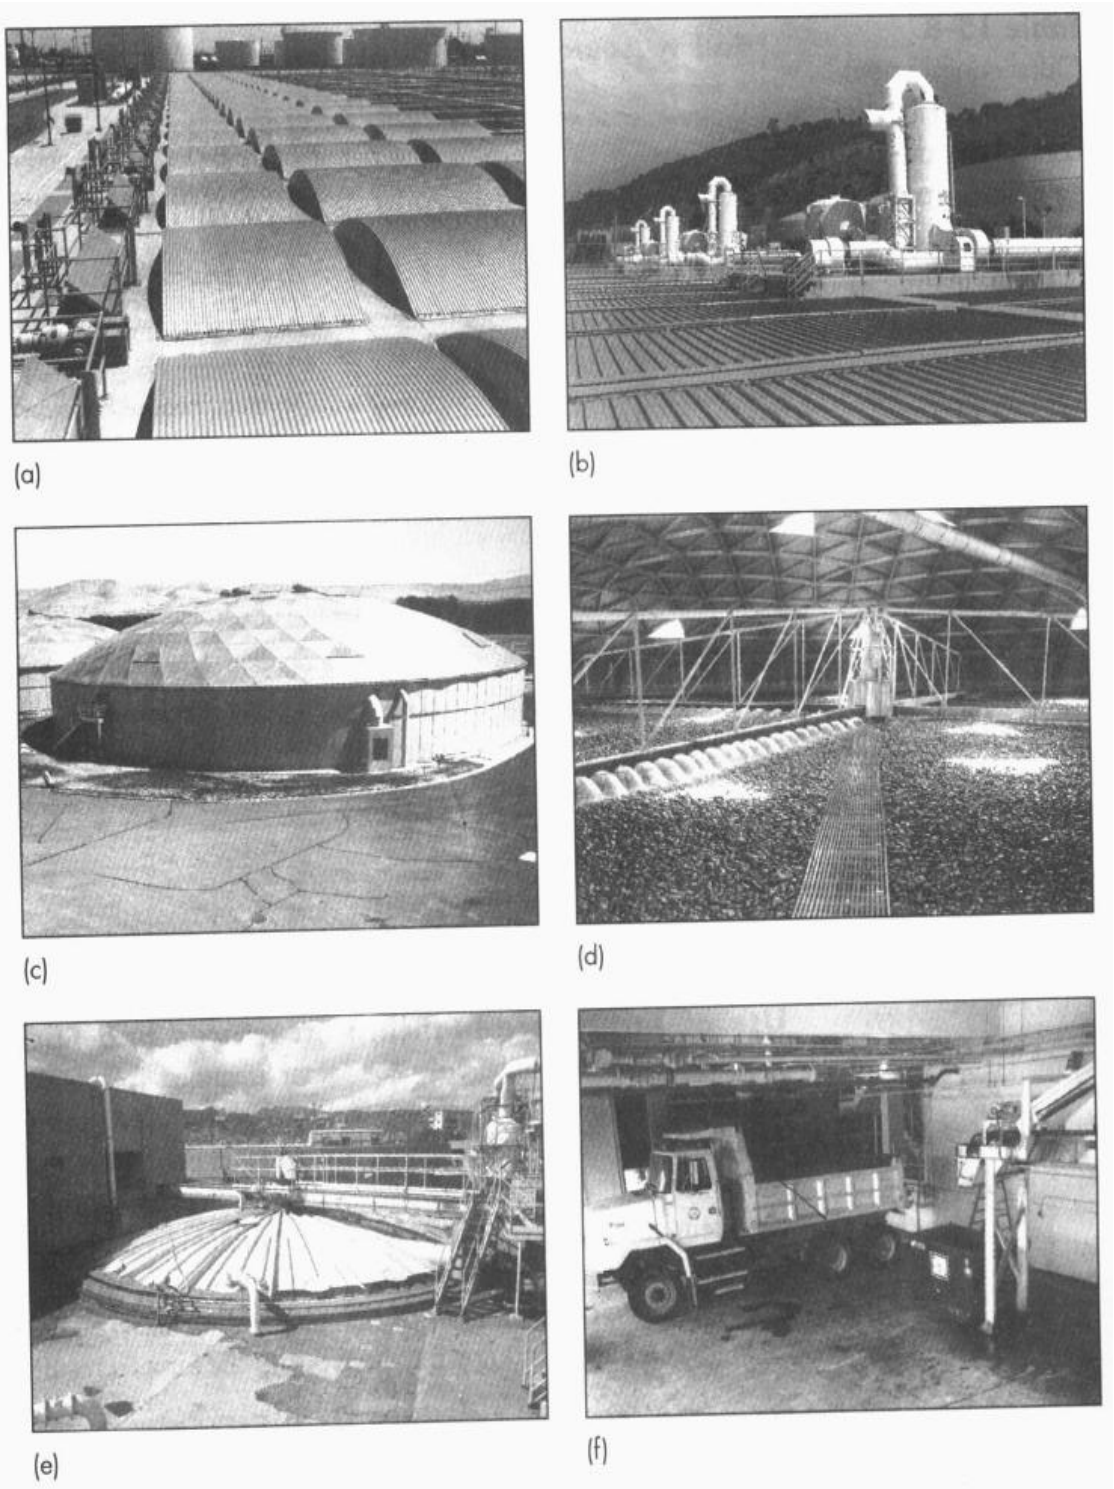

Figure 15–5

Typical odor containment facilities at wastewater treatment plants: (*a*) covered primary sedimentation tanks, (*b*) covered primary sedimentation tanks with odor-control facilities, (*c*) covered trickling filter, (*d*) view inside covered trickling filter; the large pipe shown overhead is used to remove odorous gases for treatment in a chemical scrubber, (*e*) covered sludge thickener, and (*f*) enclosed sludge-loadout facility.

ical is added to wastewater to overpower the offensive odor. Masking chemicals, however, do not modify or neutralize the offensive odors. Neutralization involves finding chemical compounds that can be combined with the odorous gases in the vapor state so that the combined gases cancel each other's odor, produce an odor of lower intensity, or eliminate the odorous compounds. Although odor masking and neutralization are viable options for short-term management of odor problems, the key to long-term odor management is to identify the source of the odors and implement corrective measures.

Table 15–8 Odor containment alternatives for the control of odor emissions from wastewater management facilities

Facility (sources)	Suggested control strategies
Wastewater sewers	Seal existing access ports (i.e., manholes). Eliminate the use of structures that create turbulence and enhance volatilization. Ventilate sewer reaches that develop positive pressure to odor control facilities
Sewer appurtenances	Isolate and cover existing appurtenances
Pump stations	Vent odorous gases from wetwell to treatment unit. Use variable-speed pumps to reduce the size of the wetwell
Bar racks	Cover existing units. Reduce headloss through bar racks
Comminutors	Cover existing units. Use in-line enclosed comminutors
Parshall flume	Cover existing units. Use alternative measuring device
Grit chamber	Cover existing aerated grit chambers. Reduce turbulence in conventional horizontal-flow grit chambers; cover if necessary. Avoid the use of aerated grit chambers
Equalization basins	Cover existing units. Use submerged mixers, and reduce airflow
Primary and secondary sedimentation tanks	Cover existing units. Replace conventional overflow weirs with submerged weirs
Biological treatment	Cover existing units. Use submerged mixers and reduce aeration rate
Sludge thickeners	Cover existing units
Transfer channels	Use enclosed transfer channels

Use of Turbulence-Inducing Structures and Facilities for Odor Dispersion. In a number of wastewater treatment plants, physical facilities used to induce atmospheric turbulence have been constructed specifically for the purpose of gas-phase odor reduction. The high barrier fence [3.7 m (12 ft)] shown on Fig. 15–6 surrounds sludge-storage lagoons. Operationally, any odorous gases that develop under quiescent conditions over the lagoons are diluted as they move away from the storage lagoons, due to the local turbulence induced by the barrier. Trees are also used commonly to dilute odorous gases by inducing turbulence (i.e., the formation of eddies) and mixing. Trees are also known to help purify the air as a result of respirometric activity.

Use of Buffer Zones. The use of buffer zones can also help in reducing the impact of odors on developed areas. Typical buffer zone distances used by regulatory agencies are presented in Table 15–10. If buffer zones are used, odor studies should be conducted that identify the type and magnitude of the odor source, meteorological conditions, dispersion characteristics, and type of adjacent development. Trees that grow rapidly are often planted at the periphery of the buffer zones to further reduce the impact of odors.

Odor-Treatment Methods

The general classification of odor-treatment methods is presented in Table 15–9, along with typical applications in wastewater management. Odor-treatment methods are designed either to treat the odor-producing compounds in the wastewater stream or to

Table 15–9
Methods used to treat odorous gases found in wastewater management facilities[a]

Method	Description and/or application
Physical methods	
Adsorption on activated carbon	Odorous gases can be passed through beds of activated carbon to remove odors. Carbon regeneration can be used to reduce costs. Additional details may be found in Chap. 11
Adsorption on sand, soil, or compost beds	Odorous gases can be passed through sand, soil, or compost beds. Odorous gases from pumping stations may be vented to the surrounding soils or to specially designed beds containing sand or soils. Odorous gases collected from treatment units may be passed through compost beds
Dilution with odor-free air	Gases can be mixed with fresh air sources to reduce the odor unit values. Alternatively, gases can be discharged through tall stacks to achieve atmospheric dilution and dispersion
Masking agents	Perfume scents can be sprayed in fine mists near offending process units to overpower or mask objectionable odors. In some cases, the odor of the masking agent is worse than the original odor. Masking agents should not be confused with neutralizing agents described below
Oxygen injection	The injection of oxygen (either air or pure oxygen) into the wastewater to control the development of anaerobic conditions has proved to be effective
Scrubbing towers	Odorous gases can be passed through specially designed gas scrubbing towers to remove odors
Turbulence-inducing facilities	Use of wind breaks, such as high fences and trees, and propeller fans
Chemical methods	
Chemical oxidation	Oxidizing the odor compounds in wastewater is one of the most common methods used to achieve odor control. Chlorine, ozone, hydrogen peroxide, and potassium permanganate are among the oxidants that have been used. Chlorine also limits the development of a slime layer
Chemical precipitation	Chemical precipitation refers to the precipitation of sulfide with metallic salts, especially iron
Neutralizing agents	Compounds that can be sprayed or atomized in fine mists to chemically react with, neutralize, and/or dissolve odorous compounds
Scrubbing with various alkalies	Odorous gases can be passed through specially designed chemical scrubbing towers to remove odors. If the level of carbon dioxide is high, costs may be prohibitive
Thermal oxidation	Combustion of off-gases at temperatures from 800 to 1400°C will eliminate odors. Lower temperatures (400 to 800°C) are used with catalytical incineration
Biological methods	
Activated-sludge aeration tanks	Odorous gases can be combined with the process air for activated-sludge aeration tanks to remove odorous compounds
Biotrickling filters	Specially designed biotrickling filters can be used to remove odorous compounds biologically. Typically, the filters are filled with plastic packing of various types on which biological growths can be maintained
Compost filters	Gases can be passed through biologically active beds of compost to remove odors
Sand and soil filters	Gases can be passed through biologically active beds of compost to remove odors
Trickling filters	Odorous gases can be passed through existing trickling filters to remove odorous compounds

[b] Actual buffer distance requirements will depend on local conditions.

treat the foul air. Most of the methods in Table 15–9 are meant to be used to treat the foul air (i.e., the gas phase). As noted above, to control the release of odorous gases from treatment facilities, it has become more common to cover wastewater treatment processes (see Fig. 15–5).

The principal methods used to treat odorous gases include the use of (1) chemical scrubbers, (2) activated-carbon absorbers, (3) vapor-phase biological treatment processes (i.e., compost filters), (4) treatment in conventional biological treatment processes, and (5) thermal processes. Each of these methods is discussed below. The specific method of odor control and treatment that should be applied will vary with local conditions. However, because odor-control measures are expensive, the cost of making process changes or modifications to the facilities to eliminate odor development should always be evaluated and compared to the cost of various alternative odor-control measures before their adoption is suggested.

Chemical Scrubbers. The basic design objective of a chemical scrubber is to provide contact between air, water, and chemicals (if used) to provide oxidation or entrainment of the odorous compounds. The principal wet-scrubber types, as shown on Fig. 15–7, include single-stage countercurrent packed towers, countercurrent spray

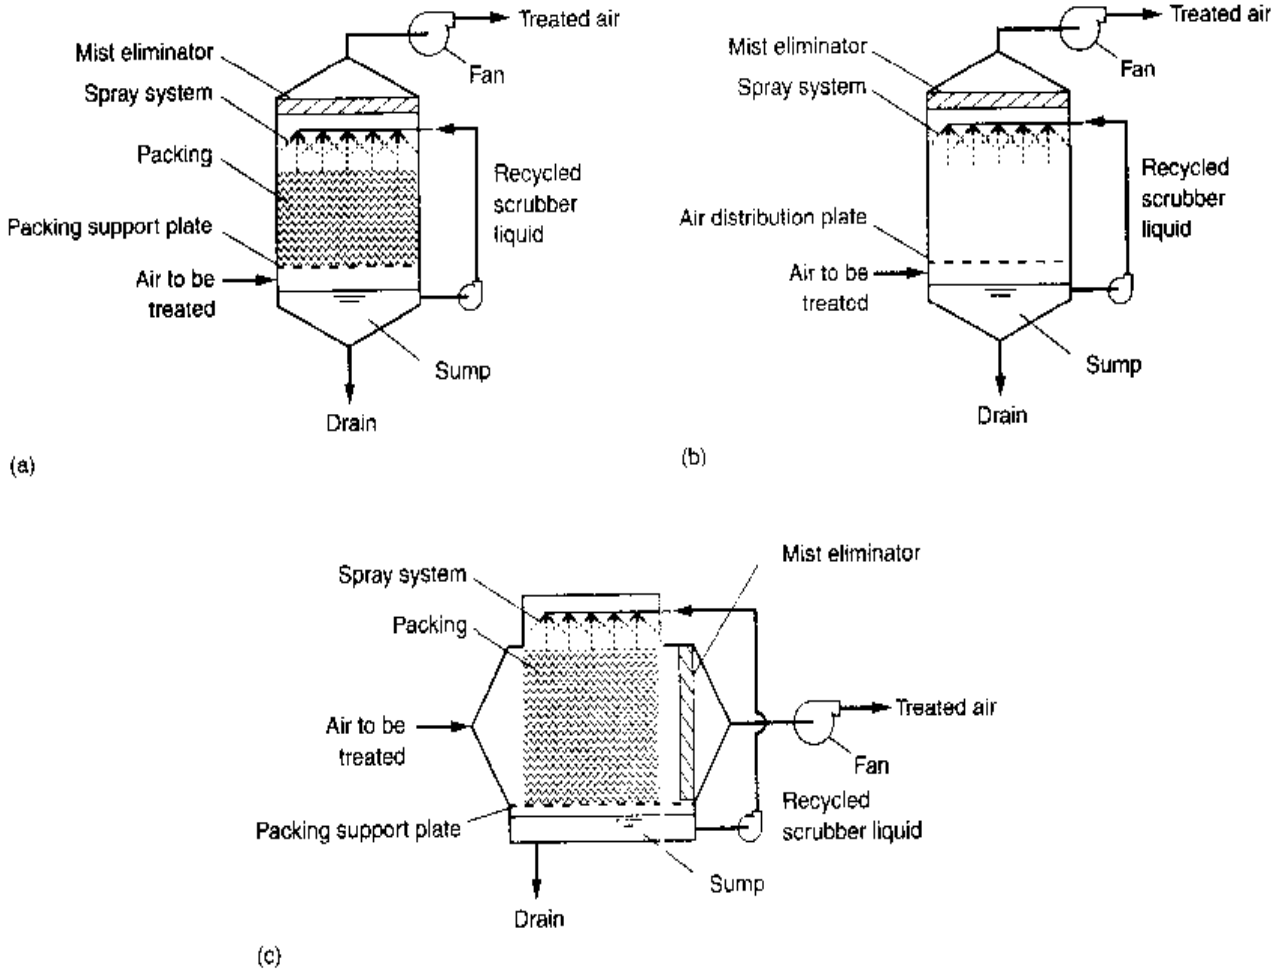

Figure 15–7

Typical wet-scrubber systems for odor control: (*a*) countercurrent packed tower, (*b*) spray chamber absorber, and (*c*) cross-flow scrubber.

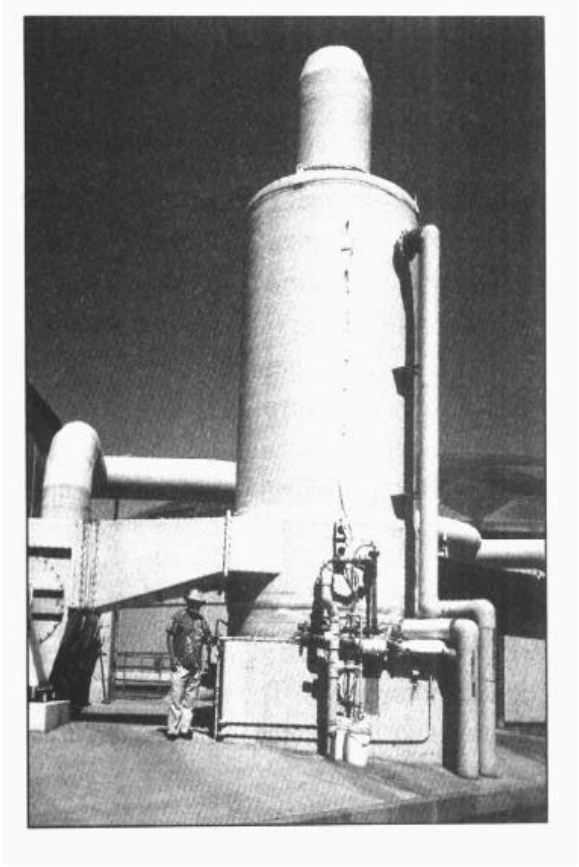

Figure 15–8
Typical sodium hypochlorite scrubber used to treat the odors from the trickling filters shown in Fig. 15–5*c* and *d*.

chamber absorbers, and cross-flow scrubbers. In most single-stage scrubbers, such as shown on Fig. 15–8, the scrubbing fluid (usually sodium hypochlorite) is recirculated. The commonly used oxidizing scrubbing liquids are sodium hypochlorite, potassium permanganate, and hydrogen peroxide solutions. Because of safety and handling issues, chlorine gas is not used commonly in scrubbing applications at wastewater treatment facilities. Sodium hydroxide is also used in scrubbers where H_2S concentrations in the gas phase are high. Typical simplified scrubbing reactions with sodium hypochlorite, potassium permanganate, and hydrogen peroxide are as follows:

With sodium hypochlorite

$$\underset{(34.06)}{H_2S} + \underset{(4 \times 74.45)}{4NaOCl} + 2NaOH \rightarrow Na_2SO_4 + 2H_2O + 4NaCl \qquad (15\text{–}3)$$

$$\underset{(34.06)}{H_2S} + \underset{(74.45)}{NaOCl} \rightarrow S^{\circ}\downarrow + NaCL + H_2O \qquad (15\text{–}4)$$

With potassium permanganate

$$\underset{(3 \times 34.06)}{3H_2S} + \underset{(2 \times 142.04)}{2KMnO_4} \rightarrow 3S + 2KOH + 2MnO_2 + 2H_2O \text{ (acidic pH)} \qquad (15\text{–}5)$$

$$\underset{(3 \times 34.06)}{3H_2S} + \underset{(8 \times 142.04)}{8KMnO_4} \rightarrow 3K_2SO_4 + 2KOH + 8MnO_2 + 2H_2O \text{ (basic pH)} \qquad (15\text{–}6)$$

With hydrogen peroxide

$$\underset{(34.06)}{H_2S} + \underset{(34.0)}{H_2O_2} \rightarrow S^{\circ}\downarrow + 2H_2O \qquad pH < 8.5 \tag{15–7}$$

In the reaction given by Eq. (15–3), 8.74 mg/L of sodium hypochlorite is required per mg/L of hydrogen sulfide, or 9.29 mg/L if the hydrogen sulfide is expressed as sulfide. In addition, in the reaction given by Eq. (15–3), 2.35 mg/L of sodium hydroxide (caustic) will be required per mg/L of hydrogen sulfide to make up for alkalinity consumed in the reaction. In practice, the required sodium hypochlorite dosage for the reaction given by Eq. (15–3) will vary from 8 to 10 mg/L per mg/L of H_2S. For the reaction given by Eq. (15–4), 2.19 mg/L of sodium hypochlorite is required per mg/L of hydrogen sulfide.

When potassium permanganate is used, the reactions that occur are typically various combinations of the reactions given by Eqs. (15–5) and 15–6). Reaction products that can occur, depending on the local wastewater chemistry, include elemental sulfur, sulfate, thionates, dithionates, and manganese sulfide. Stoichiometrically, about 2.8 and 11.1 mg/L of $KMnO_4$ are required for each mg/L of H_2S oxidized as given by Eqs. (15–5) and (15–6), respectively. However, based on operating data from actual field installations, about 6 to 7 mg/L $KMnO_4$ are required for each mg/L of H_2S oxidized. Potassium permanganate is generally used in smaller installations because of the cost (U.S. EPA, 1985; WEF, 1995).

In the reaction given in Eq. (15–7), 1.0 mg/L of hydrogen peroxide is required for each mg/L of sulfide expressed as hydrogen sulfide. In practice, the required dosage can vary from 1 to 4 mg/L per mg/L of H_2S. Because the systems used to carry out the reactions defined by Eqs. (15–3) through (15–7) are complex, especially where competing reactions may occur, some experimentation will be required to establish the correct dosage.

Hypochlorite scrubbers can be expected to remove oxidizable odorous gases when other gas concentrations are minimal. Typical removal efficiencies for single-stage scrubbers are reported in Table 15–11. In cases where the concentrations of odorous components in the exhaust gas from the scrubbers are above desirable levels, multistage

Table 15–11
Effectiveness of hypochlorite wet scrubbers for removal of several odorous gases[a]

Gas	Expected removal efficiency, %
Hydrogen sulfide	98
Ammonia	98
Sulfur dioxide	95
Mercaptans	90
Other oxidizable compounds	70–90

[a] Adapted in part from U.S. EPA (1985).

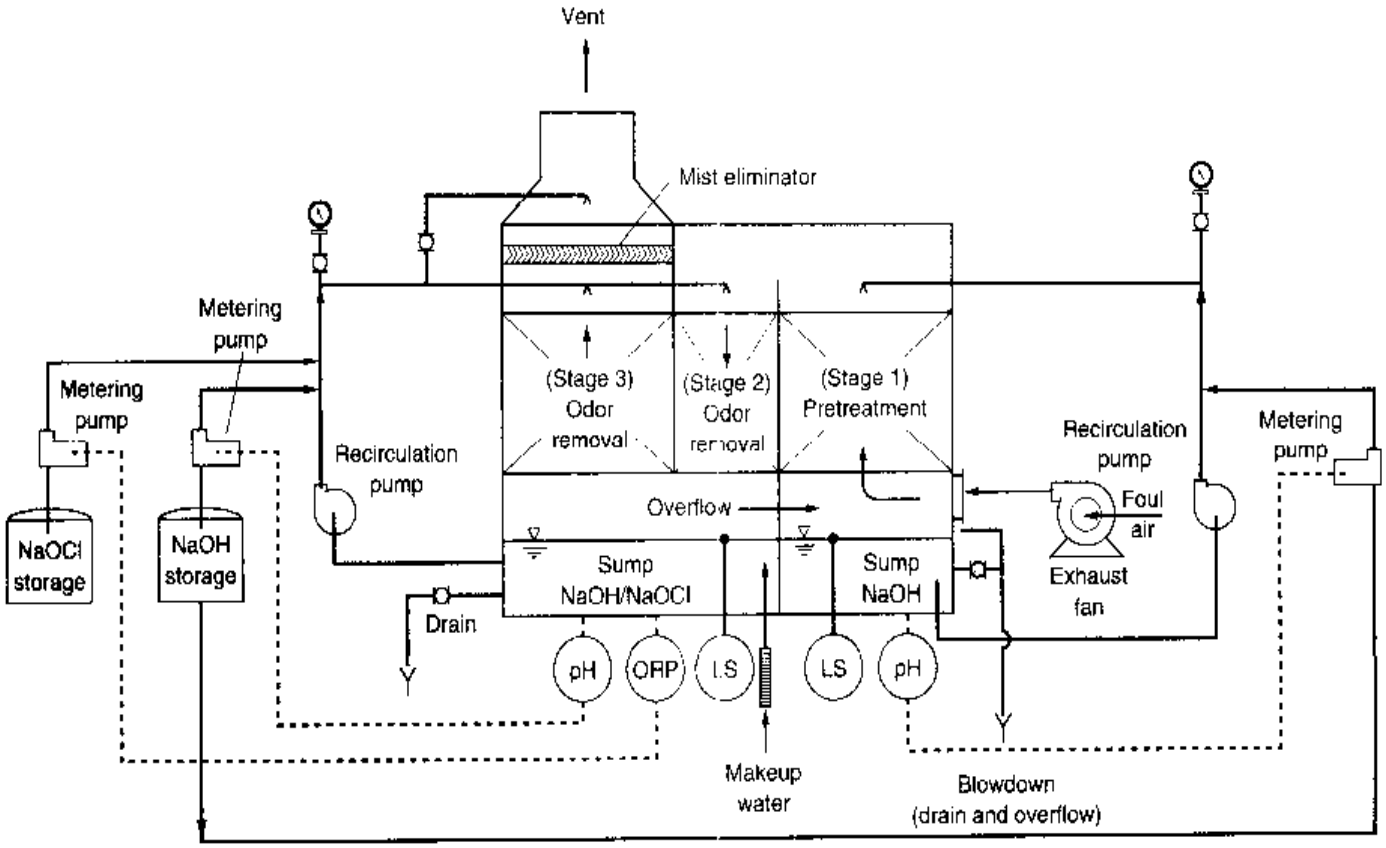

Figure 15–9

Three-stage odor-control process flow diagram. *(From Lo/Pro Systems, Inc.)*

scrubbers (see Fig. 15–9) are often used. In the three-stage scrubber shown on Fig. 15–9, the first stage is a pretreatment stage used to raise the pH so that a portion of the odorous gases (e.g., hydrogen sulfide) is reduced before treatment with chlorine in the second and third stages. The reaction that occurs in the first stage of a three-stage unit can be represented as follows.

$$H_2S + 2NaOH \rightarrow Na_2S + 2H_2O \qquad (15\text{–}8)$$

To reduce maintenance problems due to precipitation, it is recommended that a low hardness (less than 50 mg/L as $CaCO_3$) be used for the makeup water.

Activated-Carbon Adsorbers. Activated-carbon adsorbers are used commonly for odor control (see Fig. 15–10). The rate of adsorption for different constituents or compounds will depend on the nature of the constituents or compounds being adsorbed (nonpolar versus polar). It has also been found that the removal of odors depends on the concentration of the hydrocarbons in the odorous gas. Typically, hydrocarbons are adsorbed preferentially before polar compounds such as H_2S are removed (note activated carbon is nonpolar). Thus, the composition of the odorous gases to be treated must be known if activated carbon is to be used effectively. Because the life of a carbon bed is limited, carbon must be regenerated (see Sec. 11–7 in Chap. 11) or replaced regularly for continued odor removal. To prolong the life of the carbon, two-stage systems

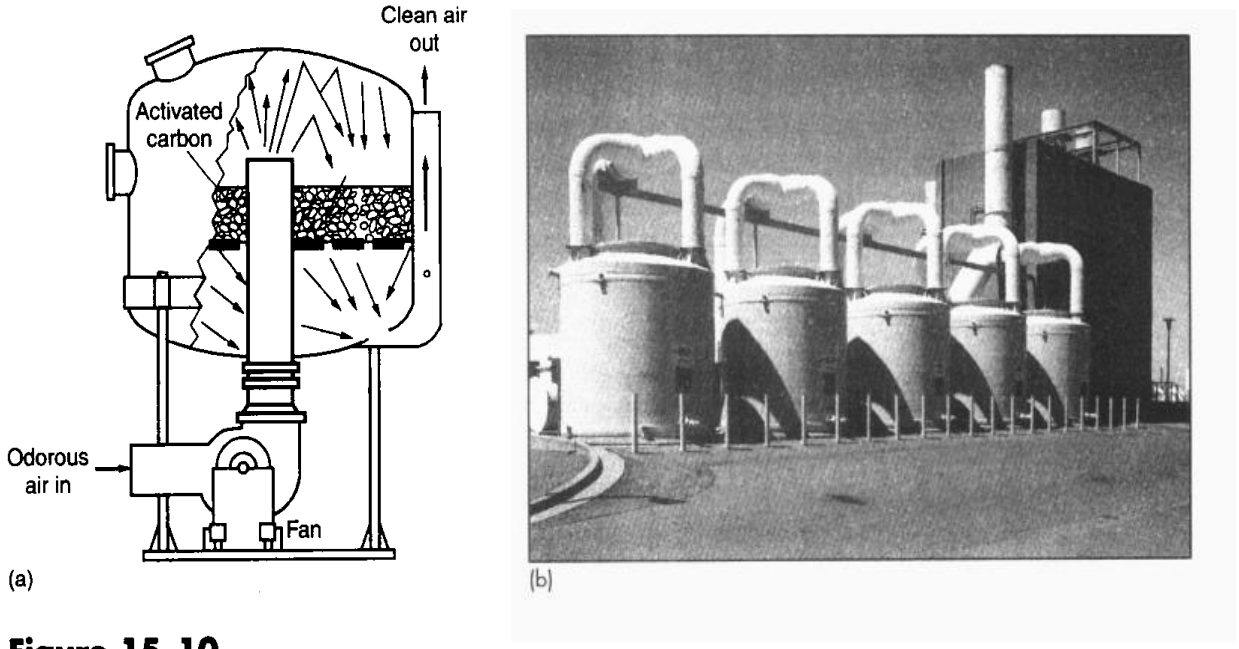

Figure 15–10

Typical activated-carbon systems for odor control: (*a*) schematic of a single-bed adsorber. In dual-bed adsorbers the foul air is introduced between the beds and is withdrawn from above the upper bed and below the lower bed, and (*b*) view of multiple dual-bed activated-carbon odor-control units. Because of operating problems, the activated carbon adsorbers have been replaced by the chemical scrubber shown in the background.

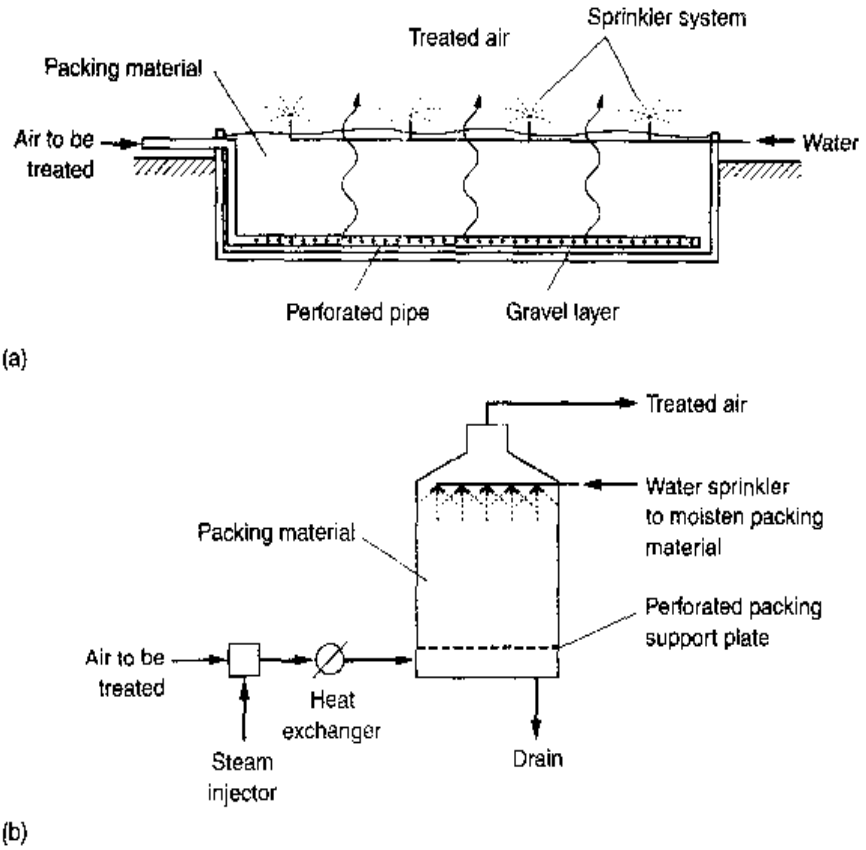
have been used, with the first stage being a wet scrubber followed by activated-carbon adsorption.

Vapor-Phase Biological Treatment Processes. The two principal biological processes used for the treatment of odorous gases present in the vapor phase are (1) biofilters and (2) biotrickling filters (Eweis et al., 1998). The use of microbial growths for the treatment of odors was the subject of an early patent by Pomeroy (1957), one of the important early researchers in the area of odor management in wastewater collection and treatment facilities.

Biofilters Biofilters are packed-bed filters. In open biofilters (see Fig. 15–11*a*), the gases to be treated move upward through the filter bed. In closed biofilters (see Fig. 15–11*b*), the gases to be treated are either blown or drawn through the packing material. As the odorous gases move through the packing in the biofilter, two processes occur simultaneously: sorption (i.e., absorption/adsorption) and bioconversion. Odorous gases are absorbed into the moist surface biofilm layer and the surfaces of the biofilter packing material. Microorganisms, principally bacteria, actinomycetes, and fungi, attached to the packing material, oxidize the absorbed/adsorbed gases and renew the treatment capacity of the packing material. Moisture content and temperature are important environmental conditions that must be maintained to optimize microorganism activity (Williams and Miller, 1992*a*; Yang and Allen, 1994; Eweis et al., 1998). Although compost biofilters are used commonly, one drawback is the large surface area (footprint) required for these units.

Figure 15–11

Typical packed-bed biofilters: (*a*) open-bed type and (*b*) enclosed type.



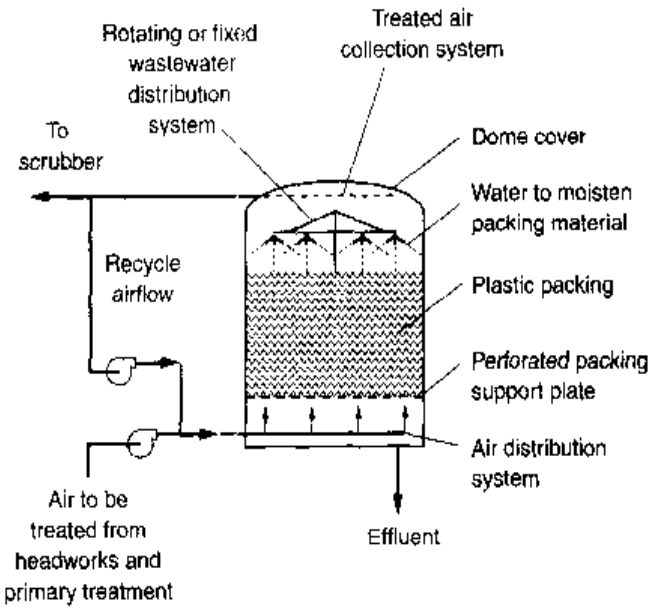


Figure 15–12

Typical covered biological stripping tower used for odor control.

Biotrickling Filters Biotrickling filters are essentially the same as biofilters with the exception that moisture is provided continuously or intermittently by applying (typically spraying) a liquid (e.g., treated effluent) over the packing (see Fig. 15–12). The liquid is recirculated and nutrients are often added. Because water is lost in the gas leaving the filter, makeup water must be provided. Similarly, because of the accumulation of salts in the recycled water, a blowdown stream is required. Compost is not a suitable

packing material for biotrickling filters because water will accumulate within the compost, thereby limiting the free movement of air within the filter. Typical packing materials include Pall rings, Raschig rings, lava rock, and granular activated carbon (Eweis et al., 1998; see also Sec. 11–8, Gas Stripping, in Chap. 11).

Conventional Biological Treatment Processes. The ability of microorganisms to oxidize hydrogen sulfide and other similar odorous compounds dissolved in the liquid under aerobic conditions is the basic concept used for the treatment of odors in liquid-based systems. The two principal types of conventional liquid-based systems used in wastewater treatment plants are the activated sludge process and the trickling filter process. In the activated sludge process, the odorous compounds are introduced into the aeration basin either with the existing air supply or injected separately through a manifold system. A major concern with this method of odor management is the high rate of corrosion in the air piping and blowers that occurs due to the presence of moist air containing hydrogen sulfide. The ability to transfer the odorous gaseous compounds to the liquid phase is also of concern.

With conventional uncovered trickling filters the major issues are how to transfer the air containing the odorous compounds to the trickling filter and how to avoid the release of untreated odorous compounds to the atmosphere. To control the release of odorous compounds, existing trickling filters that are to be used for odor control must be covered (see Fig. 15–5c)

Thermal Processing. Three thermal processing techniques have been used: (1) thermal oxidation, (2) catalytic oxidation, and (3) recuperative and regenerative thermal oxidation. The oxidation of methane (CH_4) can be used to illustrate the basic principle of all three thermal processes.

$$CH_4(gas) + 2O_2(gas) \rightarrow CO_2(gas) + 2H_2O(vapor) + heat \qquad (15\text{–}9)$$

If the gas to be combusted does not liberate enough heat to sustain the combustion process, it is usually necessary to use an external fuel source such as fuel oil, natural gas, or propane. Unfortunately, because of the low concentrations of odorous combustible gases in most waste streams, sustainable thermal oxidation is seldom possible, and large amounts of fuel are typically required to maintain the combustion temperatures needed to eliminate odors.

Thermal oxidation involves preheating the odorous gases before passing them into the combustion chamber so that complete oxidation can be achieved. Combustion occurs at temperatures in the range from 425 to 760°C (800 to 1400°F). Thermal oxidation is used, more commonly, for concentrated waste streams. The flaring of odorous gases is a relatively crude form of thermal combustion. Depending on the design of the combustion facility, incomplete combustion can occur due to variations in gas flow. For this method of odor control to be sustainable, the waste gas must typically contain 50 percent of the fuel value of the gas stream to be combusted.

Catalytic oxidation is a flameless oxidation process that occurs at 310 to 425°C (600 to 800°F) in the presence of a catalyst. Common catalysts include platinum, palladium, and rubidium. The decrease in temperature as compared to complete thermal

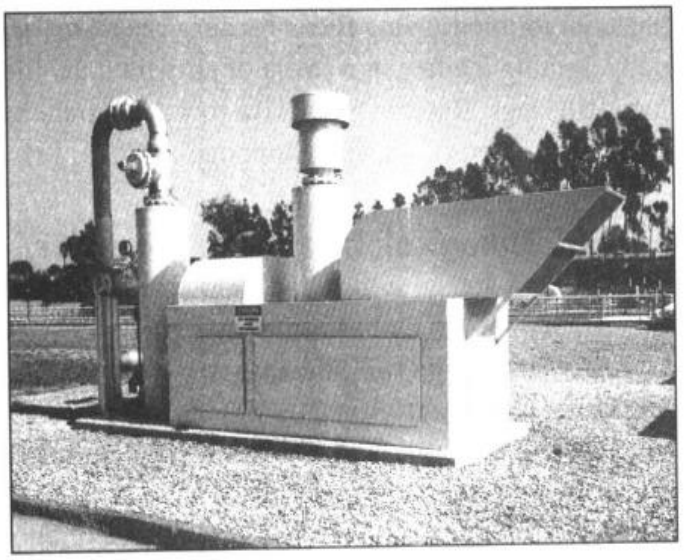

Figure 15–13
Typical self-contained chemical odor-stripping unit.

oxidation reduces the energy requirements significantly. However, because the catalysts can become fouled, the gas to be oxidized must not contain particulate material or constituents that will result in a residue. Additional information on the physical facilities used for thermal processing of VOCs may be found in Sec. 5–13 in Chap. 5.

Recuperative and regenerative thermal oxidation processes are used to reduce fuel consumption by preheating the incoming air, especially in large installations. In recuperative oxidizers, thin wall tubes are used to transfer heat recovered from exhaust air to the incoming air. In regenerative oxidizers, ceramic packing material is used to capture the heat from the hot exhaust gas and subsequently to release it to the incoming air. To maintain optimal heat recovery, the exhaust and incoming air are cycled through the packing material so that the incoming air is always passed through the hottest packing material. Typically, three beds of packing material are used in regenerative oxidizers.

Selection and Design of Odor-Control Facilities

The following steps are involved in the selection and design of odor-control and treatment facilities:

1. Determine the characteristics and volumes of the gas to be treated.
2. Define the exhaust requirements for the treated gas.
3. Evaluate climatic and atmospheric conditions.
4. Select one or more odor-control and treatment technologies to be evaluated.
5. Conduct pilot tests to determine design criteria and performance.
6. Perform life cycle economic analysis.

Many of the chemical odor-control technologies are supplied as complete packages, designed to meet a given performance specification. The analysis of chemical scrubbers and the design of biofilters is considered in the following discussion.

Design Considerations for Chemical Scrubbers

Most chemical scrubbers are supplied as a complete unit (see Fig. 15–13). Typical design factors for chemical scrubbers are presented in Table 15–12. Determination of the chemical requirements for odor scrubbing is illustrated in Example 15–3.

Table 15–12 Typical design factors for chemical scrubbers[a]

Item	Units	Value
Packing depth	m	1.8–3
Gas residence time in packing	s	1.3–2.0
Scrubbing liquid flowrate	kg H_2O/kg airflow	1.5–2.5
	L/s per m^3/s airflow	2–3
Makeup water flow	L/s per kg sulfide at pH 11	0.075
	L/s per kg sulfide at pH 12.5	0.004
pH	Unitless	11–12.5
Temperature	°C	15–40
Caustic usage	kg NaOH/kg sulfide	2–3

[a] Adapted in part from WEF (1995), Devinny et al. (1999).

EXAMPLE 15–3 Chemical Requirements for Odor Scrubbing Hydrogen sulfide is to be scrubbed from a waste airstream using sodium hypochlorite. Determine the chemical (i.e., sodium hypochlorite and caustic) and water requirements for the following conditions.

1. Waste airstream flowrate = 1000 m^3/min
2. H_2S concentration in waste stream = 20 ppm_v at 20°C
3. Specific weight of air = 0.0118 kN/m^3 at 20°C
4. Density of air = 1.204 kg/m^3 at 20°C (see Appendix B-1)
5. Assume liquid to gas ratio for scrubber = 1.75
6. Density of 50 percent NaOH solution = 1.52 kg/L

Solution

1. Determine the volume occupied by one mole of a gas at a temperature of 20°C and a pressure of 1.0 atm using Eq. (2–44).

$$V = \frac{nRT}{P}$$

$$V = \frac{(1 \text{ mole})(0.082057 \text{ atm·L/mole·K})[(273.15 + 20) \text{ K}]}{1.0 \text{ atm}}$$

$$= 24.055 \text{ L} \qquad \text{use } 24.1 \text{ L}$$

2. Estimate the sodium hypochlorite requirement.
   a. Using Eq. (2–45), convert the H_2S concentration from ppm_v to g/m^3.

$$20 \text{ ppm}_v = \left(\frac{20 \text{ m}^3}{10^6 \text{ m}^3}\right)\left[\frac{(34.08 \text{ g/mole } H_2S)}{(24.1 \times 10^{-3} \text{m}^3\text{/mole of } H_2S)}\right]$$

$$H_2S \text{ concentration} = 28.3 \times 10^{-3} \text{ g/m}^3$$

b. Determine the amount of H_2S that must be treated per day.

$$(1000\ m^3/min) \times (28.3 \times 10^{-3}\ g/m^3)(1440\ min/d)(1\ kg/10^3 g)$$
$$= 40.8\ kg/d$$

c. Estimate the sodium hypochlorite dose. From Eq. (15–3), 8.74 mg/L of sodium hypochlorite are required per mg/L of sulfide, expressed as hydrogen sulfide.

$$NaOCl_2 \text{ required per day} = (40.8\ kg/d) \times (8.74) = 356.6\ kg/d$$

3. Estimate the water requirement for the scrubbing tower.
   a. Determine the mass air flowrate.

$$(1000\ m^3/min)(1.204\ kg/m^3) = 1204\ kg/min$$

   b. Determine the water flowrate.

$$(1204\ kg/min)(1.75) = 2107\ kg/min = 2.1\ m^3/min$$

4. Determine the amount of sodium hydroxide (caustic) that must be added to replace the alkalinity consumed in the reaction.
   a. From the reaction given by Eq. (15–3), 2.35 mg/L of NaOH is required for each mg/L of H_2S removed.
   b. Determine the amount of NaOH required.

$$NaOH = 40.8\ kg/d \times 2.35 = 95.9\ kg/d$$

   c. Determine the volume of NaOH required. The amount of caustic per liter at 50% NaOH is

$$NaOH = (1.52\ kg/L)(0.50) = 0.76\ kg/L$$

$$\text{Volume of NaOH} = \frac{(95.9\ kg/d)}{(0.76\ kg/L)} = 126.2\ L/d$$

Comment The water requirement for the scrubbing tower will be specified initially by the scrubber supplier and field adjusted based on the results of pilot-plant studies and past operating experience. If the wastewater has sufficient alkalinity, it may not be necessary to add sodium hydroxide.

Design Considerations for Odor-Control Biofilters

Important design considerations for biofilters include (1) the type and composition of the packing material, (2) facilities for gas distribution, (3) maintenance of moisture within the biofilter, and (4) temperature control. Each of these topics is considered below. Design and operational parameters are presented and discussed following the discussion of the above topics. Additional details on biofilters may be found in van Lith (1989), Allen and Yang (1991, 1992), WEF (1995), Eweis et al., (1998), and Devinny et al. (1999).

Packing Material. The requirements for the packing used in biofilters are (1) sufficient porosity and near-uniform particle size, (2) particles with large surface areas and significant pH-buffering capacities, and (3) the ability to support a large population of microflora (WEF, 1995). Packing materials used in biofilters include compost, peat, and a variety of synthetic mediums. Although soil and sand have been used in the past, they are less used today because of excessive headloss and clogging problems (Bohn and Bohn, 1988). Bulking materials used to maintain the porosity of compost and peat biofilters include perlite, Styrofoam™ pellets, wood chips, bark, and a variety of ceramic and plastic materials. A typical recipe for a compost biofilter is as follows (Schroeder, 2001):

Compost = 50 percent by volume
Bulking agent = 50 percent by volume
1 meq $CaCO_3$/g of packing material by weight

Optimal physical characteristics of a packing material include a pH between 7 and 8, air-filled pore space between 40 and 80 percent, and organic matter content of 35 to 55 percent (Williams and Miller, 1992*a*). When compost is used, additional compost must be added periodically to account for the loss due to biological conversion. Bed depths of up to 1.8 m (6.0 ft) have been used. However, because most of the removal takes place in the first 20 percent of the bed, the use of deeper beds is not recommended.

Gas Distribution. An important design feature of a biofilter is the method used to introduce the gas to be treated. The most commonly used gas distribution systems include (1) perforated pipes, (2) prefabricated underdrain systems, and (3) plenums. Perforated pipes are usually placed in a gravel layer below the compost (see Fig. 15–14). Where perforated pipes are used, it is important to size the pipe so that it

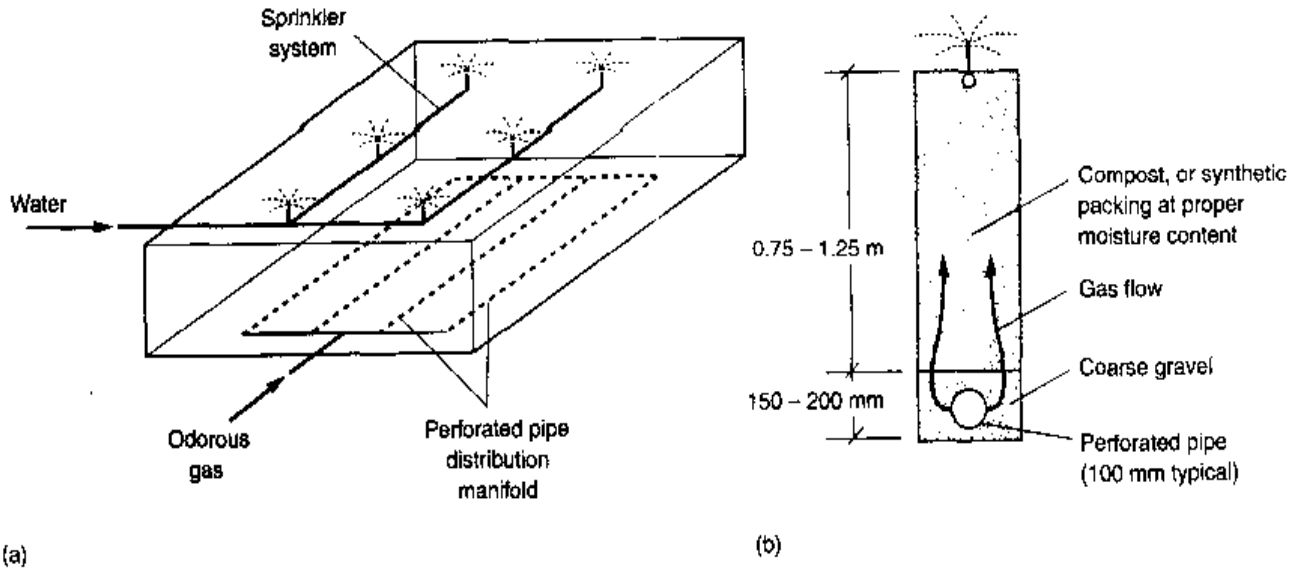

Figure 15–14

Definition sketch for open biofilters: (*a*) open bed and (*b*) trench type.

performs as a reservoir and not a manifold to assure uniform distribution (Crites and Tchobanoglous, 1998). A variety of prefabricated underdrain systems are available which allow for the movement of gas upward through the compost bed and allow for the collection of drainage. Air plenums are used to equalize the air pressure to achieve uniform flow upward through the compost bed. The height of air plenums will typically vary from 200 to 500 mm.

Moisture Control. Perhaps the most critical item in the successful operation of a biofilter is to maintain the proper moisture within the filter bed. If the moisture content is too low, biological activity will be reduced. If the moisture content is too high, the flow of air will be restricted and anaerobic conditions may develop within the bed. Also, biofilters tend to dry out unless moisture or humidity is added. The optimal moisture content is between about 50 and 65 percent, defined as follows:

$$\text{Moisture content, \%} = \left(\frac{\text{mass of water}}{\text{mass of water + mass of dry packing}}\right) \times 100 \qquad (15\text{–}10)$$

Moisture can be supplied by adding water to the top of the bed (usually by spraying) or by humidifying the incoming gas in a humidification chamber. The relative humidity of the gas entering the biofilter should be 100 percent at the operating temperature of the biofilter (Eweis et al., 1998). In biotrickling filters the liquid application rate is typically about 0.75 to 1.25 $m^3/m^2 \cdot d$.

Temperature Control. The operating temperature range for biofilters is between 15 and 45°C, with the optimal range being between 25 and 35°C. In cold climates, biofilters must be insulated and the incoming gas must be heated. Where the incoming gas is warmer, it may have to be cooled before being introduced to the biofilter. Operation at higher temperatures (e.g., 45 to 60°C) is often possible, as long as the temperature remains relatively constant.

Design and Operating Parameters for Biofilters. The sizing of biofilters is typically based on a consideration of the gas residence time in the bed, the unit air loading rate, and the constituent elimination capacity. Terms that will be encountered in the literature and the relationships commonly used to describe the performance of bulk media filters are summarized in Table 15–13. The empty bed residence time (EBRT) [see Eq. (15–11)], used to define the relationship between the volume of the contactor and the volumetric gas flowrate, is similar to Eq. (11–61) used for the analysis of activated-carbon systems. The true residence time is determined by incorporating the porosity, α [see Eq. (15–12)]. Surface and volumetric mass loading rates are often used to define the operation of bulk media filters. The elimination capacity, as given by Eq. (15–18), is used to compare the performance of different odor-control systems.

The residence time for foul air from wastewater treatment facilities is typically between 15 and 60 s and surface loading rates have ranged up to 120 $m^3/m^2 \cdot min$ for H_2S concentrations up to 20 mg/L. Constituent elimination rates are determined experimentally and are usually reported as a function of the constituent loading rate (e.g., mg $H_2S/m^3 \cdot h$). An essentially linear, 1 to 1, constituent elimination rate up to a critical load-

Table 15–13
Parameters used for the design and analysis of bulk media filters[a]

Parameter		Definition
Empty bed residence time		EBRT = empty bed residence time, h
$EBRT = \frac{V_f}{Q}$	(15–11)	V_f = total volume of filter bed contactor, m^3
Actual residence time in filter		Q = volumetric flowrate, m^3/h
$RT = \frac{V_f \times \alpha}{Q}$	(15–12)	RT = residence time, h, min, s
Surface loading rate		α = porosity of filter bed contactor
$SLR = \frac{Q}{A_f}$	(15–13)	SLR = surface loading rate, $m^3/m^2 \cdot h$
Surface mass loading rate		A_f = surface area of filter bed contactor, m^2
$SLR_m = \frac{Q \times C_o}{A_f}$	(15–14)	VLR = volumetric loading rate, $m^3/m^3 \cdot h$
Volume loading rate		RE = removal efficiency, %

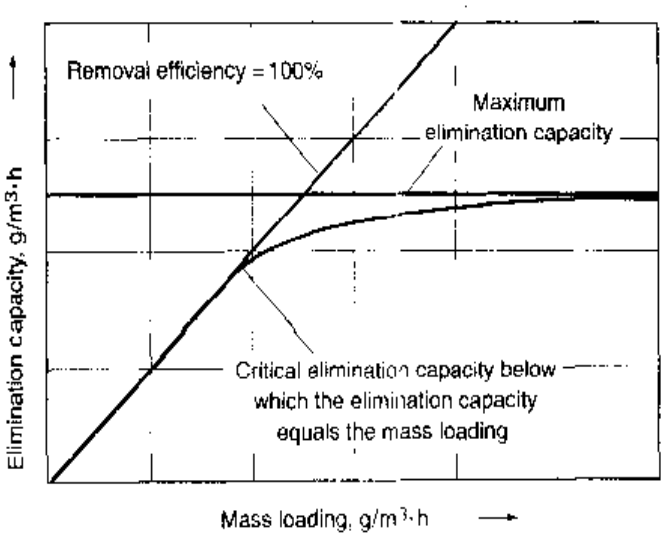
[a] Adapted in part from from Eweis et al. (1998); Devinny et al. (1999).

ing rate has been observed for hydrogen sulfide and other odorous compounds (see Fig. 15–15). Yang and Allen (1994) have reported a linear 1 to 1 elimination rate for H_2S, with loading rates for compost filters up to a maximum value of about 130 g $S/m^3 \cdot h$, beyond which the elimination rate becomes essentially constant at a rate of 130 g $S/m^3 \cdot h$ with increased loading. It should be noted that H_2S is eliminated easily as it passes through a biofilter.

Typical design criteria for biofilters are presented in Table 15–14. Typical biofilters are shown on Fig. 15–16. Some states regulate the design of compost biofilters including loading rates, biofilter emission rates, odor-sampling procedures, and setbacks from property lines. A typical odor-emission limit at the surface of the biofilter is 50 dilutions to threshold [see Eq. (2–52) in Chap. 2)] (Finn and Spencer, 1997). The design of a compost biofilter for the elimination of hydrogen sulfide is illustrated in Example 15–4.

Figure 15–15

Typical elimination capacity versus applied load. The relationship is linear up to a critical value, after which the elimination capacity approaches a maximum value asymptotically.



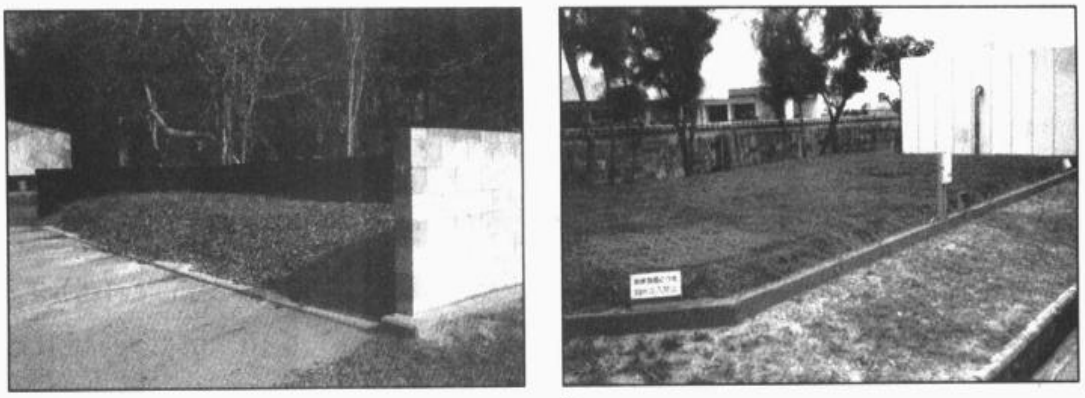


Table 15–14
Typical design factors for biofilters[a]

Item	Units	Type of biofilter: Biofilter	Type of biofilter: Biotrickling filter
Oxygen concentration	Parts oxygen/ parts oxidizable gas	100	100
Moisture			
Compost filter	%	50–65	50–65
Synthetic media	%	55–65	55–65
Temperature, optimum	°C	15–35	15–35
pH	Unitless	6–8	6–8
Porosity	%	35–50	35–50
Gas residence time	s	30–60	30–60
Depth of medium	m	1–1.25	1–1.25
Inlet odorous gas concentration	g/m^3	0.01–0.5	0.01–0.5
Surface loading rate	$m^3/m^2 \cdot h$	10–100[b]	10–100[b]
Volume loading rate	$m^3/m^3 \cdot h$	10–100	10–100
Liquid application rate	$m^3/m^2 \cdot d$		0.75–1.25
Elimination rate (capacity)			
H_2S (in compost filter)	$g/m^3 \cdot h$	80–130	80–130
Other odorous gases	$g/m^3 \cdot h$	20–100	20–100
Back pressure, maximum	mm of water	50–100	50–100

[a] Adapted in part from van Lith (1989), Yang and Allen (1994), WEF (1995), and Devinny et al. (1999).

[b] Loading rates as high as 500 $m^3/m^3 \cdot h$ have been reported, depending on the compound and its concentration.

(a) (b)

Figure 15-16

Typical soil/compost bulk biofilters filter for odor control: (*a*) compost biofilter used for odor control at an influent pump station at a wastewater treatment plant (Florida) and (*b*) soil-type biofilter with grass covering used for odor control at a wastewater treatment plant (Okinawa, Japan).

EXAMPLE 15–4 Design of a Compost Biofilter for Odor Control Determine the size of compost biofilter needed to scrub the air from a 100 m^3 enclosed volume using the design criteria given in Table 15–14. Also estimate the mass of the buffer compound needed to neutralize the acid formed as a result of treatment within the filter. Assume 12 air changes per hour are needed. Assume a bed porosity of 40 percent. Will the volume selected be adequate if the air contains 40 ppm_v of H_2S in addition to other odorous constituents? Assume an elimination rate of 65 g S/m^3·h, which incorporates a factor of safety of 2 as compared to the maximum rate given in Table 15–14. The temperature of the air is 20°C.

Solution

1. Estimate the airflow to be scrubbed.

   Flow = volume/time

   Flow = (100 m^3)(12 changes per hour) = 1200 m^3/h

2. Select a loading rate from Table 15–14; use 90 m^3/m^2·h
3. Select a filter-bed depth from Table 15–14; use 1.0 m
4. Calculate the area needed for the filter bed.

   Area = gas flow/ loading rate

   Area = (1200 m^3/h)/(90 m^3/m^2·h)

   Area = 13.3 m^2

5. Check the empty bed residence time using Eq. (15–11)

$$\text{EBRT} = \frac{V_f}{Q} = \frac{(13.3\ \text{m}^2)(1\ \text{m})}{(1200\ \text{m}^3/\text{h})}$$

$$= 0.011\ \text{h} = 39.9\ \text{s} \qquad (\text{OK } 39.9\ \text{s} > 30\ \text{s})$$

6. Determine if the volume of the biofilter determined in Step 5 is adequate to treat the H_2S.
   a. Determine the concentration of H_2S in g/m^3 using Eq. (2–45). From Example 15–3 the volume of gas occupied by one mole of a gas at a temperature of 20°C and a pressure of 1.0 atm is 24.1 L. Thus, the concentration of H_2S is

$$g/m^3 = \left(\frac{40\ L^3}{10^6\ L^3}\right)\left[\frac{(34.08\ g/mole\ H_2S)}{(24.1 \times 10^{-3}\ m^3/mole\ of\ H_2S)}\right]$$

$$= 0.057\ g/m^3$$

   b. Determine the mass loading rate of S^{2-} in g S/h.

$$M_s = \left(\frac{1200\ m^3}{h}\right)\left(\frac{0.057\ g\ H_2S}{m^3}\right)\left(\frac{32\ g\ S^{2-}}{34.08\ g\ H_2S}\right)$$

$$= 64.2\ g\ S^{2-}/h$$

   c. Determine the required volume assuming an elimination rate of 65 g $S/m^3 \cdot h$.

$$V = \frac{(64.2\ g\ S/h)}{(65\ g\ S/m^3 \cdot h)} = 0.99\ m^3$$

   Because the volume of the bed (13.3 m^3) is significantly greater than the required volume, the removal of H_2S will not be an issue.

7. Determine the mass of the buffer compound needed to neutralize the acid formed as a result of treatment within the filter.
   a. Determine the mass of H_2S in kg applied per year.

$$H_2S, kg/year = \frac{(1200\ m^3/h)(0.057\ g/m^3)(24\ h/d)(365\ d/yr)}{(10^3\ g/kg)}$$

$$= 599.2\ kg/year$$

   b. Determine the mass of buffer compound required. Assume the following equation applies:

$$\underset{34.06}{H_2S} + \underset{74.08}{Ca(OH)_2} + 2O_2 \rightarrow CaSO_4 + 2H_2O$$

   Thus, about 2.05 kg of $Ca(OH)_2$ will be required per kg of H_2S. If the compost biofilter has a useful life of 2 years, then a total of 2457 kg of $Ca(OH)_2$ equivalent will be required to be added to the bed. Typically, 1.25 to 1.5 times as much are added. The buffer compound is mixed in with the compost and the bulking agent.

Comment Based on the results of the computation carried out in Step 6, it is clear why compost and soil filters are so effective in the elimination of H_2S.

15–4 INTRODUCTION TO AUTOMATIC PROCESS CONTROL

The purpose of most wastewater automatic control systems is to maintain one or several process parameters such as SRT, DO, or clarifier sludge depth at a fixed value. If there were no changes in external conditions, such as flowrate variation, process control would be a simple task. However, external conditions are changing constantly, and, as a result, some dynamic control over treatment processes is needed. The purpose of this section is to introduce the basic concepts and design considerations involved in automatic process control. Terms commonly encountered when discussing process control are summarized in Table 15–15.

Table 15–15
Definition of terms used in wastewater process control applications

Term	Description
Bias gain coefficient	Constant value usually equal to 50 percent of the maximum value of a manipulated parameter
Cascade control mode	One feedback controller, identified as the primary controller, is used to calculate a set point of a second feedback controller
Control loop	Structure of a control system
Controlled parameter	Process parameter that is to be kept equal to the target value
Disturbance	An external cause of a measurable change in the operation or performance of a treatment process
Error	Difference between measured value of a controlled parameter and set point under non-steady-state operating conditions
Feedback control	A control method in which the value of a manipulated parameter is based on errors of a controlled parameter
Feed forward control	A control method in which the value of a manipulated parameter is based on a disturbance value
Integral control mode (*I*)	The value of a manipulated parameter is calculated based on a linear relationship with the accumulated error of a controlled variable
Manipulated parameters	Process parameters that can be changed directly to control the process
Offset	Difference between measured value of a controlled parameter and set point under steady-state operating conditions
On-off control	Simplest and the least expensive type of feedback control
Proportional control mode	The value of a manipulated parameter is calculated based on a linear relationship with the current error of a controllable variable
Proportional gain coefficient (*P*)	Coefficient relating manipulated parameter with the current error of controllable parameter
Proportional-integral control	Combination of two independent control modes: proportional (*P*) and integral (*I*)
Set point	Target operating value for a controlled variable. In advanced control systems the set point is not a fixed value

Process Disturbances

Factors that cause a change in the operation or performance of a treatment process are termed *disturbances*. There are two major types of disturbances: external, such as variations in incoming flow and wastewater characteristics; and internal, such as the actions of an operator or interaction among process units within a treatment plant. Both internal and external disturbances are discussed below.

External Disturbances. Continuous changes of influent flow, wastewater composition, and temperature introduce external disturbances to practically every process at a wastewater treatment plant. For example, the ratio of maximum to minimum oxygen demand, as well as the solids loading, will vary usually from 3:1 to 5:1 between the daytime hours (peak hours) and nighttime hours (off-peak hours). For small treatment plants this ratio is sometimes as high as 16:1. Wide variations in loads can lead to (1) inconsistent performance, (2) underloaded or overloaded unit processes, and (3) over- or underdesigned treatment facilities. Process performance deteriorates even further during storm events when hydraulic loadings increase as much as an order of magnitude, causing a loss of biological solids, and resulting in potential violations of the discharge permit.

To control a disturbance caused by widely fluctuating flows and loads, an equalization basin can be constructed to distribute the incoming mass load more evenly over the day and reduce loads during storm or peak flow events. The basin fills with wastewater during the peak hours, when flow and oxygen demand are high, and empties during the night when flow and oxygen demand are low (see Sec. 5–3 in Chap. 5). A goal of equalization basin operation is to dampen the peak incoming hydraulic load to the plant. With the introduction of on-line water-quality analyzers, more beneficial oxygen demand equalization is sometimes used. Use of diurnal load equalization (1) simplifies and reduces the cost of plant operation, (2) reduces capital costs for aerators, clarifiers, blowers, pumps, and other equipment, and (3) can reduce the variability of the constituent concentrations in the effluent. The same equalization basin can be used to reduce flow to a plant during storms.

Another method to reduce peak flow coming to a treatment plant during storm events is utilization of spare volume of the collection system. Sophisticated flow control systems are used to maximize collection-system storage capacity. Such systems utilize extensive flow monitoring and control devices including hydraulic brake regulators (Tchobanoglous, 1981) and often rely on a dynamic computer model of wastewater collection systems.

Internal Disturbances. In addition to external disturbances, there are also internal disturbances that are sometimes have a greater effect than the external disturbances. An example of an internal process disturbance is a change in the growth of filamentous organisms in the mixed liquor that reduces the settling performance of the final clarifiers. For successful design and operation of a wastewater treatment plant it must be recognized that every treatment process at the plant is not an isolated unit, but an element of a complex system. Change in operation of one element affects not only the particular process unit, but also the entire system. The actions of an operator, such as a changing the number of process units in operation, changing the *set points* (target operating

Table 15–16
Typical examples of internal disturbances at wastewater treatment plants

Source	Parameter affected	Process directly affected
Intermittent operation of pumps and other mechanical equipment	Flow	All downstream processes
Unequal flow distribution among parallel process units	Flow, TSS, oxygen demand	Parallel process units
Change in effluent ammonia and nitrite concentration	Chlorine demand	Disinfection
Change in mass of wasted solids	Solids loading	Sludge processing
Change in blanket depth of primary and secondary clarifiers	Effluent TSS, BOD, sludge TSS concentration	Downstream liquid processes, thickeners
Change in recycle flowrate and composition	Solids loading and oxygen demand	All processes located downstream of junction of the recycled flow and the main flow

values for controlled variables), and changing the flow routing, if not implemented carefully, may cause significant internal disturbances.

Another source of internal disturbances is the mode of operation of an individual unit process. Each of the process units has to not only reliably and efficiently perform its function, but also should minimize disturbances to other process units or, better yet, compensate these units for external disturbances. For example, the ammonia load in sludge supernatant from dewatering facilities that is recycled back for biological treatment can increase oxygen demand by as much as 30 percent. If this load is introduced during the nighttime hours, it will help to spread oxygen demand evenly and utilize less expensive nighttime energy; recycling supernatant during peak hours may cause problems with control, effluent quality, and cost of aeration. A list of some disturbances caused by changes in the operating modes of treatment processes is presented in Table 15–16.

Control Systems for Wastewater Treatment Plants

Even with the best efforts it is impossible, however, to eliminate disturbances completely. Thus, to maintain optimum process efficiency and reliability, it is necessary to compensate for disturbances by changing some of the process parameters. Process parameters that are to be maintained at target values are called *controlled parameters*. Process parameters that can be changed directly to maintain controlled parameters at target values are called *manipulated parameters*. Examples of controlled and manipulated parameters for wastewater treatment processes are given in Table 15–17.

Control System Architecture. The typical structure of a control system is termed a *control loop* and is shown on Fig. 15–17. As illustrated on Fig. 15–17, a control loop is comprised of (1) an instrument for input measurement, (2) a controller for calculating the action of a final control element, (3) a final control element that is used to implement control action, and (4) signal transmitters for communication between the other

Table 15–17
Typical examples of controlled and manipulated parameters

Process	Controlled parameter	Manipulated parameter
Primary treatment and gravity thickening	• Sludge depth	• Rate of sludge removal
Activated sludge	• Dissolved oxygen concentration in an aerator	• Oxygen supply rate
	• Sludge depth in a clarifier	• Return sludge flowrate
	• Solids-retention time	• Rate of sludge removal
Chlorination	• Chlorine residual	• Chlorine dosage
Dissolved air flotation	• Air to solids ratio	• Airflow
	• TSS in the supernatant	• Polymer flow
Gravity belt thickening	• Percent solids	• Belt solids loading
	• Capture percent	• Polymer flowrate

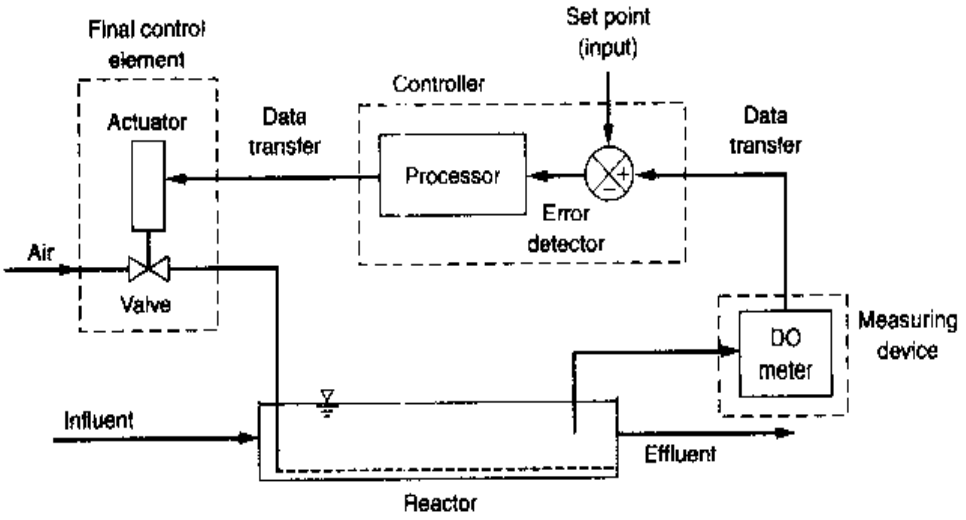

Figure 15–17

elements. In wastewater treatment plants, control-loop systems are used to control flow, pressure, liquid level, constituent concentrations, temperature, and other operating variables. The elements of the control loop are described in greater detail at the end of this section following the discussion of control algorithms.

Manual versus Automatic Control. The general control-loop structure described above and illustrated on Fig. 15–17 exists in any type of control, whether manual or automatic. For instance, manual control of solids-retention time (SRT) in an activated-sludge process consists of the following steps:

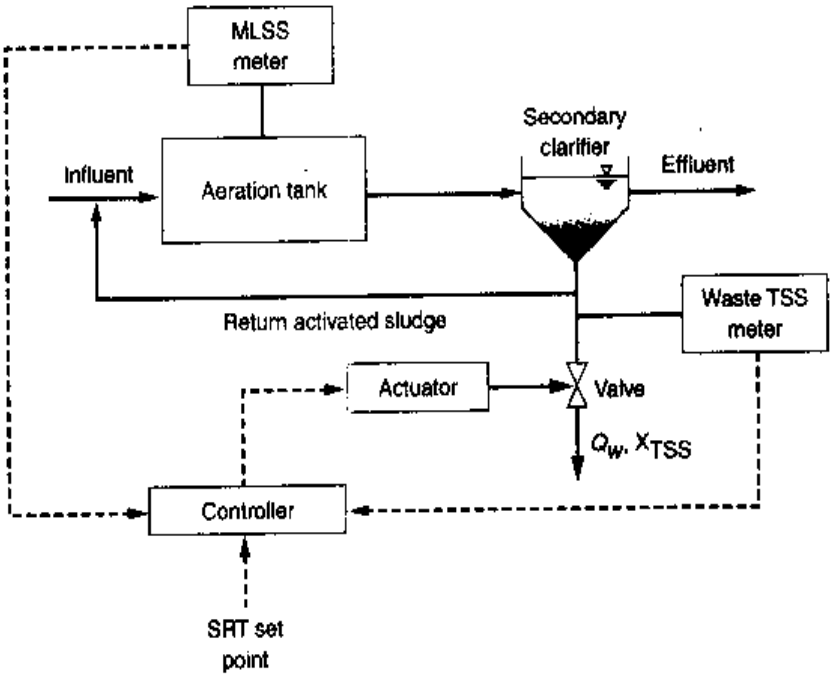
1. An operator samples both mixed liquor and return sludge.
2. Samples are brought to laboratory for analysis.
3. TSS analysis is performed during a period of several hours.

4. The results from the laboratory analysis are communicated to a person responsible for waste flow calculation.
5. The person responsible for operation determines if the sludge wasting flowrate should be changed and, if so, how much.
6. Instructions on waste sludge flow change are given to an operator.
7. The operator changes position of a valve on waste flow line using flowmeter readings.

The same structure exists in an automatic SRT control system as illustrated on Fig. 15–18. The difference, however, is that TSS measurements are conducted on-line, calculations are performed continuously by a computer, the valve position is changed by an actuator, and communication between computer and other elements is conducted without human intervention through cables and fiber optics, or by wireless. Comparison of activated-sludge performance with manual versus automatic control is illustrated on Fig. 15–19.

Advantages of Automatic Control. Based on the performance records of numerous wastewater treatment plants, automatic control systems not only reduce workload, they also allow for more precise control of process parameters. Improved control of process parameters stabilizes and improves operation of not only a process under control, but also processes located downstream. For example, automation of SRT improves operation not only of the activated-sludge process, but also of sludge-thickening processes due to more stable sludge mass load on the thickening facility.

Failure of any element (an instrument, most often) of an automatic control system may lead to serious problems if a control algorithm does not automatically recognize such a failure has occurred and compensate for it. A control algorithm is the set of instruction or logic used by the controller to bring about a change in a controllable



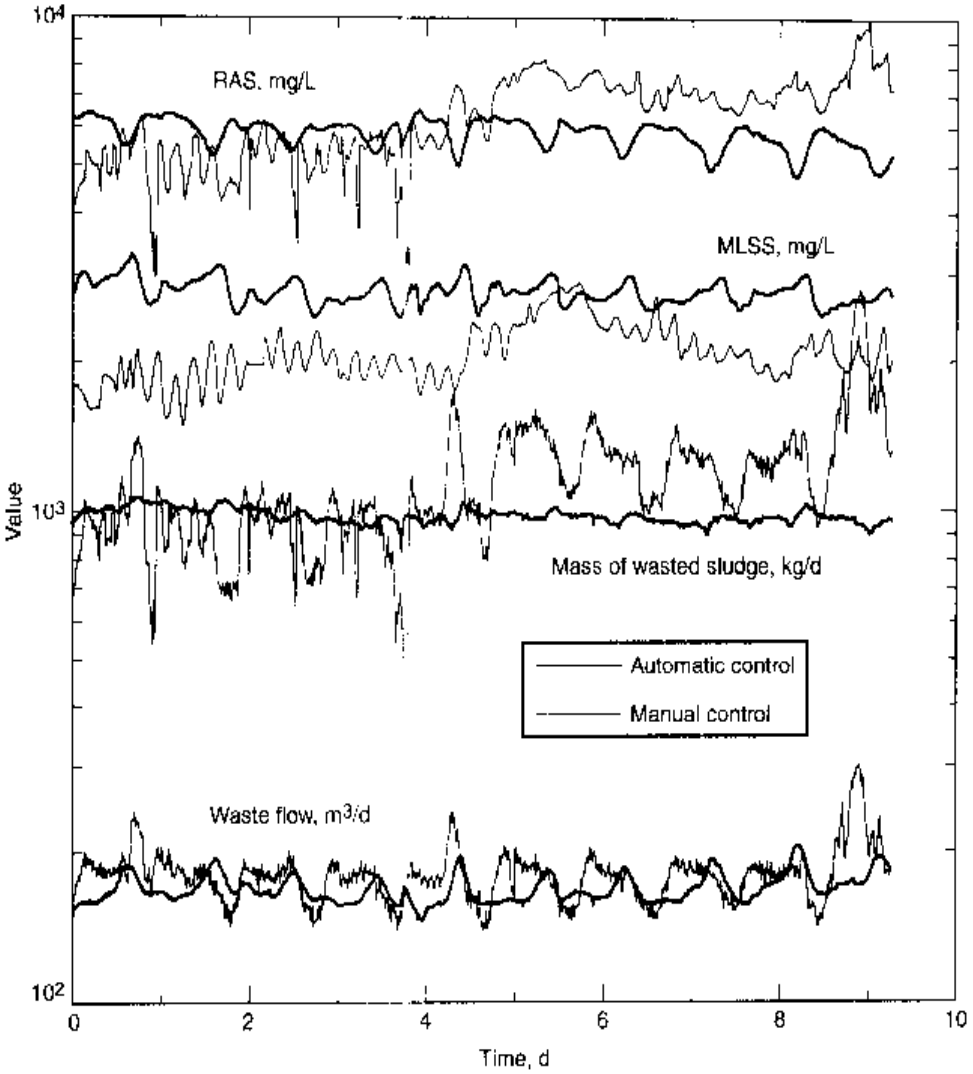


Figure 15–18
Automatic control system for an activated-sludge process based on solids-retention time (SRT).

Figure 15–19

Performance comparison for a wastewater treatment plant with manual and automatic solids-retention time (SRT) process control.

parameter. In the past, poor reliability was a major reason for the limited utilization of automatic control in the wastewater industry. Progress in computer hardware, and especially software, has made it possible for modern control systems to function reliably, even if one of the components fails (Colby and Ekster, 1997; Olson and Newell, 1992). Other advantages accrue through automatic control such as reduced operating staff, unattended operation for one or more shifts, and automatic data logging and archiving.

Control Algorithms

To compensate for process disturbances, an appropriate change of a manipulated variable must be made. The challenge of process control is to determine how much change is required. Inadequate change will not completely compensate for a disturbance; a large change may cause more problems than the disturbance itself. For example, if the airflow supply is reduced too much in the evening hours, when oxygen demand is low, effluent quality will deteriorate significantly. A new value of a manipulated parameter can be determined either by human (manual control) or automatically (automatic control). Several methodologies that can be used for the calculation of a manipulated vari-

able that will be used in an automatic control are discussed below. Additional details on control systems may be found in Shinskey (1996), Smith and Corripo (1997), Coughanowr (1991), and WEF (1993).

There are three general types of control: (1) feedback, (2) feed-forward, and (3) combination feed-forward and feedback. Feedback control involves measurement of a process variable to make adjustments to an input variable. The input variable then becomes the manipulated variable. A feedback controller cannot achieve perfect control continuously because it can respond only when an error is detected in the output. Feed-forward control, on the other hand, is used to detect disturbances at the input before the system responds and to make adjustments to one or more manipulated variables to reduce or eliminate the effect of the disturbance. Thus, the essential difference between feedback and feed-forward control is that the former acts to compensate for observed changes, whereas the latter tries to compensate for disturbances (WEF, 1993). In situations where control cannot be achieved accurately or completely with feedback control, a combination of feed-forward and feedback control can be used. Each of the three general methods of control is discussed in the following paragraphs. Cascade and adaptive control, two other methods used for process control, are also discussed.

Feed-Forward Control. The feed-forward control method consists of measuring disturbances and changing manipulated parameters so that the controlled parameters will be maintained within a desired range. For example, if the influent characteristics and flowrate (disturbances) are measured and it was possible to calculate the required change in airflow (manipulated parameter) supplied to an activated-sludge system to maintain constant dissolved oxygen (DO) concentration in the aeration tank (controlled parameter), it would be possible to implement feed-forward control.

In a very basic, so-called *static feed-forward control* algorithm, a manipulated parameter is calculated based on a linear relationship with a controlled variable. For DO, the magnitude of the required airflow signal is calculated using the following formula:

$$Q_A = (K_{ff})Q_l \tag{15–19}$$

where Q_A = airflow, m^3/min
K_{ff} = feed-forward *gain* coefficient, $(m^3/min)/(m^3/d)$
Q_l = liquid flowrate, m^3/d

In more sophisticated dynamic feed-forward control algorithms, it is common practice to take into account process dynamics.

Unfortunately, most of the time measurements of disturbances as well as calculation of a required change in a manipulated parameter are very difficult tasks. As a result, feed-forward control has limited application in the automation of wastewater treatment processes. The current-limited applications of feed-forward control include control of chemical addition and control of return activated-sludge flow from clarifiers to the aeration tanks. In both cases, only one disturbance (influent flow change) is used for calculation of change in manipulated parameters. Because the effect of other disturbances (water-quality characteristics, for example) is not considered, a controlled parameter cannot be maintained within a narrow range. Development of advanced on-line water

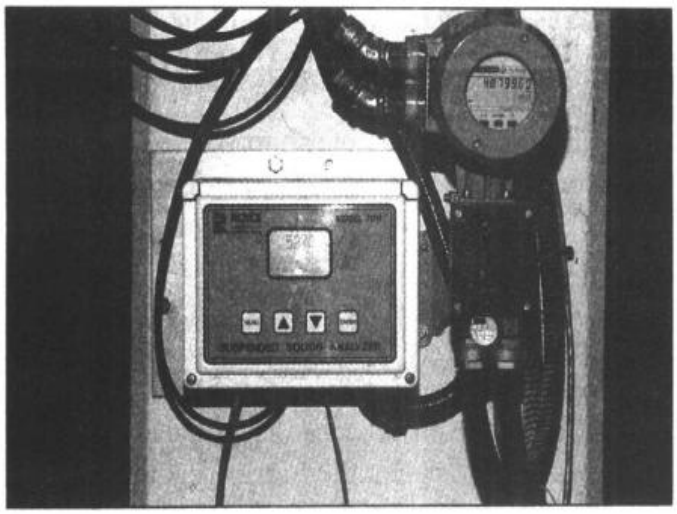

Figure 15–20
Typical on-line analyzer for total suspended solids (TSS). *(Courtesy of Royce Instruments.)*

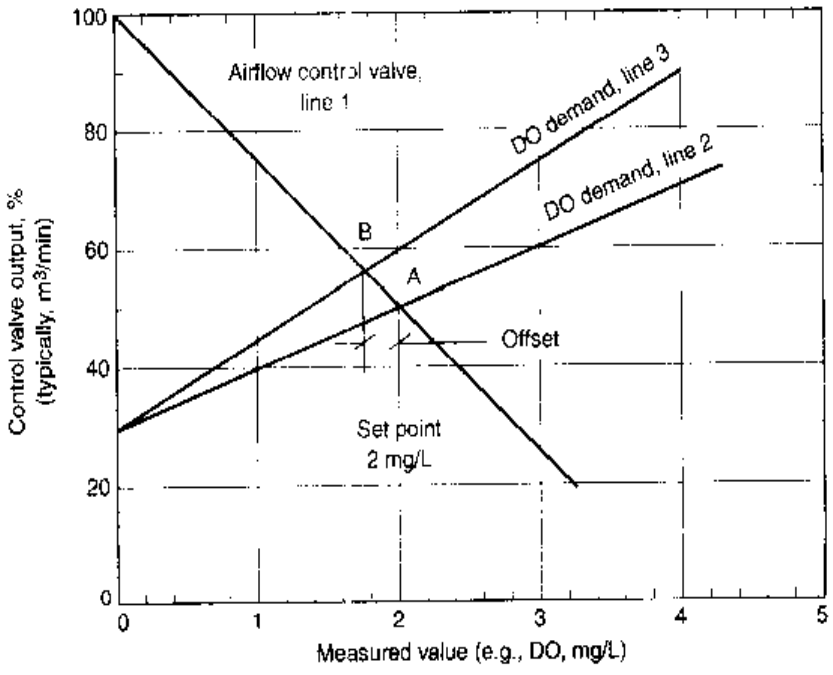
analyzers (see Fig. 15–20) and computer modeling of wastewater treatment processes may help to make this type of control more feasible in the future.

Feedback Control. The principle of feedback control is one of the most intuitive concepts for process control. An action is taken to correct a less than desirable situation; the result of corrective action is then measured and a new corrective action is applied. So instead of measuring a disturbance, a change in a controlled parameter (such as DO discussed above) is measured, and based on the measured change a manipulated parameter (airflow) is calculated. There are several types of feedback control, including on-off, proportional, integral, proportional-derivative, proportional-integral, and proportional-integral-derivative. Of these control modes, the most common are *on-off* and *proportional-integral.* As in the feed-forward discussion, DO will be used to illustrate the various control methods.

On-Off Control On-off control is the simplest and the least expensive type of feedback control. Control action is intermittent and initiated when a controlled parameter is approaching a predetermined value. Turning the aeration system on and off as the oxygen level falls below or rises above a given DO level in an aeration tank is an important example in wastewater treatment. Another example is the control of the water level in the wetwell of a pump station. Pumping is initiated when water elevation reaches a high mark and is stopped when water level reaches a low mark. Frequency of start-stop cycles of mechanical equipment is usually limited due to an extremely high electrical load that a motor experiences during startup. Thus, in wetwell level control, the high and low operating levels should be selected far enough apart to limit the frequency of pump starts (such as one start every 20 min) to avoid overheating the electric motor. As a result, on-off control cannot maintain a controlled parameter within a narrow range. On-off control actions also cause a significant disturbance to be transmitted to downstream processes. Variable-speed pumps are often used to limit disturbances to downstream processes.

Proportional Control In a proportional control mode, a manipulated parameter is calculated based on a linear relationship with the error for the controlled variable. For

purposes of this discussion, error is defined as the difference between the target value of the controlled variable and the current value. For DO, the magnitude of the required airflow signal is calculated using the following formula:



$$Q_A = (K_p)(\mathrm{DO}_{sp} - \mathrm{DO}) + M = K_p(\varepsilon) + M \qquad (15\text{–}20)$$

where Q_A = airflow, m^3/min
K_p = controller *proportional gain* coefficient, (m^3/min)/(mg/L)
DO = dissolved oxygen concentration, mg/L
DO_{sp} = targeted dissolved oxygen concentration at the set point, mg/L
M = constant, often identified as the controller *bias coefficient* or *base value*, which corresponds to the output from the controller when the error is zero. The bias coefficient is often initially set equal to 50 percent of maximum value of the manipulated variable, m^3/min
ε = difference between measured value and set point defined as the *error* under non-steady-state operating conditions and as the *offset* under steady-state conditions

The controller relationship represented by Eq. (15–20) corresponds to line 1 on Fig. 15–21. Assume, for example, when the set point (i.e., target value) DO_{sp} is reached in the aeration basin at point *A*, the line that characterizes the airflow demand-DO relationship (line 2) intercepts the controller line 1. When the BOD load is increased, the airflow demand-DO relationship changes (line 3). A new air demand will be satisfied at point *B*, and the system will reach a new equilibrium (or so-called steady state). As noted above, the difference between the new value of the controlled variable and set point under steady-state conditions is called *offset*. Under non-steady-state conditions, the offset is called an *error*. Increasing the absolute value of the gain can decrease the offset. However, an offset cannot be eliminated completely because, to achieve zero offset, proportional gain needs to be increased indefinitely (i.e., line 1 has to become parallel to the *Y*

Figure 15–21

Schematic representation of proportional control for dissolved oxygen (DO).

axis). The dynamics of the process and accuracy of measurements impose considerable limitations on the value K_p and, as a result, K_p cannot be increased indefinitely.

Integral Control In the integral control mode, the area under the curve of a plot of the offset versus time is used to determine the corrective action. The change in the manipulated parameter is calculated based on a proportional relationship. The integral mode is the best control mode to eliminate offset. If any offset is present, an action based on integral control will continue to make changes until the offset is eliminated. Integral control action for DO control can be described by the following equation:

$$Q_A = (K_p/t_i)\int(\mathrm{DO_{sp}} - \mathrm{DO})\,dt = (K_i)\int(\varepsilon)\,dt \qquad (15\text{–}21)$$

where Q_A = airflow, m^3/min
t_i = *integral time*, usually measured in minutes, min
K_i = controller integration gain factor
$= K_p/t_i$, $(m^3/min^2)/(mg/L)$
t = time, min
Other terms as defined above.

If the parameter versus time is defined by a series of discrete time step measurements, the theoretical airflow is typically approximated as

$$Q_A = (K_p/t_i)\Sigma(\mathrm{DO_{sp}} - \mathrm{DO})\,\Delta t = (K_i)\Sigma(\varepsilon)\Delta t \qquad (15\text{–}22)$$

where Δt = differential time, min

Theoretically, using integral control, the set point can always be maintained precisely without offset. However, if the dynamics of the control loop are slow and the K_i value is high, the system becomes unstable because of overly aggressive control action. Reduction of the K_i value will make the control system too slow and make it impossible to compensate for disturbances within a reasonable period of time.

Proportional-Integral (PI) Control Proportional-integral (PI) control is by far the most popular type of feedback control. A PI algorithm is a combination of two independent modes: proportional (P) and integral (I). A combination of the proportional and integral modes (PI) provides reliable and accurate control. Mathematically the proportional-integral control can be represented by the following equation:

$$Q_A = K_p(\varepsilon) + M + (K_i)\int(\varepsilon)\,dt \qquad (15\text{–}23)$$

where the terms are as defined previously.

The basic concept of PI control is to respond rapidly to an error by a proportional action and slowly eliminate an offset by an integral action. The ratio between K_p and K_i will depend on the dynamics of the control loop. For fast loops, such as flow control, integral control action should be increased; for slow processes, such as DO and level control, proportional action should be used to avoid process oscillation. The process of finding the proper values of the coefficients K_p and K_i is called *control-loop tuning*. Incorrect tuning in many cases is a cause of ineffective automatic control and sometimes leads to complete abandoning of automatic control. There are several recommended methods of tuning that use a successive trial approach (Corripo, 1990). Computer modeling is

sometimes also necessary to determine tuning coefficients for slow control loops such as SRT control of an activated-sludge system (Ekster et al., 1997).

Proportional-Derivative (PD) Control Improved process control can be achieved by adding a derivative term, obtained from a plot of the offset versus time, to the proportional control term. The resulting proportional-derivative control equation for DO is:

$$Q_A = K_p(\varepsilon) + M + K_p t_d \frac{d(\varepsilon)}{dt} \tag{15–24}$$

where t_d = derivative time, min

The purpose of the derivative term is to anticipate the change in a system by considering the time rate of change of the error term. The PD method of control is used in control loops where the dynamics of the process or processes are fast. Because the process dynamics of wastewater treatment processes are relatively slow, the PD method of control rarely is used in wastewater applications.

Proportional-Integral-Derivative (PID) Control Combining the three modes discussed above results in an even more sophisticated and effective control system, as given by the following equation.

$$Q_A = K_p(\varepsilon) + M + (K_i)\int(\varepsilon)dt - K_p t_d \frac{d(\varepsilon)}{dt} \tag{15–25}$$

The difficulty with using the PID control method is that three variables must be adjusted simultaneously to tune the control loop.

Feed-Forward and Feedback Control. Because of the limitations of feedback control, i.e., a manipulated variable is changed only when an error is detected or reaction time is slow, process response can be improved by adding feed-forward control. Under a combined control strategy, a manipulated variable responds initially to a disturbance (e.g., change of flow) using a feed-forward control algorithm. The error caused by inaccurate disturbance compensation is corrected by applying feedback PI control action. A formula for a combination of static feed-forward DO control with PI feedback control is given below.

$$Q_A = (K_{ff})Q_L + [K_p(\varepsilon) + M + (K_i)\Sigma(\varepsilon)\Delta t] \tag{15–26}$$

where the terms are as defined previously.

With proper control-loop tuning, an error caused by imperfect disturbance compensation by feed-forward control action is much less than an error when only feedback control is used. A combination of feed-forward and feedback control makes controller tuning more difficult and time-consuming because an additional tuning coefficient is required for feed-forward control action. As a result, the combination of feed-forward and feedback controls is not used very often. Advances in computer modeling of wastewater treatment processes may simplify control-loop tuning in the future, and this advanced control mode will be used more frequently. Application of combined feedback and feed-forward control is illustrated in Example 15–5.

EXAMPLE 15–5 Maintaining Proper Flow of Air for Oxygen Control in a Complete-Mix Activated-Sludge Process Changes in the DO and flowrate for the last 7 min in the aeration tank are shown in the following table. Using these data and the operating values given below, determine the airflow control signal at the end of the seventh minute to maintain dissolved oxygen concentration at 2 mg/L using a combined feedback and feed-forward control mode.

Time, min	DO, mg/L	Wastewater flowrate, m^3/d
1	1.9	18,200
2	1.9	18,600
3	2.0	18,900
4	2.1	19,300
5	2.2	19,700
6	2.2	20,000
7	2.3	21,000

Applicable operating values:

1. The feed-forward control gain factor K_{ff} is (0.0075 m^3/min)/(m^3/d).
2. Proportional gain K_p is (15 m^3/min)/(g/m^3).
3. Integration time t_i is 10 min.
4. Bias is equal to 0.

Solution

1. Determine the value of the integral gain.

$$K_i = K_p/t_i = [(15\ m^3/min)/(g/m^3)]/10\ min = (1.5\ m^3/min^2)/(g/m^3)$$

2. Determine the magnitude of the airflow signal using Eq. (15–26).

$$Q_A = (K_{ff})Q_L + [K_p(\varepsilon) + M + (K_i)\Sigma(\varepsilon)\Delta t]$$

$$Q_A = [(0.0075\ m^3/min)/(m^3/d)](21{,}000\ m^3/d) + [(15\ m^3/min)/(g/m^3)(2.3 - 2.0)\ g/m^3] + [(1.5\ m^3/min^2)/(g/m^3)] \times \Sigma[(2.0 - 1.9) + (2.0 - 1.9) + (2.0 - 2.0) + (2.0 - 2.1) + (2.0 - 2.2) + (2.0 - 2.2) + (2.0 - 2.3)\ g/m^3] \times 1.0\ min$$

$$= 152.1\ m^3/min$$

Thus, at the end of seventh minute the airflow should be equal to 152.1 m^3/min.

Comment The computations illustrated above are performed by the controller on a continuous basis, subject to the input. The gain and bias factors are characteristic of the controller.

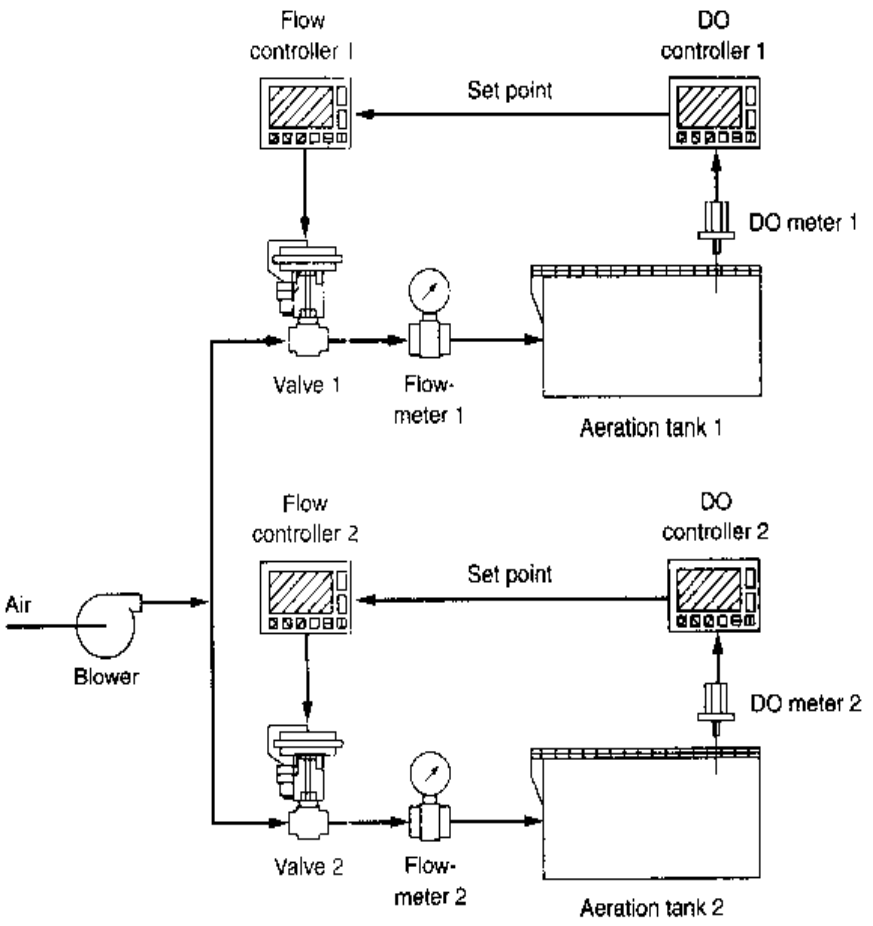


Figure 15–22
Typical example of a cascade DO control for the activated-sludge process.

Cascade Control. In a cascade control mode, one feedback controller, identified as the *primary controller,* is used to calculate a set point of another feedback controller that is called the *secondary controller.* Interaction among control loops is the most pressing reason for utilization of cascade control mode. For example, when a blower is used to supply air to two aeration tanks as shown on Fig. 15–22, an increase of airflow to one tank (Tank 1, for example) will cause a decrease of airflow to another tank (Tank 2), which will eventually lead to a decrease of DO in Tank 2. In a standard PI control system, it will take a long time before the DO error in Tank 2 will be compensated by the DO controller.

In a cascade control system, in addition to DO, airflow is also controlled. The required set point for airflow is calculated by the DO controller, so this set point is a manipulated variable for the DO controller. As soon as airflow to Tank 2 starts to decrease because of the increased airflow to Tank 1, the airflow controller, in response to an error, will trigger a fast opening of corresponding control valve 2. Manifold air pressure (P) will decrease and, in response to an error, a pressure controller will make a blower produce more air, so air demand of both tanks is satisfied. Everything will happen much faster than in the previous scenario and the DO in Tank 2 will not be affected by the increased air demand of Tank 1.

Availability of an intermediate parameter that can be controlled to compensate for interaction among control loops is a criterion for application of cascade control. In the aeration example, the airflow to each tank is such a parameter. Cascade control allows

faster compensation of disturbances caused by interacting controllers, in this example, the DO controllers. As in the case of combined feed-forward feedback control, cascade control often requires additional measurements and increases the complexity of tuning.

Distribution of flow among parallel process units is another popular application of a cascade control. The distributed method of control is called *the most opened valve* algorithm. According to this control method, a primary controller maintains one valve almost fully open (90 percent) and flowrate through this valve serves as a set point for flowrate through other parallel control valves. If opening of any valve exceeds 90 percent, this valve becomes *fully open*, its opening is reduced to 90 percent, and flowrate through this valve becomes a set point for other control loops. The described control algorithm guarantees that pressure in the distribution system will be just enough to provide the required flow through each valve. By always maintaining an optimum pressure in the system, energy use by pumps or blowers is minimized.

Adaptive Control. Most wastewater treatment processes cannot be described by simple linear equations and, as a result, a regular PI control algorithm cannot control these processes precisely. In some cases, adaptive PI control algorithms utilizing variable gains provide better results. Gain values can be programmed initially or calculated on-line using an iteration technique. Another method of adaptive control is to use self-calibrating computerized models of the wastewater treatment process to calculate control actions. Such models can be mechanistic or statistical. Adaptive algorithms use much more processing power than regular control algorithms and require more sophisticated programming techniques. To maintain robustness of adaptive algorithms, boundary conditions often have to be used. Despite numerous benefits, adaptive control is rarely used due to its complexity

Selection of Set Points. Optimization of set points is a necessary part of any control strategy. Such optimization is a tedious and complex task. For process control parameters, set points should be selected based on information provided in Table 15–18. Before final selection, it is recommended that several set points are evaluated.

Process Control Diagrams

Wastewater treatment plants are designed by a team of engineers. The process engineer, who takes the lead in the conceptual design, develops the project documentation that allows the engineers of the various other disciplines, (i.e. mechanical, structural, instrumentation, and electrical) to complete the detail of the project design. The required documentation is normally developed in three stages: (1) block flow diagrams (BFDs), (2) process flow diagrams (PFDs), and (3) piping and instrument diagrams (P&IDs), with each succeeding document adding to the detailed definition of the process flow and control.

Block Flow Diagrams (BFDs). The BFDs, typically developed in conjunction with the client, are used to identify the major process treatment elements that will be used to treat the wastewater prior to discharge or reuse. In some cases, more than one BFD may be developed.

Table 15-18
Considerations in the selection of set points for various treatment-plant processes

Process	Parameter	Potential problems if value is: Lower than optimum	Potential problems if value is: Higher than optimum
On-off pumping	Wetwell levels	• Damage to the pump motor • Vortexing of pump; cavitation • Increased pumping head (increased energy cost)	• Possible overflow and flooding of downstream processes • Reduced pump efficiency
Primary treatment	Sludge depth	• Reduction of efficiency of subsequent sludge treatment processes due to excess water in thin sludge discharged from primary clarifiers • Increased return flow from sludge processing facilities	• Increased effluent TSS, soluble and particulate BOD and H_2S generation • Increased floating solids due to *gasification* • Increased mechanical stress on sludge and scum collection mechanism
Conventional activated sludge	Solids-retention time	• Poor constituent (BOD, NH_3, etc.) removal in aeration basin • Poor sludge settleability due to dispersed growth • Deterioration of waste sludge thickening due to thin sludge discharged from secondary clarifiers	• Increased clarifier solids loading that can cause an increase in effluent TSS • Low F/M foaming and bulking • Increased energy demand to sustain endogenous respiration
	Dissolved oxygen (DO) concentration	• Poor constituent removal in aeration basin • Poor settleability due to low DO bulking • High effluent turbidity due to deterioration of sludge floc • Possible development of filamentous organisms	• High energy cost due to excessive DO • Break-up of floc and, as a result, increased effluent TSS • Nitrification encouraged
	Return flowrate from the clarifier	• Increased effluent TSS due to (a) increased sludge depth in clarifier and (b) solids floating due to denitrification	• Deterioration of waste sludge thickening due to thin sludge discharged from secondary clarifiers • Increased filamentous growth causing poor settleability and foaming • Increased energy demand because of excessive pumping

(continued)

Table 15–18 (*Continued*)

Process	Parameter	Potential problems if value is	
		Lower than optimum	**Higher than optimum**
Step-feed activated sludge	Flow to first compartment	• Increased clarifier solids loading	• Poor constituent removal in aeration basin • Low DO in first stage (compartment)
Biological nutrient removal	Internal recycle	• Incomplete denitrification	• Decreased denitrification rate due to increased oxygen concentration in the anoxic compartment
	Methanol feed rate	• Incomplete denitrification	• Increased cost of methanol, aeration, and sludge processing • Increased energy demand for recycle pumping
Dissolved air flotation thickening	Air/solids ratio	• Increased TSS in recycle flow	• Increased energy demand • Decreased sludge concentration
Gravity thickening	Sludge depth	• Decreased sludge concentration	• Increased TSS in the supernatant
Gravity belt thickening	Belt speed	• Sludge spills at inlet to the belt	• Decreased solids concentration
Chemical addition for water-solids separation	Chemical dosage rate	• Poor water solids separation due to inadequate flocculation	• Increased cost of chemicals and sludge processing • Increased turbidity and TSS in settled effluent
Chlorination	Chlorine dosage rate	• Poor disinfection • Permit violation	• Poor disinfection due to destruction of chloramines • Increased cost of chlorine • Excessive SO_2 demand and cost for dechlorination • Formation of potential carcinogenic constituents • Increased toxic to aquatic organisms

Process Flow Diagrams (PFDs). After the block flow diagrams have been agreed to, the next step is to develop PFDs in which the flow paths for all of the liquid and solids are identified. The PFDs are used to define the treatment process in greater detail including the major equipment involved in each of the various processes and material balances for the anticipated operating conditions (see Sec. 14–16 in Chap. 14). In the PFDs, the overall process control scheme for the entire facility is identified, along with the major control loops for the individual unit processes. It is important to note that the PFDs should include the critical process conditions that may be encountered in the

operation of the facility (i.e., peak flows, minimum flows, etc.). Many treatment processes have been hampered by systems designed in strict accordance with "normal" or "average" steady-state conditions, with little or no allowance for the flow or load extremes under which the unit processes may be expected to operate (see discussion in Sec. 15–2).

Piping and Instrument Diagrams (P&IDs). Once the PFDs are adopted, the P&IDs are then developed. The P&IDs are used as a pictorial representation of the treatment plant including the process equipment, with installed spares, the associated piping, valves, and instrumentation necessary for the control and safe operation of the facility. Because they encompass the complete process design, the P&IDs usually form the basis for the project scope and project control, as well as a guide for the detailed design by the discipline engineers. The P&IDs also become the principal form of communication between the designers and the owner/operator of the facility; they are also important in the training of operators. To ensure proper definition of the treatment process facilities, the capacities of equipment, piping, and instrumentation along with data for sizes, and materials of construction are normally included on the P&IDs. While the process engineer will, typically, prepare an initial issue of the P&ID, incorporating the equipment, piping, and basic instrumentation scheme, it then becomes the responsibility of the mechanical and instrumentation engineers to develop and expand the details and bring the P&IDs to the level of detail needed to proceed with the detailed design and construction drawings. One of most important tasks is to define the exact details of how the individual process control loops will function, using one or more of the control methods described in the remainder of this section.

Description of Automatic Control System Elements

The elements of an automatic control system include (1) on-line instrumentation, (2) signal transmitters, (3) controllers, and (4) final control elements. Each of these elements is described and discussed below.

On-line Instrumentation. Frequency of measurements and adjustments depends on how long it takes for a parameter to change after a disturbance affecting the parameter in question is introduced. The time required for a parameter to achieve 63.2 percent of the difference between the initial and final conditions after a disturbance is introduced is called the *time constant* (Smith and Corripo, 1997). The magnitude of time constants for some important parameters for different wastewater treatment processes is given in Table 15–19. To provide reliable control, these parameters need to be measured from ten to thirty times more frequently than the corresponding time constant. So, it is clear that for control of most parameters on-line instrumentation is necessary.

The wastewater treatment industry used on-line instrumentation for manual control long before automation was introduced. Every plant is equipped with flow, pressure, and liquid-level meters. These instruments are necessary to operate a plant reliably and efficiently, whether process adjustments are conducted manually or automatically. Methods used for flowrate and liquid-level measurement are presented in Tables 15–20 and 15–21, respectively. More recently, instruments for the on-line measurement of turbidity, TSS, DO, and residual chlorine concentration have become an integral part of

Table 15–19
Typical time constants for various treatment processes

Parameter	Time constant	
	Unit	Typical value
Pressure	s	<1
Flowrate in pressure pipe	s	1–5
Flowrate in open channels and clarifiers	min	5–30
Dissolved oxygen	min	10–20
Sludge blanket depth in secondary clarifier	min	30–120
Ammonia concentration in the aeration basin	h	>1
Ammonia concentration in the effluent	h	>1
Solids-retention time	d	>1
	d	3 × SRT[a]

[a] Approximate time to reach steady-state operation after the SRT value has been changed.

the control systems used at medium- and large-sized treatment plants. Summary information on the methods used for the measurement of these parameters of treatment process performance variables is given in Table 15–22.

Nutrient removal has made the measurement of NH_3, NO_2^-, NO_3^-, and PO_4 a necessity for proper process control. The three methods currently used for the measurement of nutrients are colorimetric, UV absorption, and ion selectivity. On-line instruments utilizing these methods are complex and expensive devices. Most of the time these analyzers can measure nutrients only in streams with low TSS concentrations, so some manufacturers supply sample filtration equipment with the instruments. At the same time, a new generation of instruments with ion-selective electrodes that do not not require sample preconditioning can measure nutrients *in situ*. Most of the older nutrient analyzers provide only batch-type measurements and require sample pumping to an analyzer.

Signal Transmitters. Information from instruments used to measure process parameters must be converted into electrical signals and transmitted to a controller. Controller output has to be transmitted to a receiver of a final control element. Until recently, analog direct current was the most popular type of electrical signal used for data transmission. Speed of data transfer is almost instantaneous and resistance of the transmission wire does not affect the quality of transmission. Transmitters and receivers are adjusted so that values of measured and controlled parameters correspond to a 4 to 20 mA (milliampere) signal.

Modern computer-based control systems do not require separate wiring from each transmitter and valve to the controllers. Data links or *data highways* can be used to transmit many encoded digital signals back and forth at very high speeds. Rules of data transmission through networks are called *protocols*. Signals can be transmitted using either ethernet or special protocols used for field buses (proprietary local area networks). Transmitting media can be copper wires, fiber optics, or air (wireless transmission).

Table 15–20
Typical methods used for flow measurements at wastewater treatment plants

Measurement principle	Application	Advantages	Limitations
Measurement of headloss in venturi tubes, orifice plates, flow tubes	Closed conduits	• Simplicity • Low cost	• Maximum to minimum measuring range should not exceed 4:1 • Prevention of sensing lines clogging is often required • Cannot be used for thick sludges • Periodic maintenance and calibration is required • The method of flow measurement is intrusive and causes pressure loss • Minimum of straight runs of piping required before and after meters
Water-level measurement in Parshall flumes and upstream of the weirs	Open channels	• Simplicity • Wide flow range • Flumes come in prefabricated sizes and configurations	• The method is flow-intrusive and causes extra headloss • Periodic cleaning of weirs and Parshall flumes is required for some applications • Slow response time • High quality of manufacturing and installation of Parshall flumes and weirs is required • Most of the time, cannot be installed without modifications to an existing channel
Magnetic	Closed conduits	• Low pressure drop • High accuracy • Low maintenance	• High cost especially for large diameters • Poor accuracy for velocities less than 1 m/s • Meter size may be less than line size
Combination of reflective sonic (Doppler) velocity and level sensors installed inside the conduit	Open conduits	• No pressure drop • Low maintenance • Low cost • Good accuracy • No construction	• Conduit size should not be less than an equivalent diameter of 600 mm (24 in)
Reflective sonic (Doppler) installed outside the pipe	Closed conduits	• No pressure drop • Low maintenance • Low cost • Noninvasive installation	• Potential problem for clean fluids • Inadequate accuracy for some applications, especially for velocities less than 0.9 m/s (3 ft/s) • Pipe should have less than 50 mm (2 in) thickness and cannot be constructed, or lined with, an aggregate material • Sensitive to pipe vibration
Transmissive sonic (through beam)	Closed and open conduits	• No pressure drop • Ease of installation • Low and convenient maintenance • Noninvasive installation • Good accuracy for large conduits	• Cannot be used for thick sludges • Accuracy is reduced for small-diameter conduits and pipes • Extremely long runs of straight pipe are required

Table 15-21
Methods used for level measurements

Methods	Application	Advantages	Limitations
Hydrostatic head	Open tanks, wetwell, open channel	• Simplicity	• Dirt and grease may interfere with measurements • May be affected by temperature change
Bubbler	Head created by flumes and weirs	• Simplicity	• Compressed air and constant air rate-of-flow regulator are required • Automatic purging is often required
Float	Wetwells of pump stations	• Simplicity • Low cost	• Grease and solids may interfere with measurements
Ultrasonic	Water level in open channels, wetwell, reservoirs	• No contact with fluid • No maintenance • Reasonable cost	• Presence of foam may create problems • Sometimes difficult to calibrate
Ultrasonic	Sludge level in clarifiers	• No contact with fluid • No maintenance	• Bubble interference • Poor accuracy in secondary clarifier with high SVI • Certain flow conditions can cause sudden decrease in accuracy • Inability to measure depth less than 75 mm (3 in)
Light adsorption with the lifting mechanism	Sludge level in clarifiers	• Ability to measure solids profile • Insensitivity to bubbles	• High cost • Presence of moving parts

Conventional transmitters and receivers use a different type of electrical signal than controllers. To translate from one type of electrical signal to another, special devices, called input/output (I/O) devices, are used. The I/O device can be located in either the same box as a main controller or the same box as a field secondary controller, or can reside separately. Historically, I/O devices were located in close proximity to a main controller; however, most recently, there is a tendency to locate I/O devices in the field and connect them with the main controller through a data highway or through wireless communication. Data transmitted through the network are not only used for control, but are also supplied to a data management system for plantwide availability and storage.

Controllers. In the simplest automatic control loop, an on-off relay is used as a controller. The next step in control sophistication is the programmable logic controller (PLC). These controllers were developed originally for manufacturing industries. By

Table 15–22
Typical analyzers used for measuring wastewater treatment process performance variables

Measured parameter	Operating principle	Operating range, mg/L	Advantages	Disadvantages
Total suspended solids	Light scatter or adsorption	12–80,000[a]	• Low cost • Good accuracy • Infrequent maintenance	• Requires periodic calibration due to changing particle size distribution • Requires color compensation and prevention of fouling • Reduced accuracy for dark sludges
	Ultrasonic	10,000–100,000	• Infrequent maintenance • Insensitivity to color	• Requires periodic calibration due to changing particle size distribution • Bubble interference
	Microwave	10,000–500,000	• Insensitivity to color, bubbles, fouling, and particle size distribution	• High cost
Dissolved oxygen in aeration channels	Electrochemical with oxygen-permeable membrane	0–20	• Low cost • Good accuracy	• Requires replacing membrane periodically • Requires periodic inspection, cleaning, and recalibration • For values below 1 mg/L galvanic system is desirable
	Electrochemical	0–15	• Low maintenance • Acceptable accuracy	• High initial cost and high cost of replacement parts • Interference with Cl_2, Fe, H_2S, and some other chemicals • Requires prevention of fouling and cleaning
	Fluorescence	0–10	• Very low maintenance	• Delayed response • Interference with fluorescent chemicals
Chlorine in the chlorine contact tank	Amperometric with membrane	0.1–10	• Low maintenance • Low cost	• Requires prevention of fouling • Interference with turbidity and conductivity
	Amperometric	0.1–50	• Insensitivity to turbidity and conductivity	• High initial and maintenance costs • Requires frequent calibration
Turbidity of effluent	Light scatter	0.1–1000	• Direct measurement	• Measurements are affected by particle size distribution, color, and flow • Results depend on type of instrument utilized • Poor correlation with suspended solids

[a]Range is covered with different sensors.

allowing programmers to input electrical ladder diagrams into a PLC, the programming requirements were simplified greatly. Only discrete logic (i.e., on-off functions, etc.) could be controlled initially with these devices. The next level in complexity is a controller that is capable to accomplish only simple mathematical operations (e.g., PI calculations) for one loop only. Such control elements are called single loop PI controllers and have processors similar to a simple calculator. A multi loop PI controller has an ability to implement cascade and other types of more sophisticated control algorithms. Modern PLC controllers combine functionality of discrete controllers and sophisticated multi loop controllers. Operators can still use ladder logic diagrams to program these devices, although more complex programming languages may be available.

A single processor failure in multi loop PI controller may lead to problems with all of the processes controlled by this device. Attempts to improve control reliability have led to development of distributed control systems (DCS) that uses duplicating I/O devices, processors, and operator's terminals. Such systems, despite their high cost, have become very popular for large treatment plants. In the past, however, DCS could utilize only simple control algorithms, and, as a result, it was not always possible to implement algorithms that could be used to address instrument failures or adaptive algorithms. Distributed control systems could not provide the required reliability for complex control loops. Current DCS are very sophisticated and are able to accomplish most of the tasks necessary for reliable automation of a wastewater treatment plant.

Personal and industrial computers are becoming increasingly part of a control system. Systems composed of a net of PLCs used for control and computers used to provide an interface between a human (operator) and a control system often are used as affordable and expandable alternatives to DCS. Computers are now being used not only for human-controller interfaces but also as controllers, and, in some cases, as a net of personal computers to replace the more expensive DCS. To improve reliability of control systems utilizing personal computers, such computer systems are used for only complex calculations, while single loop or multi loop controllers located in the field are used to implement simpler control algorithms. Failure of a main computer in such cases will not cause process interruptions, because the controllers are located in the field. Another method of improving reliability is to use *smart I/O* devices that can control the system when the main computer fails. Data transfer through either conventional point-to-point wiring, wireless communication devices, or through a data highway can be used for communication between computers and field located controllers or distributed I/O devices.

The uniqueness of wastewater treatment processes has motivated some manufacturers to supply control systems for automation of just one process or even for automatic control of one parameter within processes such as shown on Fig. 15–23. Such control systems usually utilize sophisticated proprietary control algorithms and operate either separately or as part of larger nonproprietary control systems. Savings on design, commissioning, and operation sometimes compensate for an increased initial cost of such systems.

Final Control Elements. A final control element is a necessary part of any control loop, manual or automatic. In process control systems, the final control element is the device used to bring about the desired change. At wastewater treatment plants, the final control element used most commonly is a valve. Use of these devices for auto-

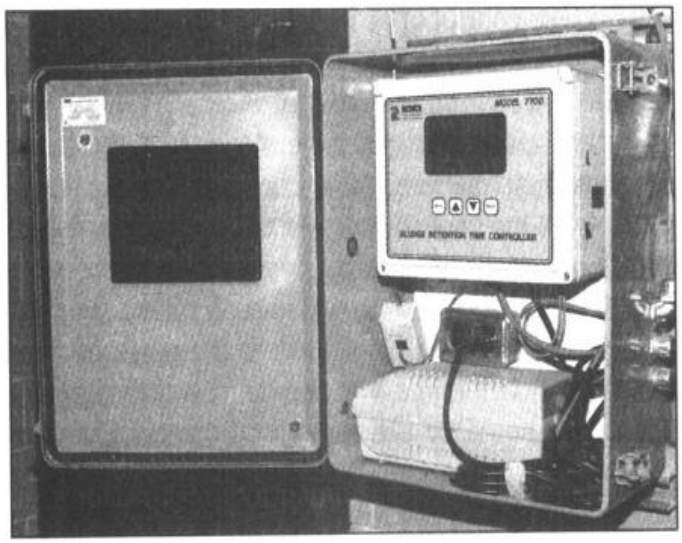

Figure 15-23
View of typical activated-sludge solids-retention time (SRT) process controller.

matic control introduces additional requirements for their selection. Control valves used to change the flowrate by modulating the valve setting (i.e., changing valve opening) are the most common types of final control elements. Proper selection of a control valve is very important for performance of automatic control. Selection should be based on required valve type, valve sizing, and valve linearity. Based on the type of throttling element movement, all valves are divided into two groups: those with linear motions and those with rotary motions. The first group includes globe, gate, and diaphragm valves; the second group includes ball, butterfly, and plug valves. Each of these valves has its application depending on the type of physical and chemical properties of controlled flow, the range between required minimum and maximum flow, and other parameters.

Independent of the type of valve, the following empirical formula is used for valve sizing:

$$K_v = \frac{Q}{\sqrt{\Delta P/\text{sg}}} \tag{15-27}$$

where K_v = metric valve capacity coefficient
Q = maximum design flow through the valve, m^3/h
ΔP = headloss through the valve at maximum design flow, kg/cm^2
(Note: ΔP = 1 m = 0.1 kg/cm^2)
sg = specific gravity relative to water

The above units must be used when calculating the value of K_v. In U.S. customary units, the valve capacity coefficient is given as C_v. The relationship between the K_v and C_v is (Coughanowr, 1991):

$$K_v = 0.856\, C_v \tag{15-28}$$

A decrease in ΔP can cause an increase in the valve size and thus the cost. An increase in size may cause a decrease of the valve operating range. Conversely, an increase in ΔP usually results in a greater headloss and increased energy use for pumping system applications. For optimum system operation some authors (Bauman, 1998) recommend use of ΔP = 0.35 kg/cm^2 (3.5 m) for rotary control valves and ΔP = 0.70 kg/cm^2 (7 m)

for ball valves. For control of airflow to activated-sludge aeration tanks using butterfly valves, a much lower ΔP value is often used.

Valves are selected on the basis of their K_v values. Valves are typically supplied only in discrete sizes, so the next highest size to K_v [calculated by using Eq. (15–27)] should be chosen. If the valve size chosen has a considerably higher capacity than required, the valve may not be able to handle low-flow conditions. For stable operation of a control loop, it is critical that valve opening at the lowest design flow should not be less than the minimum flowrate value recommended by the valve manufacturer (usually 5 to 10 percent of maximum flow). If the range of flowrates is too wide and one valve cannot satisfy that range, two parallel valves of different sizes should be installed. The larger valve should be selected based on the maximum flow and a small valve should be sized for a maximum flowrate corresponding to the flowrate when the large valve is 20 percent open.

In some applications, sluice gates and adjustable weirs are used as final control elements. However, the use of these devices for automatic control is challenging for two reasons. First, such devices usually operate very slowly because of their weight and, as a result, are poorly suited for rapid control. Second, the relationship between flow and the positions of these control elements is complex. For example, weir characteristics depend on whether flow over the weir is a free fall or the weir is submerged. If both conditions exist, use of the weir as the final control element may present a problem for developing a control algorithm.

A standard valve or gate can be automated by adding an actuator, usually a pneumatic or electrical device that positions the throttling element inside the valve body. In a manually operated valve, a person plays the role of an actuator. Pneumatic actuators function by using a flexible diaphragm or a piston cylinder. Pneumatic actuators usually are fast and well suited for automatic control. Electrical actuators use an AC reversing motor or a stepping motor and are usually more expensive than pneumatic actuators. Electric actuators are used mostly when instrument air to power the activator is not available or when high valve stem forces are required. Because an electric reversing motor usually is very slow and can have a built-in dead zone (an operating zone in which the motor does not respond to the control signal), modification of control logic is also required. In addition, a backlash can occur in the gear train between the motor and the valve shaft.

Sizing of an actuator depends on the force it has to produce to overcome the fluid pressure acting on the valve plug, including packing friction (0.5 to 5 m), and plug weight.

EXAMPLE 15–6 Determine the Size of Valve and Piston Actuator Determine whether a 150-mm (6-in) valve can be used in the discharge line from a submersible pump for control of return activated-sludge flow from a wetwell to an aeration tank. Determine the size of the piston of a pneumatic actuator for this valve, assuming that packing friction is equal to 5 percent of fluid pressure, an allowance for moving the valve is 5 percent of the hydrostatic pressure, and weight of the valve plug is negligible. The maximum and minimum flowrates are 3.1 and 0.6 m^3/min, respectively.

The valve has the following characteristics:

Percent opening	K_v
10	20
20	40
30	60
40	82
50	110
60	140
70	180
80	225
90	280
100	350

The characteristics of the submersible pump are:

Flowrate, m^3/min	Pressure, m
0.0	14.2
0.6	14.1
1.24	13.8
1.87	13.3
2.74	12.0
3.1	11.2

Design conditions:

1. The difference in elevation between the water level in the wetwell and the aeration tank is 2 m.
2. The pipeline leading from the wetwell to the aeration tank contains 4 elbows.
3. Assume that most of the friction losses in the piping system are associated with elbows and exit loss. The headloss coefficients for the elbows and pipe exit are 1.2 and 1.0, respectively.
4. Air pressure for an actuator is 55 m.

Solution

1. Determine the dynamic headloss using the following relationship.

$$H_{\text{dynamic}} = H_{\text{static}} + \Sigma H_{\text{minor}}$$

$$= H_{\text{static}} + (K_{\text{elbow}} + K_{\text{exit}})[(v)^2/2\,g]$$

a. At the maximum flowrate (3.1 m^3/min) the dynamic headloss is:
The velocity in the pipeline is

$$v = Q/A = Q/(\pi D^2/4)$$

$$v = (3.1\ m^3/min)(1.0\ min/60\ s)/[(3.14/4)(0.15\ m)^2] = 2.92\ m/s$$

$$H_{dynamic} = 2\ m + [(1.2 \times 4 + 1.0)(2.92\ m/s)^2/(2 \times 9.81\ m/s^2)]$$

$$= 2\ m + 2.53\ m = 4.53\ m$$

b. At the minimum flowrate (0.6 m^3/min) the dynamic headloss is

$$v = (0.6\ m^3/min)(1.0\ min/60\ s)/[(3.14/4)(0.15\ m)^2] = 0.0.57\ m/s$$

$$H_{dynamic} = 2\ m + [(1.2 \times 4 + 1.0)\ (0.76\ m/s)^2/(2 \times 9.81\ m/s^2)]$$

$$= 2\ m + 0.09\ m = 2.09\ m$$

2. Determine the pressure loss across the valve using the following relationship:

ΔP = pump head − dynamic headloss

a. At the maximum flowrate:

$$\Delta P = (11.2 - 4.53)\ m = 6.67\ m = 0.67\ kg/cm^2$$

b. At the minimum flowrate:

$$\Delta P = (14.1 - 2.09)\ m = 12.01\ m = 1.2\ kg/cm^2$$

3. Determine the valve capacity coefficient using Eq. (15–27) and the corresponding valve opening.
   a. At the maximum flowrate:

$$K_v = \frac{Q}{\sqrt{\Delta P/sg}} = \frac{(3.1\ m^3/min)(60\ min/h)}{\sqrt{(0.67\ kg/cm^2)/1.0}} = 228$$

   Referring to the table given above, the valve will be about 81% open at the maximum flowrate.
   b. At the minimum flowrate:

$$K_v = \frac{Q}{\sqrt{\Delta P/sg}} = \frac{(0.6\ m^3/min)(60\ min/h)}{\sqrt{(1.2\ kg/cm^2)/1.0}} = 32.9$$

   Referring to the table given above, the valve will be about 16% open at the minimum flowrate.
   c. Conclusion: Because the valve opening range is within 10 to 100% range, the valve is acceptable for the control of the return activated-sludge flowrate.
4. Determine the required diameter of the piston actuator at shutoff head. The piston actuator must have a diameter such that, with the available air pressure, it is possible to overcome the hydrostatic pressure on the valve when fully shut, plus

the frictional resistance of the valve assembly plus an allowance for moving the valve.

a. Determine area of the piston using the following relationship:

$$A_{\text{piston}} \times \text{pressure} = A_{\text{pipe/valve}} \times \Sigma\,\text{pressure}$$

b. Substitute known values and solve for the piston diameter. Assume the area of pipe and valve are the same.

$$(3.14/4)(D_{\text{piston}})^2 \times 55\text{ m} = (3.14/4)(0.15\text{ m})^2 \times 14.2\text{ m}\,(1 + 0.05 + 0.05)$$

$$D_{\text{piston}} = 0.15\text{ m}\sqrt{\frac{1.1 \times 14.2\text{ m}}{55\text{ m}}} = 0.080\text{ m} = 80\text{ mm}$$

Comment As with the previous example, the computations illustrated in this example are typical of those that must be made to size each control element properly. In this example the maximum velocity in the sludge return line was 2.92 m/s, which is in the range that is used normally (2 to 3 m/s), although flowrates as high as 4.0 m/s have been used.

Instead of using a control valve that reduces available pressure developed by a pump or a blower, a pump or blower may be equipped with a variable-speed drive that changes the pump or blower output without wasting energy by inducing increased headloss. Pump operation at a lower speed may be somewhat less efficient than at a design speed. In most wastewater applications where water and air volumes vary widely, use of a variable-speed drive is a preferable way for flow control because the incremental increase in equipment cost is small compared to energy savings. A life-cycle cost analysis should be performed to evaluate the economic benefits. In small-plant applications, the savings in power consumption may not be enough to justify the expense of a variable-speed drive.

15–5 ENERGY EFFICIENCY IN WASTEWATER TREATMENT

Water and wastewater utilities in the United States consume about 2 percent of the total amount of electricity produced (Batts et al., 1993). Typically, 30 percent of the operating cost of a wastewater treatment plant is budgeted for energy use. During the next 20 to 30 years, the electricity requirements for wastewater treatment in the United States are expected to increase an additional 30 to 40 percent. In an era where there are concerns about the adequacy of fuel supplies, cost of energy, and the increasingly higher levels of treatment that result in increased energy consumption, the design and operation of wastewater treatment plants are focused increasingly on improving the efficiency of electric energy use and reducing the cost of treatment. An overview of the use of electricity in wastewater treatment plant operation and measures that can be employed for improving energy efficiency and the cost of operation are presented in this section.

Overview of the Use of Electricity in Wastewater Treatment

The operational requirements for wastewater collection and treatment systems vary directly as the wastewater load (see Fig. 3–6). If a diurnal electricity demand curve were developed for the treatment facilities, it would be of a similar shape to the flowrate and loading curves shown on Fig. 3–6. The peak energy demand would likely occur from midday to the early evening hours when other peak demands for electricity occur in the community. As the wastewater load changes during the course of a day, the requirements for pumping, aeration, and solids processing change accordingly. Some plants modify schedules for equipment operation to meet load conditions; others operate their system components (such as aeration blowers) continuously at full capacity, regardless of the load.

As described in Table 1–7, approximately 85 percent of the wastewater treatment plants in the United States provide secondary or higher levels of treatment. In conventional secondary treatment, most of the electricity is used for (1) biological treatment by either the activated-sludge process that requires energy for aeration or trickling filters that require energy for influent pumping and effluent recirculation; (2) pumping systems for the transfer of wastewater, liquid sludge, biosolids, and process water; and (3) equipment for the processing, dewatering, and drying of solids and biosolids. A typical distribution of energy use in a conventional activated-sludge treatment plant, the most common type of plant used in wastewater treatment, is illustrated on Fig. 15–24. In activated-sludge treatment, approximately 1100 to 2400 MJ of electricity are required to process each 1000 m^3 (1200 to 2500 kWh per M/gal) of wastewater. The amount of elec-

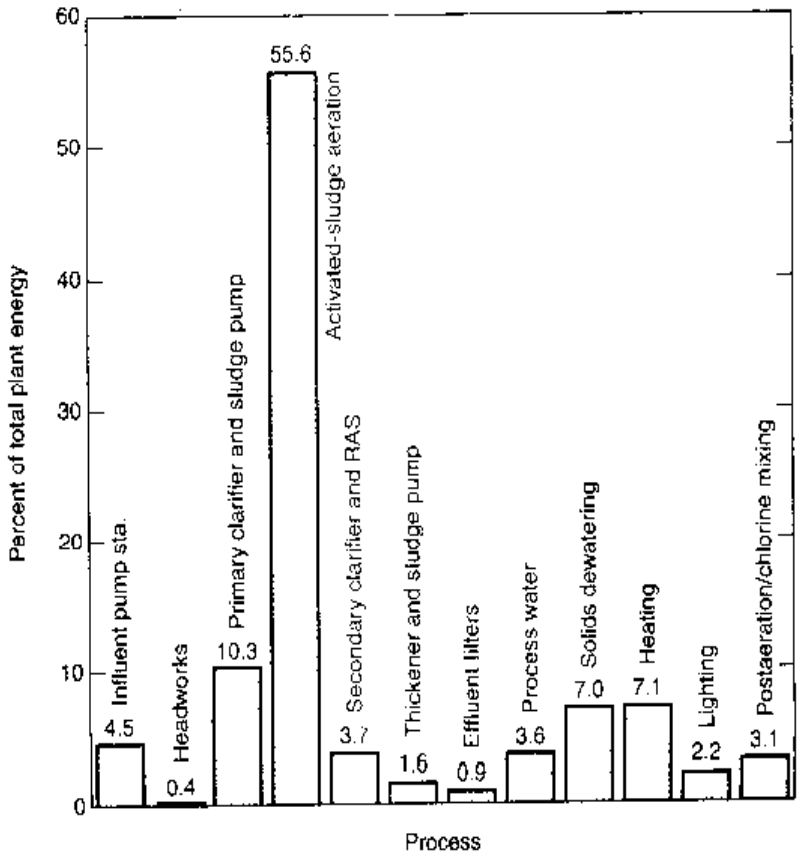

Figure 15–24

Distribution of energy usage in a typical wastewater treatment plant employing the activated-sludge process. *(From EPRI, 1994.)*

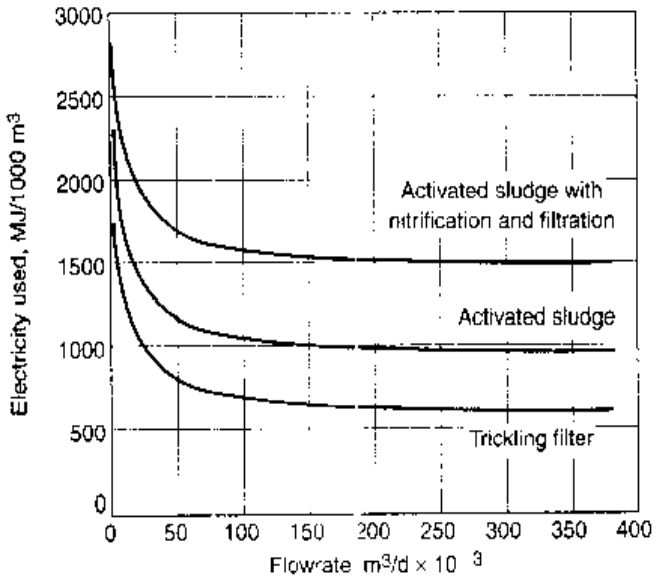

Figure 15–25

Comparison of electrical energy used for different types of treatment processes as a function of flowrate (Burton, 1996).

tricity consumed varies generally according to plant size and type of treatment system employed (see Fig. 15–25).

Combinations of physical operations (such as pumping, screening, settling, and filtration) and chemical and biological processes are used for the removal of constituents, as described in the preceding chapters. Various types of electric motor-driven equipment are involved in these operations and processes including pumps, blowers, mixers, sludge collectors, and centrifuges. Treatment processes and equipment requiring electric energy in a municipal wastewater treatment plant are presented in Table 15–23.

Advanced wastewater treatment plants require even greater amounts of electric energy. Plants that have biological treatment for nutrient removal and filtration use on the order of 30 to 50 percent more electricity for aeration, pumping, and solids processing than conventional activated-sludge treatment (see Fig. 15–25) (Burton, 1996).

With the introduction of new technologies for wastewater treatment, the energy requirements will change; the magnitude of potential impacts is summarized in Table 15–24. The impacts can be either reductions in energy use due to more efficient equipment or systems, or increases due to changes in treatment capacity requirements, higher levels of treatment, or new technologies whose operation is based on electric energy, i.e., membrane treatment, UV disinfection, and autothermal aerobic digestion (ATAD).

Measures for Improving Energy Efficiency

Opportunities exist for managing energy use in wastewater treatment by employing the concept of demand-side management. The electric power industry has long recognized the importance of integrating traditional supply-side planning with demand-side management to reduce peak demand. The goal of demand-side management is to change the electrical load characteristics (the amount of energy used at different times of the day) by improving energy efficiency and managing equipment operation. In demand-side management, it is also recognized that continued load growth will occur as the systems expand to meet new domestic and industrial wastewater collection and treatment requirements.

Table 15–23
Equipment commonly used in wastewater treatment facilities requiring electrical energy

Process or operation	Commonly used equipment	Process or operation	Commonly used equipment
Pumping and preliminary treatment	Chemical feeders for prechlorination, influent pumps, screens, screenings press, grinders and macerators, blowers for preaeration and aerated grit chambers, grit collectors, grit pumps, air lift pumps	Advanced wastewater treatment	Blowers for nitrification aeration, mechanical aerators, mixers, trickling filter pumps, pumps for depth filters, blowers for air backwash, pumps for membrane filtration
Primary treatment	Flocculators, clarifier drives, sludge and scum pumps, blowers for channel aeration	Solids processing	Pumps, grinders, thickener drives, chemical feeders, mixers for anaerobic digesters and blending tanks, aerators for aerobic digesters, centrifuges, belt presses, heat dryer drives, incinerator drives, conveyors
Secondary (biological) treatment	Blowers for channel and activated-sludge aeration, mechanical aerators, trickling filter pumps, trickling filter distributors, clarifier drives, return and waste activated-sludge pumps	Ancillary systems	
		Odor control	Odor control fans, chemical feeders
		Process water	Pumps
		Plant air	Compressors
Disinfection	Chemical feeders, evaporators, exhaust fans, neutralization facilities, mixers, injector water pumps, UV lamps		

Measures for improving energy efficiency require knowledge of how much energy is used in the wastewater treatment plant by the various elements of the treatment process. One of the best ways to understand energy use and the potential for effecting improved efficiency and energy management is to conduct an energy audit of an existing facility. Different levels of an energy audit can be performed including a preliminary "walk-through" to obtain an overview of principal energy-using equipment or a detailed process audit in which the unit energy use by process components is evaluated (EPRI, 1994). In general, one of the initial tasks in an audit is the evaluation of the largest energy-consuming operations or processes, such as aeration at activated-sludge plants or pumping systems at trickling-filter plants. As illustrated on Fig. 15–24, about 50 percent of the total plant energy at an activated-sludge plant is used for aeration, and, thus, aeration is a prime candidate for considering alternative energy-management measures that can be used to achieve reductions in power use and cost. Other recommendations for energy savings, based on audits of existing wastewater treatment plants, are summarized in Table 15–25.

Table 15–24
Energy impacts of new technologies on wastewater treatment[a]

Technology	Energy impact	
	kWh/Mgal	MJ/1000 m³
Fine pore diffusers (for aeration)	−125 to −150	−120 to −140
Ultrafine pore diffusers	−180 to −220	−170 to −210
Dissolved oxygen control systems (as compared to manual control)	−50 to −100	−48 to −95
Energy-efficient blower control systems, i.e., inlet guide vanes, inlet butterfly valves, or adjustable-speed drives	−50 to −150	−48 to −140
Energy-efficient aeration blowers (as compared to blowers with inlet guide vanes)	−100 to −150	−95 to −140
UV (ultraviolet) disinfection	+50 to +200	+48 to +190
Membranes		
Microfiltration	+200 to +400	+190 to +380
Reverse osmosis	+1000 to +2000	+950 to +1900

[a] Adapted in part from Burton (1998).

Table 15–25
Summary of common audit recommendations for energy savings at several U.S. wastewater treatment plants[a]

- Install adjustable-speed drives on pumps and blowers for variable flow operations
- Install DO monitoring and control in aeration tanks
- Conduct periodic pumps tests and repair or replace inefficient pumps
- Operate emergency generators during peak periods to reduce power demand
- Install electric load monitoring devices
- Install capacitors to improve power factor
- Change or reduce pumping operations
- Replace oversized motors
- Change selected operations to off-peak periods

[a] Burton, 1996.

Implementing operational changes or retrofitting processes and equipment can reduce energy use and cost. Operational changes can be made to a process or system usually with little or no increase in cost. Retrofitting processes or equipment, however, often requires significant expenditures for modifying or replacing existing equipment, or for constructing new physical facilities and installing equipment. A detailed cost analysis has to be made of each change considered to determine if the savings generated by making the change justify the capital cost of the change.

15–6 UPGRADING WASTEWATER TREATMENT-PLANT PERFORMANCE

Upgrading of wastewater treatment plants is defined as (1) modifying existing operations and facilities to improve operation, maintenance, and performance and (2) adding new facilities that enhance performance, improve efficiency of treatment, and provide higher levels of treatment in conformance with new regulations for reuse, discharge, or disposal.

Establishing proper control of treatment processes was always considered a primary duty of treatment-plant operating personnel. In the past, the criterion of good control and operation was producing an effluent with water-quality indicators that on the average did not exceed limits established by a regulatory authority, typically prescribed in an NPDES permit. Operational parameters and procedures usually were chosen based on intuitive approach and anecdotal evidence.

In recent years, many secondary treatment plants were converted to biological nutrient-removal and water-reclamation facilities. Some plants are even required to produce an effluent of a quality approaching that of drinking water. In a number of cases, because of funding limitations for plant expansion, some plants operate in excess of their design capacity. At the same time, more emphasis is being placed on operational reliability, and, in some cases, plants are cited and operating agencies are fined for even the slightest violation of water-quality standards. Finally, because of the need to improve plant efficiency and reduce capital and operating cost, privatization of facilities construction and operation has entered the wastewater field, resulting in cost competition between public and private operating entities.

As a result of these social, economic, and technological changes, the wastewater treatment-plant staff is faced with many challenges. Often, these challenges can be addressed by optimizing process parameters and operational procedures, modernizing facilities, and retrofitting existing equipment and processes. Development of such improvements usually requires the use of sophisticated tools and protocols rather than just intuitive approaches. The purpose of this section is to introduce the concepts of treatment process optimization and approaches used to upgrade the physical, liquid treatment, and solids processing facilities at existing wastewater treatment plants. The material presented in this section is intended to serve as a guide to topics of specialized interest related to plant upgrading. In the previous chapters and sections, many of the elements of the design of a wastewater treatment plant are discussed. Issues related to plant upgrading are reviewed, applicable theory or practical considerations are considered, and references to sources of information contained in this text are included in this section.

Process Optimization

Analysis of plant operating data is a first step in facility evaluation and optimization. Utilization of several methods can simplify this analysis including the use of (1) histograms, (2) linear correlation, (3) on-line process monitoring, (4) computer models, and (5) pilot-scale testing. Each of these methods is described in Table 15–26.

Histograms. Histograms are particularly useful if the frequency of occurrence of undesirable values, such as effluent TSS, is high. Depending on the frequency of occurrence and critical nature of the parameter, significant changes may have to be made to

Table 15–26
Methods used to evaluate process performance

Method	Description
Histograms	Graphs used to display frequency of occurrence of parameters such as wastewater characteristics, flow, and cost of chemicals and electricity
Linear correlation	A statistical method used to evaluate data from historical records such as flowrates and water-quality parameters
On-line process monitoring	Instruments are used continuously or intermittently to record and track important operating parameters such as flowrates, dissolved oxygen concentrations, chlorine residual concentrations, and tank levels. Data from such monitoring can be used to identify trends in operation so that process changes can be implemented before a problem occurs
Computer models	Computer modeling is a useful tool to simulate existing process operations and the effects of possible changes such as modifications to operating strategies or the addition of new equipment or processes
Pilot-scale testing	Pilot-scale testing is useful in evaluating the performance of new or alternative technologies and in developing criteria that can be used for the design of full-scale facilities

the process operation or perhaps to the process unit infrastructure to achieve correction. Infrequent occurrences of undesirable values often means that only minor adjustments to operation and maintenance practices may be necessary to achieve the desired results.

Another application of histograms is in establishing the priorities for the tasks that have to be performed to avoid an undesirable event. This type of histogram, called a Pareto chart, represents a graph displaying relative contribution of small problems causing one larger problem. The Pareto chart was named after Italian economist Vilfredo Pareto (1848–1923), who made the famous observation that 80 percent of the world wealth was owned by only 20 percent of people. This principle is valid in many situations, and can be equated to process operations as 80 percent of process problems are due to 20 percent of the causes. Pareto analysis is used to identify the 20 percent that causes the majority of process troubles. Analysis includes following four steps:

1. Identifying the causes of a particular problem
2. Determining the frequency of each cause
3. Calculating the percentage of each cause of the total occurrences
4. Plotting the percentage in descending order

Use of a Pareto chart in analyzing the occurrence of tank overflows due to specific causes, such as instrumentation and electrical instrumentation failures, is illustrated on Fig. 15–26.

Linear Correlation. Another statistical method that is often used to evaluate historical data is an analysis of the linear correlation between a parameter that needs to be optimized and other variables that may have some effect on that parameter. Many models used in process control are linear because they are well understood and are simple to analyze and solve. Usually, linear correlation is written as follows:

$$y = a_0 + a_1 x_1 \qquad (15\text{–}29)$$

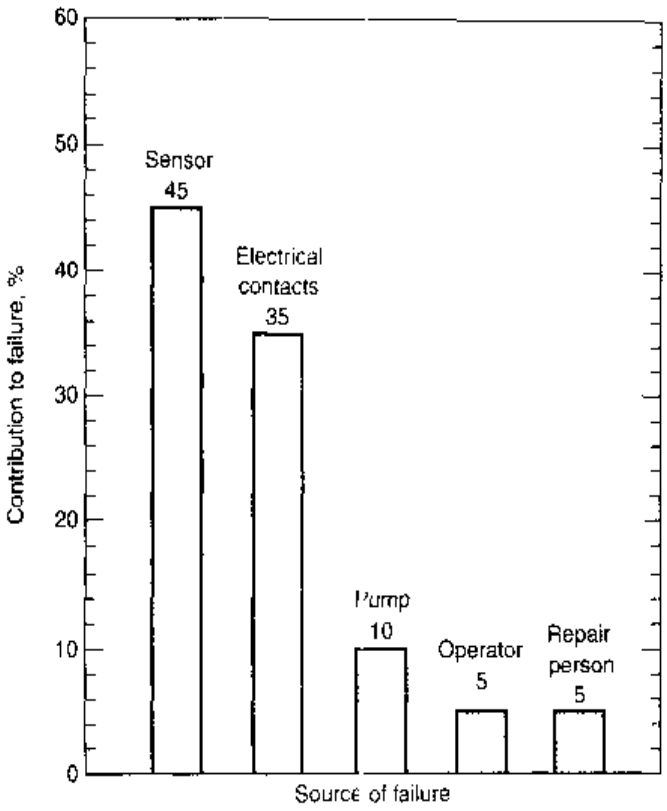

Figure 15-26

Pareto plot used to illustrate relative contribution of various causes to tank overflows.

where y = parameter to be optimized
a_0, a_1 = coefficients
x_1 = variable

The higher the probability that coefficient a_1 is not zero, the higher is the effect of the variable x_1 on the parameter y. This probability can be calculated using various statistical software packages. Usually, a 95 percent probability that a coefficient a_1 is not equal to zero is considered an indication that a variable x_1 has an effect on the optimized parameter y. The sign of the a_1 coefficient is used to determine in which direction the variable affects the optimized parameter. It is also important to note that lack of correlation between an optimized parameter and a variable does not necessarily mean that they are not related in general. In some cases, an appropriate relationship may be more complex than just a linear relationship, or the effect of their relationship was minimal within examined ranges.

On-line Process Monitoring. Since the 1950s many industries have been using a variety of statistical analyses for making continuous process improvements. In the wastewater industry, statistical process control is not as popular because effluent water-quality characteristics are not distributed normally (i.e., bell-shaped). As a result, the methods required for implementation of statistical control for municipal wastewater treatment processes have to be more sophisticated than ones used in other industries.

Conventional analysis of historical data includes the analysis of data obtained through grab and composite sampling. Such data often do not reflect the full dynamics

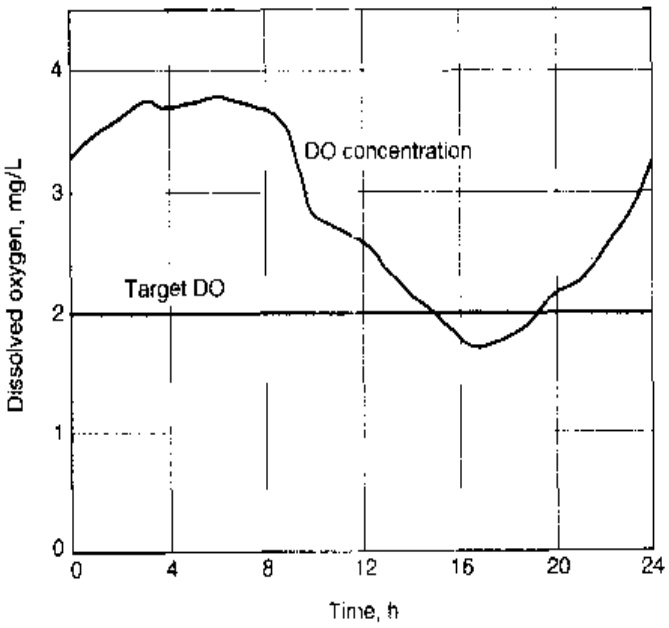

Figure 15–27
Comparison of actual dissolved oxygen concentration versus the target value.

of a treatment process. On-line instrumentation, however, can be used to provide information that is more representative of the process dynamics. An example of on-line monitoring of the dissolved oxygen (DO) concentration is shown on Fig. 15–27. The DO values vary significantly from the target value of 2 mg/L, indicating for much of the time the wastewater is overaerated. Installation of an automatic DO control can prevent overaeration as well as underaeration, resulting in savings in aeration energy and improved process control.

Computer Models. Computer modeling of treatment processes is an effective tool for development of facility improvements because it is now possible to understand the dynamics of treatment processes and to optimize operational parameters. The effect of changes in the operational modes on process performance can also be analyzed. For example, the results of computer modeling of the activated-sludge process and the hydraulic modeling of clarifiers can be used to evaluate whether an existing activated-sludge plant, designed for conventional treatment (i.e., BOD and TSS removal), can be modified to remove nutrients or/and to treat a higher flow than specified in the original design. Computer modeling is also very helpful in the evaluation of retrofit options, such as the installation of baffles in aeration tanks and clarifiers, changing of media size in filters, etc. In many cases, computer modeling can simplify physical modeling. The use of modeling in activated-sludge design is discussed in Sec. 8–10 in Chap. 8.

To provide reliable results, a computer model requires calibration to verify the values that have been chosen for the coefficients included in the model. These coefficients often depend on wastewater characteristics and the design features of the particular process. Calibration involves modifying the coefficient values until model output matches the plant performance data collected using on-line water quality and flow monitors, composite samplers, and other data-collection equipment. Sometimes to improve the quality of the model calibration, the process and equipment need to be operated

under extreme conditions. Such experiments are called *stress testing,* and require careful planning and execution to avoid threatening plant reliability. When applying stress testing to clarifier operation, for example, care must be taken to ensure TSS values do not exceed operational or permit limits.

Pilot-Scale Testing. A full-scale physical model of a treatment process is an ultimate tool for evaluation of proposed improvements. In recent years, more use has been made of pilot-scale testing of proposed improvements before they are implemented at full scale. Pilot-scale testing was discussed previously in Sec. 4–9 in Chap. 4, and a large-scale pilot facility was shown on Fig. 8–3. Pilot-scale units can be operated under a variety of different conditions, and the quality of effluent and other parameters can be compared between old and new modes of operation. Such piloting not only provides the most accurate information about the benefits of proposed process improvements, but also provides an opportunity for training the operating staff in the operation of new processes.

Upgrading Existing Wastewater Treatment Facilities

Upgrading of a wastewater treatment plant can encompass a large number or only a few factors. The scope of this text cannot include identifying and discussing all of the factors that may go into the upgrading of a specific facility, but the text does identify many of the issues confronting a number of facilities. Examples of significant issues have been prepared that include the potential resolution of an operational or physical facility problem and the sources of information available in this text. The various issues related to upgrading are divided into three categories: (1) operational changes that improve plant performance, (2) upgrading of physical facilities for liquid and solids treatment facilities, and (3) potential process modifications for meeting new requirements for constituent removal, and are discussed in the following paragraphs.

Operational Modifications. Some of the common problems faced in the operation of treatment facilities relate to the changing nature of the wastewater to be treated, variations in flows and loads, utilizing and maintaining each process component to achieve its maximum capability, and maintaining quality control so that treated effluent and plant residuals meet exacting reuse or permit requirements. Examples of operational changes that can be used to resolve plant performance issues are presented in Table 15–27.

Upgrading Physical Facilities. Most treatment plants contain all of the essential elements necessary to meet treatment goals, but in some instances, the capacity of some of the components is underutilized or overloaded, hydraulic bottlenecks exist that constrain effective and efficient operation, and inadequacies in facilities design affect plant operations and maintenance. Examples of issues relating to the upgrading of physical facilities for the treatment of wastewater (liquid treatment facilities) are summarized in Table 15–28. In some cases, a capacity evaluation is required in which a full-scale test program is required to determine the capability of the critical elements in the treatment process. For example, short circuiting may exist in the primary clarifiers, resulting in the carryover of settleable material to the biological treatment units, thus causing overloading conditions or increasing the cost of treatment. Stress testing of the

Table 15-27
Examples of operational changes that can be used to improve plant performance

Issue	Possible remedial action	See Sec. no.
General plant		
Odors from open tanks and channels	Reduce turbulence by controlling water levels to eliminate free falls and splashing	15–2
	Add chemicals (such as chlorine, ferric chloride, or hydrogen peroxide) to influent wastewater	15–2
	Modify process loading	15–2
Wide influent flow variations	Conduct collection system infiltration/inflow (I/I) investigation to identify sources of extraneous flow	3–2
Short circuiting in clarifiers and chlorine contact tanks	Conduct dye testing	4–4
	Conduct stress tests	
Headworks		
Odorous grit	Adjust air flowrates in aerated grit chambers to obtain cleaner grit	5–6
	Add lime to dewatered grit	
Odors and vectors in headworks	Cover grit and screenings receptacles	15–2
	Add lime to dewatered grit and screenings	
Inadequate grit removal	Analyze channel and grit chamber hydraulics	5–6
	Adjust flow distribution to grit chamber	
	Add temporary baffles to prevent short circuiting	
	Adjust air flowrate in aerated grit chambers	
Grit deposition in channels	Modify/adjust channel flow through velocity	
Primary clarifiers		
Poor solids removal	Check for short circuiting/modify baffling	4–4
	Improve flow distribution	8–7
	Add chemicals to influent	6–3
	Reduce return flows from other processes	14–14
Low solids concentration in primary sludge	Modify sludge pumping rate/install timers	
	Increase sludge blanket depth	
Aeration tanks		
Low DO	Determine DO profile in tank and adjust air flowrate	5–11
	Conduct oxygen transfer test	5–12
	Assess diffuser fouling/clean fouled diffusers	8–4, 8–5
	Change conventional plug-flow operation to step feed (if possible)	
	Check wastewater characteristics (rbCOD and nbVSS)	8–4
High DO	Turn off aeration equipment during low flow and loading periods	
	Install timers to control blower or mechanical aerator operation	

(*continued*)

Table 15–27 (*Continued*)

Issue	Possible remedial action	See Sec. no.
Filamentous organisms in mixed liquor	Examine mixed liquor microscopically to identify types of organisms	8–3
	Increase sludge wasting	
	Chlorinate return sludge	
Process is nitrifying	Check SRT	
Process is not nitrifying	Check SRT and temperature	
Low pH	Check if nitrification is occurring	
	Add alkalinity	
Foaming	Identify nature of foam	8–7
	Change MLSS concentration	8–7
	Add defoaming agent to spray water	
Nocardia foaming	Use dilute chlorine solution spray on foam	8–3, 8–7
	Reduce oil and grease discharges to collection system	
Trickling filters		9–2
Poor BOD removal	Reduce dosing rate	
Solids washout at peak flows	Reduce recirculation rate	
Biological nitrogen-removal process		8–5
Inadequate removal	Check rbCOD, MLSS, and temperature/revise feed	
	Increase methanol feed	
Final clarifiers		8–3
Bulking sludge	Increase or decrease dissolved oxygen concentration	
	Increase F/M ratio	
	Modify return and waste activated-sludge pumping rates	
	Chlorinate influent wastewater	
	Chlorinate return activated sludge	
Rising sludge	Increase return activated-sludge pumping rate to reduce sludge blanket depth in clarifier	
	Conduct state point analysis of final clarifiers	
Poor solids separation	Perform state point analysis	8–7
Disinfection		12–6
High coliform count in effluent	Improve chlorine mixing	12–6
	Conduct dye tests to determine short circuiting	4–4
	Check process for partial nitrification	8–4

(*continued*)

Table 15–27 (*Continued*)

Issue	Possible remedial action	See Sec. no.
Solids processing		
Low solids concentration from dissolved air flotation thickener	Check air-solids ratio	14–6
	Reduce solids loading rate	
	Add/increase polymer feed	
Poor anaerobic digester performance	Change frequency of solids feeding	14–9
	Increase concentration of feed solids	
	Check adequacy of mixing	
	Remove sludge and grit deposits	
	Increase SRT	
Poor aerobic digester performance	Check temperature/adjust SRT	14–10
	Increase concentration of feed solids	
	Check adequacy of mixing	
	Increase DO	
	Check pH/adjust alkalinity	
Odors from composting operations	Increase aeration by air addition or frequency of turning	14–11
Poor compost quality	Perform materials balance/adjust feed composition	14–11
Excessive moisture in compost mixture	Change compost mixture by adding amendment or bulking agent	14–11
	Improve sludge dewatering operations	

process components may be necessary to determine the limits of operating capability of the key components. In other cases, dye testing to document hydraulic flow patterns or measuring dissolved oxygen transfer rates to determine aeration efficiency may be employed.

Although a major focus of treatment-plant design and operation is on the liquid treatment facilities because of the standards for treated effluent reuse and disposal, solids processing facilities often receive less attention. Solids processing is often the most vexing problem for many plants because of operational difficulties, increasingly stringent requirements for reuse, and limited options for disposal. However, some of the new technologies described in this text can be used to upgrade the design and operation of solids processing facilities. Example upgrade options are described in Table 15–29.

Upgrading to Meet New Constituent Removal Requirements. As discussed in Chaps. 1, 13, and 14 and in earlier sections of this chapter, standards for constituent removal have changed in recent years and will continue to change as more scientific information is developed and as the reuse of treated wastewater and biosolids becomes increasingly important. Examples of many of the current and future issues and upgrade options in resolving these issues are summarized in Table 15–30.

Table 15-28
Examples of upgrading of physical liquid treatment facilities to improve plant performance

Issue	Remedial action/upgrade option	See Sec. no.
General plant		
Odors	Cover structures	15-3
	Add odor collection and treatment system	15-3
	Reduce turbulence by eliminating free falls and sharp bends	15-3
	Add chemical feed facilities	6-3
Wide influent flow variations	Add upstream flow equalization	5-3
	Install variable-speed drives on pumps	15-5
	Install small-capacity pumps for low flows	15-5
Flow control/ distribution	Improve flow splitting	8-7
	Add metering	15-4
Return flows from sludge-processing facilities upset biological process	Provide flow storage/equalization	3-2
	Provide sidestream treatment of return flows	14-16
	Modify operations/upgrade solids processing facilities to reduce load	14-16
Headworks		
Inadequate screenings removal	Modify/replace screens to prevent screenings carryover	5-1
	Install fine screens	5-1
	Replace comminutors	5-1, 5-2
Odorous, wet screenings	Install screenings press	5-1
	Replace screens with macerators	5-2
	Enclose and ventilate screening equipment	15-3
Odorous grit	Install grit washer	5-6
	Enclose and ventilate grit equipment	15-3
Inadequate grit removal	Add permanent baffles to prevent short circuiting	5-6
	Replace/upgrade grit-removal equipment	5-6
Primary clarifiers		
Inadequate solids removal in primary clarifiers	Add chemical treatment and flocculation	5-7, 6-3
	Add high-rate clarification	5-8
	Install baffles at effluent weirs	8-7
	Add energy dissipation inlet	5-7
Aeration tanks		
Low DO	Install DO probes for DO monitoring	15-4
	Replace coarse bubble with fine-pore diffusers	5-12
	Change diffuser placement to a grid pattern	5-12
High DO	Install variable-speed drives on centrifugal blowers to provide turndown capability	5-12, 15-5
	Install inlet guides vanes on centrifugal blowers to provide turndown capability	5-12
	Install variable-speed drives on positive-displacement blowers	5-12
	Install timers and two-speed motors on mechanical aerators	5-12
	Install automatic DO control system	15-4

(continued)

Table 15-28 (*Continued*)

Issue	Remedial action/upgrade option	See Sec. no.
Unbalanced DO profile in plug-flow aeration tanks	Change to step-feed process	8-4, 8-5
	Add DO control system	15-4
Solids deposition	Increase mixing capacity	5-12
Nocardia foaming	Add selector	8-3
Trickling filter		
Plugging and ponding of rock filters	Install plastic packing	9-2
Odors and poor BOD removal	Increase airflow by improving natural draft or adding ventilation system	9-2
Biological treatment system		
Insufficient reactor and solids separation capacity	Add chemical treatment	6-3
	Add high-rate clarification to reduce loading on biological treatment system	5-8
	Add membrane bioreactor	8-9
Solids washout from high flowrates	Add flow equalization	5-2
	Add high-rate clarification process for excess flows	5-8
	Use contact stabilization process	8-3
Secondary clarifiers		
Inadequate solids separation in secondary clarifiers	Modify flow distribution	8-7
	Modify circular clarifier center feedwell	8-7
	Add flocculating center feedwell	8-7
	Install baffles at effluent weirs	8-7
	Add tube or plate settlers	5-5
	Modify effluent weir configuration	8-7
	Modify sludge collector to improve solids withdrawal	8-7
Disinfection		
Inadequate chlorine disinfection	Add/replace chlorine mixers	5-4, 12-6
	Add/modify baffles to reduce short circuiting in chlorine contact tank	12-6
	Add chlorine residual control system	12-6
TSS in effluent	Add depth filters before disinfection	11-4
Excessive chlorine residual	Add chlorine residual analyzer and automatic control system	12-6
	Add dechlorination facilities	12-6
	Replace chlorination system with UV	12-9

Table 15-29
Examples of upgrading physical solids treatment facilities to improve plant performance

Issue	Remedial action/upgrade option	See Sec. no.
Thickening		14-6
Low solids concentration in primary sludge	Add gravity thickening	
	Add co-settling thickening	
Insufficient gravity thickening of waste-activated sludge	Use alternative thickeners (dissolved air flotation, or centrifuge)	
Alkaline stabilization		
Odor and vector problems in dewatered sludge	Add postlime stabilization	14-8
Anaerobic digesters		14-9
Excessive hydraulic overloading	Add sludge thickening prior to digestion	14-6
Inadequate mixing	Upgrade digester mixing system	14-9
	Install egg-shaped digester	14-9
Poor digestion of mixed primary and biological sludge	Install separate digesters	14-9
Inadequate solids destruction	Install two-phased anaerobic digestion process	
Aerobic digestion		14-10
Insufficient pathogen removal	Increase SRT by adding thickening or additional aerobic digester capacity	
	Add ATAD process	
Inadequate mixing	Increase mixing energy	
Composting		
Excessive plastics and inert material in product to be reused	Install fine screens in plant influent	5-1
	Install sludge screens	14-5
Dewatering and drying		
Excessive water in dewatered sludge cake	Add sludge thickeners	14-6
	Install high solids centrifuge dewatering	14-13
	Install filter press	14-13
	Add solar drying beds	14-13
	Add heat dryers	14-14
Sludge lagoons and drying beds		
Odors	Construct turbulence-inducing structures	15-3
Land application of biosolids		
Excessive attraction of vectors	Modify preapplication treatment methods or method of biosolids application	14-17
Excessive pathogen levels	For Class A biosolids, use one of the six prescribed alternative treatments	14-2, 14-17
	For Class B biosolids, use one of three prescribed alternatives for monitoring or treatment	14-2, 14-17

Table 15-30
Potential process modifications for meeting new standards for constituent removal

Issue	Remedial action/upgrade option	See Sec. no.
TSS discharge standards	Investigate alternative solids separation facilities	
	Chemical treatment to enhance settling	6-3
	Tube or plate settlers for final clarifiers	5-5
	High rate clarification	5-8
	Depth filtration	11-4
	Surface filtration	11-5
	Membrane separation	8-9, 11-6
BOD/COD standards	Investigate alternative treatment facilities	
	Supplemental chemical treatment	6-6
	Nitrification	8-4, 9-2
	Combined aerobic biological processes	9-4
	Membrane biological reactors	8-9
	Adsorption	11-7
	Advanced oxidation	11-10
Removal of nitrogen and phosphorus	Investigate alternative removal facilities	
	Chemical treatment for phosphorus removal	6-4
	Activated-sludge selector	8-3
	Suspended growth processes	
	Nitrification	8-4
	Nitrogen removal	8-5
	Phosphorus removal	8-6
	Attached growth processes	
	Nitrification	9-2, 9-3
	Nitrogen removal	9-7
	Ammonia stripping of digester supernatant	11-8
	Ion exchange for nitrogen removal	11-9
New disinfection standards	Add depth filtration (prior to disinfection)	11-3, 11-4
	Improve chlorine mixing and dispersion	12-2, 12-6
	Add dechlorination system	12-5, 12-6
	Replace chlorination with UV	12-9

(*continued*)

Table 15-30 *(Continued)*

Issue	Remedial action/upgrade option	See Sec. no.
VOC emission requirements	Investigate alternative advanced treatment systems	
	Adsorption	5–13, 11–7
	Air stripping	5–13, 11–9
	Advanced oxidation	11–10
	Thermal or catalytic incineration	5–13
Removal of residual solids for water reuse	Investigate alternative advanced treatment systems	
	Depth filtration	11–4
	Surface filtration	11–5
	Microfiltration	11–6
	Activated-carbon adsorption	11–7
	Ion exchange	11–9
	Advanced oxidation	11–10
Removal of trace constituents	Investigate alternative treatment systems	
	Chemical precipitation and oxidation	6–5, 6–6
	Microfiltration and/or reverse osmosis	11–6
	Microfiltration and/or reverse osmosis with UV oxidation	11–6, 11–10
Part 503 biosolids regulations for Class A land application	Investigate alternative processes to further reduce pathogens (PFRP) including	
	Thermophilic aerobic digestion	14–10
	Composting	14–11
	Heat drying	14–14
	Heat treatment	14–12
Part 503 biosolids regulations for Class B land application	Investigate alternative processes to significantly reduce pathogens (PSRP) including	
	Lime stabilization	14–8
	Anaerobic digestion	14–9
	Aerobic digestion	14–10
	Composting	14–11
	Air drying	14–13

15–7 IMPORTANT DESIGN CONSIDERATIONS FOR NEW WASTEWATER TREATMENT PLANTS

During the late 1980s and continuing onward to the present time (2001), the focus on wastewater engineering has changed from the goals of percent removal of solids and organic matter to the specific requirements for constituent removal for health and environmental protection. During the next decade as additional demands are placed on the quality and quantity of the nation's water supplies, greater emphasis will be placed on maintaining high standards of wastewater treatment plant performance consistently and reliably. In many cases, treated effluent will have to approach or meet drinking water standards or will have to meet not-to-exceed effluent requirements that contain harsh penalties for violation. As scientific research continues in defining wastewater constituents that may cause adverse effects, greater levels of treatment will be needed and, in some cases, will require the use of new technologies. The purpose of this section is to highlight important issues that must be considered in the planning and design of new treatment facilities. Additional information on many of the topics identified in this section may be found in the previous section.

Process Design Considerations for Liquid Streams

One of the most important issues that the designer of new plants in the United States will have to face is the exceedance criterion for effluent discharges described in Sec. 15–1. The focus of treatment-plant design will be on the nature and variability of the wastewater constituents and the processes that will be required to meet the treatment objectives. In some cases, it may be necessary to develop source control programs to limit the effects of both flow and constituent concentrations for discharges to the collection system. The source control program may also include reduction of excessive extraneous flow such as infiltration/inflow and wet weather discharges to the collection system and may even necessitate upstream flow equalization. Facilities to handle in-plant variations of flows and loads including return flows will also have to be considered. Some of the important factors that will have to be considered in the design of new facilities to meet possible future standards and possible technological solutions are listed in Table 15–31.

Process Design Considerations for Solids Processing

In selecting the appropriate methods of solids processing, reuse, and disposal, consideration must be given to the appropriate regulations. In the United States, pollutant numerical limits and management practices for the reuse and disposal of solids generated from the processing of municipal wastewater are defined in the 40 CFR Part 503 regulations (see Chap. 14, Sec. 14–2). The regulations are designed to protect public health and the environment from any reasonably anticipated adverse effects of pollutants contained in the biosolids. As many communities investigate options for solids processing, reuse, and disposal, greater emphasis is being placed on producing a cleaner product and meeting the Class A biosolids requirements. Many of the important issues that have to be considered in solids processing are also summarized in Table 15–31. Control of pathogens and vectors is of special importance for the protection of public health.

Table 15–31
Important considerations in the design of new wastewater treatment plants

Issue	Description	See Sec. or Chap.
	Liquid stream processing	
Constituent and treatment process variability	New treatment processes should be designed to meet not-to-exceed permit limits taking into account constituent and treatment process variability	15–2
Flow equalization	Improved performance by eliminating flow surges through treatment facilities	5–3
Organic load equalization	Improved performance by equalizing organic loading to treatment processes throughout the day	5–3
Automatic process control	Provision for automatic process control of dissolved oxygen and solids-retention time (SRT)	15–4
Enhanced disinfection for reuse	Improved and alternative technologies for disinfection and the control of disinfection by-products	12
Advanced treatment processes	Removal of residual constituents and constituents not achieved by conventional treatment	11
Conventional and advanced oxidation processes	Removal of specific constituents may require the use of advanced oxidation processes	6–6, 11–10
Combined processes for specific constituents	To meet stringent not-to-exceed permit limits, two or more processes may have to be used in a series arrangement	13–4
Water reuse	Issues related to risk assessment will have to be addressed	13–3
Energy management	Installation of physical facilities to allow for improved energy efficient operation	15–6
	Solids processing	
Improved screening	Removal of extraneous materials that end up in the biosolids	5–1
Grit removal	Removal of grit that can settle in primary sedimentation tanks and digesters	5
Enhanced pathogen control	To meet requirements for Class A biosolids	14–7 to 14–14
Enhanced vector control	To meet requirements for Class A biosolids	14–11
Separate treatment of return flows	Improved performance of liquid waste streams, especially for the removal of nitrogen	14–16
	Odor control	
Odor control in collection system	Implementation of source control program or addition of oxidizing agents to control odors in collection system	15–3
Odor formation in treatment facilities	Careful attention to hydraulic design to avoid dead zones with respect to flow	15–3
Odor containment	Cover facilities to eliminate odors	
Odor treatment	Separate or combined treatment of odorous gases from odor containment facilities	15–3
	Process operation	
Computer simulation models	Development of improved operational strategies through the use of mathematical simulation models	8–10

Odor Control

Gaining public acceptance for siting new wastewater treatment plants will depend, to a large extent, on meeting community concerns over odors. The prevention, control, and treatment of odors are now mandatory parts of any new treatment-plant design. Proper planning for odor management can mitigate odor-related issues and help restore public confidence in facilities operation. The important considerations in odor control are listed in Tables 15–8 and 15–9.

PROBLEMS AND DISCUSSION TOPICS

15–1 Search the literature and find 3 probability plots of effluent characteristics. How do the reported variabilities, as given by the geometric standard deviation, compare with the values given in Table 15–1?

15–2 A superintendent of a wastewater treatment plant has requested that his staff collect and analyze 6 effluent samples of a specific constituent for submittal to the regulatory agency. If the regulatory agency, in turn, sets the not-to-be-exceeded value (i.e., 99.9 percent) in the effluent discharge permit at the maximum value measured in the 6 samples, has the superintendent potentially shot himself in the foot? Explain and illustrate your analysis.

15–3 Using the data in Table 15–1, estimate the total logs of removal for coliphage with a treatment process composed of activated sludge followed by microfiltration and reverse osmosis for influent coliphage concentrations of 20,000, 40,000, 28,000, 50,000 pfu (plaque-forming units)/100 mL (value to be selected by the instructor). Assume no removal of coliphage through the microfilter and that the logs of removal achieved with the particular reverse osmosis membrane used are 2, 3.2., 3.0, or 3.7 (log removal value to be selected by the instructor). What is the removal achieved at 99 and 99.9 percent reliability?

15–4 The following monthly effluent constituent concentrations have been obtained from 4 different existing activated-sludge treatment plants. Each of these plants is to be replaced with a new plant to meet new and more stringent discharge requirements. For one of these plants (to be selected by the instructor), determine the mean design value assuming the following maximum monthly permit limits must be met: (*a*) BOD and TSS = 15 mg/L at 99 and 99.9 percent reliability, (*b*) BOD and TSS = 10 mg/L at 99 and 99.9 percent reliability, (*c*) BOD = 5 mg/L and TSS = 8 mg/L. On average, what percentage improvement would be required to meet the new discharge permit requirements? In your opinion, is the percentage improvement reasonable?

	Constituent concentration, mg/L							
	Plant A		Plant B		Plant C		Plant D	
Month	BOD	TSS	BOD	TSS	BOD	TSS	BOD	TSS
Jan	11.0	14.0	4.0	5.0	10.0	40.0	8.4	6.5
Feb	14.0	11.0	5.0	5.0	15.0	39.0	10.2	4.2
Mar	7.0	10.0	6.0	6.0	17.0	23.0	17.9	5.9
Apr	6.0	6.0	7.5	7.0	20.0	30.0	10.3	10.3
May	11.0	13.0	9.0	8.0	25.0	33.0	13.2	10.9
Jun	8.0	12.0	13.0	10.0	29.0	10.0	9.3	8.10

(continued)

(*Continued*)

	Constituent concentration, mg/L							
	Plant A		Plant B		Plant C		Plant D	
Month	BOD	TSS	BOD	TSS	BOD	TSS	BOD	TSS
Jul	9.0	8.0	16.0	14.0	30.0	18.0	8.6	6.9
Aug	10.0	8.0	18.0	17.0	25.0	50.0	12.0	8.2
Sep	16.0	10.0	6.5	15.0	35.5	60.0	13.7	9.1
Oct	10.2	10.0	10.0	1.5	25.0	70.0	13.8	14.0
Nov	7.5	10.0	12.0	10.0	40.5	77.0	16.3	14.0
Dec	4.8	10.0	5.5	9.0	50.0	82.0	17.0	18.2

15–5 Verify that for each mg/L of H_2S removed with chlorine 10.87 mg/L of alkalinity as $CaCO_3$ will be required.

15–6 Determine the amount of hydrogen peroxide (H_2O_2) required for the oxidation of hydrogen sulfide H_2S.

15–7 Using the following half reaction for permanganate (MnO_4^-), estimate the amount of permanganate that would be required per day to oxidize 100 ppm_v of H_2S from a foul airstream with a flowrate of 1500, 2000, 1800, or 2200 m^3/min (flowrate to be selected by instructor).

$$MnO_4^- + 4H^+ + 3e \rightarrow MnO_2(s) + 2H_2O$$

15–8 Determine the amount of ferrous sulfate ($FeSO_4$) that would be required to remove 150 mg/L of H_2S from digester supernatant. Assume the sulfide ion in H_2S will be converted to ferrous sulfide in an exchange reaction.

15–9 Four different waste airstreams have been sampled and the results are summarized below. For one of these waste airstreams (to be selected by the instructor), determine the chemical requirements. Sodium hypochlorite and sodium hydroxide are to be used in the chemical scrubber.

Item	Unit	Plant A	Plant B	Plant C	Plant D
Waste airstream flowrate	m^3/min	1000	2500	3200	1800
H_2S concentration	ppm_v	75	45	65	35
Liquid to gas ratio	kg/kg	1.85	2.0	2.1	1.9
Temperature	°C	28	33	30	25
Density of 50 percent NaOH solution	kg/L	1.52	1.52	1.52	1.52

15–10 Using the design criteria given in Table 15–14, determine the size of compost filter needed to scrub 65 ppm_v H_2S from foul air at a flowrate of 1500, 1880, 2100, or 2300 m^3/min (value to be selected by the instructor). Also estimate the mass of the buffer compound needed to neutralize the acid formed as a result of treatment within the filter. Assume a packed-bed porosity of 43 percent. The temperature of the foul air is 20°C.

15–11 From an analysis of several incidents of tank overflow it was found that the overflow was caused 9 times by level-sensor failure, 7 times by malfunction of electrical contacts, 2 times by pump failure, 2 times by gasket failure, and 1 time by a repairperson error. Prepare a Pareto plot and develop recommendations for limiting tank overflow. From the literature prepare a brief discussion of the use of Pareto charts for process applications (cite at least two references).

15–12 A poorly sized valve has an unnecessary pressure drop of 4 m. If the flow through the valve is 5000 m^3/d, determine the annual cost attributable to the pressure drop across the valve. Use the current cost of electricity in your region (e.g., $0.12 / kWh).

15–13 Given the following valve capacity factors for four different valves A, B, C, or D (to be selected by the instructor), determine whether the valve is adequate for the pump described in the following table. The pipe diameter is 50 mm. Assume the static head is 3.25, 3.5, 3.9, or 4.3 m (to be selected by the instructor) and the dynamic headloss is $4v^2/2g$ (the factor 4 includes allowances for friction, exit, and miscellaneous pipe losses).

Flowrate, m^3/min	Pressure, m
0.00	17.75
0.76	17.63
1.70	17.25
2.46	16.63
3.97	14.30
4.73	12.00

The valve has the following characteristics:

Percent opening	Valve capacity factor, K_v			
	Valve A	Valve B	Valve C	Valve D
10	15	35	23	20
20	34	50	40	52
30	63	68	62	95
40	120	95	90	142
50	200	121	115	200
60	280	160	140	270
70	380	202	180	350
80	500	240	240	420
90	650	290	330	510
100	850	340	480	600

15–14 Average monthly performance data have been collected over a period of a year for an activated-sludge process treating primary settled effluent followed by depth filters operated in parallel. Using these data, estimate what overall average monthly removal would be expected with the activated-sludge process followed by one of the depth filters (to be selected by the instructor)

assuming the influent constituent concentration is 150, 200, 275, or 300 mg/L (to be selected by the instructor). What would be the expected constituent concentrations that could be achieved 99 and 99.9 percent of the time?

	Removal, %		
Biological treatment	**Depth filter A**	**Depth filter B**	**Depth filter C**
80	65	45	41
98	65	50	44
80	65	49	49
84	65	55	45
90	65	58	47
85	65	68	45
78	65	70	43
93	65	40	46
88	65	45	45
92	65	57	43
94	65	61	48
89	65	54	42

15–15 An existing conventional activated-sludge wastewater treatment plant having a design capacity of 15,000 m^3/d is considering upgrading the existing solids-processing facilities to include either aerobic digestion or anaerobic digestion. List the factors the design engineer will have to consider in selecting the process and comment on the energy implications associated with the process selection.

15–16 Review three articles in the literature in which aeration systems have been retrofitted with fine-pore diffusers. Document the physical changes that were made including the type of replacement diffusers and the amount of savings in electric energy that was achieved.

Physical Properties of Selected Gases and the Composition of Air

Appendix

Table B–1
Molecular weight, specific weight, and density of gases found in wastewater at standard conditions (0°C, 1 atm)[a]

Gas	Formula	Molecular weight	Specific weight, lb/ft³	Density g/L
Air	—	28.97	0.0808	1.2928
Ammonia	NH_3	17.03	0.0482	0.7708
Carbon dioxide	CO_2	44.00	0.1235	1.9768
Carbon monoxide	CO	28.00	0.0781	1.2501
Hydrogen	H_2	2.016	0.0056	0.0898
Hydrogen sulfide	H_2S	34.08	0.0961	1.5392
Methane	CH_4	16.03	0.0448	0.7167
Nitrogen	N_2	28.02	0.0782	1.2507
Oxygen	O_2	32.00	0.0892	1.4289

[a] Adapted from Perry, R. H., D. W Green, and J. O. Maloney (eds.) (1984) *Chemical Engineers' Handbook*, 6th ed., McGraw-Hill, New York.

Table B–2
Composition of dry air at 0°C and 1.0 atmosphere[a]

Gas	Formula	Percent by volume[b,c]	Percent by weight
Nitrogen	N_2	78.03	75.47
Oxygen	O_2	20.99	23.18
Argon	Ar	0.94	1.30
Carbon dioxide	CO_2	0.03	0.05
Other[d]	—	0.01	—

[a] Values reported in the literature vary depending on the standard conditions.

[b] Adapted from *North American Combustion Handbook*, 2d ed., North American Mfg. Co., Cleveland, CH.

[c] For ordinary purposes air is assumed to be composed of 79 percent N_2 and 21 percent O_2 by volume.

[d] Hydrogen, neon, helium, kryptor, xenon.

Note: (0.7803 × 28.02) + (0.2099 × 32.00) + (0.0094 × 39.95) + (0.0003 × 44.00) = 28.97 (see Table B–1).

B–1 DENSITY OF AIR AT OTHER TEMPERATURES

In SI units

The following relationship can be used to compute the density of air ρ_a.

$$\rho_a = \frac{PM}{RT}$$

where P = atmospheric pressure = $1.01325 \cdot 10^5$ N/m^2
M = mole of air (see Table B–1) = 28.97 kg/kg-mole
R = universal gas constant = 8314 N·m/kg-mole·K
T = temperature, K (Kelvin) = (273.15 + °C)

For example, at 20°C, the density of air is

$$\rho_{a,20°C} = \frac{(1.01325 \times 10^5 \text{ N/m}^2)(28.97 \text{ kg/kg-mole})}{(8314 \text{ N·m/kg-mole·K})[(273.15 + 20)\text{K}]} = 1.204 \text{ kg/m}^3$$

In U.S. customary units

The following relationship can be used to compute the specific weight of air γ_a at other temperatures at atmospheric pressure.

$$\gamma_a = \frac{P\,(144 \text{ in}^2/\text{ft}^2)}{RT}$$

where P = atmospheric pressure = 14.7 lb/in^2
R = universal gas constant = 53.3 ft·lb/lb-air·°R
T = temperature, °R (Rankine) = (459.67 + °F)

For example, at 68°F, the specific weight of air is

$$\gamma_{a,68°F} = \frac{(14.7 \text{ lb/in}^2)(144 \text{ in}^2/\text{ft}^2)}{(53.3 \text{ ft·lb/lb-air·°R})[(459.67 + 68)\text{°R}]} = 0.0753 \text{ lb/ft}^3$$

B–2 CHANGE IN ATMOSPHERIC PRESSURE WITH ELEVATION

In SI units

The following relationship can be used to compute the change in atmospheric pressure with elevation:

$$\frac{P_b}{P_a} = \exp\left[-\frac{gM\,(z_b - z_a)}{RT}\right]$$

where P = pressure, 1.01325×10^5 N/m^2
g = 9.81 m/s^2
M = mole of air (see Table B–1) = 28.97 kg/kg-mole
z = elevation, m

R = universal gas constant = 8314 N·m/kg-mole·K
= 8314 kg·m^2/s^2·kg-mole·K
T = temperature, K (Kelvin) = (273.15 + °C)

In U.S. customary units

The following relationship can be used to compute the change in atmospheric pressure with elevation.

$$\frac{P_b}{P_a} = \exp\left[-\frac{gM(z_b - z_a)}{g_c RT}\right]$$

where P = pressure, lb/in^2
g = 32.2 ft/s^2
g_c = 32.2 ft·lb$_m$/lb·s^2
M = mole of air (see Table B–1) = 28.97 lb/lb-mole
z = elevation, ft
R = universal gas constant = 53.3 ft·lb/lb-air·°R
T = temperature, °R = (459.67+ °F)

Physical Properties of Water

Appendix

The principal physical properties of water are summarized in Table C–1 in SI units and in U.S. customary units in Table C–2 . They are described briefly below (Vennard and Street, 1975; Webber, 1971).

SPECIFIC WEIGHT

The specific weight g of a fluid is its weight per unit volume. In SI units, it is expressed in kilonewtons per cubic meter (kN/m^3). The relationship between g, γ, and the acceleration due to gravity g is $\gamma = \rho g$. At normal temperatures γ is 9.81 kN/m^3 (62.4 lb$_f$/ft^3).

DENSITY

The density of ρ of a fluid is its mass per unit volume. In SI units it is expressed in kilograms per cubic meter (kg/m^3). For water, ρ is 1000 kg/m^3 at 4°C. There is a slight decrease in density with increasing temperature.

MODULUS OF ELASTICITY

For most practical purposes, liquids may be regarded as incompressible. The bulk modulus of elasticity E is given by

$$K = \frac{\Delta p}{(\Delta V/V)}$$

where Δp is the increase in pressure, which when applied to a volume V, results in a decrease in volume ΔV. For water K is approximately 2.150 kN/m^2 at normal temperatures and pressures.

DYNAMIC VISCOSITY

The viscosity of a fluid μ is a measure of its resistance to tangential or shear stress. Viscosity in SI units is expressed in Newton seconds per square meter (N·s/m^2).

KINEMATIC VISCOSITY

In many problems concerning fluid motion, the viscosity appears with the density in the form μ/ρ and it is convenient to use a single term ν, known as the kinematic viscosity and expressed in square meters per second (m^2/s) in SI units. The kinematic viscosity of a liquid diminishes with increasing temperature.

SURFACE TENSION

Surface tension is the physical property that enables a drop of water to be held in suspension at a tap, a glass to be filled with liquid slightly above the brim and yet not spill,

or a needle to float on the surface of a liquid. The surface-tension force across any imaginary line at a free surface is proportional to the length of the line and acts in a direction perpendicular to it. The surface tension per unit length s is expressed in Newtons per meter (N/m) in SI units. There is a slight decrease in surface tension with increasing temperature.

VAPOR PRESSURE

Liquid molecules that possess sufficient kinetic energy are projected out of the main body of a liquid at its free surface and pass into the vapor. The pressure exerted by this vapor is known as the vapor pressure p_v. In SI units vapor pressure is expressed in kilonewtons per square meter (kN/m^2). The vapor pressure of water at 15°C is 1.72 kN/m^2.

Note: ppt = parts per thousand.

MPN Tables and Their Use **Appendix**

When three serial sample volumes (e.g., dilutions) are used in the bacteriological testing of water, the resulting MPN (most probable number) values per 100 mL can be determined using Table E–1. The MPN values given there are based on serial sample volumes of 10, 1, and 0.1mL. If lower or higher serial sample volumes are used, the MPN values given in Table E–1 must be adjusted accordingly. For example, if sample volumes used are 100, 10, and 1 ml, the MPN values from the table are multiplied by 0.1. Similarly, if the sample volumes are 1, 0.1, and 0.01 ml, the MPN values from the table are multiplied by 10.

In situations where more than three test dilutions have been run, the following rule is applied to select the three dilutions to be used in determining the MPN value (Standard Methods, 1998): Choose the highest dilution that gives positive results in all five portions tested (no lower dilution giving any negative results) and the two next higher dilutions. Use the results at these three volumes in computing the MPN value. In the examples given in the accompanying table, the significant dilution results are shown in boldface. The number in the numerator represents positive tubes, that in the denominator, the total tubes planted.

	1.0 mL	0.1 mL	0.01 mL	0.001 mL	0.0001 mL	Combination of positives	MPN/ 100 mL

[a] Adjusted values used to determine the MPN using Table E–1.

In example c, the first three dilutions are used so as to throw the positive result in the middle dilution. Where positive results occur in dilutions higher than the three chosen according to the above rule, they are incorporated into the result of the highest chosen dilution up to a total of five. The result of applying this procedure to the data is illustrated in examples d and e.

Carbonate Equilibrium **Appendix**

The chemical species that comprise the carbonate system include gaseous carbon dioxide [$(CO_2)_g$], aqueous carbon dioxide [$(CO_2)_{aq}$], carbonic acid [H_2CO_3], bicarbonate [HCO_3^-], carbonate [CO_3^{2-}], and solids containing carbonates. In waters exposed to the atmosphere, the equilibrium concentration of dissolved CO_2 is a function of the liquid phase CO_2 mole fraction and the partial pressure of CO_2 in the atmosphere. Henry's law (see Chap. 2) is applicable to the CO_2 equilibrium between air and water; thus

$$x_g = \frac{P_T}{H} p_g \tag{2-46}$$

where x_g = mole fraction of gas in water, mole gas/mol water

$$= \frac{\text{mole gas } (n_g)}{\text{mole gas } (n_g) + \text{mole water } (n_w)}$$

P_T = total pressure, usually 1.0 atm

H = Henry's law constant, $\dfrac{\text{atm (mole gas/mole air)}}{\text{(mole gas/mole water)}}$

p_g = mole fraction of gas in air, mole gas /mole of air

The concentration of aqueous carbon dioxide is determined using Eq (2-46). At sea level, where the average atmospheric pressure is 1 atm, or 101.4 kPa, carbon dioxide comprises approximately 0.03 percent of the atmosphere. Values of the Henry's law constant for CO_2 as a function of temperature are given in Table F–1. The values in Table F–1 were computed using Eq. (2-48) and the data given in Table 2-8 in Chap. 2.

Aqueous carbon dioxide [$(CO_2)_{aq}$] reacts reversibly with water to form carbonic acid.

$$(CO_2)_{aq} + H_2O \leftrightarrow H_2CO_3 \tag{F–1}$$

Table F–1
Henry's Law constant for CO_2 as a function of temperature

T, °C	H, atm
0	793
10	1072
20	1420
30	1846
40	2360
50	2971
60	3689

The corresponding equilibrium expression is

$$\frac{[H_2CO_3]}{[CO_2]} = K_m \tag{F-2}$$

The value of K_m at 25°C is 1.58×10^{-3}. Note that K_m is unitless. Because of the difficulty of differentiating between $(CO_2)_{aq}$ and H_2CO_3 in solution and the observation that very little H_2CO_3 is ever present in natural waters, an effective carbonic acid value ($H_2CO_3^*$) is used which is defined as:

$$H_2CO_3^* \leftrightarrow (CO_2)_{aq} + H_2CO_3 \tag{F-3}$$

Because carbonic acid is a diprotic acid it will dissociate in two steps—first to bicarbonate and then to carbonate. The first dissociation of carbonic acid to bicarbonate can be represented as:

$$H_2CO_3^* \leftrightarrow H^+ + HCO_3^- \tag{F-4}$$

The corresponding equilibrium relationship is defined as:

$$\frac{[H^+][HCO_3^-]}{[H_2CO_3^*]} = K_{a1} \tag{F-5}$$

The value of first acid dissociation constant K_{a1} at 25°C is 4.467×10^{-7} mole/L. Values of K_{a1} at other temperatures are given in Table F–2, which is repeated here from Table 6-16 in Chap. 6.

The second dissociation of carbonic acid is from bicarbonate to carbonate as given below.

$$HCO_3^- \leftrightarrow H^+ + CO_3^{2-} \tag{F-6}$$

The corresponding equilibrium relationship is defined as:

$$\frac{[H^+][CO_3^{2-}]}{[HCO_3^-]} = K_{a2} \tag{F-7}$$

The value second acid dissociation constant K_{a2} at 25°C is 4.477×10^{-11} mole/L. Values of K_{a2} at other temperatures are given in Table F–2.

The distribution of carbonate species as function of pH is illustrated on Fig. F–1.

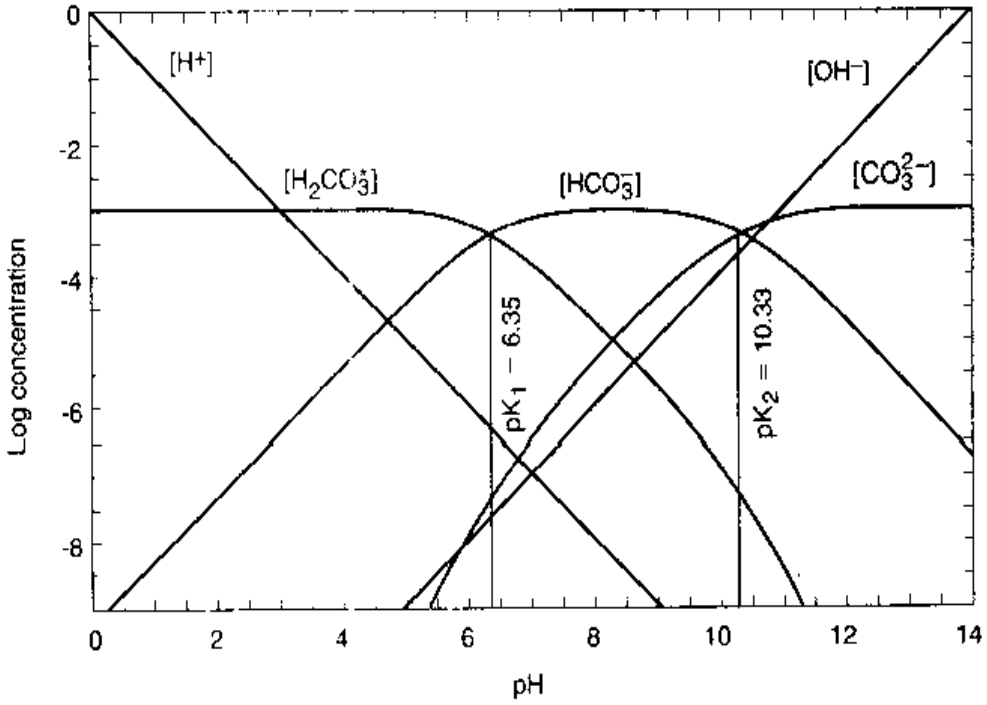
To illustrate the use of the data presented in Tables F–1 and F–2, it will be helpful to estimate the pH of a water, assuming the atmosphere above the water contains 30 percent CO_2, the bicarbonate (HCO_3^-) concentration in the water is 610 mg/L, and the temperature of the water is 20°C.

1. Use Eq. (2-47) to determine concentration of H_2CO_3 in the water. The value of Henry's constant from Table F–1 is 1420 atm, thus

$$x_{H_2CO_3} = \frac{P_T}{H} = \frac{0.30 \text{ atm}}{1420 \text{ atm}} = 2.113 \times 10^{-4}$$

Because one liter of water contains 55.6 mole [1000 g/(18 g/mole)], the mole fraction of H_2CO_3 is equal to:

Table F–2
Carbonate equilibrium constants as function of temperature[a]



Temperature, °C	Equilibrium constant, mole/L[b] $K_{a1} \times 10^7$	$K_{a2} \times 10^{11}$
5	3.020	2.754
10	3.467	3.236
15	3.802	3.715
20	4.169	4.169
25	4.467	4.477
30	4.677	5.129
40	5.012	6.026

[a] Adapted from Table 6–16 in Chap. 6.

[b] The reported values have been multiplied by the indicated exponents. Thus, the value of K_{a2} at 20°C is equal to 4.169×10^{-11}.

Figure F–1

Log concentration versus pH diagram for a 10^{-3} molar solution of carbonate at 25°C. By sliding the constituent curves up or down, pH values can be obtained at different concentration values.

$$x_{H_2CO_3} = \frac{\text{mole gas } (n_g)}{\text{mole gas } (n_g) + \text{mole water } (n_w)}$$

$$2.113 \times 10^{-4} = \frac{[H_2CO_3]}{[H_2CO_3] + [55.6 \text{ mole/L}]}$$

Because the number of moles of dissolved gas in a liter of water is much less than the number of moles of water,

$$[H_2CO_3] \approx (2.113 \times 10^{-4})[55.6 \text{ mole/L}] \approx 11.75 \times 10^{-3} \text{ mole/L}$$

2. Use Eq. (F–5) to determine the pH of the water. The value of K_{a1} at 20°C from Table F–2 is 4.169×10^{-7} mole/L, thus

$$[H^+] = \frac{K_{a1}[H_2CO_3^*]}{[HCO_3^-]}$$

Substitute known values and solve for $[H^+]$

$$[H^+] = \frac{[4.169 \times 10^{-7}\ \text{mole/L}][11.75 \times 10^{-3}\ \text{mole/L}]}{[(610\ \text{mg/L})/(61{,}000\ \text{mg/mole})]}$$

$$= 4.90 \times 10^{-7}\ \text{mole/L}$$

$$\text{pH} = -\log[H^+] = -\log[4.90 \times 10^{-7}] = 6.31$$

From Fig. F–1, the amount of carbonate present is essentially non measurable.

Subject Index

Because a number of the subjects covered in this text can be referenced (i.e., indexed) under different alphabetical listings, it has been necessary to develop an approach to limit the degree of duplication, yet not affect the utility of the index. The approach used is as follows. Each subject with multiple subentries is indexed in detail under one letter of the alphabet. Where the same subject is indexed under another letter of the alphabet, inclusive page numbers are given and a *See also* citation is given to the location where the subject is indexed in detail. For example, Activated carbon adsorption, 1138–1162, is followed by (See also Adsorption). Where a subject is indexed in detail (e.g., Biochemical oxygen demand) and a commonly used abbreviation (e.g., BOD) is also cited under the same letter of the alphabet, the abbreviated entry is followed a *See* citation. For example, the index entry BOD is followed by (See Biochemical oxygen demand). Where an abbreviation occurs under a different letter of the alphabet than where the detailed citation is given, inclusive page numbers are given followed by the *See also* citation. For older or unused terms, the *see* citation is used to direct the reader to the appropriate term used. To access the number of data tables in the textbook more easily, an index entry followed by the capital letter T in parenthesis [e.g., (T)] is used to denote a data table related to the subject matter.

Abbreviations:
  SI units, 1735
  U.S. customary units, 1736
ABR (see Anaerobic baffled reactor)
Absorbance:
  definition of, 52
  relationship to transmittance, 53
  typical values for wastewater, 53
Accelerated gravity separation, 383–384
Acidogenesis, 630
Acquired immune deficiency syndrome (AIDS), 111
Activated biofilter process, 943–944
  description, 943
  process parameters for (T), 944
Activated carbon adsorption, 1138–1162
  (See also Adsorption)
Activated sludge:
  aeration systems, 430–452
    diffused air, 430–443
    high purity oxygen, 448–452
    mechanical, 443–448
  aeration tanks, 816–819
  aerators (see Aeration systems)
  alkalinity effects:
    in nitrification, 613, 684
    in phosphorus removal, 501, 505
  combined processes, 940–957
  complete-mix, 662, 663, 741
  description of basic process, 661–663
  effects of inhibitory pollutants, 78
  effluent characteristics, 688–689
  food to microorganism ratio (F/M):
    definition of, 680
    typical values, 747
  froth control, 818
  fundamentals of process analysis and control:
    activated sludge selector processes, 700–703
    operational problems, 694–700
    process control, 689–694
    process design considerations, 677–689
    (See also individual listings under Activated sludge)
  hydraulic retention time (τ):
    definition of, 591
    typical values (T), 747
  key wastewater constituents for process design, 666–671
    alkalinity, 671
    carbonaceous, 668
    definition of terms (T), 667
    nitrogenous, 670
  kinetic analysis of process:
    complete-mix with recycle, 589–598
    plug flow with recycle, 601–602
  kinetic coefficients for:
    denitrification (T), 756
    denitrification with methanol as a growth substrate (T), 785
    heterotrophic bacteria (T), 704
    nitrification (T), 705
  microorganisms:
    causing sludge bulking, 694, 696–697
    involved in process, 555–563
  mixed liquor suspended solids (MLSS), 581
  mixed liquor volatile suspended solids (MLVSS), 581
  mixing, energy requirements for:
    anoxic selectors, 760
  nutrient requirements, 684
  observed yield:
    calculation of, 595
    definition of, 587
  operational problems:
    bulking sludge, 695–698
    clarifier operation, 698
    dissolved oxygen concentration, 698
    internal plant overloading, 698
    Nocardia foam, 699–700
    process loading/reactor configuration, 698

Activated sludge, operational problems—*Cont.*
rising sludge, 699
temporary control measures, 699
wastewater characteristics, 698
pH effects, 610, 615, 623
physical facilities for, 816–840
aeration system, 816
aeration tank, 816–820
solids separation, 820–840
plug flow, 662, 663, 741
process design computational approach:
for anoxic/aerobic process design, 757
for BOD removal and nitrification, 706
for sequencing batch reactor, 724
process control:
dissolved oxygen, 690
mass balance analysis, 691–692
microscopic observations, 694
oxygen uptake rates, 693
return activated sludge, 690
settleability, 690–691
sludge blanket level, 691
sludge wasting, 692–693
process description, 664
process design considerations:
effluent characteristics, 688–689
food to microorganism ratio, 680
general considerations for the selection of reactor type (T), 678
kinetic relationships, 677, 678
mixed liquor settling characteristics, 684–686
nutrient requirements, 684
other chemical requirements, 684
oxygen requirements, 683–684
secondary clarification, 686–688
selection of reactor type, 677
selection of solids retention time and solids loading criteria, 677
selectors, 688
sludge production, 681–683
solids retention time (SRT), 677, 680
summary of equations used in suspended growth analysis (T), 679
volumetric organic loading rate, 680
process design examples:
for BOD removal and nitrification, 707–720, 724–733, 735–738
for nitrogen removal, 766–775, 778–780, 781–784, 786–788
for phosphorus removal, 807–809
process flow diagrams:
activated sludge, 549, 662
activated sludge with Ringlace™, 956
aerated lagoons, 549
biological phosphorus removal: Phoredox (A/O), A^2O, and University of Capetown, 800
BOD removal and nitrification, 741–745
four stage Bardenpho process for nitrogen removal, 665
nitrogen removal processes, 751, 791–796
phosphorus removal processes, 624, 810–813
preanoxic suspended growth denitrification processes, 970
rotating biological contactors, 549
sequencing batch reactor, 662, 721
trickling filters, 549
process overview:
description of basic process, 661
evolution of activated sludge process, 663
historical development, 661
recent process developments, 664
process safety factor, 601
processes for BOD removal and nitrification, 703–749
Biolac™ process, 745
complete mix activated sludge (CMAS), 662, 741
contact stabilization, 742
conventional extended aeration, 743
conventional plug-flow, 741

Cyclic activated-sludge system (CAAS™), 746
high purity oxygen, 743
high rate aeration, 741
Intermittent cycle extended aeration system (ICEAS™), 746
Kraus process, 743
Orbal™, 744
oxidation ditch, 744
sequencing batch reactor (SBR), 745
step feed, 742
two sludge, 742
processes for nitrogen removal, 749–799
Bardenpho (4-stage), 792
BioDenitro, 792
intermittent aeration, 776
Ludzak-Ettinger, 791
Modified Ludzak-Ettinger (MLE), 791
Nitrox™, 793
oxidation ditch, 794
sequencing batch reactor (SBR), 792
Sharon™ process, 788, 796
simultaneous nitrification/denitrification, 759–761
single-sludge, 750–753, 793
step feed, 765, 792
two-stage (two sludge) with an external carbon source, 794
processes for phosphorus removal, 799–816
A^2/O, 810
Johannesburg process, 812
modified Bardenpho (5 stage), 813
Phoredox (A/O), 810
PhoStrip, 813
SBR with biological phosphorus removal, 813
UCT (standard and modified), 811
VIP, 812
reactor selection (T), 678
return sludge control, 690
secondary clarification:
solids loading rate (SLR), 688
typical overflow rates (T), 687
typical solids loading (T), 688

selectors:
concept of, 701
configurations of, 702
kinetics-based selector, 701–703
metabolic-based selector, 703
settling tanks, 820–840
(See also Solids separation facilities)
simulation models, 859–865
sludge wasting, 692–693
temperature effects, 585
wastewater characterization:
key constituents for process design, 666–671
measurements for, 671–674
recycle flows and loads, 676
Activated sludge with fixed film packing, 952–957
activated sludge with internal fixed packing, 955–956
description of the Bio-2-Sludge® process, 956
description of the Ringlace® process, 956
activated sludge with internal suspended packing, 952–955
description of the Captor® process, 952–953
description of the Kaldnes® process, 953–955
description of the Linpor® process, 952–953
moving bed biofilm reactor (MBBR) (see Kaldnes)
process flow diagrams:
activated sludge process with Ringlace™, 956
Bio-2-sludge process, 957
rotating biological contactors, 956
Activation energy for aqueous chlorine and chloramines, 1229
Activity, definition of, 30
Activity coefficient:
computation of, 41
Davies equation for, 140
definition of, 40
Acute toxicity, 132, 134
Acute toxicity units (TU_a), 135
Adaptive control, 1690
Adsorption, 1138–1162
adsorption from mixtures, 1146
adsorption isotherms, development of:
Freundlich isotherm, 294, 1141–1143
Langmuir isotherm, 1144
adsorption kinetics:
breakthrough adsorption capacity, 1148
carbon adsorption capacity, 1148
estimation of breakthrough time, 1149
mass transfer zone (MTZ), 1146–1147
comparison of granular and powdered activated carbon (T), 1139
contactors:
expanded-bed contactors, 1151
fixed-bed contactors, 1150
moving-bed contactors, 1150
for wastewater treatment, 1151
dechlorination, use for:
description, 1263
reaction with chlorine, 1263
reaction with combined residual, 1263
description of, 293
Freundlich isotherm constants for:
selected organic compounds (T), 1143
fundamentals of adsorption, 1140–1146
adsorption mixtures, 1146
development of adsorption isotherms, 1141
Freundlich isotherm, 1141
Langmuir isotherm, 1144
granular activated carbon (GAC):
common terms used in operational performance, 1154–1155
comparison to powdered activated carbon (T), 1139
definition of, 1138
treatment with, 1149
typical design values for (T), 1152
typical specifications for (T), 1153
odor control, use for, 1664
powdered activated carbon:
comparison to granular activated carbon (T), 1139
contactor design, 1159
definition of, 1138
treatment with, 1152
powdered activated carbon treatment (PACT):
activated sludge, use with, 1161
process flow diagram for application, 1162
preparation of, 1138
process applications:
with granular activated carbon (GAC), 1149
with powdered activated carbon (PAC), 1152
rapid small scale column test (RSSCT), 1156
reactivation of, 1139
readily and poorly adsorbed organics (T), 1142
regeneration of, 1139
types of adsorbents, 1138
Adsorption, activated-carbon (see Adsorption)
Advanced oxidation processes (AOPs), 1196–1202
applications of, 1200
disinfection, 1201
oxidation of refractory organic compounds, 1201
operational problems, 1202
oxidizing potential of various oxidizing agents (T), 1197
technologies used to produce hydroxyl radicals, 1197
hydrogen peroxide/UV, 1199
non-ozone based processes (T), 1197
ozone based processes (T), 1197
ozone/hydrogen peroxide, 1199
ozone/UV, 1198
theory of, 1196
Advanced primary treatment:
application of, 497
definition of, 11
Advanced wastewater treatment, 1035–1205
adsorption, 1138–1162
advanced oxidation processes, 1196–1202
distillation, 1202–1205
filtration, depth, 1044–1098
filtration, surface, 1098–1104
gas stripping, 1162–1180
ion exchange, 1180–1196
membrane filtration processes, 1104–1137
process flow diagrams for:
advanced oxidation using ozone and UV, 1198

Advanced wastewater
treatment, process flow diagrams for—*Cont.*
advanced treatment processes used at Water Factory 21, 1381
air stripping of ammonia from wastewater, 1179
ammonia removal by zeolite exchange, 1189
demineralization and removal of hardness by ion exchange, 1195
electrodialysis membrane process, 1134
extractive membrane bioreactor, 1129
membrane aeration bioreactor, 1129
membrane bioreactor, 1127
membranes for advanced wastewater treatment, 1126
multistage wastewater reclamation processes, 1380
potable water demonstration plant, 1381
reverse osmosis membrane process, 1115
with settled primary effluent, 1042
with settled secondary effluent, 1042
steam stripping of ammonia from centrate, 1180
tertiary treatment systems for water reclamation, 1378
technologies used for advanced treatment, 1038–1044
classification of technologies, 1038
process selection and performance data, 1044
removal of biological constituents, 1043
removal of dissolved inorganic constituents, 1041
removal of dissolved organic constituents, 1040
removal of organic and inorganic colloidal and suspended solids, 1038
residual constituents in treated wastewater, 1038, (T) 1039
unit operations and processes, (T), 1040
(See also individual listings)
Advection, 246
Aerated channels, 818
Aerated grit chamber, 386–392
design information for (T), 389
flow pattern through, 390
grit removal from, 390, 391
typical section through, 389
Aerated lagoons, 840–854
description of, 840
dual powered flow through lagoon system, 853
process design considerations for flow-through lagoons:
BOD removal, 843
cold weather operations, 844–845
effluent characteristics, 843
mixing requirements, 845
oxygen requirement, 845
process design example, 846
solids separation, 850
temperature, 844
types of suspended growth aerated lagoons, 841
aerobic flow-through partially mixed lagoon, 842
aerobic lagoon with solids recycle, 842
characteristics of different lagoons (T), 841
facultative partially mixed lagoon, 842
Aerated static pile sludge composting, 1548
Aeration systems, 430–456
for activated sludge process, 816
alpha factor, 429
beta factor, 429
description of (T), 431
diffused air, 430- 443
air piping, 441–443
alpha factor, 438
blowers, 439- 441
diffusers, 431–435
fouling factor, 438
energy requirements for mixing, 448
high-purity oxygen, 448–452
cryogenic air separation, 450
dissolution of commercial oxygen, 450
dissolution time, 450
pressure-swing adsorption, 448–450
Speece cone, 451
U-tube contactor, 451
mechanical, 443–447
alpha factors (T), 447
horizontal axis, 445–446
oxygen solibility correction factor, 447
oxygen transfer for (T), 446
performance of, 446–447
submerged with vertical axis, 444–445
surface aerators with vertical axis, 443–444
typical aeration tank dimensions for (T), 448
for postaeration, 452–456
(See also individual listings)
Aeration tanks, 816–819
design considerations, 816–818
dimensions of for mechanical aerators (T), 818
froth control, 818
Nocardia foam control, 819
Aerators:
aspirating, 435
commonly used devices (T), 431, (T) 432
jet, 435
mechanical: 443–447
(See also Mechanical aerators)
nonporous diffusers, 434–435
for oxygen dissolution, 451–452
porous diffusers, 432–434
static tube, 435
typical performance information, 446–447
U-tube, 436
Aerobic attached growth processes:
rotating biological contactors, 930–940
trickling filters, 893–930
(See also individual listings)
Aerobic combined attached and suspended growth processes, 940–951
(See also Combined attached and suspended growth treatment processes)
Aerobic sludge digestion:
autothermal thermophilic aerobic digestion (ATAD), 1541–1545
conventional air aerobic digestion:
design criteria, (T), 1536
design criteria for (T), 1536
detention time, 1463, 1536
energy requirements for mixing, 1536, 1538
feed solids concentration, 1538

oxygen requirements, 1538
process design example, 1539–1541
process operation, 1539
SRT, 1536
tank volume, 1537
temperature, 1535
volatile solids reduction, 1536, 1537
dual digestion, 1541
high-purity oxygen aerobic digestion, 1545
process description, 1534
typical BOD and SS concentrations in recycle flows (T), 1594
Aerobic suspended growth treatment processes:
aerated lagoons, 840–854
aerobic digestion, 1533–1546
for BOD removal and nitrification, 703–749
for combined aerobic treatment, 940–957
for use with membrane separation, 855
Aggregate organic constituents, 80–99
biochemical oxygen demand (BOD), 81
definition of, 80
interrelationships between BOD, COD, and TOC, 96
measurement of organic content, 81
oil and grease, 98
surfactants, 98
theoretical oxygen demand, 96
total and dissolved organic carbon (TOC and DOC), 94
total and soluble chemical oxygen demand (COD and SCOD), 93
UV-absorbing organic constituents, 95
(See also individual listings)
Aggregation, particle, 485
Agricultural and landscape irrigation, 1401–1412
evaluation of irrigation water quality, 1401
maximum concentration of trace elements in (T), 1407
water quality guidelines for (T), 1403
miscellaneous problems, 1410
physical and chemical characteristics, 1402
adjusted sodium adsorption ratio, 1406
nutrients, 1410
salinity, 1404
sodium adsorption ratio (SAR), 1406
specific ion toxicity, 1406
water infiltration rate, 1406
Air, solubility in water, 67
Air diffusers (see Aeration systems)
Air flotation, 419–425
(See also Flotation, dissolved air)
Air flow in trickling filters, 901
Air mixing:
in activated sludge process, 448
description of, 359–361
power requirements for, 362
Air piping, 441–443
air velocities in, typical, 441
design air temperatures, 442
friction factor for, 442
friction losses in, 441
headloss through appurtenances, 443
resistance factors for fittings (T), 442
velocity head, 442
Air pollution control, 1650–1676
(See also Odor management)
Air pollution control legislation, 5
Air stripping of ammonia:
air requirements for, 1168
ammonia concentration as function of pH, 62
equilibrium curves for ammonia in water, 1167
from digester supernatant:
description of, 1179
operational problems, 1178
process flow diagram for, 1179
lime requirements for pH increase, 501
temperature, effect of, 1167
from wastewater, 1178
description of, 1178
operational problems, 1178
process flow diagram for, 1179
Algae, 107
Alkaline stabilization, 1500–1505
advanced alkaline stabilization technologies:
description of, 1504
process flow diagram for chemical fixation system, 1505
chemical reactions with lime, 1500
lime stabilization, 1500–1504
(See also Lime stabilization)
Alkalinity:
definition of, 59
expressed as calcium carbonate ($CaCO_3$), 59
importance of in:
ammonia stripping, 501
anaerobic digestion, 990 (T), 1507
chemical precipitation, 494
nitrification, 613, 684
phosphorus removal, 501, 505
lime dosage required to raise pH as a function of, 501
Alkyl-benzine-sulfonate, 99
Alpha (α) factor in aeration:
definition of, 429
for diffused air systems, 438
effect of wastewater constituents on, 438
for mechanical aerators, 447
Alum:
action of hydrolyzed metal ions, 488
applications of:
for improved suspended solids removal in primary sedimentation, 494
for phosphorus removal, 506–507
dosages for:
improved suspended solids removal in primary sedimentation, 494, 497
phosphorus removal, 506
estimation of sludge quantities, 509
formation of hydrolysis products, 487
operating regions as function of pH, 492
properties of, 494
reactions involving:
alkalinity, 494
metals, 487
phosphorus, 502, 503
solubility of metal salts, 490
AMBR (see Anaerobic migrating baffled reactor)

Amines, 102
Ammonia, conversion of
from ammonia gas to ammonia ion by pH modification, 62, 501
by biological nitrification, 703–749
comparison of nitrification processes (T), 748
types of nitrification processes (T), 741
typical design parameters (T), 747
Ammonia nitrogen:
advanced treatment methods (T), 1140
removal by:
air stripping, 1178
biological denitrification, 749–798
breakpoint chlorination, 1237
ion exchange, 1187
microfiltration, 1127
reverse osmosis, 1130
solubility in water, 67
typical values in wastewater, 186
(See also individual listings)
Ammonia stripping, 1178, 1179
(See also Air stripping of ammonia)
Amphoteric compound, 487
Anaerobic bacteria, 565
Anaerobic baffled reactor (ABR), 1016–1017
Anaerobic bioreactor with membrane solids separation, 1026–1027
process diagram for, 1027
summary of operating conditions (T), 1027
Anaerobic covered lagoon process, 1024–1026
advantages and disadvantages of, 1024
operating conditions and performance data for ADI-BVF type (T), 1026
performance of plug-flow lagoons, 1024
types of, 1024
Anaerobic downflow attached growth process, 1022–1023
advantages and disadvantages of, 1023
description of, 1022
operating conditions and performance data for (T), 1023
Anaerobic fermentation and oxidation, 629–635
environmental factors, 635
growth kinetics, 634–635
microbiology, 631–633
process description, 630–631
fermentation, 630
hydrolysis, 630
methanogenesis, 630
process schematic, 631
stoichiometry, 633
Anaerobic fluidized bed attached growth reactor, 1020–1022
activated carbon use in, 1021
advantages and disadvantages of, 1022
description of, 1020
operating conditions and performance data for (T), 1022
Anaerobic lagoon, covered, 1024
Anaerobic migrating blanket reactor (AMBR), 1017–1018
Anaerobic sludge blanket processes, 1005–1018
anaerobic baffled reactor, 1016–1017
description of, 1016
design and performance results, 1018
process flow diagram for, 1017
anaerobic migrating blanket reactor, 1017–1018
description of, 1017
process flow diagram for, 1017
upflow sludge blanket reactor (UASB), 1005–1016
description of, 1005
design considerations, 1007
process design example, 1012–1016
Anaerobic sludge digestion:
application of, 1505
process fundamentals, 1506–1507
alkalinity (T), 990, 1507
solids and hydraulic retention times, 1506
temperature, 1506
Anaerobic sludge digestion (acid/gas phased), 1532
Anaerobic sludge digestion (mesophilic), 1507–1516
description of, 1507
separate, 1509
single-stage high-rate, 1508
two-stage, 1509
design parameters (T), 1519
kinetic coefficients, 1000
loading factors, 1512
methane gas production, 992
population basis, 1515
sizing criteria (T), 1513
solids retention time (T), 1511
typical design criteria, 1513
volatile solids destruction (T), 1514
volatile solids loading factors, (T), 1514
digester gas, 1523–1525
collection, 1523
heating value, 1525
production, 1523
utilization, 1525
digester heating, 1525–1529
analysis of heat requirements, 1525
heating requirements example, 1527
heat-transfer coefficients (T), 1526
digester mixing, 1516–1521
advantages and disadvantages of various types (T), 1518
description of, 1517–1521
typical design parameters, 1519
digestion tank covers, types of, 1524
enhancing solids loading and digester performance, 1522
operating temperatures, 1506
process design, 1509–1515
loading factors, 1512
population basis, 1515
solids retention time, 1510
volatile solids destruction, 1513
process flow diagram for anaerobic sludge digesters:
high rate, 1508
two-stage, 1508
process microbiology, 631–632
tank design, 1516–1522
cylindrical, 1516–1521
cylindrical and egg-shaped, comparison of (T), 1517
egg-shaped, 1521–1522
waffle bottom, 1520
two-phased, 1531–1533
typical BOD and TSS concentrations in return flows, table of, 1594

Anaerobic sludge digestion (thermophilic), 1529
Anaerobic sludge digestion (two-phased), 1531–1533
acid/gas, 1532
process flow diagram for staged anaerobic digestion processes, 1531
staged mesophilic, 1531
temperature-phased, 1532
Anaerobic suspended growth processes, 996–1005
process flow diagrams for:
anaerobic contact process, 997
anaerobic sequencing batch reactor, 997
complete mix anaerobic digester, 997
upflow anaerobic sludge blanket reactor processes, 1006
Anaerobic treatment, 984–996
advantages and disadvantages of, 984–986
application of, 987
design considerations for: 987–996
alkalinity, 988
ammonia toxicity, 995–996
liquid-solids separation, 996
methane gas production, 992–993
nutrients and macronutrients, 990
solids retention time, 991
sulfide production, 994–995
toxic and inhibitory inorganic compounds (T), 991
toxic and inhibitory organic compounds (T), 992
treatment performance, 994
wastewater characteristics, 987
with membrane separation, 1026, 1027
Analytical detection limits:
instrumental detection level (IDL), 34
level of quantification (LOQ), 35
lower level of detection (LLD), 34
method detection level (MDL), 35
Analytical results, expression of, 35, 36
Analyzers, for measuring process performance (T), 697
Annamox bacteria, 619
Anoxic biological process:
for nitrogen removal, 616, 753
for phosphorus removal, 800
for selectors, 700
Anthracite:
properties of, 1088
sizes used in depth filters, 1086–1087
typical particle size distribution, 1088
AOPs (see Advanced oxidation processes)
A/O process, 811
A^2/O process, 811
Archaea:
description, 507
place in phylogenetic tree of life, 561
ASM1 and ASM2 models, 860
ATAD (see Autothermal aerobic sludge digestion)
Atmospheric pressure:
change with elevation, 1738
standard value of, inside back cover
Atomic numbers and atomic masses (T) (see inside of back cover)
Attached growth denitrification processes, 962–971
attached growth postanoxic denitrification processes:
downflow packed-bed, 962–967
fluidized-bed, 967
submerged rotating biological contactors, 969
upflow packed-bed postanoxic, 967
attached growth preanoxic denitrification processes, 969
Biofor®, 969
staged trickling filters, 969
suspended growth-trickling filter, 969
process flow diagrams:
preanoxic attached growth, 970
preanoxic suspended and attached growth, 970
Attached growth, with activated sludge reactors, 952–957
(See also Activated sludge with fixed-film packing)
Attached growth processes, submerged, 957–961
downflow submerged:
description of Biocarbone® process, 957–958
flow diagram for, 958
fluidized bed reactor (FBBR), 961
upflow submerged:
description of the Biofor® process, 959
description of the Biostyr® process, 960
loading limits for the Biofor® process (T), 959
typical design loadings for the Biostyr® process (T), 961
Attached growth treatment processes:
activated sludge with fixed film packing, 952–957
attached growth denitrification, 962–971
combined aerobic processes, 940–952
general description, 553
rotating biological contactors, 930–940
submerged attached growth, 957–962
trickling filters, 893–930
(See also individual listings)
Automatic process control, 1677–1703
control algorithms, 1682
adaptive control, 1690
cascade control, 1689
feedback control, 1684
feed-forward and feedback control, 1687
feed-forward control, 1683
selection of set points, 1690, (T) 1691
control systems for wastewater treatment plants, 1679
advantages of automatic control, 1681
controlled and manipulated variables, examples of (T), 1680
control system architecture, 1679–1680
manual versus automatic control, 1680
definition of terms for control processes (T), 1677
description of automatic control system elements, 1693
automatic control diagram for the activated sludge process, 1681
controllers, 1696
final control elements, 1698

Automatic process control,
description of automatic control system elements—*Cont.*
flow measurement, methods of (T), 1695
level measurement, examples of (T), 1696
on-line instrumentation, 1693
performance analysis, methods of (T), 1697
signal transmitters, 1694
process control diagrams, 1690
block flow diagrams (BFDs), 1690
piping and instrument diagrams (P&IDs), 1693
treatment process time constants (T), 1694
process disturbances, 1678
external disturbances, 1678
internal disturbances, 1678, (T) 1679
Autothermal thermophilic aerobic digestion (ATAD):
description of, 1541
design considerations (T), 1544
design criteria (T), 1545
process control, 1544
process design, 1543
process flow diagram for, 1664
process theory, 1542
Autotrophic microorganisms:
chemoautotrophs, 564
definition of, 564
Axial dispersion:
definition of, 230
determination of, 251
plug flow reactors axial dispersion, 246, 247
in wastewater treatment facilities, 250

Backwashing, filter (see Filtration, depth)
Bacteria:
cell chemical composition (T), 558
cell enzymes, 557
chemical formula for, 558
chemical structure, 106
classification according to carbon and energy source:
autotrophs, 564
chemotrophs, 564
heterotrophs, 564
phototrophs, 564
classification by ability to utilize oxygen:
aerobic autotrophs, 563
aerobic heterotrophs, 563
anaerobic heterotrophs, 563
facultative heterotrophs, 563
classification, general (T), 563
classification of:
phylogenetic, 560, 561
taxonomic, 559
using molecular tools, 561
coliform organisms, 115
description of, 107
destruction by various processes, 1221
enumeration and identification of, 118
nutrient and growth factor requirements, 565
pathogenic, 109
concentration of, 111
present in wastewater, 110
pH ranges, 559
reproduction, 107
size of, 108
survival of, 114
temperature ranges (T), 559
use as indicators of pathogens, 115
Bacterial growth and energetics, 565–580
bacteria growth and biomass yield, 567
bacterial growth patterns in a batch reactor, 566
bacterial reproduction, 566
biomass synthesis yields for different growth conditions, 579
estimating biomass yield and oxygen requirements from stoichiometry, 568
estimating biomass yield from bioenergetics, 571
measuring biomass growth, 567
observed versus synthesis yield, 580
stoichiometry of biological reactions, 578
Bacterial yield:
biomass synthesis yields for different growth conditions, 579
definition of, 567
estimating biomass yield and oxygen requirements from stoichiometry, 568
estimating biomass yield from bioenergetics, 571
observed versus synthesis yield, 580
Bacteriological tests for coliform organisms:
completed test, 122
confirmed test, 122
membrane filter technique, 119
most probable number (MPN), 122, 1749
MPN tables, 1750
multiple tube fermentation, 121
presumptive test, 122
Bacteriophage:
as an indicator organism, 118
definition of, 128
removal of:
by chlorination, 1253
by reverse osmosis, 1388
by secondary treatment, 1385
Baffles:
for aerated grit chambers, 388
for chlorine contact tanks, 1272–1274
for secondary sedimentation tanks, 840
for use with depth filters, 1095
for UV channels, 1327
Ballasted flocculation:
description of, 415
design and performance data, 415
systems for, 416
Bar racks, 316–322
(See also Coarse screens)
Bardenpho process:
four-stage, 665, 793
five-stage (modified), 811
Batch reactor:
analysis of with reaction, 269
applications of, 220
definition of, 218
Belt filter press:
description of, 1564
design considerations, 1565
performance data (T), 1566
ranges of polymer addition (T), 1556
system operation and performance, 1564
typical performance data (T), 1556
Beta (β) factor in aeration, 429
Bingham plastic, 1478

Bioassay toxicity tests:
analysis of test results:
acute toxicity data, 134
chronic toxicity data, 135
application of test results:
example of, 136
toxic unit acute (TU_a), 136
toxic unit chronic (TU_c), 136
identification of toxicity components, 137
organisms used (T), 133
toxicity testing, 133
toxic unit, 136
test methods (T), 133
uses of, 130
Biochemical oxygen demand (BOD), 81–92
analysis of BOD data, 88
basis for BOD test, 81
carbonaceous biochemical oxygen demand (CBOD), 88
definition of, 81
determination of k:
by daily-difference method, 88
by Fujimoto method, 90
by least squares, 88–89
by method of moments, 88
by rapid-ratio method, 88
by respirometer, 91
by Thomas method, 88
effect of particle size, 92
formulation of first stage, 85
kinetics of, 85
limitations of BOD test, 92
method of determination, 82–85
modeling of BOD reaction, 85
nitrification in BOD test, 87
particle size, effect on BOD reaction rates, 92
ratio to other parameters, 97
respirometric determination of, 91
seeding, 82
temperature effects, 86
test procedure, 82–83
typical k values for wastewater, 85
Bioenergetics, 571–578
application of, 575–578
fundamentals of, 574
Biofilter/activated sludge process, 943–944
description, 943
process parameters for (T), 944
Biofilters for odor control:
description of, 1665
design considerations, 1670–1676
Biological characteristics of wastewater (see Wastewater characteristics, biological)
Biological denitrification (see Nitrogen removal by biological denitrification)
Biological growth kinetics (see Activated sludge, kinetic analysis of process; Kinetics of biological growth)
Biological nitrification/denitrification (see Nitrogen removal by nitrification/denitrification)
Biological nutrient removal:
as compared to chemical methods, 12
nitrogen removal by attached growth processes, 962–971
nitrogen removal by suspended growth processes, 749–798
phosphorus removal by suspended growth processes, 799–815
(See also Nutrient removal)
Biological odor control, 1665–1667, 1670–1676
Biological treatment, fundamentals of, 547–644
aerobic biological oxidation, 607
environmental factors, 610
growth kinetics, 610
microbiology, 609
process description, 608
stoichiometry of aerobic biological oxidation, 609

process description, 616
stoichiometry of biological denitrification, 619
biological phosphorus removal, 623
environmental factors, 629
growth kinetics, 629
microbiology, 625
process description, 624
stoichiometry of biological phosphorus removal, 627
biological removal of heavy metals, 644
biological removal of toxic and recalcitrant organic compounds, 635
abiotic losses, 638
aerobic biodegradation, 638
anaerobic degradation, 637
development of biological treatment methods, 645
modeling biotic and abiotic losses, 640
composition and classification of microorganisms, 555
cell components, 555
cell composition, 557
environmental factors, 558
microorganism identification and classification, 559
use of molecular tools, 561
environmental factors, 623
biological nitrification, 611
environmental factors, 615
growth kinetics, 614
microbiology, 6121
process description, 611
stoichiometry of biological nitrification, 612
introduction to microbial metabolism, 563
carbon and energy sources for microbial growth, 563
nutrient and growth factors requirements, 565

Biological treatment, fundamentals of—*Cont.*
microbial growth kinetics, 580
effects of temperature, 585
kinetic coefficients for substrate utilization and biomass growth, 584
microbial growth kinetics terminology, 581
net biomass yield and observed yield, 587
other rate expressions for the utilization of soluble substrate, 582
rate of biomass growth with soluble substrates, 584
rate of oxygen uptake, 585
rate of soluble substrate production from biodegradable particulate organic matter, 583
rate of utilization of soluble substrates, 581
total volatile suspended solids and active biomass, 586
modeling suspended growth treatment processes, 588
biomass mass balance, 589
description of suspended growth treatment processes, 589
design and operating parameters, 598
mixed liquor solids concentration and solids production, 592
modeling plug-flow reactors, 601
observed yield, 595
oxygen requirements, 595
process performance and stability, 600
substrate mass balance, 592
overview of biological wastewater treatment, 547
objectives of biological treatment, 548
role of microorganisms in wastewater treatment, 548
some useful definitions, 548
types of biological processes for wastewater treatment, 551
substrate removal in attached growth treatment processes, 602
substrate flux in biofilms, 604
substrate flux limitations, 606
substrate mass balance for biofilm, 605
Biological unit processes:
attached growth:
anaerobic fluidized bed, 1020
anaerobic packed bed, 1018–1023
denitrification, 962–971
membrane bioreactor, 854–858
packed bed reactor, downflow, 957
rotating biological contactor (RBC), 930–940
submerged, 957–961
trickling filter, 890–930
(See also individual listings)
combined attached and suspended growth, 940–957
activated biofilter, 943
activated sludge with fixed film, 952–961
biofilter activated-sludge, 943
filter/solids contact, 940
roughing filter/activated sludge, 941
trickling filter/activated sludge, 940
(See also individual listings)
major biological treatment processes (T), 552
suspended growth:
activated sludge, 661–840
aerated lagoons, 840–854
aerobic digestion, 1533–1546
anaerobic baffled reactor, 1016
anaerobic complete-mix, 997
anaerobic contact, 997
anaerobic digestion, 1505–1533
anaerobic lagoons, 1024
anaerobic migrating blanket reactor, 1017
anaerobic sequencing batch, 999
for biological nitrogen removal, 749–798
for biological phosphorus removal, 799–815
for BOD and nitrogen removal, 703–749
sequencing batch reactor (SBR), 720–733
upflow anaerobic sludge-blanket, 1018–1023
(See also individual listings)
Biomass yield, estimation of, 568–578
from bioenergetics, 571–578
from stoichiometry, 568–571
Biosolids and residuals management, 22–24
current status, 22
future trends, 23
new directions and concerns, 23
Biosolids application to land, 1608–1621

Biosolids conveyance and storage:
conveyance methods, 1622
storage basins and lagoons, 1622
Biosolids drying:
artificial-media drying beds, 1575–1576
conventional sand drying beds, 1570–1573
heat drying, 1579–1586
lagoons, 1578–1579
paved drying beds, 1573–1575
reed beds, 1578
solar drying beds, 1576–1577
vacuum-assisted drying beds, 1576
(See also individual listing)
Biosolids landfilling, 1621
Biotrickling filters for odor control, 1666
(See also Odor control)
Blom's plotting position, 172
Blowers, 439–441
centrifugal, 439
effects of temperature, 440
operating characteristics, 439
inlet guide vane-variable diffuser, 440
positive-displacement, 439
power requirements, 440
types of, 439
BOD (see Biochemical oxygen demand)
BOD/COD ratio, 97
BOD/TOC ratio, 97
Boundary, control volume, for mass balance analysis, 223
Boundary, system, for mass balance analysis, 223
Breakpoint chlorination, 1237–1241
acid generation, 1239
buildup of total dissolved solids, 1240
chemistry, 1237

Breakthrough in carbon adsorption:
description of, 1146
impact of adsorbable, nonadsorbable, and biodegradable constituents, 1147
typical curve with throughput volume, 1146
Brine:
definition of, 1105
disposal options for (T), 1136
Brownian motion, 347
Buchner funnel test for sludge dewaterability, 1555
Bulking sludge:
causes of, 695
control of:
by process analysis, 697–699
by selector, 700–703
by temporary measures, 699
factors affecting (T), 697
filamentous organisms found in (T), 697
types of:
filamentous bulking, 695
viscous bulking, 695
variables affecting, 697–699
Butanol wheel for odor measurement, 75
(See also Odor)
Byproducts, disinfection:
formation and control of with:
chlorine, 1255
chlorine dioxide, 1260
ozone, 1293
UV radiation, 1329
importance of, 102, 1255
list of formed with chlorine (T), 1256

C curve:
analysis of, 234–238
definition of, 233, 234
determination of, 232
Cadmium:
importance of in wastewater management (T), 78
maximum concentration for land application of biosolids, 1616
maximum concentration in irrigation waters, 1407
removal by ion exchange, 1194
Calcium hydroxide:
characteristics of, 494, 527
chemical reactions involving, 495, 501
Calcium hypochlorite:
description of, 1234
flow diagram for dry feed system, 1268
Carbohydrates, 80
Carbon, total organic:
definition of, 94
relationship of DOC to UV adsorption, 95
typical values in wastewater, 186
(See also Total and dissolved organic carbon)
Carbon adsorption (see Activated carbon, adsorption)
Carbon analyzer 95
Carbon contactors, 1150, 1151

Charge reversal, 485
Chemical coagulation, 478–493
basic definitions for, 479
development and measurement of surface charge, 481
the electrical double layer, 481
ionization, 481
isomorphous replacement, 481
measurement of surface potential, 482
preferential adsorption, 481
structural imperfections, 481
nature of particles in water, 480
particle shape and flexibility, 480
particle size and number, 480
particle solvent interaction, 480
particle destabilization and aggregation with polymers, 485
charge neutralization, 485
charge neutralization and polymer bridge formation, 486
polymer bridge formation, 486

Chemical coagulation—*Cont.*
particle destabilization and removal with hydrolyzed metal ions, 486
action of hydrolyzed metal ions, 488
formation of hydrolysis products, 487
importance of initial mixing, 492
operating regions for action of metal salts, 492
solubility of meat salts, 490
particle destabilization with, 483
electrolytes, 485
potential determining ions, 483
particle-particle interactions, 482
Chemical composition:
of bacteria, 558
of wastewater, 186, 187
(See also Wastewater, constituents in)
Chemical conditioning of sludge, 1554–1558
(See also Sludge conditioning)
Chemical equilibrium, definition of, 39
Chemical feeders, 533
characteristics of chemical feeders (T), 537
dry type, 533
liquid type, 536
process flow diagrams for:
dry chemical feed, 535
liquid chemical feed, 539
types of:
dry, 533, 535
gas, 537
liquid, 536
Chemical feed systems:
for belt press dewatering, 1565
for chlorination/dechlorination with:
chlorine and sulfur dioxide, 1267
sodium hypochlorite and sulfur dioxide, 1268
for the addition of sulfur dioxide, 1270
Chemical fixation of sludge, 1505
Chemical neutralization, 526–532
analysis scaling potential, 528
pH adjustment, 526
scaling control, 532
stabilization, 532
Chemical oxidation, 517–526
applications:
chemical oxidation of ammonia, 524
oxidation of BOD and COD, 523
oxidation of nonbiodegradable organic compounds, 524
table of (T), 523
dosages for:
BOD reduction with chlorine, 524
COD reduction with ozone, 524
fundamentals of, 517
equilibrium constants for redox equations, 521
half reaction potential, 518
oxidation-reduction reactions, 517
rate of oxidation-reduction reactions, 522
reaction potentials, 520
standard electrode potentials (T), 518
(See also Advanced oxidation processes
Chemical oxygen demand (COD): 93–94
biodegradable, 668
BOD/COD ratios, 96
definition of, 93
fractionation of, 94, 668
nonbiodegradable, 668
soluble COD, 94
typical values in wastewater, 186
Chemical precipitation, 493
chemicals used for (T), 494
design of storage, feeding, piping, and control systems, 532–540
for enhanced removal of suspended solids, 497
for independent physical-chemical treatment, 498
for phosphorus removal, 500–513
chemistry of, 501
coprecipitation, 505
postprecipitation, 505
pre-precipitation, 505
strategies for, 503
summary of advantages and disadvantages (T), 510
for removal of dissolved inorganics:
heavy metals, 509–517
phosphorus, 500–509
for removal of heavy metals, 514
coprecipitation with phosphorus, 517
precipitation reactions, 514
fundamentals of chemical coagulation, 478–493
(See also Chemical coagulation)
reactions involving:
alum, 494
ferric chloride, 496
ferric chloride and lime, 497
ferric sulfate and lime, 497
ferrous sulfate and lime, 495
lime, 495
phosphate removal, 501, 502
sludge quantities, estimation of, 499
surface loading rates for, 497
Chemical treatment:
applications: improved BOD removal, 477, 497
improved TSS removal, 477, 497
in independent physical-chemical treatment, 498
phosphorus removal, 500–514
chemicals used (T), 494
sludge quantities, estimation of:
from chemical precipitation, 499
from phosphorus precipitation (T), 511
Chemical unit processes:
application of in wastewater treatment (T), 477
considerations in use of, 478
definition of, 216, 476
Chemicals used in tracer studies, 231
Chemotrophic organisms, 564
Chemoautotrophs, 564
Chemohereotrophs, 564
Chick's law:
definition of, 1224
departures from, 1226
Chick-Watson law, 1225
Clinoptilolite (natural zeolite), 1181
Chloramines:
formation of, 1238
germicidal effectiveness, 1242–1244
Chloride:
buildup due to chlorination, 1241
guidelines for irrigation, 1403
importance of, 59

increase due to domestic usage, 187
typical values in wastewater, 186
use as a tracer, 231
Chlorination:
application of:
dosages, 1265
uses, 1231
breakpoint reaction, 1237–1241
acid generation, 1239
buildup of total dissolved solids, 1240
chemistry, 1237
chlorine chemistry, 1234–1237
reactions in water, 1234
reactions with ammonia, 1235
chlorine compounds:
calcium hypochlorite, 1234
chlorine dioxide, 1258
chlorine gas, 1231
sodium hypochlorite, 1233
equipment and dosage control:
for chlorine, 1267
for chlorine dioxide, 1270
for hypochlorite feeders, 1268, 1269
germicidal efficiency:
of chlorine, 1242
of chlorine compounds (T), 1244
mixing and contact, 1270–1272
process flow diagrams for:
calcium hypochlorite disinfection with tablet chlorinators, 1269
chlorination/dechlorination using a chlorine injector, 1267
chlorination/dechlorination using vapor induction, 1267
sodium hypochlorite disinfection with sulfur dioxide dechlorination, 1268
of return sludge for bulking control, 695–698
Chlorinators:
capacity, 1266
evaporators, 1266, 1267
Chlorine:
actual and available (T), 1236
chemistry of, 1234–1237
hydrolysis reaction, 1234
ionization reaction, 1234
compounds of:
calcium hypochlorite, 1234
chlorine gas, 1231
sodium hypochlorite, 1233
containers, 1231
containment facilities, 1284
demand, determination of, 1254
dosage control, 1269
dosages of:
for coliform disinfection (T), 1253
for non disinfection applications (T), 1265
evaporators, 1266
formation of disinfection byproducts, 1255
free available, 1234
hydrolysis and ionization reaction, physical properties of (T), 1232
reactions with ammonia, 1235, 1236
safety measures, 1284–1286
storage facilities, 1284
toxicity to plants, 1410
(See also Disinfection with chlorine)
Chlorine contact basins:
chlorine residual, measurement of, 1283
design of:
basin configuration, 1272
number of basins, 1274
use of baffles and guide vanes, 1272, 1273
precipitation in, 1275
predicting performance, 1278–1283
solids transport velocity, 1276
Chlorine dioxide:
advantages and disadvantages of (T), 1331
characteristics of, 1258
chemistry of, 1259
properties of (T), 1232,
(See also Disinfection with chlorine dioxide)
Chlorine feeders, 1266
ChlorTainer™ for storage of chlorine containers, 1285
Chromium, 78
Chronic daily intake, (CDI), 1369
Chronic toxicity, 132, 135
CID (see Critical initial dilution)
Clarification (see Sedimentation; Sedimentation tanks)
Classification of microorganisms:
phylogenetic, 560, 561
taxonomic, 559
Clean Air Act, 5
Clean Water Act (CWA), 5
Climber bar screen, 319
CMAS (see Complete-mix activated sludge)
CMR (see Complete-mix reactor)
Coagulation, chemical 478–493
(See also Chemical coagulation)
Coagulation concentration, critical (CCC), 485
Coarse screens (bar racks):
design of facilities for, 320
design considerations, 320
design information (T), 316
headloss, 320
hand cleaned, 316
mechanically cleaned, 317
advantages and disadvantages (T), 318
catenary, 319
chain driven screens, 317
continuous belt, 319
reciprocating rake, 319
screenings:
handling and disposal, 329
quantities (T), 328
Coarse solids reduction, 330–333
comminutors, 331
design considerations, 333
grinders, 333
macerators, 332
Cobalt thiocyanate active substances (CTAS), 31, 99
Co-composting of sludge with solid wastes, 1551
COD (see Chemical oxygen demand)
Coefficient of reliability (COR):
application of, 1643
definition of, 1641
as function of the coefficient of variation (T), 1642
Coefficient of rigidity for sludge, 1478
Coincineration of sludge with municipal solid waste, 1592
Coliphage, 118
Coliform organisms:
criteria for water reuse (T), 1362
completed test, 122
confirmed test, 122
determination of most probable number (MPN), 122
estimation of by:
direct counts, 118
membrane filter technique, 119

Coliform organisms, estimation of by—*Cont.*
pour and spread plate method, 119
use of MPN tables, 1749
MPN tables, 1750
presumptive test, 122
Collimated beam:
determination of UV dose with, 1311
examples of, 1312
reporting collimated beam results, 1312
Colloids:
destablization of, 483–493
nature of, 480–483
size range of, 44, 45
Color, 52
Combined attached and suspended growth treatment processes, 940–951
activated biofilter, 943
biofilter activated-sludge, 943
process flow diagrams for:
activated biofilter, 943
biofilter/activated sludge, 943
series trickling filter-activated sludge
trickling filter/activated sludge process, 941
trickling filter/solids contact process, 941
process parameters for:
activated biofilter (T), 944
biofilter/activated sludge (T), 944
roughing filter/solids contact (T), 942
series trickling filter-activated sludge (T), 945
trickling filter/solids contact (T), 942
roughing filter/activated sludge, 941
trickling filter/activated sludge, 940
trickling filter/solids contact, 940
Combined collection system:
definition of, 17
flowrate modeling, 170
flowrates, 168
wastewater characteristics, 191
Combined sewer overflows (CSOs):
description of, 17
first flush effect, 191
treatment of:
with fine screens, 324
with high-rate clarification, 414
with vortex separators, 417
wastewater characteristics, 191
Combined sewer system (see Combined collection system)
Combined treatment processes, estimation of performance, 1390
Combustion, 1586
Comminutors, 331–332
Complete-mix activated sludge, 741
(See also Activated sludge)
Complete-mix reactor (CMR):
analysis of with reaction, 270
applications of, 220
description of, 218
hydraulic characteristics of, 221
Complete-mix reactors in series:
analysis of with chemical reaction:
analytical solution, 271
graphical solution, 272
applications of, 220
description of, 218
hydraulic analysis of, 252
Completed test for coliforms, 122
Composition of wastewater:
constituents in, 186
mineral increase during usage, 187
(See also Wastewater, constituents in)
Compost filter for odor control:
description of, 1065
design considerations, 1670–1676
(See also Biofilters for odor control; Odor management)
Composting of sludge, 1546–1554
characteristics of bulking agents (T), 1553
cocomposting with solid waste, 1551
composting systems:
aerated static pile, 1548
design considerations (T), 1544
in-vessel, 1550
windrow, 1549
pathogen and parasite destruction (T), 1533
process description, 1546
process flow diagram for generalized composting processes, 1548
process microbiology, 1547
public health and environmental issues, 1554
Compression settling, 383
Computational fluid dynamics, 16, 361
Conditioning of sludge, 1554–1558
(See also Sludge conditioning)
Conductivity, 56
definition of, 56
relationship to ionic strength, 32
relationship to salinity, 1404
relationship to total dissolved solids, 32
Confirmed test for coliforms, 122
Constants, physical (see inside of back cover)
Constituent, definition of, 3
Constituent mass loading data, 181–185
analysis, 170, 181
typical composition of untreated domestic wastewater (T), 186
typical constituent concentrations in the U.S. (T), 183
typical constituent data for various countries (T), 184
typical quantities discharged by individuals (T), 182
typical unit waste loading factors for the U.S. (T), 183
Constituents, in wastewater, 29–139
(See also Wastewater, constituents in)
Contact basin, chlorine, 1270–1278
Contactors, carbon, 1149–1151
Contact-stabilization activated sludge, 742
(See also Activated sludge)
Containment facilities:
for chemicals, 533, 535
for chlorine, 1284
for individual chlorine cylinders, 1285
Contaminants in wastewater (see Wastewater, constituents in)
Continuous backwash filter, deep bed, 1072, 1075
Continuous belt bar screen, 319
Continuous deflection separator, 418–419
Control algorithms, 1682
adaptive control, 1690
cascade control, 1689
feedback control, 1684
feed-forward and feedback control, 1687

feed-forward control, 1683
selection of set points, 1690
Control, process 1677–1703
(See also Automatic process control)
Control system elements:
controllers, 1698
final control elements, 1698
on-line instrumentation, 1693
signal transmitters, 1694
Control systems for wastewater treatment plants:
advantages of automatic control, 1681
manual versus automatic control, 1680
system architecture, 1679
Control volume for mass balance analysis, 223
Conventional plug-flow activated sludge, 741
(See also Activated sludge)
Conversion factors:
for environmental engineering computations (T), 1733
metric (SI) to U.S. customary units (T), 1729
U.S. customary to metric (SI) units (T), 1731
Conveyance methods for sludge and solids, 1622
Cooling towers:
cycles of concentration, 1416
makeup water for, 1413
operating problems:
biological growth, 1417
fouling, 1417
metallic corrosion, 1416
scaling, 1416
water and salt balances in, 1414, 1415
Coordination compounds, 487
COR (see Coefficient of reliability)
Co-settling thickening of sludge:
chemical addition, 1490
description of, 1489
effects of sludge blanket retention on TSS removal, 1490
Critical coagulation concentration (CCC), 485
Critical component analysis (CCA), 1639
$C_R t$ value (for disinfection):
definition of, 1242
review of concept, 1252
typical values for disinfection (T), 1244
use of in predicting disinfection performance, 1250
Cryogenic air separation for oxygen generation, 449–450
Cryptosporidium parvum, 18, 111–112
life cycle, 112
size of, 112

CTAS (see Cobalt thiocyanate active substances)
CWA (see Clean Water Act)
Cycles of concentration, 1416
Cyclone degritter, 393

DAF (see Dissolved air flotation)
DBC (see Downflow bubble contactor)
Dead space
in sedimentation tanks, 230
in UV reactors, 1326, 1327
Death phase, bacterial, 567
Decay:
of bacteria in biological systems, 567
endogenous:
application of, 584
definition of, 584
typical values of, 585
of organic matter, 85
Dechlorination:
chemical quantities required (T), 1263
of chlorine and chlorine compounds, 1261–1264
with activated carbon, 1263
with sodium thiosulfate, 1263
with sulfite compounds, 1262
with sulfur dioxide, 1261
of chlorine dioxide with sulfur dioxide, 1264
Dedicated land disposal (DLD), 1619
Definition of terms for:
(See also Terminology for)
automatic process control (T), 1677
biological unit processes, 216
chemical unit processes, 216
hydraulic analysis of reactors (T), 234
infiltration/inflow, 163
membrane processes (T), 1105
physical unit operations, 217, 313
time scale in mixing, 349
toxicity assessment in aquatic environments (T), 132
used in the field of wastewater engineering (T), 4
for wastewater treatment (T), 11
water reclamation and reuse applications (T), 1348
Denitrification, biological, 616–623, 749–799
(See also Nitrogen removal by attached and suspended growth processes)
Dense-sludge process, 417
Density currents, in settling facilities, 230
Density of wastewater, 56
Density of water:
definition of, 56, 1741
values of:
in SI units (T), 1742
in US customary units (T), 1743
Deoxyribose nucleic acid (DNA), 105, 555–557
Depth filtration, 1044–1098
(See also Filtration, depth)
Detection limits, analytical:
instrumental detection level (IDL), 34
level of quantification (LOQ), 35
lower level of detection (LLD), 34
method detection level (MDL), 35
Detergents, 99
Dewatering of sludge and biosolids, 1558–1579
(See also Sludge and biosolids dewatering)
Diffused-air aeration:
air piping, 441–443
blowers, 439–441
diffuser performance, 436
diffusers, 431–435
for post-aeration, 454
(See also Aerators: diffused air)
Diffusers:
for aeration, 431–439
for chlorine injection, 1271
Diffusion baffle:
for chlorine contact basin, 1274
for UV reactors, 1327
Diffusion, molecular:
computation of, 284
definition of, 283
Stokes-Einstein law of diffusion, 284

Digester gas, 1523–1525
(See also Anaerobic sludge digestion)
Digester heating, 1525–1529
(See also Anaerobic sludge digestion)
Digester mixing:
aerobic, 1538
anaerobic, 1516–1522
Digesters (see Aerobic sludge digestion; Anaerobic sludge digestion)
Digestion, aerobic, 1533–1546
(See also Aerobic sludge digestion)
Digestion, anaerobic, 1505–1533
(See also Anaerobic sludge digestion)
Diluted sludge volume index (DSVI), 685
Dimethylamine, 102
Direct injection for groundwater recharge, 1425
Discrete particle settling, 367–372
Diseases, waterborne (T), 110
Disinfection byproducts:
formation and control of with:
chlorine, 1255
chlorine dioxide, 1260
ozone, 1293
UV radiation, 1329
importance of, 102, 1255
list of, formed with chlorine (T), 1256
Disinfection (general theory of):
bacterial removal by various treatment processes (T), 1221
disinfectants: characteristics of an ideal disinfectant (T), 1220
classification of hazardous materials used (T), 1285
comparison of disinfectants (T), 1222
mechanisms of, 1223
types of, 1220
factors influencing the action of disinfectants, 1223–1231
concentration of chemical agent, 1225
contact time, 1224
intensity and nature of physical agent, 1229
nature of suspending liquid, 1230
number of organisms, 1230
temperature, 1229
types of organisms, 1230
mechanisms of disinfectants using chlorine, UV and ozone (T), 1223
methods and means of, 1220
process flow diagrams for:
calcium hypochlorite with tablet chlorinators, 1269
chlorination/dechlorination using a chlorine injector, 1267
chlorination/dechlorination using vapor induction, 1267
chlorine dioxide, 1270
generation of chlorine dioxide, 1259
ozone disinfection using alternative oxygen sources, 1288
ozone disinfection using liquid oxygen, 1290
sodium hypochlorite with sulfur dioxide dechlorination, 1268
Disinfection with chlorine:
breakpoint reaction, 1237
acid generation, 1239
buildup of total dissolved solids, 1240
chemistry, 1237
chlorine chemistry:
chlorine reactions in water, 1234
hypochlorite reactions in water, 1235
reactions with ammonia, 1235
chlorine compounds:
actual and available chlorine, 1236
calcium hypochlorite, 1234
chlorine gas, 1231
sodium hypochlorite, 1233
dechlorination:
with activated carbon, 1263
with sodium thiosulfate, 1263
with sulfite compounds, 1262
with sulfur dioxide, 1261
disinfection byproducts, formation and control of, 1255
environmental impacts, 1257
discharge of disinfection byproducts, 1258
regrowth of microorganisms, 1258
factors that affect disinfection efficiency of chlorine:
characteristics of microorganisms, 1247
characteristics of wastewater (T), 1246
germicidal efficiency of chlorine compounds, 1242
initial mixing, 1244
particles in wastewater, 1247
particles with coliform organisms, 1247
range of $C_R t$ values (T), 1244
(See also Chlorination)
Disinfection with chlorine dioxide, 1258–1261
advantages and disadvantages of (T), 1331
byproduct formation and control, 1260
characteristics of, 1258
chemistry of, 1259
chlorine dioxide chemistry, 1259
dechlorination with sulfur dioxide, 1264
disinfection byproducts, formation and control of, 1260
effectiveness of chlorine dioxide, 1259
environmental impacts, 1261
process flow diagram for:
disinfection with chlorine dioxide, 1270
generation of chlorine dioxide, 1259
properties of (T), 1232,
Disinfection with ozone, 1286–1295
advantages and disadvantages of (T), 1331
disinfection by products (T), 1294
dosages (T), 1293
effectiveness of ozone:
environmental impacts, 1295
other benefits, 1295
energy requirements for (T), 1289
Henry's constant for (T), 1288
impacts of wastewater characteristics (T), 1291
ozone chemistry, 1287
ozone generation, 1289
process flow diagram for:
ozone disinfection using alternative oxygen sources, 1288

ozone disinfection using liquid oxygen, 1290
properties of (T), 1287
Disinfection with ultraviolet (UV) light, 1298–1329
(See also Ultraviolet (UV) radiation disinfection)
Disk aerator, 445, 446
Disk filter:
cloth media disk filter (CMDF), 1100–1104
discfilter (DF), 1098–1100
Dispersed-air flotation, 421
Dispersion:
coefficient of, 246
definition of, 245
distinction between molecular diffusion, turbulent diffusion, and dispersion, 245, 246
Dispersion index, Morrill, 242
definition of, 243
determination of, 243
relationship to volumetric efficiency, 243
Dispersion number, d:
definition of, 247
degree of dispersion, values for, 249
typical values for various treatment facilities (T), 250
Dissolved air flotation (DAF):
description of, 420
design considerations for, 422
air-to-solids ratio, 422
design considerations, 422
design example, 423–424
recycle flow, 421
solids loading information, 1496
(See also Flotation; Flotation thickening of sludge)
Dissolved inorganic substances:
definition of, 43
removal of by:
chemical precipitation, 500, 514
electrodialysis, 1134
ion exchange, 1195
microfiltration, 1127
reverse osmosis, 1130
Dissolved oxygen (DO):
demand of wastewater (see Biochemical oxygen demand)
effect in biological nitrogen removal, 622
importance of, 69
solubility in water:
as a function of temperature and barometric pressure (T), 1747
as a function of temperature and salinity (T), 1745
Henry's law constants for, 67
Dissolved solids:
definition, 43, 44
typical values in wastewater (T), 186
Dissolved total organic carbon (DTOC), 95
Distillation, 1202–1205
concentrated waste, disposal of, 1205
operating problems, 1205
performance expectations, 1204
processes, 1202–1205
multiple-effect evaporation, 1202
multistage flash evaporation, 1203
vapor-compression distillation, 1204
Distribution systems for trickling filters, 900
DLD (see Dedicated land disposal)
DNA (see Deoxyribose nucleic acid)
DNA probe for identification of bacteria, 125

Draft in trickling filters, 902
Drag, equation for:
paddles in flocculation, 357
particles in sedimentation, 363
Drag force:
in flocculation, 357
in sedimentation, 363
Dryers, 1579–1586
(See also Heat drying of sludge)
Drying beds, sludge, 1570–1577
(See also Sludge drying beds)
DSVI (see Diluted sludge volume index)
DTOC (see Dissolved total organic carbon)
Dual digestion, 1541
Dual powered aerated flow through lagoon system, 853
Dyes used in tracer studies, 231
Dynamic forced-choice triangle olfactometer, 76
Dynamic viscosity of water:
definition of, 1741
values of:
in SI units (T), 1742
in US customary units (T), 1743

E curve:
definition of, 238
determination of, 239
EBCT (see Empty bed contact time)
EBRT (see Empty bed residence time)
EC (see Elimination capacity)
EC (see Electrical conductivity)
ED (see Electrodialysis)
Eddy diffusion:
definition of, 245
range of values for, 246
Effective size (d_{10}):
definition of, 1046
in selection of filter materials, 1086–1088
EE/O (see Electrical energy per log order reduction)
Effluent characteristics:
from advanced wastewater treatment, 1386
from microfiltration, 1227
from reverse osmosis, 1130
from secondary treatment, 1386
Effluent filtration, 1044–1098
(See also Filtration, depth)
Effluent reuse, 1347–1356
(See also Wastewater reclamation and reuse)
Effluent standards, minimum national, 6
Egg-shaped anaerobic digester:
comparison to cylindrical (T), 1517
description of, 1521
mixing systems for, 1521–1522
Electrical conductivity (EC):
definition of, 56, 1404
importance of in agricultural reuse, 1403, 1404
relationship to total dissolved solids (TDS), 56
Electrical double layer, 481

Electrical energy per log order reduction:
definition of, 1199
typical values for removal of NDMA, 1200
Electrodialysis, 1131–1134
(See also Membrane filtration processes)
application of, 1133
operating parameters for (T), 1134
process flow diagram for, 1134
theory of, 1131
Electrolysis cell for BOD measurement, 91
Electrolytic respirometer, 91, 92
Electron acceptors and donors in bacterial reactions, 564
Electroneutrality, 37
Elimination capacity (EC), 1673
Emerging microorganisms, 130
Emerging organic compounds:
definition of, 102
listing of (T), 103
quality after various levels of treatment, 1386
reported removals for selected compounds, 1387
Empty bed contact time (EBCT), 1154
Empty bed residence time (EBRT), 1673
Endocrine disruptors, 8
Endogenous decay coefficient, 584
Endogenous respiration, 82, 584
Energy dissipating clarifier feed well, 839
Energy dissipation in mixing, 348
Energy dissipation in static mixing, 352
Energy management in wastewater treatment, 1703–1708
energy audit recommendations (T), 1707
energy impacts of new technologies (T), 1707
equipment requiring electric energy (T), 1706
measures for improving energy efficiency, 1706
overview of energy use, 1704
Energy reactions in biological systems:
description of, 571–578
half-reactions (T), 572–573
Energy requirements:
for activated sludge mixing, 448
for aerobic digester mixing, 1538
for anaerobic digester mixing (T), 1519
for anoxic reactor mixing, 753
for blowers, 440
for flow equalization basins, 344
for mixing and flocculation:
paddle mixers, 357
pneumatic mixing, 360
propeller and turbine mixers, 354
static mixing, 351
in wastewater treatment, 1704
Enteric viruses, 126–128
Enumeration and identification of bacteria, 118
direct counts, 118
identification of specific bacteria and protozoa, 124
heterotrophic plate count, 124
membrane-filter technique, 119
multiple-tube fermentation, 121
pour and spread plate method, 119
presence-absence test, 124
Enumeration and identification of viruses, 126
bacteriophage, 128
enteric viruses, 126
Environmental factors:
in aerobic biological oxidation, 610
in anaerobic fermentation and oxidation, 635
in biological denitrification, 623
in biological nitrification, 615
in biological phosphorus removal, 629
Epidemiological studies, sensitivity of, 1368
Equalization, flow, 333–344
(See also Flow equalization)
Equilibrium constants:
for ammonia (T), 995
for carbonate (T), 1755
for hydrogen sulfide (T), 995
Escherichia coli (*E. coli*):
infection by bacteriophage, 118
infection by virus, 128
occurrence of, 116
use as indicator organism, 116
(See also Coliform organisms)
Eukaryotic cell:
characteristics of, 106
place in phylogenetic tree of life, 561
structure of, 106
Eutrophication, 611
Exfiltration from collection systems, 167
Expanded (fluidized) bed reactor:
application for:
for anaerobic treatment, 1020
BOD and nitrfication, 961
for postanoxic denitrification, 967
description of, 219, 220
Explosion hazards, 1585
Extended-aeration activated sludge, 739
(See also Activated sludge)
Extractive membrane bioreactor (EMBR), 1128

F curve:
definition of, 238, 239
determination of, 240
Facilities plan for water reuse, 1437
Facultative processes, 550
Fate processes:
description of (T), 262
typical rate expressions for (T), 264
Fats in wastewater, 98
FBBR (see Fluidized bed bioreactors)
Fecal coliforms:
concentrations found in wastewater, 111
disinfection of:
model coefficients, 1230
survival of as a function of $C_R t$ value, 1250
enumeration of, 118–123
importance in disinfection, 1219
sources of, 116
use as indicator organism, 115, 116
Feedback control, 1684
integral control, 1686
on-off control, 1684
proportional-derivative control, 1687
proportional control, 1684
proportional-integral control, 1686
Feeders, chemical, 533
characteristics of (T), 537
type of:
dry, 533
gas, 537
liquid, 536
Feed-forward and feedback control, 1687
Feed-forward control, 1683
Fermentation in anaerobic oxidation, 630

Fermentation reactors for phosphorus removal, 805
Ferric chloride:
precipitation of wastewater with, 496, 497
properties of, 494
Ferric sulfate:
precipitation of wastewater with, 497
properties of, 494
Ferrous sulfate:
precipitation of wastewater with, 495
properties of, 494
Fertilizer:
value of biosolids, 1454
value of commercial products, 1454
Filamentous organisms:
in activated sludge (T), 697
in causing bulking sludge, 695
effects of selectors on, 700
examples of, 696
prevention and control of, 697
(See also Bulking sludge)
Filter presses for sludge dewatering, recessed plate, 1568–1570
advantages and disadvantages of, 1568
design considerations, 1570
types of:
fixed-volume, 1568
variable-volume, 1568
typical performance data, 1593, 1594
Filtering materials (see Filtration, depth)
Filters:
depth (see Filtration, depth)
surface (see Filtration, surface)
trickling, 890–930
(See also Trickling filters)
Filtration, depth, 1044–1098
analysis of filtration process, 1057–1068
equation of continuity, 1057
generalized rate equation, 1061
headloss development, 1061
rate equation, 1059
available filtration technologies, 1069–1078
comparison of filter technologies (T), 1069
conventional downflow filters, 1070
deep-bed downflow filters, 1071
deep-bed upflow continuous backwash filters, 1072
pulsed bed filters, 1074
synthetic medium filters, 1077
traveling bridge filters, 1075
two-stage filtration, 1078
description of filtration process, 1044–1050
the backwash process, 1047
filter medium characteristics, 1045
the filtration process, 1047
particle removal mechanisms, 1047, (T) 1048
physical features of a depth filter, 1045
design variables for depth filters (T), 1085
effluent filtration with chemical addition, 1095
effects of chemical characteristics of wastewater on alum addition, 1096
use of organic polymers, 1095
filter appurtenances, 1093
surface washers, 1093
underdrain systems, 1093
washwater troughs, 1093
filter backwashing systems, 1091
air and water backwash flowrates (T), 1092
combined air-water backwash, 1091
water backwash with auxiliary air scour, 1091
water backwash with auxiliary surface wash, 1091
filter-bed characteristics, 1084
design data for:
mono-medium filters (T), 1086
multi-medium filters (T), 1087
filter-bed configuration, 1084
properties of filter materials (T), 1088
selection of filter-medium, 1084
filter flowrate control, 1089
constant rate filtration with fixed head, 1089
constant rate filtration with variable head, 1089
variable rate filtration with fixed or variable head, 1089
filter hydraulics, 1050–1057
backwash hydraulics, 1054
clean-water headloss, 1050
formulas for clean-water headloss (T), 1051
filter instrumentation and control systems, 1093
filter problems, 1096, (T) 1097
importance of influent wastewater characteristics, 1081
floc strength, 1081
particle size and distribution, 1081
suspended solids/turbidity, 1081
need for pilot-plant studies, 1096, 1098
performance of different types of filter technologies:
removal of particle size, 1079
removal of total suspended solids, 1079
removal of turbidity, 1079
selection of filtration technology, 1081
backwash-water requirements, 1084
filtration driving force, 1082
filtration rate, 1082
number and size of filter units, 1083
type of filter: proprietary or individually designed, 1081
two-stage, 1078
Filtration, surface, 1098–1104
cloth-media disk filter (CMDF), 1100
backwashing of, 1102
design information for CMDF (T), 1102
operation of, 1102
performance characteristics, 1103
disc filter (DF), 1100
backwashing of, 1100
design information for DF (T), 1101
operation of, 1099
Filtration, two stage, 1078
Financing for water reuse projects, 1435
Fine screens, 322–326
description of (T), 323
headloss through, 326

Fine screens—*Cont.*
screenings, 328
compactor for, 330
disposal of, 329
quantities of, 329
screens for combined sewer overflows:
horizontal reciprocating, 324
tangential, 326
screens for preliminary and primary treatment:
rotary drum, 322
static, 322
step, 322
typical removal of BOD and TSS (T), 323
Fire hazards, 1585
First flush effect, 191
First-order reaction:
definition of, 260
examples of, 260
FISH (see Fluorescence in situ hybridization)
Fish:
typical setup for effluent toxicity tests, 131
used in bioassay tests, 133
Fixed film processes (see Attached growth treatment processes)
Fixed screen, inclined, 325
Fixed solids:
suspended, 43, 44, 45
total, 43, 44, 45
Flash dryers, 1580
(See also Heat drying)
Floating digester covers, 1524
Flocculent, definition of, 479
Flocculent particle settling, 372–374
Flocculation:
ballasted, 415
design information (T), 346
energy dissipation, 347–350
function, 345
macroflocculation (orthokinetic), 346, 479
microfloculation (perikinetic), 345, 479
types of mixers used in, 355–359
typical detention times and velocity gradient values (T), 348
Flotation, 419–424
air, 419
applications, 419
chemical additives, 422
description of, 418–422
dispersed-air, 421
dissolved-air:
air-to-solids ratio, 422
design considerations, 422
design example, 423–424
recycle flow, 421
solids loading information, 1496
of industrial wastewater, 421
of sludge, 1494
test apparatus for, 422
of untreated wastewater, 419
Flotation thickening of sludge:
capture values (T), 1593
description of, 1494
performance of, 1593
polymer dosage, 1495
return flow concentrations (T), 1594
typical solids loading (T), 1496
Flow deflection vanes, use of, 1275
Flow equalization, 333–344
description and application, 333
design considerations:
basin configuration and construction, 342–344
basin geometry, 342
in-line vs. off-line, 335
locations of, in wastewater treatment, 334, 335
mixing and air requirements, 344
volume requirements for, 335
process flow diagram for wastewater treatment with flow equalization, 334
Flow measurement devices:
for closed conduits (T), 1695
for open channels (T), 1695
Flow models, hydraulic for combined sewer systems, 170
Flowrates, 154–170
(See also Wastewater sources and flowrates)
Flow reduction, devices and appliances (T), 161
Fluid classification:
Newtonian, 1477
Non-Newtonian, 1478
Fluidized-bed bioreactor (FBBR):
application for:
for anaerobic treatment, 1020
BOD and nitrification, 961
for postanoxic denitrification, 967–969
description of, 219, 220
Fluidized-bed incineration, 1590–1592
description of:
bubbling bed, 1590
circulating bed, 1591
operating temperature, 1590
recycle flows, 1591
Fluorescence in situ hybridization (FISH), 561, 562
Fluorometer, use of for tracer studies, 232
Flux, 1105
Foaming:
in aeration tanks, 699, 819
in anaerobic digesters, 1517
in autothermal aerobic digesters (ATAD), 1543
Food-to-microorganism ratio:
application of, 680
typical values for activated-sludge processes (T), 747
Forest land biosolids application, 1618
Fouling:
in aeration, 430
in cooling towers, 1417
indexes for membrane processes, 1119–1121
in membranes, 1117
Fouling factors in oxygen transfer, 438
Fractionating of wastewater samples to identify particulate and soluble fractions:
COD, 94, 668
nitrogen, 61, 670
to identify total suspended solids, 43, 44
to identify toxicity components (T), 138, 139
Free vortex, 383
Freeze/thaw for sludge conditioning, 1557
Freundlich adsorption isotherm, 294, 1141–1143
Freundlich isotherm constants for selected organic compounds (T), 1143
Friction factors, Moody diagrams for, 1757
Froth-control systems for activated sludge process, 818
Fundamentals biological treatment, of, 547–644
(See also Biological treatment, fundamentals of)

Fungi:
in activated sludge (see Activated sludge)
description of, 107
in trickling filters, 892

G (velocity gradient):
definition of, 348
typical values for mixing and flocculation (T), 348
GAC (see Granular activated carbon)
Garbage grinders (effects on wastewater composition) (T), 182
Garnet:
sizes used in depth filters, 1087
properties of, 1088
Gas, digester, 1523–1525
(See also Digester gas)
Gases, 64
composition of dry air (T), 1737
dissolved oxygen, 69
Henry's law for dissolved gases, 66
hydrogen sulfide, 70
the ideal gas law, 65
methane, 70
physical properties of selected gases (T), 1737
solubility of gases in water, 65
unitless form of Henry's law, 69
Gas stripping, 1162–1180
air requirements for ammonia stripping, 1168
analysis of, 1163
characteristics of compounds to be stripped, 1163
mass balance analysis, 1163
mass balance multistage stripping tower, 1170
methods used to contact phases, 1163
application of:
removal of ammonia, 1178
removal of ammonia from centrate by steam stripping, 1179
design parameters for (T), 1175
design of stripping towers, 1174–1178
height of stripping towers, 1173
height of transfer unit (HTU), 1173
number of transfer of transfer units (NTU), 1173
mass balance analysis:
for continuous tower, 1163
for multistage tower, 1170
process flow diagrams for:
air stripping of ammonia from wastewater, 1179
steam stripping of ammonia from centrate, 1180
towers for:
typical air flow patterns in, 1164
typical schematic for, 1164
for VOC removal, 456
Gas (oxygen) transfer:
analysis of, 425–430
description of, 425
evaluation of aerator performance, 446
factors affecting oxygen transfer:
application of correction factors 429, 430
mixing intensity, 429
tank geometry, 429
temperature, 427
wastewater characteristics, 429
Henry's law:
constants for (T), 67
definition of, 66
temperature correction for, 67, 68
unitless form of, 69
oxygen transfer coefficient:
in clean water, 425
in wastewater, 426
oxygen transfer devices:
diffused air, 430–443
mechanical aerators, 443–447
two-film theory, 285
volumetric mass transfer coefficient, $K_L a$:
application, 288–292
development, 285–288
Giardia lamblia, 11, 111–112
life cycle, 112
size of, 112
Granular activated carbon (GAC), 1138
(See also Adsorption)
Granular medium filtration, 1044–1098
(See also Filtration, depth)
Graphical analysis for:
adsorption isotherms, 294
number of stages in stripping tower, 1170
reactors in series, 272
for selection of mean design value, 1641
Gravity belt thickening of sludge:
capture values (T), 1593
description of, 1497
hydraulic loading rates (T), 1498
performance of (T), 1593
Gravity filtration, 1070–1071
(See also Filtration, depth)
Gravity separation, theory of, 361–384
compression settling, 383
description of, 362
detention time, 368
discrete particle settling, 367–372
column settling test, 368
definition sketch for, 369
removal efficiency, 370
terminal velocity, 367
flocculent particle settling, 372–374
analysis of settling column data, 372
definition sketch for, 369
removal efficiency, 373
gravity separation in an accelerated flow field, 383–384
hindered (zone) settling, 378–383
area requirement based on single-batch test results, 379
area requirement based on solids flux analysis, 382
definition sketch, 379
description of, 378
(See also Solids separation)
inclined plate and tube settling, 374–378
cocurrent settling, 378
countercurrent settling, 376
cross-flow settling, 378
definition sketch, 375
description of, 374
lamella settler, 377
particle settling theory, 363–367
drag coefficient, 364
Newton's law, 363
Reynolds number, 363
settling in laminar region, 364
settling in transition region, 365
settling in turbulent region, 366
shape factor, 364
types of gravitational phenomena (T), 362

Gravity thickening of sludge, 1491–1494
application of, 1491
capture values (T), 1593
description of, 1491
performance of, 1593
return flow concentrations (T), 1594
solids loadings (T), 1492
typical solids concentrations (T), 1492
Grease:
accumulation in sludge piping, 1482
content of sludge, 1454
forms of, 98
importance of, removal of, 98
typical values, in wastewater, 186
Grinders:
in-line sludge, 1482
for screenings, 333
Grit:
characteristics of, 394
definition of, 394
disposal of, 395
quantity of (T), 395
separation and washing, 395
Grit chambers:
aerated, 386–392
design information (T), 389
flow pattern, 390
grit removal equipment, 388
release of VOCs, 389
horizontal flow, 386
design information, 387
rectangular, 386
settling area curves, 388
square, 386
location of, 384
traveling bridge, 388
types of, 385–392
vortex, 392
design information for (T), 394
types of, 392
Grit removal, 384–396
Grit separator, 384
Grit washer, 395
Groundwater recharge with reclaimed water, 1422–1429
fate of contaminants in groundwater, 1427
dissolved inorganic and organic contaminants, 1427
particulate contaminants, 1427
pathogen removal, 1428
groundwater recharge guidelines, 1429
groundwater recharge methods, 1423
by direct injection, 1425
by surface spreading, 1423
pretreatment requirements for groundwater recharge
Growth coefficients (see Kinetic coefficients for bacterial growth; Kinetics of microbial growth)
Growth kinetics, biological, 580–588 (See also Kinetics of microbial growth)
Growth rate, specific, 582
Guide vanes for chlorine contact basins, 1275

Half reactions:
for biological systems (T), 572–573
for chemical disinfectants (T), 518
for selected oxidation reduction reactions (T), 519
Half velocity constant, 582
Haloacetic acids (HAAs), 1255, 1256
Handling and storage of chemicals (T), 534
Headloss:
in air piping, 441–443
through coarse screens (bar racks), 320
through comminutors, 333
in depth filtration:
clean water, 1050–1054
wastewater, 1061–1068
through fine screens, 326
in sludge pumping, 1475–1481
through static mixers, 351
through submerged baffles, 1273
through surface filters, 1100, 1102
Health and environmental effects:
air quality, 9
constituents of concern, 8
environmental issues, 1358
future concerns, 1634
public health issues, 1358
water quality issues, 7
in water reuse, 1358
Heat drying of sludge
air-pollution and odor control, 1585
direct dryers:
flash dryer, 1580
fluidized-bed, 1582
rotary dryer, 1581
heat transfer methods:
conduction, 1579
convection, 1579
radiation, 1580
indirect dryers:
horizontal, 1583
vertical, 1584
prevention measures for dust hazards (T), 1586
product characteristics, 1584
product transfer and storage, 1585
Heat treatment of sludge, 1557
Heating, digester:
analysis of heat requirements, 1525
heating equipment, 1529
heat loss computations, 1527–1529
heat transfer coefficients (T), 1526
Heating value of sludge and biosolids (T), 1586,
Heavy metals:
effluent discharge limits, 78, 80
importance of, 77, 78
removal of:
by chemical precipitation, 514–517
by ion exchange, 1194
reverse osmosis, 1123
sampling and methods of analysis, 77
sources of, 77
Hedstrom number, 1478
Helminths (worms):
description of, 113
diseases caused by, 113
Henry's law:
application of:
for dissolved gases, 66–69
for gas-liquid mass transfer, 286
constants for:
carbon dioxide (T), 1753
ozone (T), 1288
various gases (T), 461
definition of, 66
unitless form of, 69
Herbicides, 101
Heterotrophic organisms, 564
Heterotrophic plate count (HPC), 124
High-purity oxygen:
activated sludge, 743
aerobic digestion, 1545–1546

dissolution of:
commercial oxygen, 450
by conventional diffused aeration, 452
dissolution time, 450
by Speece cone, 451
by U-tube contactor, 451
generation of:
by cryogenic air separation, 450
by pressure-swing adsorption, 448
process flow diagram for, 449
High-rate aeration activated sludge, 741
(See also Activated sludge)
High rate clarification, 411–417
application of, 414
ballasted flocculation, 415
dense-sludge process, 417
lamella plate clarification, 417
process features (T), 415
process flow diagrams for, 416
process performance (T), 415
Hindered settling, 378–383
Hollow fiber membrane, 1108
Horizontal reciprocating screen, 324
HPC (see Heterotrophic plate count)
Human and veterinary antibiotics (T), 102
Human immunodeficiency virus (HIV), 114
Human prescription and nonprescription drugs (T), 103
Hydraulic retention time (τ):
definition of, 222
typical values for:
commonly used activated sludge processes, 747
commonly used biological phosphorus removal processes, 814
commonly used nitrogen removal processes, 797
Hydraulics, filter, 1050–1057
clean water headloss, 1050
filter backwashing, 1054
formulas for clean-water headloss (T), 1051
Hydrogen ion concentration (pH), 57
Hydrogen peroxide:
oxidation processes:
with acetate, 1296
with ozone, 1199, 1297
with UV, 1199
oxidizing potential of, 1197
Hydrogen sulfide:
characteristics of, 70
distribution as a function of pH, 996
equilibrium reactions in water, 995
odor problems, 72
production in anaerobic treatment, 994
removal by biological means:
biofilters, 1665
biotrickling filters, 1666
removal with chemicals:
hydrogen peroxide, 1663
potassium permanganate, 1662
sodium hypochlorite, 1662
solubility in water, 67
Hydrolysis products, formation of, 487
Hydroxylapatite, formation of, 501
Hypochlorite:
application methods of, 12
disinfection, 1268
odor control, 1662, 1664
applications for:
disinfection, 1233
odor control, 1662
forms of:
calcium, 1234
sodium, 1233
germicidal efficiency of, 1243
ionization constant, 1235
reactions in water, 1235
Hypochlorite compounds:
calcium, 1234
sodium, 1235
Hypochlorous acid:
ionization constants (T), 1234

(I/I) (see Infiltration/inflow)
Ideal gas law:
definition of, 65
universal gas constant, values of, inside back cover
Ilmenite, properties of, 1088
Imhoff cone:
example of, 45
use of, 42, 44
Imperforate basket centrifuge, 1559
Incineration:
advantages of, 1586
catalytic, 466
coincineration with municipal solid waste, 1592
combustion calculations, 1587–1588
fluidized-bed, 1590–1592
heating values of sludge and biosolids (T), 1588
multiple hearth, 1588–1590
(See also individual listings)
Inclined plate and tube settling, 374–378
cocurrent settling, 378
countercurrent settling, 376
crossflow settling, 378
description of, 374
lamella plate settler, 377
Inclined screen, 323, 325
Indicator organisms, use of, 115
bacterial indicators, 115
characteristics of an ideal indicator organism, 115
of human contamination, 115
other indicator organisms, 118
proposed as indicators of fecal contamination (T), 116
proposed for various water uses (T), 117
Indirect potable reuse of wastewater:
definition of, 1348
planned systems, 1432
Industrial and household wastewater products (T), 103
Industrial wastewater:
typical flowrate design values, 162
variations in composition, 188
variations in flowrates, 180
Industrial water reuse, 1412–1422
common water quality problems in cooling tower systems, 1416
biological growth, 1417
fouling, 1417
metallic corrosion, 1416
scaling, 1416
cooling tower makeup water, 1413
industrial water withdrawals, 1413
water and salt balances in cooling tower, 1414
cycles of concentration, 1416
salt balance, 1415
water balance, 1415
water quality requirements, 1419
for cooling and heat exchangers (T), 1419
for steam generation (T), 1419
Infectious agents in wastewater, 110
Infiltration:
computation of, 165
definition, 163
sources of, 165

Infiltration/inflow (I/I):
computation of, 165
definition of, 163
effects on peak flowrates, 205
Inflow:
computation of, 165
definition of terms, 163
Initial mixing:
in chlorination, 1270
importance of, 540
mixing chamber, 356
timescale in mixing, 350
types of mixers, 350–355
typical diffusers and injector mixers, 1270, 1271
typical mixing times (T), 346
Injection, chlorine, methods of, 1271
Inlets, clarifier:
design of, 838
energy dissipating, 839
flow splitting, 837
Inorganic compounds in anaerobic digestion:
toxic and inhibitory concentration values (T), 991
Inorganic metallic constituents, 77–80
importance of metals, 77, (T) 78
sampling and methods of analysis, 77
sources of metals, 77, (T) 79
threshold of inhibitory effects of (T), 78
typical effluent discharge limits for metals (T), 80
Inorganic nonmetallic constituents, 57–76
alkalinity, 59
chlorides, 59
gases, 64
nitrogen, 60
odors, 70–76
pH, 57
phosphorus, 63
sulfur, 64
(See also individual listings)
In-vessel composting systems:
dynamic, 1551
plug flow, 1550
Ion exchange, 1180–1196
applications for, 1189
removal of ammonia, 1189
removal of dissolved solids, 1195
removal of hardness, 1195
removal of heavy metals, 1194
removal of nitrate, 1189
in wastewater reuse, 1382
chemistry of:
equilibrium reactions, 1185
selectivity coefficients, 1185
selectivity scale for anions (T), 1187
selectivity scale for cations (T), 1187
exchange resins, 1181
classification of (T), 1182
exchange capacity, 1183
operational considerations, 1196
process flow diagrams for:
ammonia removal by zeolite exchange, 1189
demineralization and removal of hardness by ion exchange, 1195
typical reactions for:
natural zeolites, 1182
synthetic resins, 1183
Ionic strength:
computation of, 41
definition of, 40
Iron as a nutrient, 78
Irrigation, 1353, 1401–1412
(See also Agricultural and landscape irrigation)
Isomorphous replacement, 481
Isotherms, adsorption, 1141–1145
development of, 1141
Freundlich, 1141–1143
Langmuir, 1144

Jet aerator, 435, 437 (T)
Jet mixing, 352

Kessener brush aerator, 445, 446
Kinematic viscosity of water:
definition of, 1741
values of:
in SI units (T), 1742
in US customary units (T), 1743
Kinetic coefficients for bacterial growth:
for anaerobic digestion (T), 1000
for ASM1 model (T), 864
for denitrification (T), 756
for heterotrophic bacteria (T), 704
for methanol as a growth substrate (T), 785
for nitrification (T), 705
Kinetics of:
adsorption (carbon), 1146
anaerobic suspended growth processes, 999
biochemical oxygen demand test, 85
biological treatment (see Kinetics of biological treatment)
disinfection, 1224, 1225
gas absorption transfer, 288, 290
gas desorption, 291
microbial growth (see Kinetics of microbial growth)
oxygen transfer, 426
VOC removal, 459
wastewater disinfection with chlorine, 1249
(See also Activated sludge, kinetic analysis of process)
Kinetics of biological treatment, theory of:
attached growth processes, 602–607
suspended growth processes, 588–602
Kinetics of microbial growth, 580–588
effects of temperature, 585
kinetic coefficients for substrate utilization and biomass growth, 584
microbial growth kinetics terminology, 581
net biomass yield and observed yield, 587
organic matter, 583
other rate expressions for the utilization of soluble substrate, 582
rate of biomass growth with soluble substrates, 584
rate of oxygen uptake, 585
rate of soluble substrate production from biodegradable particulate
rate of utilization of soluble substrates, 581
total volatile suspended solids and active biomass, 586
Kjeldahl nitrogen, total:
definition of, 60, 61
typical values in wastewater, 186
Kolmorgoroff microscale length, 349
Kraus process activated sludge, 743
(See also Activated sludge)

Laboratory studies:
bench scale tests, 301
for activated carbon, 1156
for flotation, 422
for sludge filterability, 1555
Lag growth phase, bacterial, 566
Lagoons:
aerated, 840–854
(See also Aerated lagoons)
for biosolids drying, 1578–1579
for biosolids storage, 1622
covered anaerobic, 1024–1026
dual powered flow through lagoon system, 853
Lamella plate clarification, 417
Land application of biosolids, 1608–1621
application methods:
for dewatered biosolids, 1619
for liquid biosolids, 1617
application to dedicated land, 1619
Class A and Class B biosolids, definition of, 4
dedicated land disposal, criteria for (T), 1620
definition of, 1461
design loading rates:
land requirements, 1615
for metals (T), 1616
for nitrogen, 1614
for pollutants, 1614
exceptional quality, definition of, 1613
management practices (T), 1612
metals concentrations and loading rates (T), 1616
nitrogen uptake for selected crops (T), 1615
nutrient levels:
in commercial fertilizers (T), 1454
in stabilized wastewater biosolids (T), 1454
pathogen reduction, 1461, 1611
pathogen reduction alternatives (T), 1462
regulated pollutants for, 1609
regulatory requirements, U.S. EPA (T), 1611
setback distances (T), 1611
site evaluation and selection, 1609
site restrictions, Class B biosolids (T), 1613
slope limitations (T), 1610
surface disposal, 1461
typical metal content in wastewater solids (T), 1455
vector attraction reduction, 1461, 1612
vector attraction reduction options (T), 1463
Langelier saturation index (LSI):
(See also Ryzner Index)
application of, 529
computation of, 529
definition of, 528
Langmuir adsorption isotherm, 1144
LAS (see Linear-alkyl-sulfonate)
Leaching fraction:
definition of, 1404
relationship to percolating water, 1405
Legionella pneumophilia, 130
Level measurement, liquid (T), 1696
Levels of wastewater treatment (T), 11
Lewis-Whitman two-film theory, 285
(See also Gas transfer)
Ligand, 487
Lime:
addition:
for air stripping, 501
for chemical precipitation, 495
with ferric chloride, 497
with ferric sulfate, 497
with ferrous sulfate, 495
phosphate precipitation, 501
for sludge conditioning, 1555
for sludge stabilization (T), 1503
characteristics of, 494
dosages for untreated wastewater, 501
(See also Calcium hydroxide)
Lime stabilization:
chemical reactions, 1500
heat generation, 1502
lime posttreatment, 1503
lime pretreatment, 1502
temperature increase using quicklime, 1504
typical dosages for pretreatment (T), 1503
Linear-alkyl-sulfonate, 99
Liquid level measurement (T), 1696
Loading criteria:
for activated carbon contactors for wastewater treatment, 1152
for activated sludge process:
for BOD removal (T), 747
for nitrogen removal (T), 797
for phosphorus removal (T), 814
for aerobic digesters (T), 1536
for anaerobic digesters (T), 1513
for anaerobic suspended growth processes (T), 998
for attached growth processes:
rotating biological contactors (T), 933
trickling filters (T), 909
for autothermal aerobic digestion (ATAD) (T), 1545
for combined aerobic treatment processes:
for ABF and BF/AS processes (T), 944
for series trickling filter-activated sludge process (T), 945
for TF/SC and RF/AS processes (T), 942
for dissolved air flotation units (T), 1496
for gravity belt thickeners (T), 1498
for gravity thickeners (T), 1492
for land application of biosolids, 1613–1617
for membrane separation technologies (T), 1124
for microscreens (T), 328
for moving bed biofilm reactor (MBBR) (T), 955
for primary sedimentation tanks (T), 398
for secondary clarifiers (T), 687
for sedimentation tanks for chemical treatment (T), 497
for sludge drying beds:
open sludge beds (T), 1572
vacuum assisted beds (T), 1577
for stripping towers for removal of VOC and ammonia (T), 1175
for surface filtration with a Cloth-Media Disk Filter® (T), 1102
for surface filtration with a Discfilter® (T), 1100
for UASB reactors (T), 1008, 1009

Loading data for treatment plants, analysis of, 181–197
calculation of mass loadings, 194
flow-weighted average, 192
sustained peak mass loadings, 181
typical mass loading factors (T), 199
variations in constituent concentrations, 185
wastewater constituent concentrations, 181
LOEC (see Lowest observable effect concentration)
Log-mean temperature, 902
Log-normal distribution, 171
Lowest observable adverse effect level (LOAEL), 1372
Lowest observable effect concentration (LOEC), 132
LSI (Langelier saturation index), 528–529

Macerators, 332
Macroflocculation (orthokinetic), 346, 479
Mass balance analysis:
application of, for:
cooling towers, 1415
determining of solids quantities, 1592–1608
gas stripping, 1163, 1171
reactor analysis, 222–226
removal of VOCs, 459
return sludge pumping, 691–692
mass balance principle, 222
control volume for, 223
system boundary for, 223
preparation of, 224
steady-state simplification, 225
Mass loadings, 194–197
curves for BOD, SS, nitrogen, and phosphorus, 195
definition of, 194
effect on treatment performance, 197
typical mass loading factors (T), 199
Mass transfer:
in aeration, 285,
coefficient for gas transfer, 457
definition of, 283
rates VOCs, 457
Mass transfer processes:
application of (T), 283
basic principles of, 283
gas-liquid mass transfer, 284
absorption of gases, 288
absorption of gases under quiescent conditions, 290
desorption (removal) of gases, 291
two-film theory of gas transfer, 284
liquid-solid mass transfer, 293
adsorption, 293–296, 1138–1162
ion exchange, 296, 1180–1196
principal applications of (T), 283
Mass transfer zone (MTZ), 1146
Materials balance equations, 223–225
(See also Mass balance analysis)
MBR (see Membrane bioreactor)
MBAS (see Methylene blue active substances)
MCRT
(Old term, see Solids retention time or SRT)
MDI (see Morrill dispersion index)
MDTOC (see Minimum detectable threshold odor concentration)
Mean cell residence time (MCRT):
(old term see Solid retention time, SRT)
Measurement methods for wastewater characterization, 671–674
nitrogen compounds, 673
nonbiodegradable volatile suspended solids, 672
readily biodegradable COD, 671
Measurement of organic content of wastewater, 31, 80–99, 99–104
Mechanical aerators, 443–447
alpha factors (T), 447
disk aerator, 446
energy requirement for mixing, 448
with horizontal axis, 445
Kessener brush, 446
oxygen solubility correction factor, 447
oxygen transfer rate (T), 446
performance correction for field conditions, 447
submerged with vertical axis, 444
surface aerators with vertical axis, 443
tank dimensions for surface aerators (T), 448
Mechanical dewatering (see Sludge and biosolids dewatering)
Mechanically cleaned bar screens, 317–319
(See also Coarse screens)
Membrane aeration bioreactor (MABR), 1128
Membrane biological reactor (MBR), 854–859, 1126–1128
fouling control, 857
general description of, 854
process capabilities, 858
process description:
integrated system, 855
recirculated type, 856
typical operational and performance data (T), 858, 1128
Membrane bioreactor, extractive (EMBR), 1128, 1129
Membrane filter technique,
for microorganisms, 119, 120,
for total suspended solids, 43, 44, 49
Membrane filtration processes, 1104–1137
advantages and disadvantages of (T), 1125
application of membranes, 1121
applications in wastewater treatment (T), 1123
for removal of specific constituents (T), 1123
general characteristics of membrane processes (T), 1106
disposal options for concentrate brines, 1135 (T), 1136
electrodialysis,
application of, 1133
operating parameters for (T), 1134
process flow diagram for, 1134
theory of, 1131
energy consumption and product recovery (T), 1125
membrane configurations:
hollow fiber, 1108
plate and frame, 1111
pleated-cartridge filters, 1111
pressure vessels, 1111
spiral wound, 1108
tubular modules, 1108
membrane fouling, 1117
assessing need for pretreatment for NF and RO, 1119
caused by buildup of solids, 1117
control of membrane fouling, 1118

constituents affecting (T), 1118
fouling index values (T), 1120
pretreatment for nanofiltration and reverse osmosis, 1119
membrane operation, 1111
microfiltration and ultrafiltration, 1111
reverse osmosis, 1114
membrane performance:
microfiltration performance summary (T), 1127
reverse osmosis performance summary (T), 1130
operating characteristics of membrane technologies (T), 1124
pilot studies for membrane application, 1134
membrane operating parameters, 1135
water quality measurements, 1135, 1136
process classification, 1104
driving force, 1107
membrane materials, 1106
removal mechanisms, 1107
size of separation, 1107
process flow diagrams for:
electrodialysis membrane process, 1134
extractive membrane bioreactor, 1129
membrane aeration bioreactor, 1129
membrane bioreactor, 1127
membranes for advanced wastewater treatment, 1126
reverse osmosis membrane process, 1115
process terminology, 1104, (T) 1105
stabilization of reverse osmosis product water, 532
Membrane separation anaerobic treatment process, 1026–1027
description of, 1026
summary of operating conditions (T), 1027
Mercaptans:
characteristics of, 72
formation of, 70
Mesophilic anaerobic digestion, 1507–1516
[See also Anaerobic sludge digestion (mesophilic)]
Mesophilic organisms, 559
Metabolism:
fermentative, 564
respiratory, 564
Metals, heavy:
classified as priority pollutants (T), 79
effluent discharge limits, 78, 80
importance of, 77, 78
removal of:
by chemical precipitation, 514–517
by ion exchange, 1194
reverse osmosis, 1123
sampling and methods of analysis, 77
sources of, 77
Methane:
description of, 70
in digester gas, 1523
Henry's constants and temperature coefficients for (T), 67
production of in anaerobic treatment, 992, 1510, 1523
uses, 1525
(See also Digester gas)
Methanogenesis, 630
Methanol:
kinetic coefficients for as a growth substrate (T), 785
use in attached growth denitrification, 962, 963 (T)
use in suspended growth denitrification, 784
Methyl tertiary butyl ether (MTBE), 8
Methylene blue active substances (MBAS), 31, 99
Metric (SI) conversion factors to U.S. customary units, 1731
MFI (see Modified fouling index)
Microbial growth, kinetics of 580–588
(See also Kinetics of microbial growth)
Microfiltration:
applications of, in wastewater reclamation, 1122
energy consumption (T), 1125
general characteristics of (T), 1106
operating characteristics (T), 1124
operating size range, 1108
(See also Membrane filtration processes)
Microfloculation (perikinetic), 345, 479
Micrograph:
of *E. coli*, 117
of filters used for TSS test, 45
Microorganisms:
bacteria:
description of, 107, 109–111
enumeration and identification of, 118–126
bacterial growth and energetics, 565–580
classification:
comparison of prokaryote and eukaryote cells (T), 106
eukaryote, 105
prokaryote, 105
composition of, 555–558
bacterial cells (T), 558
cell components, 555
cell composition, 557
environmental factors, 558
concentrations in untreated wastewater (T), 111
descriptions of (T), 107
identification and classification of, 559
phylogenetic, 560
phylogenetic tree of life, 561
taxonomic, 559
indicator organisms, 115–118
bacterial indicators, 115
of fecal contamination (T), 116
other indicators, 118
used for establishing performance criteria (T), 117
microbial metabolism, 563–565
nutrient and growth factor requirements, 565
sources of energy and carbon, 563
molecular tools, 561
new and emerging, 130
pathogenic, 109–115
bacteria, 109
detection of, 129
helminths, 113
life cycle of *Cryptosporidium parvum* and *Giardia lamblia*, 112
present in untreated wastewater (T), 110
protozoa, 111
typical survival times (T), 114
viruses, 114
polymerase chain reaction (PCR), 129
regrowth, 1258

Microorganisms—*Cont.*
shapes, sizes, and resistant forms of (T), 108
temperature ranges (T), 559
viruses:
description of, 107, 114
enumeration and identification of, 126–129
Microsand ballasted floc particle, 412
Microscreens, 326–328
description of, 326
functional design of, 327
typical design information (T), 328
Mineral increase due to water use, 187
Minerals required for bacterial growth, 78
Minimum detectable threshold odor concentration (MDTOC), 72, 73
Mixed-liquor suspended solids (MLSS), 581
Mixed-liquor volatile suspended solids (MLVSS), 581
Mixed-medium filtration (see Filtration, depth)
Mixers:
design parameters for:
flocculators (T), 359
mixing operations (T), 356
power requirements for, 360–361
types of:
for anoxic reactors, 360
for continuous mixing, 359–361
for flocculation, 355–359
for rapid mixing, 350
types of mixing impellers (T), 353
Mixing, 344–361
application:
in activated-sludge aeration tanks, 448
in aerated lagoons, 845
in aerobic digesters, 1538
in anaerobic digesters, 1516–1522
in anoxic reactors, 360, 753
in chemical conditioning of sludge, 1556
in chemical treatment, 540
in chlorination, 1270
in flocculation, 345, 346, 357
in flow equalization basins, 344
in mixing and blending (T), 346
continuous, 345
continuous rapid, 345
detention times:
for flocculation, 346
for mixing, 346
energy dissipation, 347
importance of, 345
Kolmogoroff microscale length, 349
methods of, 345, 346
new developments in, 361
power number, 354
power requirements for:
mechanical aerators, 361
paddle mixers, 357
pneumatic mixing, 360
propeller and turbine mixers, 359
pumping number, 354
time scale for chemical mixing (T), 540
types of:
for continuous mixing, 359–361
for flocculation, 355–359
for rapid mixing, 350–355
velocity gradients (G):
for flocculation, 348
for mixing, 348
vortexing in, 355
Mixing times:
importance of, 540
typical values for, 346, 540
MLSS (see Mixed-liquor suspended solids)
MLVSS (see Mixed-liquor volatile suspended solids)
Modeling hydraulic flow in reactors:
ideal flow in reactors, 225–229
complete-mix, 226
hydraulic characteristics of, 220, 221
plug-flow, 227
nonideal flow using dispersion, 245–256
complete-mix reactors in series, 252–256
molecular diffusion, turbulent diffusion, and dispersion, 245
plug-flow with axial dispersion, 246–252
typical dispersion values for treatment facilities (T), 250
typical range of diffusion and dispersion values (T), 246
nonideal flow using tracers, 229–245
analysis of tracer response curves, 233–242
factors leading to nonideal flow, 229–245
interpretation of tracer measurements, 242–245
need for tracer analysis, 231
tracer tests, 231–233
types of tracers, 231
types of reactors, 218–220
(See also Mass balance analysis)
Modeling treatment process kinetics, 269–282
comparison of complete-mix and plug-free reactors, 275
complete-mix reactor with reaction, 270
complete-mix reactors in series with reaction, 271
ideal plug-flow reactor with reaction, 274
ideal plug-flow with retarded reaction, 277
plug-flow with axial dispersion and reaction, 279
(See also Mass balance analysis)
Modified fouling index (MFI), 1120
Modified Ludzack-Ettinger (MLE) process, 791
(See also Activated sludge)
Molecular diffusion:
coefficient of, for
carbon dioxide, 291
nitrogen, 291
oxygen, 291
computation of, 284
definition of, 283
Molecular weight cut off (MWCO), definition of, 1105
Mole fraction, 35, 37
Monod equation, 582
Moody diagrams for fluid flow, 1757
Morrill dispersion index (MDI), 242
definition of, 243
determination of, 243
relationship to volumetric efficiency, 243
Most probable number (MPN):
application, 121, 1749
definition of, 121
determination of, 121, 1749
tables of, 1750
MPN (see Most probable number)
MTZ (see Mass transfer zone)

Mudball formation in filtration, 1097
Multiple-effect evaporation, 1202
Multiple hearth incineration, 1588–1590
ash handling, 1590
description of, 1589
emissions from, 1464, 1590
sludge loading rates, 1590
Multiple-tube fermentation, 121–123

Nanofiltration membrane process:
applications of in wastewater reclamation, 1122
energy consumption (T), 1125
general characteristics of (T), 1106
operating characteristics (T), 1124
operating size range, 1108
(See also Membrane filtration processes)
National pollution discharge elimination system (NPDES), 5, 1647
NDMA (See N-nitrosodimethylamine)
Nephelometric turbidity unit (NTU):
determination of, 51
relationship to TSS, 51
source of, 51
Nernst potential, 482
Neutralization, chemical:
chemicals used for (T), 527
pH adjustment, 526
Newtonian fluids, 1475
Newton's law for gravity settling, 363
Nitrate, in wastewater, 62
Nitrate dumping, 1190
Nitrification, biological:
in BOD test, 87
environmental factors:
metals, 616
pH, 615
toxicity, 615
un-ionized ammonia, 616
growth kinetics, 614
microorganisms involved in, 611
stoichiometry, 612
Nitrification/denitrification, biological:
biological denitrification of:
in attached growth processes, 616–623, 909–930
suspended growth processes, 616–623, 749–799
biological nitrification:
in attached growth processes, 611–616, 909–930, 962–971
in suspended growth processes, 611–616, 703–749
Nitrogen:
cycle in the aquatic and soil environment, 63
definition of terms used to define forms of (T), 61
distribution of ammonia as a function of pH, 62
forms in wastewater, 60
ammonia, 60–62
Kjeldahl, 60

nitrite, 61, 62
organic, 61
fractionation of, 670
importance of, 60
oxidation states for, 60
pathways in nature, 62
requirements for cell tissue, 558, 565
solubility of gas in water, 67
sources of, 60
transformation in biological treatment processes, 617
typical values in wastewater, 186
Nitrogen and phosphorus, combined removal of, 799, 1377
Nitrogen cycle in the aquatic and soil environment, 63
Nitrogen removal by attached growth biological processes, 962–971
description of postanoxic reactors:
downflow packed-bed, 962–967
fluidized-bed, 967–969
submerged rotating biological contactors, 969
upflow packed-bed, 967
description of preanoxic reactors, 969–971
Biofor®, 969
moving bed fixed film reactor, 969
trickling filter, 969
design data for postanoxic reactors:
downflow packed-bed (T), 963
fluidized-bed, 967–969
submerged rotating biological contactors (T), 969
upflow packed-bed, 967
Nitrogen removal by biological assimilation, 617
Nitrogen removal by physical and chemical methods:
air stripping of ammonia, 1178
chemical oxidation by breakpoint chlorination, 524–526
ion exchange, 1189–1194
steam stripping of ammonia, 1179
Nitrogen removal by suspended growth biological processes, 749–799
advantages and limitations of suspended growth, 797–798
alternative process configurations, 789–798
process descriptions (T), 791–796
process design considerations, 753–761
process design for:
anoxic/aerobic process, 761–765
intermittent aeration, 776–780
sequencing batch reactor, 781–784
step-feed for anoxic/aerobic process, 765–776
process design parameters (T), 797
process flow diagrams for, 791–796
preanoxic, 751, 791–793
postanoxic, 751, 793–794
Sharon™ process, 796
simultaneous nitrification/denitrification, 751, 795–796
two stage nitrification/denitrification, 751
process selection considerations, 789–790
single-sludge biological nitrogen removal processes, 750–753
stoichiometry, 619
typical design parameters for, 797
Nitrogeneous biochemical oxygen demand, 88
N-nitrosodimethylamine (NDMA):
concentrations in wastewater, 1257
description of, 102
formation of, 102, 1257
potency factor for, 1370
removal by:
microfiltration, 1387
reverse osmosis, 1387
secondary treatment, 1387
UV oxidation, 1199
sources of, 102

NOAEL (see No observable adverse effect level)
Nocardia foam:
control of, 700, 819
microbiology of, 699–700
NOEC (see No observable effect concentration)
No observable adverse effect level (NOAEL), 1372
No observable effect concentration (NOEC), 135
Nonideal plug-flow reactor:
analysis of with:
axial dispersion, 246
axial dispersion and reaction, 279
characteristics of, 221
Non-Newtonian fluids, 1478
NPDES (see National pollution discharge elimination system)
NTU (see Nephelometric turbidity unit)
NRC (National Research Council) formulations trickling filters, 910
Nuisance organisms:
in activated sludge processes, 608, 695–698, 699–700
in anaerobic processes, 632
in trickling filters, 892
Nutrient removal:
nitrogen and phosphorus, combined removal of, 1377
(See also Nitrogen removal; Phosphorus removal)
Nutrient requirements:
for anaerobic processes, 990
for microbial cell synthesis and growth, 565
for suspended growth biological systems, 684
Nutrients:
in biological systems, 565, 684
in commercial fertilizers (T), 1454
metallic, necessary for biological growth (T), 78
nitrogen, 60–63
phosphorus, 63
processes for the removal of:
nitrogen, 749–799, 962–971
phosphorus, 500–519, 799–816, 962–971
in reclaimed water, 1410
requirements for biological growth:
inorganic ions, 565
nitrogen, 565
phosphorus, 565
uptake rates for selected crops (T), 1615
in wastewater biosolids (T), 1454

Odor, 70–76
causes of, 70
characterization and measurement of, 71–76
classification of odor detection methods, 73
control methods (see Odor control)
detection of, 71
effects of, 71
errors in sensory detection (T), 74
major categories of odorous compounds (T), 72
measurement of:
with butanol wheel, 75
with dynamic forced-choice triangle olfactometer, 776
with scentometer, 76
minimum detectable threshold odor concentration (MDTOC), 72
threshold odor number (TON), 74
thresholds of odorous compounds in untreated wastewater (T), 72
Odor management, 1650–1676
chemical scrubber reactions with:
hydrogen peroxide, 1663
potassium permanganate, 1662
sodium hypochlorite, 1662
design considerations for chemical scrubbers, 1668
design considerations for odor control biofilters, 1670
biofilters design parameters (T), 1674
bulk media filters design parameters (T), 1673
design and operating parameters for biofilters, 1672
gas distribution, 1671
moisture control, 1672
packing material, 1671
temperature control, 1672
minimum buffer distances (T), 1660
movement of odors from wastewater treatment facilities, 1654
odor threshold values (T), 1651
odor treatment methods, 1658
activated carbon adsorbers, 1664
chemical scrubbers, 1661
conventional biological treatment processes, 1667
methods used to treat odorous gases (T), 1659
process flow diagram for three stage odor control process, 1664
thermal processing, 1667
vapor phase biological treatment processes, 1665
selection and design of odor control facilities, 1668
sources of odors, 1650
sludge and biosolids handling facilities, 1651–1654
sources of odors in wastewater management systems (T), 1652
wastewater collection systems, 1650
wastewater treatment facilities, 1651
strategies for odor management, 1654
control of discharges to collection system, 1654
odor containment alternatives (T), 1658
odor containment and treatment, 1656
odor control in wastewater collection systems, 1654
odor control in wastewater treatment facilities, 1654
use of buffer zones, 1658
use of odor masking and neutralization, 1656
use of turbulence inducing structures, 1658
wastewater for odor control, 1656
types of odors, 1650
Odorous compounds:
associated with wastewater (T), 72
odor threshold values (T), 72, (T) 1651
Odorous gases:
sources of (T), 1652
treatment of (T), 1659

Oil and grease, 80, 98
definition of, 98
in wastewater, 186
Oil films:
appearance of, 98
thickness of, 98
Olfactometer, dynamic forced-choice triangle, 75–76
Oligonucleotide probe, 561
Operating parameters:
for electrodialysis units, 1134
for moving-bed biofilm reactor/solids contact process (T), 955
Organic carbon, total and dissolved (TOC and DOC):
definition of, 94
typical values in wastewater, 186
Organic compounds in anaerobic digestion:
toxic and inhibitory concentration values (T), 992
Organic matter in wastewater:
aggregate organic compounds, 80
carbohydrates, 80, 96
oil and grease, 80, 96, 98
proteins, 80, 96
separation and measurement technique (T), 46
size ranges of, 46
specific ultraviolet adsorption (SUVA), 96
surfactants, 98
UV-absorbing organic constituents, 95
individual organic compounds, 99
classes of compounds identified as individual compounds (T), 101
disinfection byproducts, 102
emerging organic compounds, 102
measurement of individual compounds, 100,
pesticides and agricultural compounds, 102
priority pollutants, 99
size ranges of, 46
volatile organic compounds (VOCs), 100
Organic nitrogen, 61
Organic volumetric loading rate, 600
Organisms (see Microorganisms)
ORP (see Oxidation-reduction potential)
Orthokinetic flocculation, 346, 479
OTE (see Oxygen transfer efficiency)
OUR (see Oxygen uptake rate)
Overflow rates for sedimentation tanks:
for primary clarifiers (T), 398
for secondary clarifiers (T), 687
(See also Sedimentation tanks, for suspended and attached growth processes)
Overflows, combined sewer (see Combined sewer overflows)
Oxidation,
advanced, 1196–1202
(See also Adanced oxidation processes)
chemical, 517–525
(See also Chemical oxidation)
Oxidation ditch activated sludge, 744, 794
(See also Activated sludge)

fluidized-bed, 220
packed-bed, 219
plug-flow, 218
(See also individual listings)
Reactors, treatment:
application of (T), 220
dispersion numbers, typical values of (T), 250
hydraulic analysis terminology (T), 234
Readily biodegradable chemical oxygen demand (rbCOD):
importance of, 668
measurement of, 671–672
processes affected by (T), 669
Recharge, groundwater (see Groundwater recharge with reclaimed wastewater)
Reclaimed water, storage of 1391–1401
(See also Storage of reclaimed water)
Recycling, wastewater, 1347–1366
(See also Water reuse)
Reduction of flow, devices, and appliances (T), 168
Reed beds:
description of, 1578
loading rates for, 1578
Regrowth of microorganisms, 1258, 1397, 1399
Regulations:
for air pollution control from incinerators, 1464
for incineration of biosolids and sludge, 1464
for the reuse and disposal of biosolids (sludge):
pathogen reduction alternatives (T), 1462
processes to further reduce pathogens (T), 1464
process to significantly reduce pathogens (PSRP) (T), 1465
for secondary treatment, 6
for wastewater management (T), 5
Reliability concept in wastewater treatment and plant design, 1636–1640
Removal mechanisms in depth filtration (T), 1048
Reservoirs for storage of reclaimed water, 1391–1401
(See also Storage of reclaimed water)
Residence time distribution (RTD) curves, 238–242
E curve, 239
F curve, 239
Residential water use (T), 160
Residual chlorine:
impact of, 1242, 1248
measurement of, 1242
Residual constituents in treated wastewater (T), 1039
Respiration (decay), endogenous:
application of, 584
definition of, 584
Retentate, 1104
Return activated sludge:
flowrates:
methods of determining, 690–692
typical, by process, 747, 797, 814
importance in process control, 690
Reuse of reclaimed wastewater, 1347–1366
(See also Water reuse)
Reverse osmosis:
(See also Membrane filtration processes)
concentrate disposal, 1135, 1136
definition of, 1108, 1114
energy consumption (T), 1125
general characteristics (T), 1106
membrane:
configurations, 1110
fouling, 1117
operation, 1114
operating characteristics (T), 1124
operating size range, 1108
performance summary (T), 1130
pilot studies for membrane application, 1134
membrane operating parameters, 1135
water quality measurements, 1135, 1136
for removal of total dissolved solids (TDS), 1195
stabilization of reverse osmosis product water, 532
for wastewater reclamation, 1381–1384
Reynolds number:
in mixing, 354
in open channel flow, 251
in sedimentation, 364
in sludge headloss computations, 1478
values in Moody diagram, 1757
Rheology, in sludge headloss computations, 1477–1481
Ribose nucleic acid (RNA), 105, 555–557
Risk assessment, introduction to, 1366–1376
carcinogenic chemicals, selected toxicity data for (T), 1370

Risk assessment, introduction to—*Cont.*
discrete steps in risk assessment, 1366
dose response assessment, 1367–1372
exposure assessment, 1367
hazard identification, 1366
risk characterization, 1372
ecological risk assessment, 1373
limitations in risk assessment for water reuse, 1374
risk assessment for water reuse, 1373
risk assessment in standard setting, 1372
risk management, 1372
Rising sludge, 699
RNA (see Ribose nucleic acid)
RNA probe for identification of bacteria, 127
Rotary drum screen, 323, 324
Rotary drum thickening of sludge:
description of, 1499
typical performance ranges (T), 1499
Rotating biological contactors (RBCs), 930–940
design of physical facilities, 935–936
disk materials, 936
drive systems, 936
enclosures, 936
settling tanks, 936
shafts, 936
tankage, 936
history of loading criteria, 935
process description, 930
process design considerations:
BOD removal, 937
effluent characteristics, 935
nitrification, 940
staging, 932
typical design information (T), 933
Rotifers, 107
Roughing filter/activated sludge process:
description, 940
process parameters for (T), 942
RTD curves (see Residence time distribution curves)
Ryzner stability index:
(See also Langelier saturation index)
application of, 529
computation of, 529
definition of, 529

Safety:
chlorine containment facilities, 1284
containment for individual chlorine cylinders, 1285
digester gas, 1523
fire and explosion hazards, 1585
Salinity:
definition of, 1404
effects, of, 1403–1405
Salmonella in biosolids, 1461
Salt balance in cooling towers, 1414–1416
Sample analysis:
detection limits, 34
instrumental detection level (IDL), 34
level of quantification (LOQ), 35
lower level of detection (LLD), 34
method detection level (MDL), 35
units of measurement, 35–36
Samplers, 182
Sampling:
data requirements, 29,
protocol for, 32–33
sample preservation, 33
Sand:
properties of, 1088
sizes used in depth filters, 1086–1087
Sand drying beds for sludge (see Sludge drying beds)
Sanitary system overflows (SSOs), 18
SAR (see Sodium adsorption ratio)
Saturation index
determination of, 528–530
Langelier, 528–529
Ryzner, 529
SBR (see Sequencing batch reactor)
Scale-up for mixers, 355
Scaling:
analysis of scaling potential, 528
calcium carbonate, 528
control of, 532
in cooling towers, 1416
in distillation processes, 1205
formation potential, 528
Langelier saturation index, 528–529
Ryzner index, 529

Scentometer for odor measurement, 76
Scour velocity:
in chlorine contact basins, 1276
in sedimentation tanks, 405
Screening:
classification of, 315
coarse screens (bar racks), 316–322
advantages and disadvantages of various types (T), 318
design of facilities for, 320
hand cleaned, 316
headloss through coarse screens, 320
mechanically cleaned, 317–320
quantity of coarse screenings, 328–329
typical design information for (T), 316
(See also Coarse screens)
fine screens, 322–326
for combined sewer overflows, 324
description of (T), 323
design of facilities for, 320
headloss through fine screens, 320
for preliminary and primary treatment, 322
quantity of fine screenings (T), 329
(See also Fine screens)
microscreens, 326–328
description of, 326
functional design of, 327
typical design information for, 328
Screenings:
characteristics of:
coarse screenings (T), 329
fine screenings (T), 329
compactor, 330
definition of, 315
disposal of, 330
grinding, 335
quantities removed from:
coarse screens (T), 329
combined sewer flows, 328
fine screens (T), 329
Screenings compactor, 330
Scrubbers for odor control, chemical, 1661
design consideration for, 1668
with hydrogen peroxide, 1663

with potassium permanganate, 1662
single and multistage, 1663
with sodium hydroxide, 1662
Scum:
control of, in anaerobic digesters, 1518, 1522
pumping, 1468
sources of, 1453
Scum pumps (see Sludge and scum pumping)
Scum removal:
in primary sedimentation tanks, 400
in secondary settling tanks, 839–840
SDI (see Silt density index)
SDNR (see Specific denitrification rate)
Secondary sedimentation tanks (see Sedimentation tanks, for suspended and attached growth processes)
Secondary treatment:
definition of, 11
minimum national standards for, 6
Sedimentation, theory of, 361–384
(See also Gravity separation, theory of)
Sedimentation tanks, for primary treatment, 396–411
characteristics and quantities of sludge and scum (T), 411
description of:
circular tanks, 400–402
combination flocculator-clarifier, 402–403
rectangular tanks, 397–400
stacked (multi-level), 403–405
design considerations, 406–411
dead space, 230
density currents, 230
detention time, 407
energy dissipation, 402
scour velocity, 408
surface loading rates, 407
weir loading rates, 408
design information for:
dimensions for rectangular and circular tanks (T), 398
primary sedimentation followed by secondary treatment (T), 398
performance of, for BOD and TSS removal, 405–406, 411
Sedimentation tanks, for suspended and attached growth processes:
density currents, 230, 407, 833
energy dissipation devices, 402, 839
flow distribution, 837
overflow rates:
for activated biofilter, 944
for activated sludge processes (T), 687
for biofilter/activated sludge, 944
for rotating biological contactors, 936
for roughing filter/activated sludge process, 942
for series trickling filter-activated sludge process, 945
for trickling filters, 905
for trickling filter/solids contact process, 942
scum removal, 400, 839
settling characteristics of sludge, 684–686, 696
sidewater depth:
for activated sludge processes, 837
for trickling filters, as related to overflow rates, 904
sludge blanket, 833
sludge collectors, 397, 399, 401, 834–836
sludge volume index (SVI), 685
solids loading rates (T), 687, 836
surface loading rates (T), 687, 836
tank inlets, 837
tank types, 833
circular tanks, 833
combination flocculator-clarifier, 402–403
inclined plate and tube, 374–378
intrachannel, 836
lamella, 377
rectangular tanks, 834
stacked clarifiers, 403
weir placement and loading, 838
Segmented flow analysis:
application to analysis of chlorine contact basin performance, 1280
description of, 1279
Selection of set points, 1690
Selector for control of filamentous organisms, 700–703
(See also Activated sludge),
Sequencing batch reactor (SBR):
for BOD and nitrification, 720–733
application of process kinetics, 722
description of, 720, 745
operating sequence for, 722
process design, 723–733
sludge wasting, 721
for nitrogen removal, 781–784, 792
for phosphorus removal, 813
Serial filtration for particle size distribution:
description of, 48
illustration of, 40
Series trickling filter/activated sludge process, 944–945
description, 944
design considerations, 944
process parameters for (T), 945
Settleable solids:
definition of, 43
determination of, 45
typical values in wastewater, 186
Settling (see Sedimentation)
Settling column analysis, 367–372
Settling tanks (see Sedimentation tanks)
Settling tests for flocculent suspensions, 369
Settling velocities for various particle sizes, 365
Sewage (older term, see Wastewater)
Sex and steroidal hormone (T), 103
Sharon™ process, 788, 796
Short circuiting:
in chlorine contact basins, 1272–1274
nonideal flow in reactors, 229
in reactors, 222, 230
in sedimentation tanks, 406
Shultz-Hardy rule, 484
SI units:
base units (T), inside front cover
derived SI units with special names (T), inside front cover
derived units by combining base units and units with special names (T), inside front cover
SI prefixes, inside front cover
Sieve analysis, 1046
Sieve sizes, U.S. (T), 1046
Silt density index (SDI):
definition of, 1119
values of, 1120

Simultaneous
nitrification/denitrification (SNdN):
alternative processes for, 795–796
application of, 752
description of, 750
process design for, 759
Sludge:
activated (see Activated sludge)
application on land, 1608–1621
(See also Land application of biosolids)
regulated pollutants in, for land application (T), 1616
sources of, (T) 1452
specific resistance of, 1555
Sludge and biosolids dewatering:
by belt filter press, 1563
by centrifugation, 1559
comparison of alternative methods (T), 1560
on drying beds, 1570
by filter press, 1568
in lagoons, 1578
typical BOD and TSS concentrations in recycle flows (T), 1594
typical dewatering performance for belt filter press (T), 1566
typical solids capture values (T), 1593
typical solids concentration values (T), 1593
(See also individual listings)
Sludge and scum pumping:
headloss determination, 1475
application of rheology, 1477
simplified determinations, 1476
sludge piping, 1481
types of pumps: advantages and disadvantages of (T), 1469
application of (T), 1468
centrifugal, 1474
chopper, 1474
diaphragm, 1474
high-pressure piston, 1475
hose, 1475
plunger, 1467
progressive cavity, 1473
rotary-lobe, 1475
torque flow, 1474
Sludge beds (see Sludge drying beds)
Sludge blending, 1484
Sludge bulking, 695–698
(See also Bulking sludge)
Sludge characteristics:
chemical composition and properties (T), 1454
comparison of nutrient levels with fertilizer (T), 1454
description of, 1451
physical characteristics (T), 1456
quantities of (T), 1456
specific gravity (T), 1456
typical concentrations from operations and processes (T), 1457
typical heating values (T), 883
typical metal content (T), 1455
volume-mass relationship, 1455
Sludge composting, 1546–1554
(See also Composting of sludge)
Sludge concentration (see Sludge thickening)
Sludge conditioning:
by chemical addition, 1555
chemicals used, 1555
dosage, typical, 1555
factors affecting, 1555
mixing, 1556
polymer addition (T), 1556, 1566
by freeze-thaw, 1557
by heat treatment, 1557
by sludge preheating, 1557
Sludge degritting, 392
Sludge digestion:
aerobic, 1533–1546
(See also Aerobic sludge digestion)
anaerobic, 1505–1533
(See also Anaerobic sludge digestion)
Sludge disinfection:
processes to further reduce pathogens (PFRP) (T), 1464
processes to significantly reduce pathogens (PSRP) (T), 1465
Sludge disposal and reuse, 22–24
(See also Biosolids and residuals management),
Sludge drying, 1579–1586
(See also Heat drying)
Sludge drying beds:
application of, 1570
artificial media drying beds:
description of, 1575
solids loading rates, 1575
conventional sand drying beds:
area requirements for (T), 1572
description of, 1570
paved:
computation of area requirements, 1573
description of, 1573
solar (enclosed), description of, 1576
vacuum-assisted:
description of, 1576
performance data (T), 1577
Sludge grinding:
description of, 1482
operations or processes requiring (T), 1483
Sludge headloss determinations:
multiplication factors, 1476
simplified methods, 1476–1477
using rheology, 1477–1481
Sludge incineration, 1586–1592
(See also Incineration)
Sludge lagoons, 1622
Sludge piping, 1481
Sludge processing methods:
methods and functions (T), 1450
process flow diagrams for:
biological sludge digestion and alternative sludge dewatering processes, 1467
generalized sludge processing, 1466
typical characteristics and quantities produced from (T), 1456
Sludge pumps, 1465–1482
(See also Sludge and scum pumping)
Sludge screening, 1482–1484
Sludge sources, 1451
Sludge stabilization, 1500–1554
(See also Stabilization of solids and biosolids)
Sludge storage, 1485
Sludge storage basins, 1622
Sludge storage pads, 1623
Sludge thickening:
application of, 1488
description and design of equipment:
centrifuge, 1495
co-settling, 1489
flotation, 1494
gravity, 1491
gravity belt, 1497
rotary drum, 1498
(See also individual listings)

hydraulic loading rates:
gravity, 1491
gravity belt (T), 1498
impacts of return flows (T), 1595
methods of, in solids processing (T), 1489
performance, rotary drum (T), 1499
polymer addition, 1495, 1496
solids loadings:
dissolved-air flotation (T), 1496
gravity (T), 1492
typical BOD and SS concentrations in return flows (T), 1594
typical solids capture values (T), 1593
typical solids concentration values, gravity (T), 1492
Sludge volume index (SVI), 685
Sludge volume-mass relationships, 1455
Sludge wasting, 692–693
Small-scale column test, 1156–1159
SNdN (see Simultaneous nitrification/denitrification)
Sodium adsorption ratio (SAR):
adjusted value, computation of, 1409
adjusted value, definition of, 1406
definition of, 1406
Sodium hypochlorite, 1233
Soil beds for odor control, 1671
(See also Biofilters for odor control; Odor management)
Solids:
chemical composition of:
digested biosolids (T), 1454
untreated sludge (T), 1454
untreated wastewater (T), 186
concentrations from treatment operations and processes (T), 1457
description of (T) 43, (T) 1453
metals content of (T), 1455
physical characteristics of (T), 1456
quantities discharged by individuals in the U.S. (T), 182
quantities discharged by various countries (T), 183
quantities produced from treatment operations and processes (T), 1456
sources of (T), 1452
type of:
total dissolved, 44
total suspended, 43
volatile and fixed, 45
typical values in untreated wastewater (T), 186
Solids flux analysis of settling data, 820–826
application, 820, 824–826
theory of, 820–823
Solids loading rate (SLR), 688
Solids loadings:
definition of, 820
loading criteria (see Loading criteria)
solids flux analysis, 820–826
state point analysis, 827–833
Solids mass balance:
concentration and capture values for processing methods (T), 1593
impact of return flows (T), 1595
performance data for, 1593
preparation of, 1593
return flow BOD and TSS concentrations (T), 1594
Solids processing, methods of (T), 1450
Solids retention time (SRT):
definition of, 677
typical minimum values for activated sludge treatment (T), 680
typical values:
commonly used for activated sludge processes, 747
commonly used for biological phosphorus removal processes, 814
commonly used for nitrogen removal processes, 797
Solids separation:
solids flux analysis, 382–383, 820–826
state point analysis, 827–833
Solubility of gases in water, 65
Solubility of metal salts, 490
SOTE (see Standard oxygen transfer efficiency)
Specific denitrification rate (SDNR):
biokinetic coefficients values for model simulation (T), 756
curves for, 755
definition of, 754
design of anoxic tank using, 754–756
Specific gravity of water:
definition of, 57, 1741
values of:
in SI units (T), 1742
in US customary units (T), 1743
Specific growth rate, 582
Specific ion toxicity, 1406
Specific substrate utilization rate, 582
Specific ultraviolet adsorption (SUVA), 96
Specific weight of water:
definition of, 57, 1741
values of:
in SI units (T), 1742
in US customary units (T), 1743
Speece cone (Downflow bubble contactor), 451, 456
Sphaerotilus natans, 697
Sphericity of filter materials (T), 1088
Spiral wound membrane, 1108
SRT (see Solids retention time)
SS (older term, see Total suspended solids)
Stabilization of demineralized water, 532
Stabilization of solids and biosolids:
aerobic digestion, 1533–1546
alkaline stabilization, 1500–1505
anaerobic digestion, 1505–1533
attenuation achieved by (T), 1501
composting, 1546–1554
description of processes (T), 1501
process flow diagrams for:
autothermal aerobic digestion (ATAD) process, 1664
biological sludge digestion and alternative sludge dewatering processes, 1467
chemical fixation system, 1505
generalized composting processes, 1548
high rate anaerobic sludge digesters, 1508
staged anaerobic digestion processes, 1531
two-stage anaerobic sludge digesters, 1508
purpose of, 1499
(See also individual listings)
Staged activated sludge process, 734–738
Standard oxygen transfer efficiency (SOTE), 436

Standards for secondary treatment (T), 6
State point analysis, 827–833
Static mixers:
description of, 351
headloss through, 351, 352
Static screen, inclined, 323
Static tube aerator, 431, 432
Static wedgeware screens, 324
Statistical analysis of flowrates, constituent concentrations, and mass loadings:
graphical analysis, 171
mass loading rates, 170–178
parameters for (T), 172
plotting position, 172
Statistical distributions:
arithmetic, 170
determination of, type of distribution, 172
log-normal, 170
Statistical measures:
common statistical parameters, 170
statistical parameters (T), 171
Steam stripping of ammonia, 1179
Step-feed aeration activated sludge, 742
(See also Activated sludge)
Step-type fine screens, 322, 324
Stern potential, 482
Stoichiometry:
of advanced oxidation, 1198
of aerobic biological oxidation, 82, 609
of biological denitrification, 619
of biological nitrification, 612
of biological phosphorus removal, 627
of biological reactions, 578
of chemical precipitation of wastewater:
with alum, 494
with ferric chloride, 496
with ferric chloride and lime, 497
with ferric sulfate and lime, 497
with ferrous sulfate and lime, 495
with lime, 495
phosphate precipitation with calcium, 501
definition of, 257
of ion exchange, 1183
Stokes' law for gravity settling, 365
Stokes-Einstein law of diffusion, 284
Storage and handling of chemicals (T), 534
Storage of reclaimed water, 1391–1401
enclosed storage reservoirs:
management strategies (T), 1400
problems encountered in operation of (T), 1399
problems with enclosed reservoirs, 1399
management strategies for open and enclosed reservoirs, 1399
meeting discharge requirements, 1392
need for storage, 1392
open storage reservoirs:
management strategies (T), 1400
problems encountered in operation of (T), 1398
problems with open reservoirs, 1397
operation of storage reservoirs, 1393
sizing of storage facilities, 1394
Storage of sludge (see Sludge storage)
Storm water management model (SWMM), 170
Stormwater overflows (see Combined sewer overflows)
Stormwater, typical values for, 191
Stripping, air:
for ammonia removal, 1175, 1179
for VOC removal, 1175
Stripping towers, gas, 1162–1180
design equations for, 1173
design of, 1174
(See also Gas stripping)
design parameters for (T), 1175
pressure drop curves for, 1176
types of, 1163, 1164
typical air flow patterns in, 1164
typical schematic for, 1164
Submerged attached growth processes, 957–962
Substrate:
conversion of, 583
definition of, 550
effluent concentration, 688–689
flux limitations, 606
kinetic coefficients for utilization (T), 585
mass balance, 581
removal in attached growth processes, 602–607
flux in biofilms, 604
mass balance for biofilm, 605
utilization, 584
Sulfate, importance of, 31
Sulfite:
dechlorination dosages for various compounds (T), 1263
dechlorination with compounds of, 1262
Sulfur, 64
Sulfur dioxide:
dechlorination with, 1261
properties of (T), 1232
reactions with combined chlorine, 1262
reactions with free chlorine, 1262
Surface aerators:
description of, 443
tank dimensions for surface aerators (T), 448
(See also Mechanical aerators)
Surface charge:
development of, 481
ionization, 481
isomorphous repacement, 481
preferential adsorption, 481
structural imnprefections, 481
electrical double layer, 481
importance of, 481
measurement of surface potential, 482
Surface spreading for groundwater recharge, 1423
Surface tension of water:
definition of, 1741
values of:
in SI units (T), 1742
in US customary units (T), 1743
Surfactants, 98
description of, 98
tests for:
cobalt thiocyanate active substances (CTAS), 99
methylene blue active substances (MBAS), 99
Suspended growth biological treatment processes:
aerobic processes:
activated sludge, 676–840
aerated lagoons, 840–854

aerobic digestion, 1533–1546
combination with attached growth, 940–957
with membrane separation, 854–859
anaerobic processes:
anaerobic baffled reactor, 1016
anaerobic contact, 997
anaerobic digestion, 1505–1533
anaerobic migrating blanket reactor, 1017–1018
anaerobic sequencing batch reactor, 999
nitrogen removal in anaerobic digester recycle streams, 788
phosphorus removal, 799–816
upflow anaerobic sludge blanket, 1005–1016
anoxic processes:
denitrification, 749–799
selector, 700–703
fundamentals of process analysis and control of, 676–703
activated sludge selector processes, 700
general considerations for reactor selection (T), 678
minimum SRT ranges (T), 680
operational problems, 694–700
process control, 689–694
process design considerations, 740
summary of equations (T), 679
(See also Activated sludge)
general description of, 551
(See also individual listings)
Suspended solids (SS)
(older term, see Total suspended solids)
Sustained mass loadings:
curves for BOD, SS, nitrogen, and phosphorus, 195
definition of, 194
Sustained peaking factor, 181
SUVA (see Specific ultraviolet adsorption)
SVI (see Sludge volume index)
SWMM (see Storm water management model)
Synthetic detergents, 99
Syntrophic relationship in anaerobic digestion, 632
System boundary for mass balance analysis, 223
Taxonomic classification of microorganisms, 559
TDS (see Total dissolved solids)
Temperature:
classification for biological processes (T), 559
log-mean, 902
optimum for biological activity, 55
of wastewater, 54
Temperature correction coefficients (θ):
for aeration, 427
for aerated lagoons, 841
for biochemical oxygen demand, 86
for biochemical reaction rates, 585
for conventional biological treatment processes, 681
for denitrification, 756
for heterotrophic bacteria (T), 704
for nitrification, 704
for nitrogen removal, 756
for oxygen transfer, 427, 438, 447
for trickling filters, 917
van't Hoff-Arrhenius relationship, 55
Temperature effects:
on activation energies for chlorine and chloramines, 1229
on aerated lagoons, 844
on aeration, 429
on aerator performance, 429
on aerobic digestion, 1535
on air flow in pipes, 442
on air flow in trickling filters, 901–905
on ammonia stripping, 1168
on anaerobic digestion, 1506, 1511
on anaerobic treatment, 985, 987
on autothermal thermophilic aerobic digestion, 1541
on bacterial species, optimal ranges, 559
on bacterial survival, 114
on bacterial testing, 116
on biochemical oxygen demand, 86
on biofilters for odor control, 1672
on biological growth kinetics:
aerobic, 585
anaerobic, 1000
for nitrification, 705
on biological reaction rates, 55
on biological treatment processes, 704, 705
on cascade aeration, 452
on chemical scrubbers, 1669
on chlorination, 1229
on chlorine reactions in water, 1234, 1235
on composting, 1547, 1553
on denitrification process, 756
on density of water, 1742
on digester heating, 1525–1529
on disinfection, 1229, 1230
on dissolved air flotation, 423
on dissolved oxygen concentration in water, 1745–1748
on equilibrium constants for:
ammonia, 995
carbonate, 1755
hydrogen sulfide, 995
on gas stripping, 1168
on headloss through granular filter mediums, 1051
on heat drying:
convection, 1579
radiation, 1580
on heat treatment, 1557
on Henry's law coefficients for:
carbon dioxide, 1753
gases, various, 69
ozone, 1228
on ideal gas law, 65, 1738
on incineration, 1587
on ionization constant for hypochlorus acid, 1235
on kinematic viscosity, 1742
on Kolmorgoroff microscale length, 349
on Langelier saturation index, 530
on molecular diffusion coefficient, 284
on nitrification process, 585, 705
optimum for biological activity, 55
on oxygen transfer, 427, 429
on performance of fluidized bed reactors, 1022
on particle stability, 484
on pathogen and parasite destruction in composting, 1553
on pathogen reduction in biosolids, 1465
on phased digestion, 1532
on physical properties of water:
in SI units, 1742
in U.S. customary units, 1743
on post-lime stabilization, 1504

Temperature effects—*Cont.*
on reaction rate coefficients, 261
on reaction rates, 55
on sedimentation rates for particles, 388
on sedimentation tank performance, 406, 407, 408
on settling, 363–364, 406
on sludge pumping, 1478
on solubility of gases in water, 65, 67
on specific weight of water, 1742
on survival of pathogenic organisms, 114
on thermal incineration, 465
on thermophilic digestion, 1529
on trickling filter process:
for nitrification, 924
for organic carbon removal, 902, 907
on unitless form of Henry's law, 69
on UV lamps, 1300
on vapor pressure of water, 1742
on vector attraction, 1463
on viscosity of water, 1742
Terminology for:
automatic process control (T), 1677
biological treatment (T), 550
characteristics of an ideal disinfectant (T), 1220
constituents of concern in wastewater (T), 32
forms of nitrogen (T), 61
hydraulic analysis of reactors (T), 234
infiltration/inflow, 163
membrane processes (T), 1105
terms used in the field of wastewater engineering (T), 4
toxicity assessment in aquatic environments (T), 132
wastewater treatment (T), 11
water reclamation and reuse applications (T), 1348
Tertiary treatment (see Advanced wastewater treatment)
Theoretical oxygen demand (THOD), 96
Thermal incineration, 1586–1592
(See also Incineration)
Thermophilic digestion:
anaerobic, 1529
in autothermal aerobic digestion, 1541
in dual digestion, 1541
in two-phased anaerobic digestion, 1531
Thermophilic organisms, 559
Theta (θ) (see Temperature correction coefficient)
Thickeners:
centrifugal, 1495
co-settling, 1489
flotation, 1494
gravity, 1491
gravity belt, 1497
rotary drum, 1498
(See also individual listings)
Thickening, 1488–1499
(See also Sludge thickening)
Thin-film composite membrane, 1110, 1130
ThOD (see Theoretical oxygen demand)
Thomas equation for MPN determination, 122
Thomas method for analysis of BOD data, 88
Threshold odor:
definition of, 74
determination of, 74
(See also Odor)
Threshold odor number (TON), 74
TKN (see Total Kjeldahl nitrogen)
TMDL (see Total maximum daily load)
TOC (see Total and dissolved organic carbon)
TON (see Threshold odor number)
Total and dissolved organic carbon (TOC and DOC):
BOD/TOC ratio, 96, 97
definition of, 94
relationship of DOC to UV adsorption, 95
removal of by ion exchange, 1195
typical values in wastewater, 186
Total dissolved solids (TDS):
definition of, 43, 44
guidelines for irrigation, 1403, 1404
relationship to electrical conductivity, 56
typical values in wastewater, 186
Total Kjeldahl nitrogen (TKN):
definition of, 60, 61
typical values in wastewater, 186
Total maximum daily load (TMDL), 5, 7
Total solids:
components of, 43, 44
definition of, 43
typical values, in wastewater, 186
Total suspended solids (TSS):
definition of, 43
determination of, 44
relationship to turbidity, 51
removal of:
chemical precipitation, 497
depth filtration, 1079
flotation, 419
microfiltration, 1127
microscreening, 326
reverse osmosis, 1130
sedimentation, 405
surface filtration, 1103
typical values in wastewater, 196
volatile, 43, 45
Towers, cooling:
cycles of concentration, 1416
makeup water for, 1413
operating problems:
biological growth, 1417
fouling, 1417
metallic corrosion, 1416
scaling, 1416
water and salt balances in, 1414, 1415
Toxic compounds and refractory organics, removal of:
by carbon adsorption (T), 1142
by chemical oxidation, 1196
fractionating techniques, 138
by powdered activated carbon treatment (PACT), 1161
treatment methods (T), 1142
Toxicity:
acute, definition of, 132
in anaerobic processes, 991
of chlorine residuals, 1255
chronic, definition of, 132
of heavy metals, 991
test for, 133
Toxicity tests, 130–139
analysis of toxicity test results, 134
acute toxicity data, 134
chronic toxicity data, 135
application of toxicity test results, 136
toxic unit acute (TUa), 136
toxic unit chronic (TUc), 136
identification of toxicity components, 137
organisms used (T), 133

test methods (T), 133
toxicity terminology, 131 (T), 132
toxicity testing, 133
toxic unit, 136
uses of, 130
Toxicity units:
acute (TU_a), 136
chronic (TU_c), 136
Trace elements:
nutrients required for plants, 1410
recommended maximum concentrations in irrigation waters (T), 1407
required for biological growth, 565
toxicity to plants, 1404, 1407
in wastewater, discharge limits, 80
Tracer response curves:
analysis of:
concentration versus time response curves, 234
residence time distribution curves, 238
concentration versus time (C curve), 234
residence time distribution curves:
cumulative residence time distribution (F curve), 239
exit age curve (E curve), 239
Tracers:
application of, 231
detection of with fluorometer, 232
important characteristics of, 231
types of, 231
Tracer studies, conduct of:
need for tracer analysis, 231
practical interpretations of tracer measurements, 242
process flow diagram for conduct of tracer studies, 232, 1318
Transformation processes in the environment (T), 262
Transmittance:
computation of, 53
definition of, 53
importance of in UV disinfection, 1308, 1309
relationship to absorbance, 53, 1312
typical values for:
lagoon effluent, 53, 1313
wastewater effluent, 53, 1313
Transport processes:
advection, 246
diffusion, 246
dispersion, 246
Traveling-bridge filter, 1075
Treatment biological, fundamentals of, 547–644
(See also Biological treatment, fundamentals of)
Treatment kinetics (see Kinetics of microbial growth)
Treatment process reliability and process selection:
development of input-output data, 1649
performance of combined processes, estimation of, 1389, 1647
selection of process design parameters, 1640
graphical approach, 1641
statistical approach, 1641
variability in wastewater treatment, 1636
equipment reliability, statistical measures (T), 1639
influent flowrate and characteristics, 1637
mechanical process reliability, 1639
mechanical reliability, summary statistics (T), 1640
variability in wastewater treatment processes, 1637
variability observed in selected treatment processes, 1638
Trickling filter, 890–930
applications (T), 909
BOD removal and nitrification, 896, 922–930
predator problems, 930
specific nitrification rate, 924
tertiary nitrification, 926–930
volumetric oxidation rate, 923
classification of, 893–896
high-rate, 894
historic classification (T), 893
intermediate-rate, 894
low-rate, 894
roughing, 894
two-stage, 896
design of physical facilities, 896–908
airflow, 901–905
clarifier overflow rate, 905
distribution systems, 900–901
dosing rate (T), 899
draft, 902
headloss correction factors (T), 905
oxygen requirements, 903
packing materials, 896
settling tanks, 905
underdrains, 901
microorganisms in, 892
packing materials, 896–898
physical properties of (T), 898
types of, 897
process description, 890–893
process design considerations, 909–930
applications and loading criteria (T), 909
BOD removal design, 912
effect of temperature, 911
effluent quality (T), 909
formulations for plastic packing, 916–918
Germain equation values (T), 918
loading criteria, 909–912
mass transfer limitations, 919
minimum hydraulic application rate, 918
nitrification design, 922–930
nitrification rates (T), 928
NRC equations, 913–915
recirculation, 918–919
solids production, 919
treatability rate constants (T), 918
recirculation, 918
sloughing in, 893
typical flow diagrams, 895
Trickling filter/activated sludge process:
description, 940
design considerations, 944
process parameters for (T), 942
Trickling filter/solids contact process:
description, 940
design considerations, 944
process parameters for (T), 942
TSS (see Total suspended solids)
Tube and plate settlers, 374–378
(See also Inclined plate and tube settling)
Turbidity:
distribution in filtered effluent, 1385
measurement of, 51
relationship to TSS, 51
reported as NTU, 51
requirements for reuse applications, 1360
in wastewater, 51

Turbine aerator, 445
Turbine mixer:
analysis of:
power for mixing, 354
power for pumping, 354
application of:
flocculation, 357
mixing chemicals, 356
description of, 352
examples of, 353
flow number for, 354
power number for, 354
Two-film theory of oxygen transfer, 285–288
(See also Gas transfer)
Two-stage activated sludge for nitrogen removal, 794
Two-stage anaerobic digestion (see Anaerobic sludge digestion)
Two-stage filtration, 1078
Two-stage trickling filters, 895, 896

UASB (see Upflow anaerobic sludge blanket process)
UCT process for phosphorus removal, 811
Ultimate BOD (UBOD):
definition of, 82, 85
determination of, 85, 88
Ultimate disposal:
of biosolids to land, 1608–1621
of concentrated brines, options for (T), 1136
of screenings, 330
Ultrafiltration:
applications of, in wastewater reclamation, 1122
energy consumption (T), 1125
general characteristics of (T), 1106
operating characteristics (T), 1124
operating size range, 1108
(See also Membrane filtration processes)
Ultraviolet (UV) radiation disinfection, 1298–1329
advantages and disadvantages of (T), 1332
environmental impacts of UV radiation disinfection, 1329
estimating UV dose, 1311
determination of UV dose by collimated beam bioassay, 1311
reporting collimated beam test results, 1312
using bioassay collimated beam test results, 1312
germicidal effectiveness of UV radiation, 1304
characteristics of the microorganisms, 1307
definition of UV dose, 1305
effect of wastewater chemical constituents, 1308
impact of particles, 1307
impact of system characteristics, 1305
impact of wastewater characteristics (T), 1309
nonideal approach hydraulics, 1307
relative effectiveness of, 1308
modeling the UV disinfection process, 1309
selection and sizing of a UV disinfection system, 1324
source of UV radiation, 1298
emerging UV lamp technologies, 1301
low-pressure high-intensity lamps, 1299
low-pressure low-intensity lamps, 1298
medium-pressure high-intensity lamps, 1300
operational characteristics of UV lamps (T), 1300
troubleshooting UV disinfection systems, 1326
biofilms on walls of UV channels and on UV equipment, 1327
effect of upstream treatment processes on UV performance, 1329
overcoming the impact of particles by increasing the UV intensity, 1328
UV disinfection system hydraulics, 1326
ultraviolet disinfection guidelines, 1316
application of UV guidelines, 1316
relationship of UV guidelines to UV system design, 1317
UV system performance validation, 1317
UV system components and configurations, 1301
closed channel disinfection systems, 1304
open channel disinfection systems, 1302
Underdrains:
for granular-medium filters, 1093, 1094
for sludge drying beds, 1570
for trickling filters, 901
Uniformity coefficient:
application, 1052, 1088
definition of, 1046
typical values for depth filters, 1986–1087
(See also Effective size)
Unit loading factors for wastewater, 182
Unit operations:
definition of, 11
used for constituent removal (T), 13
(See also Physical unit operations)
Unit processes:
definition of, 11
used for constituent removal (T), 13
(See also Biological unit processes; Chemical unit processes)
Unit waste-loading factors, 182
Units of expression for analytical measurements, 36
Upflow anaerobic sludge blanket (UASB) process, 1005–1016
description of, 1005–1007
design considerations for, 1007–1011
gas collection and solids separation, 1011
hydraulic retention times (T), 1009
physical features, 1010
reactor height (T), 1009
reactor volume and dimensions, 1010
upflow velocity, 1008–1009
volumetric organic loadings, 1007–1008, (T) 1009
wastewater characteristics, 1007
Upflow filter, granular medium, 1072, 1075
(See also Filtration, depth)

Upgrading existing wastewater treatment plants, 1708–1721
liquid treatment facilities, examples of (T), 1716–1717
for meeting new standards (T), 1719–1720
operational modifications, examples of (T), 1713–1715
process optimization, 1708–1712
computer models, 1711
histograms, 1708
linear correlation, 1709
on-line process monitoring, 1710
Pareto chart, 1709
pilot-scale testing, 1712
solids treatment facilities, examples of (T), 1718
Urea, 60, 80
U.S. customary units, conversion factors to metric (SI) units (T), 1731
U.S. sieve sizes (T), 1046
U-tube aerator, 436
U-tube contactor for high purity oxygen, 451
UV-absorbing compounds, 95
UV disinfection
(see Ultraviolet (UV) radiation disinfection)
UV-radiation, sources, 1298

Vacuum-assisted sludge drying beds:
description of, 1576
performance data (T), 1577
sectional view of, 1576
Vacuum filters, 1559
van der Waals forces, 483
Vanes, flow deflection, use of, 1275
van't Hoff-Arrhenius temperature relationship, 55, 261
Vapor phase treatment of odors:
biofilters, 1665
biotrickling filters, 1666
conventional biological treatment processes, 1667
thermal processing, 1667
Vapor pressure:
definition of, 1742
values of:
in SI units (T), 1742
in US customary units (T), 1743
Variability in wastewater treatment, 1636–1639
(See also Treatment process reliability and process selection)
Vector attraction reduction, 1461, 1463
Velocity gradient (G)
definition of, 348
typical values for mixing and flocculation (T), 348
Ventilation in trickling filters, 901
Veterinary and human antibiotics (T), 97
VFAs (see Volatile fatty acids)
VIP process, 812
Viruses:
classification of, 105
description of, 107
pathogenic types, 114
removal of:
by chlorination, 1244, 1248, 1253
in groundwater recharge,
by reverse osmosis, 1388
in secondary treatment, 1385, 1386
by UV radiation, 1244, 1308
sizes of, 108
typical present in wastewater, 110
Viscosity of water:
definition of:
dynamic, 1741
kinematic, 1741
values of for dynamic and kinematic:
in SI units, 1742
in U.S. customary units, 1743
Volatile fatty acids (VFAs):
role in anaerobic digestion, 631
role in phosphorus removal, 625, 805
Volatile organic compounds (VOCs):
control strategies for, 463
definition of, 100
emission of, 456
gas stripping, 456
locations where VOCs are emitted, 457
mass transfer from aeration processes, 459
complete-mix reactor with diffused-air aeration, 459
complete-mix reactor with surface aerators, 459
mass transfer rates for VOCs, 457
physical properties of (T), 461
removal of, by aeration, 456–467
sources and methods of release (T), 458
treatment of off gas containing VOCs, 463
biofilters, 1665
biotrickling filters, 1666
catalytic incineration, 466
combustion in a flare, 466
disposal of off-gases, 467
thermal incineration, 465
vapor phase adsorption, 463
volatilization of, 456
Volatile solids:
definition of, 45
suspended (VSS), 43, 44
total (TVS), 43, 44
destruction in digesters:
aerobic, 1536, 1537
anaerobic, 1514
loading factors for anaerobic digesters (T), 1514
typical values, in wastewater, 186
Volatilization:
application of, 460
definition of, 456
rate of, 457, 459
Volume-mass relationships for sludge, 1455
Vortex, free, 383
Vortex separator:
for combined sewer overflows, 417
for grit removal, 392
Vortexing in mixers, 355
VSS (see Volatile solids, suspended)

Waffle-bottom anaerobic digester, 1520
Wastewater:
analyses used to assess constituents in, 30
calculation of mass loadings, 194
classification of constituents found in wastewater (T), 1357
composition of in collection systems, typical, 186
constituent data for various countries (T), 184
effect mass loading variability on treatment plant performance, 197
effluent quality after various levels of treatment (T), 1386
flowrates, 154–170
(See also Wastewater flowrates)
flow weighted constituent concentrations, 192

Wastewater—*Cont.*
mineral increase due to usage, 187
sampling and analytical procedures, 29–42
statistical analysis of flowrates, constituent concentrations, and mass loading rates, 170–178
variations in constituent concentrations in collection systems, 189
in industrial wastewaters, 188
seasonal, 186
short term, 185
Wastewater characteristics, 9–10
(See also Wastewater, constituents in)
Wastewater characterization, for activated sludge processes, 666–676
definition of terms (T), 667
key constituents for process design, 666
measurement methods for, 671
recycle flows and loads, 676
typical characterization parameters (T), 666
Wastewater, constituents in:
aggregate organic constituents, 80–99
biochemical oxygen demand (BOD), 81
interrelationships between BOD, COD, and TOC, 96
measurement of organic content, 81
oil and grease, 98
surfactants, 98
theoretical oxygen demand (ThOD), 96
total and dissolved organic carbon (TOC and DOC), 94
total and soluble chemical oxygen demand (COD and SCOD), 93
UV-absorbing organic constituents, 95
biological characteristics, 104–130
development of microorganisms typing techniques, 130
enumeration and identification of bacteria, 118
enumeration and identification of viruses, 126
microorganisms found in surface waters and wastewater, 104
new and reemerging microorganisms, 130
pathogenic organisms, 109
polymerase chain reaction (PCR), 129
use of indicator organisms, 115
individual organic compounds, 99–104
analysis of individual organic compounds, 100
disinfection byproducts, 102
emerging organic compounds, 102
pesticides and agricultural chemicals, 102
priority pollutants, 99
volatile organic compounds (VOCs), 100
inorganic nonmetallic constituents, 57–76
alkalinity, 59
chlorides, 59
gases, 64
nitrogen, 60
odors, 70
pH, 57
phosphorus, 63
sulfur, 64
metallic constituents, 77–80
importance of metals, 77
sampling and methods of analysis, 77
sources of metals, 77
typical effluent discharge limits for metals, 78
physical characteristics, 42–57
color, 52
conductivity, 56
density, specific gravity, and specific weight, 56
particle size distribution, 48
solids, 42
temperature, 54
transmittance/absorption, 52
turbidity, 51
principal constituents of concern (T), 32
table of (T), 30
(See also individual listings)
Wastewater constituent concentrations:
from combined collection systems:
characteristics of (T), 191
factors affecting characteristics (T), 190
mineral increase from domestic use (T), 187
typical composition of (T), 186, 666
typical data for various countries (T), 184
typical unit loading factors (T), 184
Wastewater design flowrates, selection of:
components of, 154
definition of terms, 178
design flowrate terminology (T), 199
design flowrates, 199
forecasting flowrates, 200
minimum flowrates, 200
peak flowrates, 201
rational for selection of, 200
statistical analysis of, 170
sustained flowrates, 200
upstream control of peak flowrates, 205
Wastewater flow, measurement of (T), 1695
Wastewater flowrate reduction, 158
Wastewater flowrates (see Wastewater sources and flowrates)
Wastewater metering:
flow measurement (T), 1695
level measurement (T), 1696
Wastewater reclamation and reuse (see Water reuse)
Wastewater sampling and analytical procedures, 29
methods of analysis, 34
sampling, 29
units of measurent for physical and chemical parameters, 35
useful chemical relationships, 35
activity coefficient, 40
chemical equilibrium, 39
electroneutrality, 37
ionic strength, 40
mole fraction, 35
solubility product, 40

Wastewater sources and flowrates, 154–170
combined system flowrates, 168–170
components of wastewater flows, 154
domestic sources and flowrates:
from commercial facilities (T), 157
from institutional facilities (T), 158
from recreational facilities (T), 159
from urban residential (T), 156
exfiltration from collection systems, 167
flowrate analysis, 178–181
flowrate variations, 178–180
industrial, 180
seasonal, 180
short-term, 179
terminology for (T), 179
flowrates for design, 199–205
industrial, 162
infiltration/inflow, 163–167
infiltration, 164
inflow, 165
peaking factors, 180–181, 201–203
statistical analysis of flowrate data, 170
strategies for reducing flowrates, 158–162
upstream control of, 205
(See also Wastewater design flowrates)
Wastewater treatment:
definition of terms for (T), 11, 550
effect of wastewater characteristics on, 9–10
health and environmental concerns, 7–9
methods of treatment, 11, 551
operations (see Physical unit operations)
processes (see Biological unit processes; Chemical unit processes)
process flow diagrams:
for treatment of wastewater with physical, biological, and chemical processes, 313
typical for secondary treatment: with biological methods, 549
for wastewater treatment with flow equalization, 334
process reliability, 1636–1650
(See also Treatment process reliability)
role of microorganisms in, 548
status:
current, 12
future trends, 20
new directions and concerns, 15–19
number of facilities in the U.S. (T), 14
unit operations and processes for constituent removal (T), 13
Wastewater treatment plant design:
automatic process control, 1677–1703
chlorination and dechlorination facilities, 1264–1286
considerations for new plants, 1721–1723
liquid streams, 1721
odor control, 1723
solids processing, 1721
energy efficiency, 1703–1707
flow measurement methods (T), 1695
flowrate selection:
for design, 199–205
peaking factors, 180–181, 201–203
typical flowrate and mass loading factors (T), 199
impact of return flows and loads, 676, 1594–1596
level measurement methods (T), 1696
mass loadings selection, 205
odor management, 1650–1677
process selection:
for BOD removal and nitrification, 740, 748
impact of flowrates and mass loadings on, 154, 1594
important factors in (T), 298–299
introduction to, 297–303
for nitrogen removal, 789–790, 797
for phosphorus removal, 809, 815
reliability considerations for, 1636–1650
regulations:
affecting discharge requirements, 3–7, 1635–1636
affecting reuse and disposal of solids, 1460–1465, 1610–1613
for biosolids reuse and disposal, 1460–1465
for chlorine storage and containment, 1284
for land application of biosolids, 1610–1613
minimum standards for secondary treatment (T), 6
summary of U.S. federal regulations (T), 5
solids mass balance, 1592–1608
upgrading existing plants, 1708–1721
UV systems, 1317, 1324–1327
(See also individual listings)
Water:
dissolved oxygen concentration in:
as a function of temperature and barometric pressure, 1745
as a function of temperature and salinity, 1745
physical properties of:
SI units (T), 1742
U.S. customary units (T), 1743
solubility of gases in, 65–69
Water conservation:
devices for (T), 160, 161
effects on interior water use, 160
strategies for, 158
typical flowrate reduction (T), 161
Water gun sprinkler system, 1353
Water Quality Act of 1987 (WQA), 5, 6
Water quality criteria:
for cooling water, 1419
for irrigation water, 1403, 1407
for secondary treatment, 6
for steam generation, 1419

Water reclamation technologies, 1376–1391
advanced wastewater treatment process flow diagrams, 1377, 1379–1381
process flow diagram for advanced treatment processes used at Water Factory 21, 1381
process flow diagram for multi-stage wastewater reclamation process, 1380
process flow diagram for potable water demonstration plant, 1381
constituent removal technologies, 1376
removal of conventional constituents, 1379
removal of nonconventional emerging constituents and compounds, 1379, (T) 1382
unit treatment processes and operations (T), 1382
conventional reclamation treatment process flow diagrams, 1377
contact filtration, 1379
direct filtration, 1378
full treatment, 1378
treatment process performance:
achievable levels with process combinations (T), 1377
effluent quality for various levels of treatment (T), 1386
performance expectations for reclamation treatment processes, 1379
predicting the performance of treatment process combinations, 1387–1389
typical performance data for a water reclamation facility (T), 1384
treatment process reliability, 1391
Water reuse:
categories of municipal reuse (T), 1352
definition of terms, 1347
epilogue on water reuse issues, 1438
estimates of fresh water withdrawals and water reclamation (T), 1356
estimates of water reclamation in the U.S. (T), 1351
historical perspective, 1349
need for water reuse, 1354
planning considerations, 1433
market assessment, 1434
market assessment for reclaimed water (T), 1435
monetary analysis, 1434
other planning factors, 1436
planning basis, 1433
planning report, 1437
reclamation and reuse facilities plan (T), 1437
the role of water recycling in the hydrologic water cycle, 1347
status of, 21
wastewater reuse applications, 1351
Water reuse applications:
agricultural and landscape irrigation, 1351, 1401–1412
evaluation of irrigation water quality, 1401
miscellaneous problems, 1410
physical and chemical characteristics, 1402
categories of water reuse (T), 1352
groundwater recharge with reclaimed water, 1352, 1422 1429
fate of contaminants in groundwater, 1427
groundwater recharge guidelines, 1429
groundwater recharge methods, 1423
pretreatment requirements for groundwater recharge, 1426
industrial water reuse, 1352, 1412–1422
common water quality problems in cooling tower systems, 1416
cooling tower makeup water, 1413
industrial water withdrawals, 1413
water and salt balances in cooling tower, 1414
water quality requirements, 1419
planned indirect and direct potable water reuse, 1354, 1429–1433
planned direct potable water reuse, 1432
planned indirect potable water reuse, 1431
planned potable water reuse criteria, 1432
what is it the ultimate reuse goal?, 1433
(See also Storage of reclaimed water)
Water reuse guidelines and regulations:
constituents in reclaimed water, 1356
environmental issues, 1358
evolution of water reuse guidelines, 1358
assessment of water reuse guidelines, 1359
federal guidelines, 1359
state guidelines and regulations, 1359
groundwater recharge:
factors considered in formulating guidelines (T), 1430
framework for groundwater recharge criteria (T), 1431
guideline and regulations:
California recycling criteria (T), 1362
guidelines for water quality for irrigation (T), 1403
state reuse regulations and guidelines (T), 1361
U.S. EPA guidelines for (T), 1360
water quality guidelines for irrigation water (T), 1403
public health issues, 1358
Water use data:
in developing countries (T), 163
effects of water conservation devices (T), 161
flow reduction devices and appliances (T), 161
proportion reaching collection system, 155
strategies for reducing interior use, 158
typical residential interior use in the United States (T), 160
by various devices and appliances (T), 160
Wehner and Wilhelm equation, 279
Weir loadings:
for activated-sludge settling tanks, 839

for primary sedimentation tanks, 398, 408
Windrow sludge composting, 1549
WQA (see Water Quality Act of 1987)

Yield coefficient, bacterial:
definition of, 567
determination of, 568
effect of endogenous metabolism, 584
observed values of: in bacterial growth, 565–580
typical values for:
activated sludge process, 704
anaerobic digestion process, 1000
ASM1 model, 864
common biological reactions (T), 580
denitrification process, 756
methanol as a growth substrate, 785
nitrification process, 705
Yield, observed, 580, 587, 595
Yield stress of sludge, 1478

Zeolite, natural, 1181
Zero-order reaction, 260
Zeta potential, 482
Zone settling, 378–383
(See also Hindered settling)
Zone settling velocity (ZSV), 686

for primary sedimentation tanks, 398, 408
Windrow sludge composting, 1549
WQA (see Water Quality Act of 1987)

Yield coefficient, bacterial:
definition of, 567
determination of, 568
effect of endogenous metabolism, 584
observed values of: in bacterial growth, 565–580
typical values for:
activated sludge process, 704
anaerobic digestion process, 1000
ASM1 model, 864
common biological reactions (T), 580
denitrification process, 756
methanol as a growth substrate, 785
nitrification process, 705
Yield, observed, 580, 587, 595
Yield stress of sludge, 1478

Zeolite, natural, 1181
Zero-order reaction, 260
Zeta potential, 482
Zone settling, 378–383
(See also Hindered settling)
Zone settling velocity (ZSV), 686

for primary sedimentation tanks, 398, 408
Windrow sludge composting, 1549
WQA (see Water Quality Act of 1987)

Yield coefficient, bacterial:
definition of, 567
determination of, 568
effect of endogenous metabolism, 584
observed values of: in bacterial growth, 565–580
typical values for:
activated sludge process, 704
anaerobic digestion process, 1000
ASM1 model, 864
common biological reactions (T), 580
denitrification process, 756
methanol as a growth substrate, 785
nitrification process, 705
Yield, observed, 580, 587, 595
Yield stress of sludge, 1478

Zeolite, natural, 1181
Zero-order reaction, 260
Zeta potential, 482
Zone settling, 378–383
(See also Hindered settling)
Zone settling velocity (ZSV), 686
